Dedicated to our children and grandchildren, who will not only be taking care of us, but will lead the charge in improving the care of the next generation of vulnerable older adults across the healthcare continuum.

Preface to the Third Edition

In 2012 the first baby boomer turned 65, and now every day 10,000 people in the United States turn 65. By the end of the current decade, one in five people will be over age 65, and by 2050, there will be nearly 20 million over age 85. As we know, many of the diseases that surgeons treat, such as cancer, cardiac diseases, and musculoskeletal disorders, are diseases of aging. All of us, except perhaps our pediatric surgery colleagues, are seeing more and more, older and older patients in our practices every day. As we do, we increasingly realize that older adults have unique medical, surgical, and psychosocial care needs that must all be addressed if high-quality surgical care that is consistent with each patient's health goals is to be consistently achieved.

We are now very pleased to present the third edition of our book: *Principles and Practice of Geriatric Surgery*. This has been a work of love for us, and we are so pleased to help this unique field of surgical care grow over 20 years. When the first edition of this book was published in 2001, only a few surgeons pursued Geriatric Surgery as an academic niche interest or as a personal mission or both (some of us for 15–20 years before that). Twenty years later, it is a core value of surgeons in every field. We have all become Geriatric Surgeons, and to borrow the words of an American College of Surgeons (ACS) promotional video, "Care has come of age."

We have had wonderful partners in this journey. In the early days, interest in the field was more grassroots than organized. In 1995, the American Geriatrics Society with support of the John A. Hartford Foundation established the Geriatrics for Specialists Initiative. This eleven-specialty collaborative developed novel programs, such as the Jahnigen Research Scholarship and the Geriatrics Education for Specialty Residents grants, designed to encourage young surgeons to pursue a career in geriatric surgery. In 2008, the American College of Surgeons established the Geriatric Surgery Task Force which led educational and clinical awareness initiatives. This evolution culminated into evidence-based clinical initiatives, when in 2015 the American College of Surgeons, again with the generous support of the John A. Hartford Foundation, assembled a coalition of 58 national stakeholder organizations. Representatives of older adults, their families and caregivers, medical and surgical specialties, nurses, allied health professionals, insurers, and regulators convened to identify the requirements for providing high-quality, patient-centered care to senior citizens. Over a 4-year period, this Coalition for Quality in Geriatric Surgery defined a group of 30 evidence-based or consensus-derived (where evidence was lacking) standards that were both valid and feasible for hospitals to adopt. These standards address how to assure truly shared surgical decision-making and how to identify and plan for optimizing the vulnerabilities that aging has imposed on each individual, throughout the surgical care continuum.

These standards have formed the foundation for the development of the American College of Surgeons Geriatric Surgery Verification Program, which was introduced in July of 2019 and began taking applications in October 2019. This quality program is based on the same four pillars as all ACS quality programs:

1. Identify the standards for quality care.
2. Define the infrastructure needs.
3. Collect appropriate data to allow for measurement of improvement.
4. Verify that the standards are in fact being met to assure the public.

The hope is that this program will be adopted by all hospitals across the country where surgical care of older adults takes place and thereby raise the bar for the care of all hospitalized older adults.

But no program will be successful without healthcare providers who are familiar with the differences between older and younger adults. Older adult patients are unique. It is the purpose of this text to bring the latest scientific, clinical, and social information on the changes in aging, and their impact on the conduct of all aspects of surgery, to all healthcare providers.

2020 Ronnie A. Rosenthal
Michael E. Zenilman
Mark R. Katlic

Preface to the Second Edition

It has been a decade since the first edition of this textbook came to press, and the field of geriatric surgery is growing. Over the last decade, Geriatrics has been recognized as a distinct aspect of surgery by leadership in our field and others. The American College of Surgeons established the Task Force for Geriatric Surgery, a Geriatrics Section in the Surgical Forum, and a community for Geriatric Surgery on the ACS Web portal. The American Geriatrics Society created the Jahnigan Scholars Program to expand geriatric clinical and basic research in the surgical disciplines as part of its Geriatrics-for-Specialists Initiative. Recently, the American Board of Surgery and Surgical Residency Review Committees expanded the requirements for working knowledge of the geriatric patient, most notably using the ABS Surgical Council on Resident Education (SCORE) curriculum project, which now includes a Geriatric module. Evidence of the growing interest in geriatric aspects of surgery can be found in the rapidly growing literature and in the numerous panels, discussions, and presentations at local and national meetings. One of the most notable of these was the panel at the 2009 American College of Surgeon's Clinical Congress entitled "She's 92, what do I do?" The audience was standing room only; the questions were thoughtful and nearly unending; there is obvious hunger for knowledge by surgeons from all practice venues. Most importantly, in 2008 the Institute of Medicine published a 250-page report on "Retooling for an Aging America: Building the Health Care Workforce." In it, the Committee on the Future Health Care Workforce for Older Americans clearly outlined the population statistics, described the prevalence of chronic disease in the elderly population, and predicted the resource challenges for our health-care system. The report suggested a three-pronged program to meet these challenges: (1) to enhance the competencies of all practitioners in geriatric care, (2) to increase the recruitment and retention of geriatric specialists, and (3) to redesign models of care and broaden provider and patient roles to achieve greater efficiencies. Surgery will be an integral part of the care for this population, and this textbook provides the foundation of knowledge for the teams that will be caring for these patients. In this edition of *Principles and Practice of Geriatric Surgery*, we have kept the same format as the last edition, with each section preceded by an invited commentary from a well-known and widely respected senior member of each discipline. The opinion pieces submitted are all highly relevant and informative. For the chapters, we chose authors who are recognized leaders in their fields, and were gratified with their enthusiasm and high quality of the submissions. We added a number of new chapters to enhance the focus on the latest topics of interest such as frailty (Chap. 9), geriatric models of care (Chap. 21), unique complications (Chap. 29), oral cavity (Chap. 41), and dysphagia (Chap. 44). Another new chapter addresses geriatric surgical education and provides links and information for a number of additional educational resources (Chap. 15). The final addition provides a hard look in our own mirror as surgeons, with an excellent discussion of the effects of age on surgeon performance (Chap. 18).

Also new to this edition, the physiology chapters begin with a table that summarizes the key points regarding changes in physiologic function with age. The clinical chapters contain an illustrative clinical vignette designed to drive home the critical learning points for each topic. As you will see, a simple example makes a seemingly complex topic manageable. The passion for bringing this book to completion was palpable from our first informal editorial lunch in New York in the spring of 2007 to the present volume in your hands. The editors have become close friends and greatly appreciate the hard work done by all the authors. On the editorial side, Portia Bridges, our development editor from Springer was as dedicated as we. She was professional, persistent, and relentless in the pursuit of fresh ideas, manuscript deadlines, quality figures, and simple excellence (we have several thousand emails from Portia in our archives, etc.). We have all been through a lot over the last few years and hope this book symbolizes both the deep affection we have for each other and the commitment we have to improve the quality of care for older surgical patients. We each would like to thank our families, coworkers, and patients for their patience and support in creating this textbook. They all understand that Geriatric Surgery is a real discipline and have lived with our enthusiasm to bring this field to the forefront of surgery. Maybe the next edition will start off with a chapter whose title is borrowed from the pediatricians: "Your geriatric patient is not just an 'older human,' s/he has specific needs."

New Haven, CT, USA — Ronnie Ann Rosenthal
Bethesda, MD, USA — Michael E. Zenilman
Wilkes-Barre, PA, USA — Mark R. Katlic

Preface to the First Edition

More than two decades ago, in response to the special healthcare needs of the aging American population, interest in the field of geriatric medicine began to grow and blossom in the United States. In 1984 and 1985, under the editorial leadership of Christine K. Cassel and William R. Hazzard, respectively, two major textbooks devoted to the medical care of aged patients were published. These scholarly, comprehensive texts provided insight into the principles of aging and guidance in the care of the geriatric patient. Three editions later, the need to understand the special issues involved in the medical care of the elderly is widely accepted by internists, primary care providers, and medical specialists. For the editors of this book, the special issues involved in the surgical care of the elderly have been apparent for nearly as long. Although there have been a few scholarly texts on the subject, including one in 1990 by Mark R. Katlic, general acceptance of the concept of geriatric surgery by our surgical and medical colleagues has, however, lagged. This is not the result of a proportionately smaller number of older patients with surgical disease, because cancer, cardiovascular disease, and orthopaedic problems are diseases, of the aged. It is rather the result of uncertainty about the value of surgery in the elderly and concerns about the risks of operations. In the past, such concerns prevented primary care givers from referring patients for surgical care and prevented surgeons from agreeing to operate. With the improvements in technology, monitoring, and anesthesia, we are now able to safely operate on most older patients, based on indications that are determined by the disease and the patient's overall health rather than by age. Since 1980, the percentage of operations performed in which the patient was over age 65 has nearly doubled to almost 40%. It is now estimated that approximately half of the patients in most general surgery practices, and even higher percentages in most cardiac and vascular surgery practices, are 65 years of age or older. This recent rapid increase in the elderly surgical population has increased the awareness that older surgical patients are different from younger surgical patients and therefore require special consideration. In 1995, shortly before this text was conceived, the American College of Surgeons, with input from three well-respected senior surgeons, George E. Block, Ben Eiseman, and Gerald O. Strauch, added a panel on Surgery in the Elderly to that year's program at the Annual Clinical Congress. Similar programs have since been presented at each of the last three Clinical Congresses. Also in 1995, the American Geriatrics Society in association with the Hartford Foundation began a program to increase geriatric expertise in nonprimary care specialties, including general surgery, orthopedics, urology, and gynecology. As part of this program, Drs. Walter Pories and Sherralyn Cox developed a geriatric syllabus that has now been added to the Surgical Resident Curriculum of the Association of Program Directors in Surgery. The field of "Geriatric Surgery" has begun to emerge. Our goal in developing the present book was not to form the basis for a new surgical specialty because most surgeons, with the exception of our podiatric colleagues, will need to be "geriatric surgeons" soon. It was rather to provide a comprehensive collection of information that would allow all providers of healthcare to the elderly to understand the issues involved in choosing surgery as a treatment option for their patients. We have, by now, shown that we can operate on the elderly, the question is often whether we should. To help answer this question, we have divided the book into two parts. Part I, General Principles, describes general aspects of the physiology of aging and gives an overview of surgical management and important ethical considerations. Part II, Specific Issues, is organized by organ system. The first chapter in each section details the physiologic changes of that organ system with age. The subsequent chapters describe the pathophysiology, surgical treatment, and outcome of treatment for the disease of that organ system that are commonly encountered in elderly patients. With this information in hand, geriatricians, internists, and other primary care providers can better decide which of their patients will benefit from surgical referral; surgeons, surgical residents, and students can better understand how aging changes the assessment of risks, the choice of operation, the perioperative management, and treatment outcome. Each section is also preceded by an invited commentary from well-known and widely respected senior members of each discipline. We have asked them to reflect on the changes they have seen in their area of expertise over the course of their careers and to comment on how they feel these changes have influenced the care of the elderly. We are extremely grateful to them for graciously agreeing to share their thoughts. The road from concept to reality of this book has been long and somewhat bumpy, but throughout, there has been a genuine commitment to the importance of such a book by all involved. We are most grateful to our editor at Springer-Verlag, Laura Gillan, and her assistants for maintaining the high level of enthusiasm for the topic and commitment to the quality of the work. It has been a great pleasure to work with, and learn from, someone who understands so well why we embarked on this kind of journey and who so clearly shares our goal. Without her help, it would not have happened. We also thank Barbara Chernow and her associates for the very skillful copyediting done under considerable pressure. Finally we are extremely grateful to all of our authors, who have given so generously of their valuable time and effort to produce outstanding chapters in an era when rewards for such efforts are primarily internal. It is our belief that the information they have so carefully provided will bring significant improvements to the overall healthcare of our elderly patients.

About the Editors

Ronnie A. Rosenthal M.D., is a graduate of the SUNY Downstate College of Medicine, where she also did her general surgery residency training and had her first faculty position. She is currently Professor of Surgery and Geriatrics at Yale University School of Medicine and is in her 21st year as Chief of Surgery at the VA Connecticut Healthcare System. She also serves as the Chief Surgical Consultant for VA New England Healthcare System (VISN 1). She is Chair of the ACS Geriatric Surgery Task Force and Co-Director of the ACS NSQIP Geriatric Surgery Pilot. Currently, she is the Co-PI on the "Coalition for Quality in Geriatric Surgery" grant with Dr. Clifford Ko, Director of Quality Programs for the ACS. Through this 4-year national grant, funded by the John A. Hartford Foundation (JAHF), she has worked with 60 stakeholders to develop a set of standards for the surgical care of older adults, which has culminated in the creation of the ACS Geriatric Surgery Verification Program.

Michael E. Zenilman, M.D., graduated college at State University of New York at Stony Brook and received his medical degree from SUNY Downstate Medical School in Brooklyn in 1984. He served as Clarence Dennis Professor and Chair of Surgery at SUNY Downstate, Brooklyn, NY, for 10 years. From 2011 to 2016, Dr. Zenilman led the integration of surgical care between the community hospitals and main campus as the inaugural Regional Director of Surgery for the Johns Hopkins Health System. He is currently doing similar work for Weill-Cornell and the NewYork-Presbyterian healthcare network.

An established clinician, teacher, and researcher, Dr. Zenilman has published extensively on pancreatic disease and geriatric surgery and served on the editorial board of *JAMA Surgery* and the *American Journal of Surgery*. He remains clinically active and has mentored over 100 surgical residents and over 50 students, fellows, and junior faculty.

Mark R. Katlic is a Phi Beta Kappa graduate of Washington and Jefferson College and an Alpha Omega Alpha graduate of the Johns Hopkins University School of Medicine. He completed residencies in Surgery and Cardiothoracic Surgery at the Massachusetts General Hospital. A practicing thoracic surgeon since 1984, Dr. Katlic also earned a Master of Medical Management degree from the John Heinz School of Public Policy and Management at Carnegie Mellon University in 1999.

Dr. Katlic has had a special interest in caring for the elderly for over 35 years. His paper, “Surgery in Centenarians,” was published in the *Journal of the American Medical Association* in 1985, and he went on to publish seven textbooks and to lecture frequently on this subject. As a thoracic surgeon, Dr. Katlic has pioneered video-assisted thoracic surgery (VATS) under local anesthesia and sedation, with results of 576 cases published in 2017.

Dr. Katlic is presently Chairman of the Department of Surgery and Surgeon-in-Chief of Sinai Hospital in Baltimore, Maryland. He also directs the Sinai Center for Geriatric Surgery. In 2014, Dr. Katlic established The Aging Surgeon Program, a comprehensive, objective evaluation of a surgeon’s cognitive and physical faculties, at Sinai Hospital of Baltimore. He was named Maryland Innovator of the Year in 2013 and Maryland Physician of the Year in 2019. In his free time he trains for triathlons.

Contents

Abstract

The world population is aging and the conditions that require surgery – atherosclerosis, cancer, arthritis, prostatism, cataract, pelvic floor disorders, and others – increase in incidence with increasing age. What do we know about surgery in the elderly that will help us improve our care of these conditions? Six general principles are useful for teaching purposes. These include the fact that the clinical presentation of surgical problems may be subtle or different from that of the general population; the elderly handle stress well but not severe stress due to lack of reserve; preoperative preparation and attention to detail are crucial; when these are lacking, as in emergency surgery, risk dramatically increases; and the results of elective surgery in the elderly are good in many centers and do not support prejudice against advanced age. Surgeons must become students of the physiologic changes that occur with aging and, guided by these few principles, apply this knowledge to daily clinical care. We owe it to our elders to become good geriatric surgeons and in so doing we will become better surgeons to patients of all ages.

Introduction

With a few obvious exceptions, those of us who are surgeons must become geriatric surgeons. The population as a whole is aging, with the most explosive growth in the over 85 year group, and the conditions that require surgery (atherosclerosis, cancer, arthritis, prostatism, cataract, pelvic floor disorders, and others) increase in incidence with increasing age. Improving our care of the elderly surgical patient will become progressively more important to all of us.

Admittedly, surgeons have always cared for the elderly, but the definition of "elderly" has changed. A threshold of 50 years was chosen for the 167 patients described in a paper in 1907 [1], and 20 years later influential surgeons still wrote that elective herniorrhaphy in this age group was not warranted [2]. Now, though, we are performing complex operations in octogenarians, nonagenarians, and occasionally centenarians [3–8]. In addition, the salutary results of such surgery can even influence general sentiment about medical care of the elderly. Linn and Zeppa's study [9] of junior medical students reported that the surgery rotation, in contrast to other clerkships, positively influenced the students' attitudes about aging regardless of the students' career choices, as the elderly surgical patients were admitted and treated successfully.

Surgery therefore has much to offer the geriatric patient, but that patient must be treated with appropriate knowledge and attention to detail. Discussions of physiologic changes in the elderly and results of specific operations comprise the bulk of this book and are not presented here. The authors' three decade study in this area, in addition to caring for an elderly oncology population, has led to a distillate of several general principles (Table 1) which are relevant to all who care for the aged. These principles are worthwhile chiefly for teaching purposes, as they cannot apply to every patient or every clinical situation. Some principles also apply to surgery in the young patient, but the quantitative differences in the elderly are significant enough to approach qualitative status. Risks of many emergency operations in the young, for example, are indeed greater than the risks of similar elective operations, but the differences are small compared to the threefold increase in the elderly. With respect to these principles, the elderly need not be treated as a separate species but perhaps as a separate genus or order within the same larger group of surgical candidates.

Table 1 Principles of geriatric surgery

I.	The *clinical presentation* of surgical problems in the elderly may be subtle or somewhat different from that in the general population. This may lead to delay in diagnosis
II.	The elderly handle stress satisfactorily but handle severe stress poorly because of *lack of organ system reserve*
III.	Optimal *preoperative preparation* is essential, because of Principle II. When preparation is suboptimal, the perioperative risk increases
IV.	The results of elective surgery in the elderly are excellent in some centers; the results of emergency surgery are poor though still better than nonoperative treatment for most conditions. The risk of *emergency surgery* may be many times that of similar to elective surgery because of Principles II and III
V.	Scrupulous *attention to detail* intraoperatively and perioperatively yields great benefit, as the elderly tolerate complications poorly (because of Principle II)
VI.	A patient's age should be treated as a *scientific fact, not with prejudice*. No particular chronologic age, of itself, is a contraindication to operation (because of Principle IV)

Although our results have generally improved over the years [10–12] (Fig. 1), this improvement has not been universal [13, 14] (Fig. 2) and emergency surgery is still risky. Understanding these six general principles may help us improve our care of the elderly patient who requires surgery.

Principle I: Clinical Presentation

The clinical presentation of surgical problems in the elderly may be subtle or somewhat different from that in the general population. This may lead to delay in diagnosis.

Classic symptoms of appendicitis are present in a minority of elderly patients, as few as 26% in Horattas' series over 20 years [15] (Table 2). Rebound tenderness was present in fewer than

Deaths	(4) 4%	(4) 4%	(8) 4%

half the patients in another [16] and leukocytosis in only 42.9% in another [17]. Clouding the picture further, objective tests may suggest alternative diagnoses: one in six patients has an elevated bilirubin and one in four has signs of ileus, bowel obstruction, gallstones, or renal calculus on abdominal radiographs [18]. Even astute diagnosis may not prevent perforation, present in 42–60% of elderly patients despite operation within 24 h of symptom onset [15, 17].

Biliary tract disease is the most common entity requiring abdominal surgery in the elderly, yet the diagnosis is often delayed. More than one-third of patients with acute cholecystitis are afebrile, one-fourth are nontender, and one-third are without leukocytosis [19–22]. Cholangitis may appear only as fever of unknown origin or as confusion [23]. Consequently, the elderly predominate in series of patients with complications of biliary disease (gallbladder perforation, empyema, gangrene, gallstone ileus, cholangitis) [24], and the complication may result in the first apparent symptom [21, 25]. Saunders [26] reported that abdominal pain was a less prominent symptom and that the bilirubin level was nearly double in elderly patients presenting with bile duct carcinoma, compared to the findings in young patients seen during the same time period.

Peptic ulcer disease may present as confusion, malaise, anemia, or weight loss as opposed to pain [27]; even with perforation pain may be absent or minimal. Rabinovici [28] found a discrepancy between "severe intraoperative findings" and preoperative objective findings such as heart rate (mean 88/min), temperature (37.2 °C), and white blood cell count (10,900/dl). Some have suggested that the elderly and possibly their physicians become tolerant over the years to abdominal pain, loss of energy, and other symptoms, resulting in a delay in diagnosis or an emergency presentation [29]. In Mulcahy's [30] series of patients with colorectal carcinoma, for example, elderly patients were nearly twice as likely (18%) as younger patients (11%) to present emergently. Elderly patients with perforated diverticulitis are three times more likely to have generalized peritonitis at operation than young patients [31].

Gastroesophageal reflux disease in the elderly is less likely to cause heartburn and more likely to cause regurgitation or cough ($p = 001$) [32]. In Pilotto's study of 840 consecutive patients [33], typical heartburn/acid reflux, pain, and indigestion were more likely in the young ($p < 0.001$); older patients more often experienced dysphagia, anorexia, anemia, or vomiting ($p < 0.001$ each) or weight loss ($p < 0.007$).

Head and neck disease may also present differently in the elderly. Sinusitis may lead to subtle signs such as delirium or fever of unknown origin [34, 35], and head and neck cancers are less likely to be associated with smoking ($p < 0.01$) [36] and alcohol use ($p < 0.001$) [36, 37]. Hyperparathyroidism is more likely to cause dementia or skeletal complaints and less likely to cause renal stones [38]. In Thomas and Grigg's series [39] of patients with carotid artery disease, stroke was the most common indication for surgery in octogenarians and was the least common indication in younger patients. Unstable angina is as likely to present with dyspnea, nausea, or diaphoresis as it is with classic chest pain [40]. Cioffi's group found that normal presenting vital signs are unreliable in elderly patients admitted for blunt trauma [41].

Even the eureka moments that keep us energized as diagnosticians [42] may be "subtler and less electric" [43] in the elderly.

The clinician who understands that classic presentations of surgical disease occur in a minority of elderly patients will maintain the high index of suspicion needed to minimize delay in diagnosis.

Principle II: Lack of Reserve

The elderly handle stress satisfactorily but handle severe stress poorly because of lack of organ system reserve.

Functional reserve may be considered the difference between basal and maximal function; it represents the capacity to meet increased demands imposed by disease or trauma. Although there is variability among individuals, this organ system reserve inexorably declines in one's 70s, 80s, and 90s. With excellent anesthetic and perioperative care, the aged patient may tolerate the stress of even complex surgery – particularly if elective – but not the added stress of exceptional or emergency surgery.

The elderly patient with lung cancer, for example, can undergo routine pulmonary lobectomy with results nearly indistinguishable from those of the general population [44, 45], but the added stress of concomitant chest wall resection leads to a disparate increase in risk. In Keagy's series [46], the one death and two of the three respiratory failures were in patients who underwent the *en bloc* chest wall resection. An elderly patient, entering the operating room with decreased chest wall compliance and strength and decreased elastic recoil as a baseline, may tolerate lung resection but lacks the reserve to tolerate an extended operation. Other researchers have reported increased mortality in septuagenarians and octogenarians following pneumonectomy, especially right pneumonectomy or completion pneumonectomy [47–49].

On the other side of the spectrum, more limited procedures, such as video-assisted thoracic surgery, may decrease stress further by preserving respiratory muscle strength [50–53]. Yim [53] reported no deaths or pulmonary complications following thoracoscopic surgery in 22 patients over age 75 years, five with major resections, and Jaklitsch [51] found decreased mortality, length of hospital stay, and postoperative delirium after 307 video-assisted procedures in patients aged 65–90 compared to that associated with open thoracotomy. Video-assisted pulmonary lobectomy in half of a group of elderly lung cancer patients resulted in fewer complications ($p = 0.04$) and decreased length of stay ($p < 0.001$) compared to the half who underwent open (thoracotomy) lobectomy [54]. Patel [55] reported shorter hospitalization and similar late outcomes following endovascular thoracic aortic procedures in patients greater than 75 years, compared to open procedures. Endovascular repair of abdominal aortic aneurysm in the elderly had decreased all-cause and aneurysm-related mortality compared to open repair [56]. Partial as compared to radical nephrectomy resulted in improved survival in elderly patients who were candidates for either procedure [57].

Left ventricular functional reserve assumes critical importance in elderly patients undergoing cardiac surgery. In general, results in the elderly diverge from those of young age groups only in the worst functional classes. Bergus et al. [58], for example, found that length of stay following aortic valve replacement was significantly longer ($p < 0.05$) in septuagenarians in New York Heart Association class IV but not in class III, compared to patients under age 70. Patients over age 75 in Salomon's large series [59] had significantly higher mortality after coronary artery

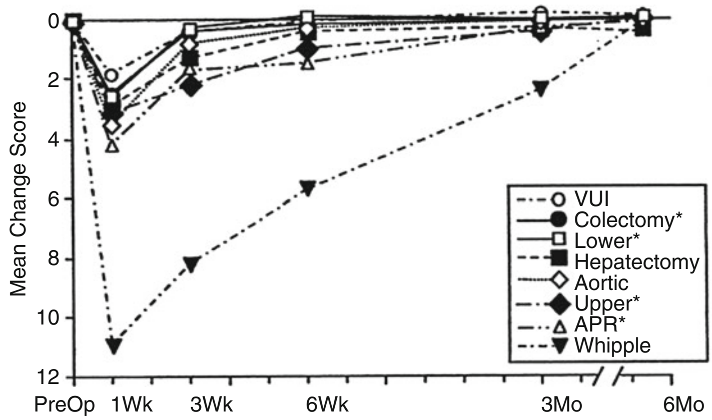

Fig. 3 Return to Activities of Daily Living after major surgery (function returns rapidly after stressful operations but not the most stressful, speaking to lack of reserve). (From Lawrence [72] with permission)

bypass grafting if they had suffered a myocardial infarction less than 3 weeks preoperatively compared to more than 3 weeks (14.1% vs. 5.2%); there was much less difference in patients younger than age 75 (3.5% vs. 2.3%). When patients over age 70 years undergo a third coronary reoperation, only those in the worse Canadian Functional Class experience increased mortality, an increase not seen in young patients in a similar class [60]. Elayda [61] reported that mortality for isolated aortic valve replacement in patients over age 80 was acceptable (5.2%), but addition of concomitant procedures increased this figure significantly (27.7%). In cardiac surgery, too, a lesser procedure may be just as good in the elderly: contrary to a younger population, limited coronary revascularization appears to be acceptable in the high-risk elderly [62, 63].

Similar findings pertain to major abdominal surgery. Fortner and Lincer [64] found that the increased number of deaths among elderly patients undergoing hepatic resection for liver cancer were nearly all in the extended-resection group (i.e., extended right hepatectomy or trisegmentectomy), among whom 60% of deaths were due to hepatic insufficiency. In another group of hepatic resections done for metastatic colon cancer, where cirrhosis and functional hepatic reserve are less important factors, there was no difference in mortality between young and old patients [65]. Even the addition of common duct exploration to open cholecystectomy significantly increased mortality in the elderly (3.5% vs. 1.8%, $p < 0.05$) [66]. For some oncology cases (e.g., gastric cancer, lung cancer), a more limited operation in the elderly need not decrease survival [67–70].

The elderly can return to normal function after stressful operations (such as colectomy and hepatectomy), but after the most stressful operations (such as Whipple pancreaticoduodenectomy) it will take longer [71, 72]. (Fig. 3)

With modern anesthetic and critical care management, an elderly patient can tolerate the stress of even complex operations. However, if the most extended procedures are contemplated, a comprehensive preoperative evaluation of functional reserve is recommended.

Principle III: Preoperative Preparation

Optimal preoperative preparation is essential because of Principle II. When preparation is suboptimal the perioperative risk increases.

A patient's advanced age is immutable, but some factors can be improved preoperatively, with benefits in excess of those to a younger patient. No universal threshold of blood hemoglobin applies to every patient, but correction of anemia and dehydration do assume greater importance in the elderly because of their general lack of reserve and particularly the physiology of the aged heart and kidney. Among the predictors of an overall good postoperative course in Seymour's series of

288 elderly general surgery patients were a hemoglobin level of more than 11.0 g/dl and absence of volume depletion [73]. Contrary to this, Dzankic found that routine blood testing in the elderly surgical patient rarely showed abnormal results and even when abnormal did not correlate with adverse postoperative outcome [74].

Few would argue that pulmonary problems are among the most common perioperative complications in the elderly, in part due to decreased respiratory muscle strength. Nomori [52] showed that following thoracotomy patients older than 70 years experience significant reductions in both maximum inspiratory and expiratory pressures, unlike their younger counterparts; this effect persists for 12 weeks (Fig. 4). Although few data exist to support the routine use of preoperative pulmonary conditioning or rehabilitation, most authors strongly advocate smoking cessation [75] and treatment of bronchitis and reactive airways disease such as asthma [76, 77]. Prophylaxis against deep vein thrombosis (DVT), clearly a risk in the elderly [78], and against pulmonary embolism should be routine [79].

Another unsettled issue concerns the value of aggressive preoperative screening for coronary and carotid artery disease, particularly in patients scheduled for peripheral vascular surgery. Leppo [80] considered age over 70 years one of several risk factors (the others being a history of angina, congestive heart failure, diabetes mellitus, prior myocardial infarction, and ventricular ectopy), which should trigger further cardiac assessment. Echocardiogram and dobutamine stress testing have been shown to bear incremental value over clinical evaluation [81].

There is some evidence that performance testing may hold value. Maximal oxygen consumption (VO2 Max) tests [82] may not be readily available in all hospitals, but reasonable surrogates – stair climbing [83–85], shuttle walk [86], long distance corridor walk [87], gait speed [88, 89], metabolic equivalent (MET) – have been shown to correlate. Weinstein [90] reported prolonged length of stay following thoracic cancer surgery in those patients with METs ≤4 (equating to calisthenics or walking briskly). The International Society of Geriatric Oncology has studied a standardized Preoperative Assessment in Elderly Cancer Patient (PACE); postoperative complications were associated with poor preoperative performance status and lower score on Instrumental Activities of Daily Living, but major complications correlated only with American Society of Anesthesiologists (ASA) Physical Status ≤2 [91] (Table 3). However, as Internullo recently concluded, "a practical and

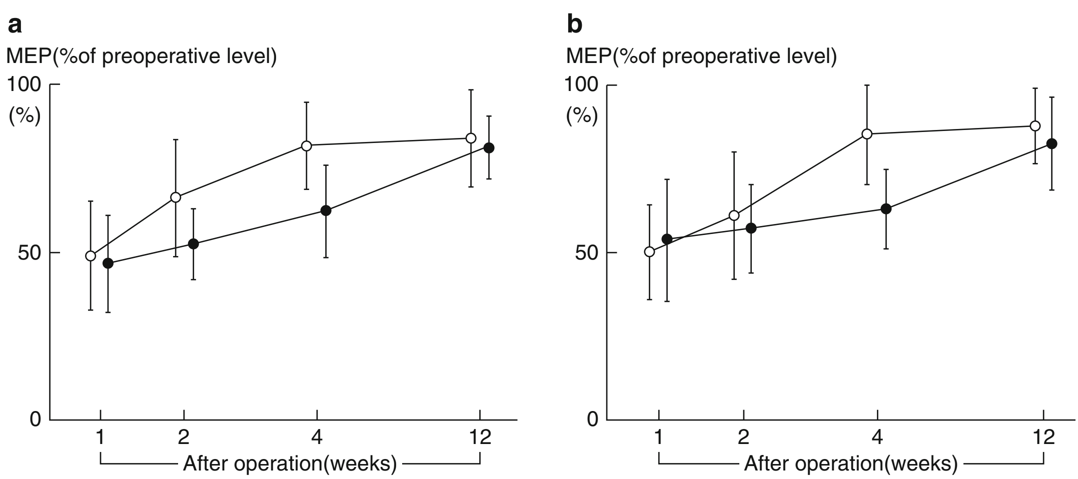

Fig. 4 Postoperative changes in mean (**a**) maximum inspiratory pressure (MIP, percent of preoperative level) and (**b**) maximum expiratory pressure (MEP, percent of preoperative level) following pulmonary resection in 36 patients younger than 69 years (open circles) and 12 patients older than 70 years (closed circles). (From Nomori [52] with permission)

Table 3 Univariate association between components of PACE with 30-day morbidity (any and major complication) adjusted for age, sex, type, and stage of cancer and severity of surgery

Component of PACE	Any complication RR[a]	95% CI	Major complication RR[a]	95% CI

[a]Bold italics: significant relationship ($p < 0.05$)

reliable individual risk assessment tool is still lacking" [92]. We have termed this simple, reliable test to assess perioperative risk the Holy Grail of Geriatric Surgery [93].

Preoperative antibiotics are not necessary for every type of elective surgery, but researchers agree that advanced age is a risk factor for nosocomial infection. Iwamoto [94] studied 4380 patients who underwent general anesthesia for thoracic, abdominal, or neurologic surgery and concluded that advanced age is a risk factor for nosocomial pneumonia, especially after thoracic surgery. Age greater than 70 years has been shown to be a risk factor for both positive bile cultures ($p < 0.001$) [95] and septic complications of biliary surgery compared to younger patients [96]; antibiotic prophylaxis can reduce these complications [97].

Efforts to improve our elderly patients' preoperative nutritional state would seem desirable – even active, community-dwelling older adults manifest impaired recovery of strength after major surgery [98] – but it is unclear how to do this. Low levels of serum albumin, for example, correlate strikingly with postoperative problems [99] (Fig. 5) but cannot be improved to a great degree preoperatively. Souba [100] reviewed the literature on nutritional support and concluded that preoperative support should be reserved for severely malnourished patients scheduled to undergo major elective surgery and then should be provided for no more than 10 days.

In addition to those already cited, a number of surgeons have attributed their improved results in elderly patients to compulsive preoperative preparation. Bittner [101] believed that the significant decrease in mortality after total gastrectomy in septuagenarians (32.0% in 1979 to 4.4% in 1996) was the result of standardized perioperative antibiotics, thromboembolic prophylaxis, "a systemic analysis of risk factors and their thorough preoperative therapy," and nutritional support for the malnourished.

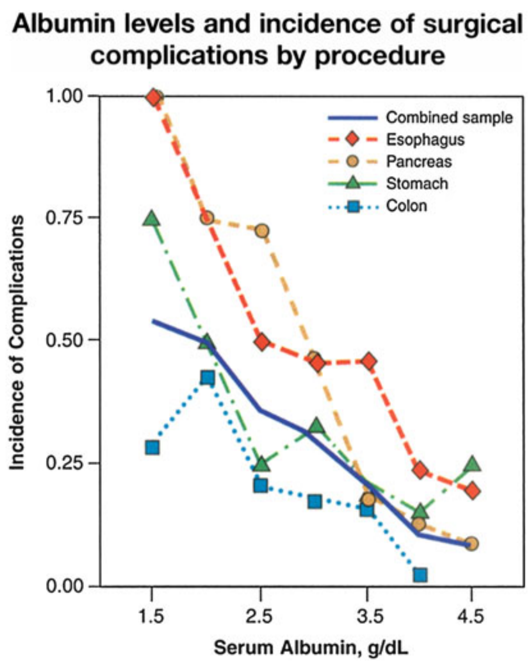

Fig. 5 Preoperative albumin level and major postoperative complications. (From Kudsk [99] with permission)

Hypovolemia is tolerated poorly by the elderly patient and it must be corrected. Smoking should be stopped. Treating other correctable aberrations such as anemia, bronchitis, and hypertension preoperatively increases the elderly patient's chance for a smooth postoperative course.

Principle IV: Emergency Surgery

The results of elective surgery in the elderly are excellent in some centers; the results of emergency surgery are poor though still better than non-operative treatment for most conditions. The risk of emergency surgery may be many times that of similar elective surgery because of Principles II and III.

Many centers have been able to achieve excellent results for elective surgery in the elderly, results indistinguishable from those in younger counterparts [102–104]. Coyle [105] reported the results of carotid endarterectomy in 79 octogenarians and summarized the results of five other series (634 total patients); mortality and morbidity were similar to those in a younger cohort. Maehara [106] had 0% operative mortality in 77 patients over age 70 who underwent resection of gastric carcinoma, and Jougon's [107] results for esophagectomy in 89 patients aged 70–84 years were identical to those in 451 younger patients. An 85-year-old patient with lung cancer could anticipate mortality and survival after pulmonary lobectomy statistically identical to that of younger patients with similar stage disease [76, 102, 108–110].

Identical operations performed emergently in the elderly, however, carry at least a threefold (and as much as a tenfold) increased risk [111] (Table 4). Keller [112], for example, reported 31% morbidity and 20% mortality in 100 patients over age 70 who underwent emergency operations, which is significantly more ($p < 0.0005$) than the 6.8% morbidity and 1.9% mortality following elective operation in 513 similar patients. Elective cholecystectomy can be performed in young and old with the risk of death approaching 0% [25, 113, 114]; the risk of mortality for emergency cholecystectomy increases somewhat in the younger group (1–2%) but increases greatly in the elderly (5–15%) [25]. Surgical priority clearly affects cardiac surgery risk [115, 116]. Elective operative mortality for colorectal surgery is as low as 1.5–3.0%, rising to over 20% for emergency operation [117, 118]. Nearly all of the deaths following paracolostomy hernia repair in Gregg's series were in patients older than 70 years who required emergency surgery [119].

Table 4 Emergency surgery

80–103 Years of age		
Predictive factors	Odds ratio (95% CI)	*p* Value
Emergency operation	11.4 (4.7–27.5)	<0.0001
ASA classification: 1, 2	0.1 (0.03–0.7)	0.0134
ADL impairment	3.2 (1.3–8.1)	0.0116
–	–	–
–	–	–
RVU	1.06 (1.009–1.103)	0.0176
Operative duration	1.17 (1.05–1.3)	0.0039
Hypertension	0.3 (0.1–0.6)	0.0019
–	–	–
–	–	–
–	–	–

A patient's advanced age therefore weighs in favor of commencing rather than deferring needed elective surgery.

Principle V: Attention to Detail

Scrupulous attention to detail intraoperatively and perioperatively yields great benefit, as the elderly tolerate complications poorly (because of Principle II).

Perioperative blood loss is the *bete noire* of geriatric surgery, as the elderly lack the responsive compensatory mechanisms necessary to restore equilibrium. Fong [65] reported that the only independent predictor of postoperative complications in 138 patients over age 70 who underwent pancreatic resection was intraoperative blood loss exceeding two liters. This finding has been mirrored in reports from cardiac surgery and neurosurgery. Sisto [120] reported that six of 23 octogenarian coronary bypass patients who required reexploration for tamponade died;

Logeais [121] found that reoperation for tamponade following aortic valve replacement placed the elderly patient at high risk for mortality ($p < 0.001$). Hemostasis is exceptionally important in the elderly craniotomy patient, possibly because the elderly brain is less likely to expand to obliterate dead space: Maurice-Williams [122] reported that postoperative bleeding following resection of meningioma occurred in 20% of 46 elderly patients and 0% of 38 young patients ($p < 0.05$).

Meticulous surgical technique is important in any patient, but it becomes crucial in those of advanced age. Anastomotic leak after esophageal or gastric resection, a dreaded complication in any patient, embodies an exceptional risk of mortality in the elderly [123]; yet this complication can be minimized by careful technique [124, 125]. Only one of Bandoh's [126] elderly patients who underwent gastrectomy for cancer experienced a leak, as did only 2 of 163 patients over age 70 in Bittner's series [101]. Despite having significantly greater preoperative co-morbidity, the elderly patients undergoing gastrectomy in Gretschel's series experienced no greater postoperative morbidity [68]. The elderly cardiac surgery patient may benefit from extra care when they have a calcified aorta (e.g., intraoperative ultrasound or modified clamping and cannulation technique) or a fragile sternum (e.g., additional or pericostal wires) [127]. Operative speed is less important than technique: in Cohen's series of 46 nonagenarians undergoing major procedures [7], the duration of operation did not correlate with mortality.

Perioperative monitoring is more important in the elderly, since they may manifest few signs or symptoms of impending problems (see section "Principle I: Clinical Presentation"). Bernstein [128] credits intensive hemodynamic monitoring in his lack of mortality among 78 patients over age 70 who underwent abdominal aortic aneurysmectomy. Such monitoring and intensive care were also emphasized by Alexander [3], who reported excellent results for 59 octogenarians having major upper abdominal cancer operations, and by Lo [129] for 85 elderly patients undergoing adrenal surgery at the Mayo Clinic. Giannice [130] credits attention to perioperative care (DVT prophylaxis, antibiotics, monitoring, respiratory care, pain management, early mobilization) for his group's improved recent results in gynecologic oncology patients. Adequate resources such as skilled nursing facilities for the more complex patients are important [131].

Table 5 Complications

Multivariate analysis of failure to return to premorbid function		
All cases	Odds ratio	95% Confidence interval
Emergency operation	2.7	0.99–7.24
ASA III or IV	1.0	0.29–3.56
Comorbidity index >5	1.8	0.48–6.66
Dependence on activities of daily living	1.8	0.42–7.73
Preexisting cardiac disease	1.9	0.69–5.44
Preexisting chronic pulmonary disease	2.0	0.54–7.47
Preexisting cerebrovascular disease	2.0	0.43–9.06
Development of postoperative complications	**24.5**	**3.08–194.88**
Elective cases only		
Comorbidity index >5	**11.2**	**1.08–116.26**
Development of postoperative complications	**10.6**	**3.08–194.88**

We may continue to teach the surgical aphorism, "Elderly patients tolerate operations but not complications" (Table 5).

Principle VI: Age is a Scientific Fact

A patient's age should be treated as a scientific fact, not with prejudice. No particular chronologic age, of itself, is a contra-indication to operation (because of Principle IV).

Great biologic variability exists among the elderly, with some octogenarians and nonagenarians proving to be healthier than their sons and daughters. Even an 85-year-old patient has a life expectancy exceeding 5 years [132, 133], so why not offer him resection of his lung cancer? No other treatment is likely to give him those 5 years. Yet even in 2005 this does not always happen: prejudice against the elderly, so-called "ageism" exists.

Despite the fact that elderly patients treated for lung cancer have survival equal to their younger matched counterparts, Nugent [134] found that patients older than 80 years were significantly less likely ($p < 0.05$) to be treated surgically. In England, the elderly are less likely to have histologic confirmation of their lung cancer and less likely to undergo anticancer treatment [135], although resection rates are increasing [136]. Kuo [137] also reported that octogenarian patients with lung cancer were more likely ($p < 0.01$) to receive only palliative care; when offered, they tolerate chemotherapy [138].

Elderly patients with ovarian cancer are less likely to undergo aggressive chemotherapy and surgery [139, 140] despite results equal to the young [141]. This has been reported with adjuvant treatment following pancreatic resection as well [71]. Older women with breast cancer were less likely to have had screening mammograms [142, 143] and were more likely to present in advanced stages than younger women [143]; once diagnosed, they tolerated surgery well [144, 145]. Guadagnoli [146] presented evidence against ageism in the treatment of early breast cancer, but Herbert-Croteau [147] found that only tamoxifen use was similar in women over and under age 70 ($p < 0.41$), while all other treatments (breast-conserving surgery, radiotherapy, axillary node dissection, chemotherapy) differed significantly ($p < 0.0001$). When elderly patients do receive chemotherapy for breast cancer, they tolerate it [148] and they benefit from it [149]. Elderly patients with colon cancer are less likely to undergo extensive lymph node dissection ($p < 0.0001$) [150]. Fewer than one in ten eligible older patients, with a low cardiac ejection fraction following myocardial infarction, received an implantable cardioverter-defibrillator [151]. Selection bias in the elderly may also lead to delay in referral for abdominal aortic aneurysm surgery [152] and coronary artery bypass surgery [153].

When patients are denied surgery they often do poorly. In Pierard's [154] study of 163 octogenarians with severe aortic stenosis and clear indication for operation according to established guidelines, 40% either refused or were denied operation; this resulted in twofold excess mortality even after adjustment for co-morbidities (Fig. 6). In a study of pancreatic cancer patients across the United States, those undergoing resection, regardless of age group into the 80s, were less than half as likely to die as the youngest group of unresected patients [155]. Owonikoko [156] noted, "Published evidence suggests that elderly patients are denied potentially beneficial treatment and participation in clinical trials solely because of chronologic age and because of physician perception that they are too frail to withstand treatment."

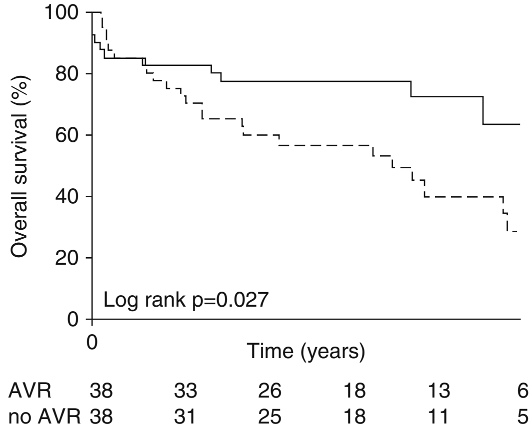

Fig. 6 Propensity score matched patients who refuse or are denied surgery for aortic valve diseased (dashed line) have decreased survival compared to those who undergo aortic valve replacement (solid line). (From Pierard [154], with permission)

Some studies do report increased operative mortality [14, 111, 157–159] (Fig. 7), increased complications [160, 161] (Fig. 8), and increased lengths-of-stay in the elderly [162–167], but overall results in many centers do not differ from the young for a wide variety of procedures: neurosurgery [122, 168]; head and neck surgery [36, 169, 170]; carotid endarterectomy [171, 172]; cardiac surgery [61, 127, 153, 173–177]; esophagectomy [92, 107, 124, 178–180] (Fig. 9); gastrectomy [3, 106, 181–183] (Fig. 10); colectomy [184–186] (Fig. 11); hepatectomy [65, 187–190] (Fig. 12); pancreaticoduodenectomy [65, 71, 191, 192]; radical hysterectomy [193]; total knee/hip replacement [194–196]; microvascular free tissue transfer [197]; cardiac transplant [198–200]; lung

transplant [201]; endovascular surgery [202]; gastric bypass [203]; laparoscopic colectomy [204]; and hernia [205]. Return to preoperative quality of life (QOL) is gratifying after elective surgery for gastric or colorectal surgery [206], joint replacement [196], thoracic aneurysm [207] (Fig. 13), and aortic valve replacement [208, 209].

For most patients, general medical condition and associated medical problems are more important than age. Dunlop [210] studied 8889 geriatric surgical patients in Canada and concluded that severity of illness on admission was a much better predictor of outcome than was age; Akoh [211] had similar findings in 171 octogenarians undergoing major gastrointestinal surgery. Co-morbidities were a greater influence on survival than age in several series of elderly patients with lung cancer [44, 45, 212]. Mehta [213] reported that separation of mitral valve replacement patients into low, medium, and high risk medical groups was more important than stratification by age within these three groups. Within the American Society of Anesthesiologists (ASA) Physical Status system [214], the ASA status influences results more than age. For elderly patients undergoing surgery for cancer, the stage of the malignancy also influences outcome more than age [45, 215–218].

Ageism may even be detrimental for the ageist [219].

Many geriatric surgery patients, including nonagenarians, have survival rates equal to those expected in the general population; even the sobering results of emergency surgery in the elderly are better than the results of nonoperative treatment for the same conditions. A patient's age should therefore be considered but not feared.

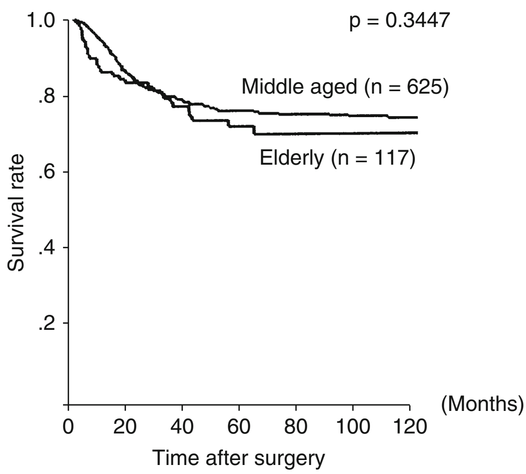

Fig. 10 Surgical outcome in elderly (≥75 years) and middle-aged (45–65 years) patients with gastric cancer. (From Kunisaki [182] with permission)

Conclusion

Surgical problems abound in the elderly and the numbers of elderly are increasing worldwide. Surgeons must become students of the physiologic changes that occur with aging and, guided by a few general principles, apply this knowledge to daily clinical care. The results of surgery in the elderly do not support prejudice against advanced age. We owe it to our elders to become good geriatric surgeons and in so doing we will become better surgeons to patients of all ages.

Defining Quality of Care

2

Jill Klausner and Marcia McGory Russell

Contents

Abstract

The aging of the US population will place significant stress on the current health-care system. The impact of the aging population on the surgical disciplines is especially apparent given the inherent risks of undergoing surgery. It is essential that we develop strategies to deliver high quality and patient-centered care for this vulnerable population. Quality of care in surgery dates back to the early 1900s when Ernest Amory Codman was among the first to systematically measure, analyze, and compare patient care and outcomes. However, only recently has quality of care in geriatric surgery received systematic attention. For example, there have been efforts from the Institute of Medicine, American College of Surgeons, and American Geriatrics Society to improve the quality of care in this population. Using the Donabedian model of quality evaluation (e.g., structure, process, and outcomes), it is clear that there have been marked improvements within five domains important in the perioperative care of geriatric patients: cognitive impairment, functional status, frailty, medication management, and patient

goals and preferences. Quality improvement in the relatively young field of geriatric surgery is progressing at a rapid rate and beginning to gain the national attention needed to optimize care for this unique patient population.

Impact of the Aging Population

The aging of the US population will place significant stress on the current health-care system. Baby boomers began turning 65 in 2011 and life expectancy has also significantly increased [1]. As a result, the growth rate of the elderly population (aged 65 and older) exceeds the growth rate of the population as a whole. The elderly population currently represents 15% of the total population, but is expected to increase to 21% by 2030 [2]. By 2050, this population is expected to reach 83.7 million individuals, and the population of even older individuals (over age 85) is predicted to reach 18 million [1].

It logically follows that the elderly population is responsible for a disproportionate amount of health-care utilization and cost. In 2007, patients aged 65 years and over represented 37% of hospital discharges and 43% of hospital days, even though this age group only accounted for 13% of the population at that time [3]. Patients aged 65 years and over also stay in the hospital for longer, with an average length of stay of 5.6 days, compared to 5.1 in 45–64 year olds and 3.7 days in 15–44 year olds [3]. Greater than one third of all patients aged 85 and older were discharged to a long-term care facility, compared to less than 25% of their younger elderly counterparts. It has long been known that the aging of the population will affect the overall allocation of health care resources. However, the impact on the surgical disciplines is especially apparent given the inherent risks of undergoing surgery.

As our surgical expertise grows and less invasive operations become more widespread, it is not surprising that the threshold for performing surgery in the elderly has decreased. Older patients now consume a great proportion of surgical care. Patients aged 65 and older account for 36% of all inpatient operations in the USA [3] and more than half of all general surgery, orthopedic, and urological surgical procedures [4]. These numbers are expected to increase 31% by 2020 [4]. Given this significant increase in demand for surgical services in the elderly population, it is essential that we develop strategies to deliver high quality and patient-centered care for this vulnerable population.

Quality of Care in Surgery

The history of quality of care in surgery dates back to the early 1900s when Ernest Amory Codman founded the End-Result Hospital where he was among the first to systematically measure, analyze, and compare patient care and outcomes. He later published his work in an article titled *A Study in Hospital Efficiency* [5]. Decades later, it was clear that despite Codman's efforts and contributions, there was still much work to be done. In the 1980s, the US Congress brought into question the quality of surgical care provided by the Department of Veterans Affairs (VA) hospitals. Congress was concerned that operative mortality rates were inappropriately high – above the national average. Unfortunately, the "national average" was unknown at this time because this data did not exist. In response, the VA began collecting data on pre- and intraoperative variables and outcomes and the VA Surgical Quality Improvement Program (VASQIP) was established in 1994. After the introduction of this program, outcomes at VA hospitals significantly improved. By the year 2000, there was a 27% decrease in 30-day postoperative mortality and a 45% decrease in 30-day morbidity [6]. With the addition of private hospitals and academic centers, the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) was born, and has been named the best in the nation for measuring and reporting surgical quality and outcomes by the Institute of Medicine (IOM). Today there are almost 700 hospitals participating in ACS NSQIP, and the program continues to grow.

The past few decades have been marked with great improvements in the quality of care in surgery, but it is difficult for one database alone to cater to all subpopulations of patients. In addition to ACS NSQIP, organizations, initiatives, and coalitions have formed, each with a more narrow focus. Most relevant for this chapter, elderly surgical patients have recently been recognized as a unique population and there are ongoing efforts to identify factors most important to this population in order to improve care. The IOM addressed the health-care issues of our aging population through the Committee on the Future Healthcare Workforce for Older Americans in a 2008 report entitled *Retooling for an Aging America: Building the Healthcare Workforce* [7]. The committee proposed three mechanisms for improving the ability of our health-care system to care for older Americans: (1) enhance the competence of all individuals in the delivery of geriatric care, (2) increase the recruitment and retention of geriatric specialists and caregivers, and (3) redesign models of care and broaden patient and provider roles to achieve greater flexibility. More recently the ACS NSQIP and ACS Geriatric Surgery Task Force initiated the ACS NSQIP Geriatric Surgery Pilot Project to assess the value of adding geriatric-specific variables to the NSQIP database with the ultimate goal of using this data to evaluate interventions for improving outcomes in the elderly population. Data collection began in January 2014 and data has now been collected on more than 30,000 patients [8]. The variables collected fall into the following elderly specific domains: function, mobility, cognition, and healthcare goals. Additionally, the Coalition for Quality in Geriatric Surgery (CQGS) is a project supported by the John A. Hartford Foundation and the ACS that aims to set standards for geriatric care, verify these standards, develop patient-centered geriatric measures, and educate patients and providers over a 4-year grant period (2015–2019) [8]. These efforts specific to older adults are timely given the aging of the population and the emerging body of research suggesting that novel ways of providing surgical care to this population are needed.

Until recently, no guidelines existed for the perioperative care of older adult patients. Motivated by the projected growth of the over-65 age group and the increasing demand for surgical services from this population, in 2009, McGory et al. identified 91 valid quality indicators for elderly patients. Of note, 78% of these indicators were not routinely used in the assessment or management of younger patients, underscoring the uniqueness of this population and the importance of developing similarly unique quality indicators [9]. This work laid the foundation for the ACS NSQIP/American Geriatrics Society (AGS) Best Practices Guidelines published in 2012 and 2016. The 2012 ACS NSQIP/AGS Best Practices Guidelines: Optimal Preoperative Assessment of the Geriatric Surgical Patient provided guidelines within nine categories: cognitive/behavioral disorders, cardiac evaluation, pulmonary evaluation, functional/performance status, frailty, nutritional status, medication management, patient counseling, and preoperative testing [10]. In 2016, the ACS NSQIP/AGS published a comprehensive set of guidelines for the perioperative management of geriatric patients, also based upon the quality indicators developed by McGory et al. These guidelines addressed issues in the immediate preoperative period (e.g., preoperative fasting antibiotic prophylaxis, venous thromboembolism prevention), the intraoperative period (e.g., anesthesia, analgesia, perioperative nausea and vomiting), and the postoperative period (e.g., delirium, pulmonary complications, fall prevention, functional decline) [11]. The development of clinical practice guidelines was an important step toward improving the quality of care, but a multifaceted systems-based approach will likely be necessary to optimize the care of older adults undergoing surgery.

Quality of Care Definitions

The conceptual framework driving quality improvement is based on the Donabedian model of quality evaluation, where care can be categorized into three types: structure, process, and outcomes [12]. As shown in in Fig. 1, structural items

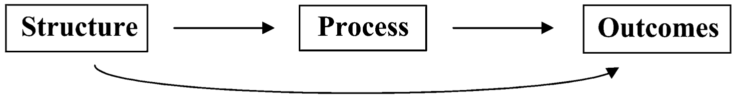

Fig. 1 Donabedian model of quality of care

are thought to influence both process and outcomes. Specifically, structural items include characteristics of the clinician (e.g., board certification), hospital (e.g., staffing patterns, procedure volume), and patients (e.g., insurance type, severity of comorbidities). Process refers to whether the medically appropriate decisions are made and whether care is provided in an effective and skillful manner. Process items are the activities that occur between the patient and practitioner (e.g., diagnosis, treatment, patient education). Outcomes data apply directly to patients and include mortality, morbidity, functional status, and quality of life. With respect to quality of care in geriatric surgery, examples of structural items include presence of a hospital ward designed for elderly patients or presence of a geriatric care coordinator. Examples of process items unique to geriatric surgery may include co-management of a geriatric surgery patient by a geriatrician or internist, and preoperative completion of a comprehensive geriatric assessment. Examples of outcomes unique to the geriatric surgery population may include postoperative delirium, change in functional status, and discharge to a skilled nursing facility.

We will now address five domains important in the perioperative care of older adult patients: cognitive impairment, functional status, frailty, medication management, and patient goals and preferences. There are current efforts to improve quality in each of these domains, and we will highlight examples of improvement in structure, process, and outcomes in each section.

Cognitive Impairment

Preoperative cognitive impairment has been shown to predict worse postoperative outcomes, and thus is an important domain to target in order to improve quality of care. Older adults with cognitive impairment have higher rates of postoperative pneumonia, renal insufficiency, urinary tract infections, venous thromboembolism, increased length of hospital stay, discharge institutionalization, and death when compared to matched counterparts without impaired cognition [13, 14]. Preoperative cognitive impairment also strongly predicts postoperative delirium [15], which in itself is associated with poor outcomes [16].

Early studies suggested that prevention of delirium is likely to have the most favorable impact on outcomes, so one focus of quality improvement in this domain is primary prevention [20]. Programs such as the Hospital Elder Life Program (HELP) and Nurses Improving Care for Healthsystem Elders (NICHE) have improved the quality of geriatric care in many ways, including a reduction in the incidence of delirium [17, 18]. HELP targets the processes of care and is specifically designed to reduce cognitive and functional decline during hospitalization by utilizing a skilled interdisciplinary team to implement targeted interventions [19]. The program screens patients for specific risk factors such as cognitive impairment, sleep deprivation, immobility, dehydration, and vision or hearing impairment and then implements targeted interventions (e.g., daily visitor/orientation, early mobilization, oral volume replacement, sleep enhancement) [19]. NICHE, on the other hand, targets both structure and process. Structural components of NICHE include the use of the Geriatric Resource Nurse model and the Acute Care for Elders (ACE) model, as well as an enhanced physical environment with flooring, furniture, fixtures, and beds adaptable to age-related changes. Process elements of NICHE include the use of a geriatric institutional assessment profile, staff development tools (e.g., use of a 5-part NICHE Introduction to Gerontology learning program), and the use of research-based clinical protocols (e.g., improving detection and management of delirium) [17].

The prevention and treatment of delirium in older adults differs from that in younger adults, and must be addressed as well. The AGS published clinical practice guidelines for postoperative delirium in older patients in 2015, emphasizing eight strong recommendations to assist providers in preventing and treating postoperative delirium (see Table 1) [20]. This is an example of process improvement – ensuring that medically appropriate decisions are made. Delirium in older adults is still incompletely understood and research further investigating risk factors and outcomes is ongoing. One current project underway is the Successful Aging After Elective Surgery Study (SAGES), which is a long-term prospective cohort study and an ongoing effort to examine novel biomarkers, neuroimaging markers, and long-term outcomes associated with delirium [21].

Table 1 Summary of strongly recommended AGS clinical practice guidelines for postoperative delirium in older adults

Recommendation
1) Healthcare systems should implement formal educational programs for healthcare professionals on delirium in older surgical adults
2) Healthcare systems should implement nonpharmacologic intervention programs for the entire hospitalization in at-risk older adults undergoing surgery
3) The healthcare professional should evaluate for and treat underlying contributors to delirium after an older adult has been diagnosed with postoperative delirium
4) Healthcare professionals should optimize postoperative pain control, preferably with nonopioid medications
5) Prescribing practitioners should avoid medications that induce delirium postoperatively (e.g., benzodiazepines, anticholinergics, diphenhydramine, meperidine)
6) Prescribing practitioners should not newly prescribe cholinesterase inhibitors perioperatively to prevent or treat delirium
7) Prescribing practitioners should not use benzodiazepines as a first-line treatment of postoperative delirious patients threatening substantial harm to self and/or others. Treatment with benzodiazepines should be at the lowest effective dose for the shortest possible duration and employed only if behavioral measures have failed or are not possible. Ongoing use should be evaluated daily
8) Prescribing practitioners should not prescribe any antipsychotic or benzodiazepine for the treatment of older adults with postoperative delirium who are not agitated or threatening substantial harm to self or others

Functional Status

Functional status is both a predictor of postoperative outcomes and an important patient-centered outcome itself. There are a variety of assessments used to classify functional status, including independence in activities of daily living (ADLs), walking speed, and the timed up and go test. Studies have used each of these measures and have clearly shown that impaired functional status is related to poor postoperative outcomes. One study showed that having a timed up and go test score >20 s is an independent risk factor for postoperative delirium [22]. A study of patients undergoing elective general and vascular surgery showed that patients who require any assistance from another person for activities of daily living have 75% greater odds of mortality and 51% greater odds of major morbidity postoperatively than matched functionally independent patients [23].

Berian et al. used data from the ACS NSQIP Geriatric Surgery Pilot Project to show that older patients are more likely than their younger counterparts to experience loss of independence (LOI) after surgery. LOI was defined as a decline in function, increased care needs, or discharge to a post-acute care facility. LOI occurred in more than half of elderly surgical patients, and the risk of LOI increased with age, to 84% in patients 75 years and older [24]. In addition to the direct negative effect LOI has on quality of life for the elderly, it was also shown to increase the risk of readmission by 70% and the risk of death after discharge by 6.7-fold [24].

Quality improvement in this domain initially started with addressing structure, which secondarily improved process. Several programs emerged in the 1990s that restructured the hospital environment in an attempt to improve the care delivered to elders and thus improve outcomes, most notably the ACE model [25]. The ACE unit was developed with the goal of lessening functional decline in elderly hospitalized patients. ACE units are equipped with elderly friendly elements such as carpeted floors, handrails, uncluttered hallways, and adequate space for visitors in dining rooms and patient rooms. They also employ the use of protocols to assess medications, review plans for medical care and procedures, and prepare early for discharge from the hospital [25]. Randomized controlled studies showed great efficacy of ACE units in preventing functional decline and long-term institutionalization, specifically by using a change in structure to affect change in processes and outcomes [26]. Unfortunately, ACE units are not currently the standard of care, likely because of high initiation cost, scarcity of geriatricians, and a perception that benefits are limited to a small population within each hospital.

Because ACE units have not been widely adopted, efforts have been made to disseminate ACE concepts to hospitals that do not have ACE units or geriatricians by teleconferencing and a software program called the ACE Tracker. The ACE tracker uses data from the electronic health record to generate a daily report of elderly specific information for all patients aged 65 and older in the hospital [27]. Examples of data included in this report include history of cognitive impairment, assessment for delirium, use of restraints, total number of prescribed medications, recent use of high-risk medications, fall risk, activities of daily living, and whether physical and occupational therapy assessment has been ordered. The goal is that this report serves as a guide to enable the multidisciplinary team to review multiple older patients in an efficient and effective manner. The HELP, NICHE, ACE, and the ACE Tracker models of care are all currently implemented and successful at select hospitals, but the next step in quality improvement will involve broad dissemination of these programs or at least their core concepts.

More recently, the idea of prehabilitation for elderly surgical patients has emerged as a potential intervention to improve postoperative outcomes. Prehabilitation programs aim to enhance the preoperative condition of a patient by improving functional capacity, and have been implemented in multiple surgical fields including orthopedic surgery, bariatric surgery, cardiac surgery, and colorectal surgery. There is wide variation in the composition of prehabilitation programs and the outcome measures used to evaluate their impact, and many studies are small in size and poor in quality, making it difficult to show that such programs can improve postoperative outcomes [28, 29]. However, some studies have shown good outcomes, including one randomized controlled trial in colorectal surgery in which postoperative functional capacity improved after implementation of a prehabilitation program consisting of aerobic exercise, nutritional counseling, and relaxation exercises [30].

Frailty

Frailty is defined as a “biologic syndrome of decreased reserve and resistance to stressors” and has recently emerged as a geriatric-specific preoperative variable strongly associated with adverse surgical outcomes including postoperative complications, increased length of stay, discharge to a post-acute care facility, readmission, and both short- and long-term mortality [31–33]. There is universal agreement on the broad concept of frailty, the general predisposition of frail individuals toward poor outcomes, and the potential of frailty as a powerful tool to help guide patient-centered perioperative care. However, there are more than 70 tools available to measure frailty and there is currently no consensus on which tools are best used in clinical practice [34]. Frailty assessment tools range from single item surrogate assessments such as gait speed or timed up-and-go score to the FRAIL scale (Fatigue, Resistance, Ambulation, Illness, and Loss of weight) to phenotypic frailty, to the deficit accumulation frailty index, and many others.

Quality improvement in this domain is related to improving process, as the assessment of frailty is performed by the provider and helps guide clinical management. The use of frailty assessments will aid in improving patient-centered outcomes in several ways. Most simply, physical frailty itself as a medical condition can be treated with modalities such as exercise, nutritional supplementation, and reduction of polypharmacy. As a more complex example, a high frailty score may prompt a goals-of-care discussion between the surgeon and patient that leads to a less aggressive surgical approach which ultimately leads to an outcome that is better-aligned with the patient’s wishes.

Medication Management

Medication use is common in older patients. More than 80% of elderly patients take one or more prescription medications, and the majority of patients aged 60 years or older take multiple medications and supplements [35]. The management of medications in older individuals in the perioperative period is multifaceted and includes stopping nonessential medications, continuing essential medications, planning for the resumption of medications postoperatively, minimizing polypharmacy, adjusting dosages for renal function, and avoiding potentially inappropriate medication use. A critical first step in this process is obtaining an up-to-date list of the patient's current medications, which may be difficult in the cognitively impaired older patient [10].

Quality improvement in this domain is focused on both structure and process. In order to ensure adequate preoperative review of medications and counseling regarding medication adjustments perioperatively, the healthcare system must be structured to provide a time and infrastructure for this. Although not primarily designed to minimize inappropriate medication use, geriatric models of care such as ACE units and HELP likely reduce inappropriate medication use during inpatient hospitalization given the intimate involvement of geriatricians and pharmacists in the care of these patients.

Process items have also been directly targeted to improve quality of care in the form of published criteria to ensure that practitioners do not prescribe inappropriate medications to elderly patients. In 1991, Dr. Mark Beers created the Beers Criteria for determining inappropriate medication use in nursing home residents [36]. These criteria have been updated a number of times and now take into consideration patients' comorbidities and renal function as well as potential drug-drug interactions that have been shown to harm older adults [37].

Despite these well-delineated guidelines, practitioners still frequently prescribe inappropriate medications to elderly patients. A national study of medication use in elderly surgical patients found that one in four patients received a potentially inappropriate medication (PIM) during their admission [38]. One common example is the use of Benadryl, despite moderate evidence to support avoiding the use of first-generation antihistamines in older adults. Some practitioners may be unaware that the use of Benadryl is not recommended in older adults and has been shown to increase the risk of cognitive decline. Additionally, Benadryl is frequently included within patient-controlled anesthetic order sets and thus may inadvertently be administered. Another example is the use of benzodiazepines in older adults with agitation. There is moderate evidence to avoid the use of benzodiazepines in older adults because it has been shown to increase the risk of cognitive impairment, delirium, falls, fractures, and motor vehicle crashes in the elderly [37].

Avoiding the use of PIMs will likely involve both practitioner education and structural changes. There is evidence of a relationship between polypharmacy and potentially inappropriate prescribing which supports reconciling medications at both hospital admission and discharge. Hudhra et al. evaluated the relationship between polypharmacy and potentially inappropriate prescribing (as measured by the Beers criteria and other similar guidelines) based on medications prescribed at hospital discharge [39]. Potentially inappropriate prescribing was higher in patients taking more than 12 medicines and each additional medication increased the odds of potentially inappropriate prescribing by 14–15%. The authors concluded that patients taking more than six medications at discharge should undergo medication review. With regards to how best to perform this type of medication reconciliation, Poudel et al. reviewed the literature to develop an algorithm for medication review in frail older adults [40]. The algorithm consists of the following four steps: (1) identify a high-risk medication; (2) determine the current indications for the medication and assess their validity; (3) assess if the drug is providing ongoing symptomatic benefit; and (4) consider stopping, changing, or continuing the medication. Sonnichsen et al. seek to evaluate the impact of the "Polypharmacy in chronic diseases-Reduction of Inappropriate Medication and Adverse drug events in older populations" (PRIMA), an electronic decision support consisting of an indication check and recommendations for the reduction of polypharmacy and inappropriate prescribing based on systematic reviews and guidelines [41]. The authors are planning a cluster randomized controlled trial with the principal hypothesis that reducing polypharmacy and inappropriate medication use can improve the clinical composite outcome of hospitalization or death. This study will not only help determine if reducing polypharmacy improves clinical outcomes, but it will also assess whether or not providers are willing to follow the recommendations of the decision support tool. Despite robust guidelines for medication management in older adults, quality improvement in this domain will require changes in both structure and process to assist practitioners in complying with these guidelines.

Patient Goals and Preferences

Advance care planning is another topic especially pertinent to elderly patients undergoing surgery. Studies have shown that surgeons do not routinely discuss patient goals preoperatively and that elderly patients undergoing surgery rarely have an advance directive in the medical chart [42, 43]. It is especially important for surgeons to speak with patients about treatment preferences and expected outcomes given the high risk of functional decline and discharge to a nonhome location in elderly patients undergoing surgery. Studies have found that a variety of factors are related to failure in communication that leads to nonbeneficial emergency surgery in elderly patients, including time constraints, uncertainty about prognosis, patient and surrogate fear of inaction, inadequate provider communication, and inadequate advance care planning [44]. While surgeons are trained extensively in surgical treatments for disease, they are not necessarily well-trained in communicating with patients about nonsurgical alternatives.

Quality improvement in this domain requires structural changes that will improve processes and communication between surgeon and patient. First, it is essential to ensure that surgeons are trained in basic palliative care and communication about patient goals and preferences. Opportunities for education exist – there are courses in palliative care available through the ACS and other organizations, and over 100 Accreditation Council for Graduate Medical Education-accredited Hospice and Palliative Medicine fellowship programs exist. However, there are fewer than 100 surgeons with this subspecialty board certification [45]. More importantly, there is no training requirement during residency, so it is no surprise that many practicing surgeons have had no training in this area. Strategies such as case-based palliative care workshops and didactic sessions have been found to improve surgical residents' attitudes and knowledge and may be one element of a solution [46, 47]. Additionally, providing a concrete framework for communication with patients about goal-concordant care has been explored in the emergency surgery field. Cooper et al. has proposed a structured approach to communication that includes nine elements: (1) formulating prognosis, (2) creating a personal connection, (3) disclosing information regarding the acute problem in the context of the underlying illness, (4) establishing a shared understanding of the patient's condition, (5) allowing silence and dealing with emotion, (6) describing surgical and palliative treatment options, (7) eliciting patient's goals and priorities, (8) making a treatment recommendation, and (9) affirming ongoing support for the patient and family [48]. Kruser et al. designed the Best Case/Worst Case framework which uses both narrative description and a graphic aid to help promote shared decision making in high-stakes acute surgical scenarios [49]. With this framework, the surgeon must (1) break bad news; (2) identify two clear treatment options; (3) create a graphic aid that illustrates the range of outcomes; (4) use storytelling to describe the best, worst, and most likely outcomes; (5) elicit preferences; and (6) make a recommendation. Using this framework has been successful in shifting conversations from having a surgical focus to including a broader discussion about treatment alternatives and outcomes. While these frameworks are designed for critically ill patients in the acute setting, variations on these frameworks may also be beneficial for surgeons communicating with elderly patients about elective surgery.

Secondly, we must ensure that there is structural support for the discussion and documentation of advance care planning prior to surgery. The ACS NSQIP/AGS Best Practice Guidelines have emphasized the importance of documentation of advance directives and health care proxy information in the patient's medical chart [10, 11]. An ideal time to address or revisit patient goals and preferences is during the preoperative clinic visit. This is a time during which the surgeon and patient can discuss the operation, alternatives, and predicted outcomes including the possibility of discharge to a nonhome location.

The Coalition for Quality in Geriatric Surgery (CQGS)

As discussed in each of the sections above, the health care community has begun to develop tools and strategies to improve the quality of care of geriatric surgical patients in many ways. However, a collaborative effort is necessary to affect meaningful change. The CQGS Project is a quality improvement program supported by the ACS and the John A. Hartford Foundation that seeks to define the processes, resources, and infrastructures necessary to provide optimal care to the older surgical patient. The CQGS is comprised of a team of surgeons, nurses, geriatricians, ACS staff, and research scholars and is supported by over 50 diverse organizations representing surgical specialties, anesthesiology, geriatrics, nursing, pharmacy, social work, physical therapy, advocacy, and patients. The goals of this 4-year initiative are to set standards, engage key stakeholders, develop measures that matter, develop the verification process to ensure delivery of high-quality care, educate patients and providers, pilot the program, and launch the Geriatric Surgery Quality Campaign. Work from this project will be relevant and generalizable to all health care centers that provide surgical care to older adults.

The Project began on July 1, 2015, and since then, over 300 preliminary standards have been drafted and rated for validity and feasibility. The CQGS Stakeholders rated 99% of standards as valid and 94% as feasible for improving the quality of care provided to elderly surgical patients [50]. The next steps will be to develop a data registry to track and measure geriatric-specific elements, and to better understand and address challenges to implementation of the standards. The CQGS Project builds on the work done by individual researchers and organizations in years past to provide a contemporary, comprehensive set of standards, processes of care, data collection system, and measurement of outcomes to systematically optimize the surgical care for older adults.

Conclusion

Just as pediatric surgery became a specialty unto itself, the expanding and aging population has created a potential niche for the specialty of geriatric surgery at the opposite end of the age spectrum. The field of geriatric surgery may indicate a focus on elderly patients for the surgeon, but more importantly the specialty of geriatric surgery represents a multidisciplinary collaboration between surgeons, geriatricians, internists and many other health-care providers who together will address the complex issues unique to the growing elderly surgical patient population. Progress has been made over the past few decades, with the establishment of guidelines and quality indicators, as well as a focus on collecting data and measuring outcomes specifically relevant to geriatric surgical patients. The CQGS Project represents a significant milestone in defining quality of care in geriatric surgery, as it will for the first time provide a unified set of standards that all hospitals caring for elderly surgical patients should uphold. Despite this progress, there continue to be significant hurdles to overcome in order to optimize care for this vulnerable patient group. Even once standards are set and important geriatric patient-specific outcomes are established, the implementation of necessary interventions and structural elements will pose a new challenge. Nonetheless, quality improvement in the relatively young field of geriatric surgery is progressing at a rapid rate and beginning to gain the national attention needed to eventually optimize care for this unique patient population.

3 Biology of Aging

Daniel Parker and Mitchell Heflin

Contents

Abstract

Principles distilled from geroscience, the scientific study of aging, can facilitate surgical decision making by identifying appropriate surgical candidates, anticipating surgical complications, and predicting functional outcomes. Theories of aging can be divided into program theories that emphasize genetically driven limits on lifespan and stochastic theories that focus on the accumulation of "wear and tear" with age. These changes lead to distinct patterns of dysfunction in intracellular processes and intercellular communication that culminate in organ system-specific alterations, which are reviewed here. The inter-related concepts of frailty and resilience synthesize these diverse changes into a unified conceptual framework that can be used to support surgical decision making. Frailty, which is defined as increased vulnerability to stress, is a risk factor for surgical complications and poor outcomes. Conversely, resilience is the ability to resist functional decline following health stressors. The assessment of frailty and resilience can be integrated into pre-surgical evaluation to gauge risk, support shared decision-making, and improve patient outcomes.

Geroscience and the Surgical Patient

Over a third of surgeries occur in people over 65. Providing high quality care for this population in the perioperative period requires a deeper understanding of expected age-related changes at the cellular, physiologic, and phenotypic levels. These changes have important implications at the individual level for effective completion of the surgery itself and a safe and efficient postoperative recovery. Moreover, the population of older adults is remarkably heterogeneous with respect to health and ability and, as a result, decisions regarding candidacy for any given surgery may differ dramatically between people of the same age.

Aging is the decline in physiologic function that increases an organism's susceptibility to disease and ultimately leads to death. Aging is the predominant risk factor for neurodegenerative disease, diabetes, cardiovascular disease, and most cancers [1]. Advances in aging research, hereafter referred to as *geroscience*, have elucidated some of the molecular and cellular changes associated with aging. These changes span core systems regulating genomic stability, protein homeostasis, energy dynamics, and stem cell function (Fig. 1). They eventually culminate in impaired tissue and organ function through loss of functional parenchyma and the acquisition of a maladaptive cellular phenotype, a state referred to as *senescence*. Eventually, the series of changes, like falling dominos, results in impaired resilience to stress, increased susceptibility to disease and, in many cases, the clinical syndrome of *frailty*.

Many of the advances in geroscience have emerged through exploration of interventions that extend lifespan or decrease the incidence of aging-associated diseases, i.e., enhance health span. While multiple interventions using model organisms have achieved success in these twin aims, only caloric restriction and exercise have demonstrated efficacy in humans. Understanding how these age-related changes in fundamental biological processes translate into decreased resilience and frailty and the available interventions to modify them can inform clinical decision making. In this chapter, we relate these concepts to the care of the older surgical patient, exploring how biological aging leads to decline in resilience and the development of frailty. Finally, we describe the differential impact of aging on organ systems. These changes are summarized in Table 1.

Theories of aging fall into two camps, program theories, and damage-accumulation theories.

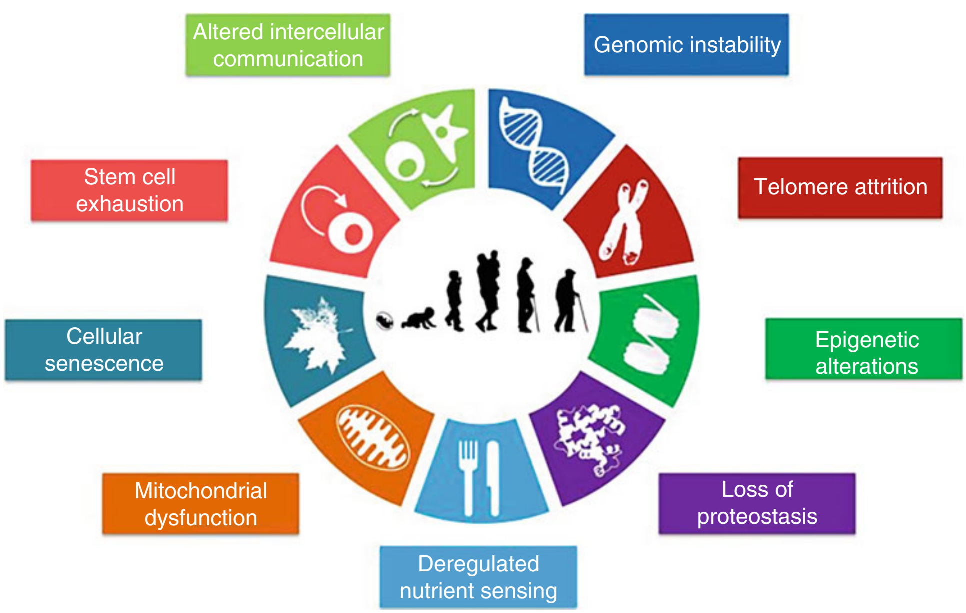

Fig. 1 Hallmarks of aging (Cell. 2013 Jun 6; 153(6):1194–1217. doi:10.1016/j.cell.2013.05.039)

Table 1 Summary of age-related changes by organ system

Organ system	Age-related changes	Clinical implications
Immune system	↑ Basal inflammation (inflamm-aging) ↓ Adaptive immune response	↑ Susceptibility to infections and sepsis ↓ Responsiveness to vaccination ↓ Wound healing
Hematologic	Hemostatic balance → thrombosis ↓ Platelet responsiveness to NO	↑ Risk of thrombotic complications
CNS	↓ Brain volume ↑ In neurodegenerative pathology	↑ Susceptibility to delirium
Cardiovascular	↑ Arterial stiffness leading ↑ Left ventricular hypertrophy ↑ Peripheral vascular resistance ↑ Myocardial fibrosis	↓ Organ perfusion ↓ Compensatory response to acute fluid shifts ↑ Risk of atrial arrhythmias
Gastrointestinal	↑ Oropharyngeal muscle loss ↑ Gastric contact time with noxious agents ↓ Hepatic drug clearance ↓ Gastric transit	↑ Dysphagia, aspiration, and malnutrition ↑ Susceptibility to adverse effects of medications ↑ Constipation
Endocrine	↑ Use of exogenous glucocorticoids ↓ Renin-angiotensin-aldosterone activation	↓ Compensatory response to hypovolemia ↓ Insulin sensitivity
Renal	↓ Renal blood flow and GFR	↓ Renal drug clearance ↑ Sensitivity to renal hypoperfusion

Program theories emphasize evolutionarily conserved genetic limits on lifespan. Damage or stochastic theories emphasize the effects of accumulated damage and environmental stressors.

Research in comparative biology supports evolutionarily conserved limits on lifespan. Maximum lifespans vary greatly by species, but show little variation among members of the species. The jellyfish *Turritopsis dohrnii* has evolved replicative immortality by reverting to a less mature developmental stage [2], but other phylogenetically related jellyfish have much shorter lifespans.

Telomeres are sequences of repetitive nucleotide sequences capping chromosomes that progressively shorten with each mitosis eventually triggering replicative senescence. Studies of their relationship to age-related disease provide additional support for programmed aging. Telomere-determined limitations on the number of cellular divisions, termed the Hayflick limit, may serve as a check on cancer. Indeed, most cancers demonstrate constitutive activation of telomerase, the enzyme responsible for maintenance of telomere length [3]. Conversely, telomere dysfunction that leads to premature telomere shortening causes premature aging syndromes like dyskeratosis congenita [4]. However, these observations, drawn from disease states, fail to establish a causal link between telomeres and normal aging.

Genome-wide association studies (GWAS) in humans have revealed allelic variants that enhance longevity through reduction in mortality due to diabetes, cancer, and coronary artery disease. Studies of the genetics of longevity suggest a contribution to lifespan variance of 20–30% [5]. This is despite long-lived families carrying a similar number of disease causing allelic variants [6], suggesting that enhanced longevity comes from genetic variants that delay aging or protect from disease. However, GWAS studies in different populations have identified conflicting candidate genes, suggesting that the contribution of any single nucleotide polymorphism (SNP) to longevity is small with difficult to predict effects in diverse groups [7, 8].

Unlike genetic contributions to aging, stochastic drivers of aging are better understood and potentially more amenable to intervention. Stochastic theories encompass many avenues of inquiry including metabolism, macromolecular damage, epigenetics, inflammation, adaptation to stress, proteostasis, and stem cells and regeneration. The most studied of these interventions is caloric restriction, which prolongs lifespan in organisms from yeast to mammals through activation of a conserved starvation response pathway.

Caloric restriction, which is defined as limiting energy intake while preserving essential nutrients, increases longevity and delays the onset of age-related diseases in many animal models including rhesus monkeys. The effects of caloric restriction on humans are unknown and difficult to study given the length of human lifespans, but a 2-year study of caloric restriction in young- and middle-aged healthy adults demonstrated significant reductions in cardiometabolic risk factors including LDL, systolic and diastolic blood pressure, and glucose control [9].

In model organisms, caloric restriction activates multiple, inter-related programs that vary based on the content of the diet. Accumulating evidence supports an integrative effect of caloric restriction on pathways that enhance mitochondrial function, decrease production of reactive oxygen species (ROS) and pro-inflammatory cytokines, and improve insulin sensitivity. These changes in cellular bioenergetics lead to decreased white adipose tissue mass and reduced systemic inflammation.

In aged animals, caloric restriction prevents downregulation of nuclear-encoded genes of the mitochondrial electron transport system (ETS), thereby preserving the integrity of mitochondrial energy metabolism. Caloric restriction also stimulates autophagy, an evolutionarily conserved mechanism for degrading and recycling intracellular proteins and organelles that is essential to mitochondrial health. Muscle biopsies from calorically restricted humans show increased expression of autophagy-associated genes and protein levels [10]. Normal aging is associated with decreases in autophagy, and autophagy of mitochondria, referred to as mitophagy, is required for production of new mitochondria. In humans, autophagy is essential to the adaptations of skeletal muscle in response to endurance exercise [11].

How do age-related changes at the cellular level impact function of the organism? Normal aging is characterized by both a loss of functional parenchyma, which is driven by stem cell exhaustion, and the accumulation of cells within tissues expressing a maladaptive phenotype known as senescence. Apoptosis of aged or damaged cells coupled with stem cell exhaustion leads to an imbalance between cellular loss and replenishment that reduces the functional capacity of organ systems. This manifests as decreased glomerular filtration rate (GFR) and maximum heart rate seen in normal aging. In addition to the loss of functional tissue, senescent cells can impair the function of remaining healthy cells and secrete pro-inflammatory factors that contribute to the development of age-related disease.

Cellular senescence was first described as a tumor suppression mechanism and is universal to all eukaryotic cells. Unlike apoptosis, or programmed cell death, which leads to rapid cell clearance, senescent cells acquire a unique phenotype with an associated secretome, referred to as the senescence associated secretory phenotype (SASP) that negatively impacts the surrounding microenvironment. Senescent cells accumulate in tissues with age and eventually, through the actions of the SASP, negatively impact the function of the whole organism [12, 13].

Multiple factors including telomere shortening, ROS-associated damage, and irreparable DNA damage trigger the acquisition of the senescent phenotype. The SASP is composed of multiple pro-inflammatory factors including IL-1 and IL-6, growth factors, and proteases that modify the tissue microenvironment [12]. Transfusion of blood from aged to young mice resulted in poorer performance on tests of strength, endurance, and learning; decreased hippocampal neurogenesis; and decreased hepatogenesis. These effects are likely related, at least in part, to factors produced by the SASP [14].

Progress in geroscience has demonstrated that the mechanisms underlying aging are multiple, complex, and interrelated. This complexity explains, in part, the dramatic variation in the observable biologic features of aging in patients of the same chronological age. Geroscience allows us to translate this observation into clinically relevant tools for use in surgical practice, particularly in the determination of surgical risk versus clinical benefit and overall fitness for surgery.

These clinical tools are built on the inter-related concepts of frailty and resilience. Frailty is defined as a physiologic vulnerability to stressors and is an important prognostic indicator for functional decline and death (Fig. 2) [15]. Conversely,

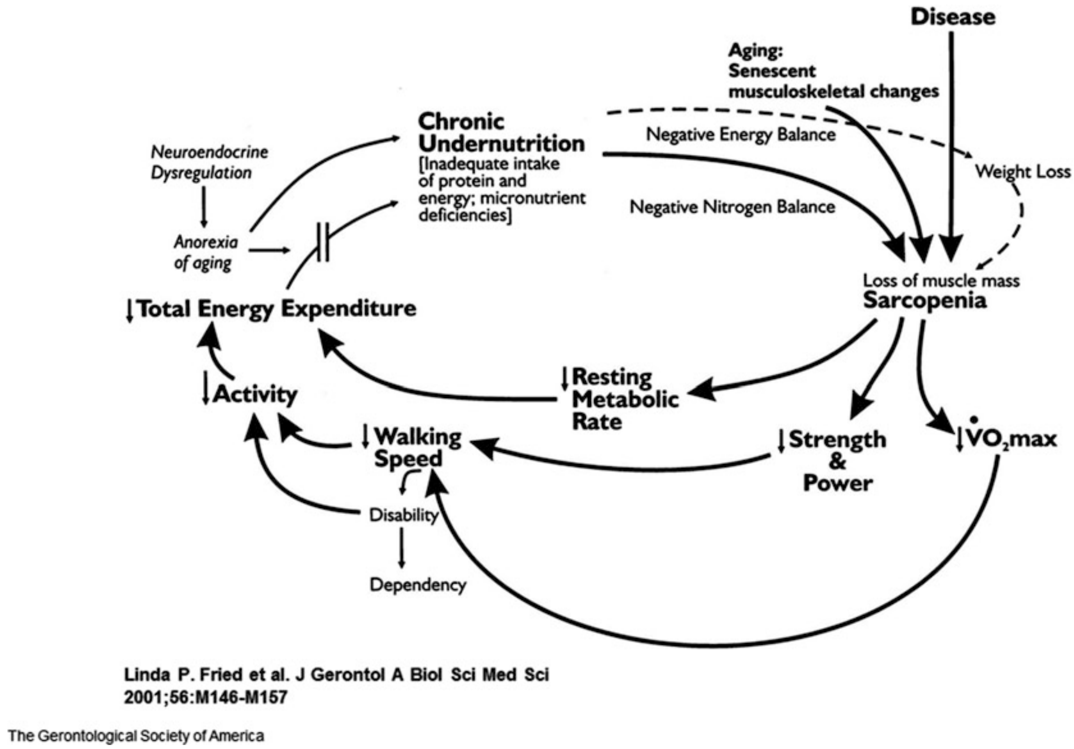

Fig. 2 Cycle of frailty hypothesized as consistent with demonstrated pairwise associations and clinical signs and symptoms of frailty [15]

physical resilience is the ability to resist or recover from functional decline following health stressors [16]. Multiple environmental and host factors contribute to physical resilience, but age-associated physiologic changes eventually erode an individual's capacity to recover from stress. When an individual's physical resilience has declined beyond a certain threshold, they may present with weight loss, weakness, exhaustion, slowness, and low activity, which define the phenotypic characteristics of frailty [15]. The incidence of frailty, defined by the presence of three of the five phenotypic characteristics, increases from 5 to 10% of adults over 65 to 30% of those over 80 [15, 17]. Chronologic age offers only a rough approximation of the equipoise between frailty and resilience.

Frailty has already demonstrated utility as a predictor of surgical outcomes. A systematic review of cohort studies evaluating the association of frailty with outcomes after cardiac surgery found that frailty predicted mortality 6 months after major and minimally invasive cardiac surgery [18]. This review also suggested frailty assessment was predictive of functional decline, lack of symptomatic benefit, and decreased quality of life after minimally invasive procedures. These findings emerged despite the heterogeneity of the frailty assessment tools used, some of which only measured a single frailty domain. Another study in 351 patients undergoing major abdominal surgery found that frailty was associated with 30-day morbidity and mortality [19].

Frailty is defined as both a characteristic, i.e., decreased reserve in response to stressors, and a measurable phenotype, i.e., three of the five objective findings described above. While the phenotypic definition is helpful in identifying those most likely to experience poor outcomes, frailty is only definitively assessed after exposure to a significant health stressor. This gap between phenotypic frailty and increased susceptibility to poor outcomes drove the development of physical resilience as a complementary parameter.

Research is currently underway to develop biomarkers and noninvasive "stress tests" to measure physical resilience in patients who are not phenotypically frail, but may be at higher risk of adverse outcomes following stressors such as surgery [16].

Immunosenescence and Inflammaging

Dysregulation of the immune response, particularly the development of chronic inflammation, is one of the hallmarks of aging. The immune system can be divided into an innate or nonspecific response, driven by macrophages, neutrophils, monocytes, and dendritic cells and an adaptive response, governed by B and T lymphocytes. Immunosenescence, or aging of the immune system, is associated with a decline in the adaptive immune response and an increase in basal activation of the innate immune system, characterized by a chronic pro-inflammatory state, referred to as "inflammaging."

Immunosenescence of the adaptive immune system is characterized by decline in the population of naïve T-lymphocytes and decreased antibody production. The decline in naïve T-lymphocytes is due to lifelong thymic involution coupled with shifts in T-lymphocyte subsets to an effector phenotype directed against chronic subacute infections, most commonly cytomegalovirus (CMV) and Epstein-Barr virus (EBV) [20]. As T-cells are activated and expand, but are unable to clear their target, some resist apoptosis and become senescent. These senescent immune cells inhibit clonal expansion of naïve cells and contribute to the pro-inflammatory state. This increases vulnerability to new bacterial and viral infections as well as cancerous cells. In centenarians, the pool of naïve lymphocytes, while still functionally capable of activation and proliferation [21], is almost completely lost [22].

As the adaptive immune system wanes, the innate immune system exhibits chronic low-level activation that leads to a pro-inflammatory milieu with systemic consequences [23]. Inflammation is defined as a tissue-remodeling state that occurs in response to traumatic stimuli, but inflammation is also an essential response to exercise, trauma, and maintenance of normal physiologic function.

The systemic inflammatory response seen in response to surgery is characterized by the same elevation in pro-inflammatory cytokines seen in inflammaging. IL-6 and C-reactive protein (CRP) increase in an age-dependent manner even in the absence of age-related diseases and IL-6 levels are 10-fold greater in centenarians compared to young adults [24, 25]. In surgical patients, IL-6 production peaks 18–24 h after surgery and is correlated with the invasiveness of the surgical procedure [26]. The key difference between pathologic and physiologic inflammation is the duration of the response, with concurrently activated anti-inflammatory mechanisms tempering the pro-inflammatory response under normal conditions. The dysregulated inflammation associated with aging is well established as a risk factor for development and accelerated progression of age-related diseases including cardiovascular disease, diabetes, and cancer.

Immunosenescence, through waning of the adaptive immune response and the development of chronic inflammation, accounts for the decreased responsiveness to vaccination, delayed wound healing, and the increased incidence of sepsis in older adults. As one might expect, inflammaging may contribute to the development of frailty. A meta-analysis comparing frail and prefrail individuals with robust individuals found that C-reactive protein, IL-8, and IL-6 were significantly elevated in frail and prefrail states [27]. This relationship was moderated by age and BMI, an expected finding given that both age and obesity are associated with elevated inflammatory markers. Higher inflammatory markers were also associated with decreased muscle strength, osteoporosis, mortality, hospitalization, and development of co-morbid diseases in older adults [28–30]. Experiments in mice disrupting pro-inflammatory signal transduction led to preserved skeletal muscle strength and mass suggesting a direct link between chronic inflammation and impaired muscle function, one of the core components of frailty [31]. Interestingly, exercise may attenuate immunosenescence and aging more generally by generating an acute pro-inflammatory response that increases the susceptibility of senescent cells to apoptosis [32]. As described below, immunosenescence is also implicated in the higher rates of postoperative complications seen in older adults.

Hemostasis

Age-related changes in hemostasis are likely driven by inflammaging, the chronic low-level inflammatory state associated with normal aging. Inflammation is tightly coupled with hemostasis through the complement and coagulation cascades. As IL-6 and other pro-inflammatory markers increase with age, so do coagulation factors. This general increase in the quantity of circulating coagulation factors interacting with an aging endothelium explains the age-related increase in the rates of arterial and venous thrombosis. This is reflected clinically in the recent adoption of age-adjusted cutoffs for d-dimer, a product of fibrin degradation, for the diagnosis of venous thromboembolism [33]. Levels of von Willebrand Factor (vWF), the multimeric glycoprotein that binds platelets to damaged endothelium, increase with age so much so that patients with mild von Willebrand disease who are generally prone to bleeding, may achieve normal hemostasis with age. Platelet function changes with age, with decreased production and responsiveness to nitric oxide, a potent vasodilator and inhibitor of platelet activation [34].

In addition to an increase in pro-thrombotic factors, advanced age is associated with downregulation of the fibrinolytic system. This is due, in part, to increased levels of plasminogen activator inhibitor-1 (PAI-1), an important regulator of fibrinolysis. Interestingly, increased PAI-1 is not just associated with an increased incidence of thrombotic diseases, but also obesity, type 2 diabetes, and inflammation [35]. This occurs through shared promoter response elements that link expression of PAI-1 to expression of other pro-inflammatory cytokines, providing another intersection between inflammation and pro-thrombotic states [36]. Data also suggest that PAI-1 is a component of the SASP and capable of inducing the senescent phenotype [37].

Delirium

Neurologic complications are the leading cause of morbidity in geriatric surgical patients [38]. Of these, delirium is the most common, affecting between 10 and 20% of geriatric surgical patients [39]. Delirium is defined by the DSM-V as an acute impairment in attention and cognition. Delirium has been shown to double the average length of stay and add an average of $2,500 to the cost of hospitalization [40]. The development of delirium also has significant deleterious effects on long-term morbidity and mortality. In patients with preexisting dementia, the development of delirium may accelerate cognitive decline [41, 42]. Advanced age and preexisting cognitive impairment are the two biggest risk factors for delirium with metabolic derangements, uncontrolled pain, sleep-wake cycle disruption, and adverse medication effects also contributing. In elderly ICU patients, for every year over age 65, the risk of developing delirium increases by 2% [43].

The pathophysiology of delirium is poorly understood but, like its precipitants, is probably multifactorial. Delirium may be due to neurotransmitter dysregulation, excess inflammation, and sleep-wake cycle disruptions. Delirious patients demonstrate cerebral hypoperfusion in frontal, temporal, and parietal regions on PET imaging [44]. Alterations in neurotransmitters in delirium are well documented, including increases in dopamine and serotonin and decreases in levels of acetylcholine. The latter likely explains the tendency of anticholinergic medications to precipitate delirium in susceptible patients.

Alterations in neurotransmitters leading to delirium may be precipitated by the acute inflammatory state in postoperative patients. As aging is associated with increased permeability of brain blood barrier (BBB), rendering the CNS more susceptible to the negative effects of systemic inflammation. Many of the direct and indirect physiologic consequences of surgery such as blood loss, use of anesthetic agents, tissue trauma, hypoxia, and ischemia are independently associated with delirium, independent of the additional stress of surgery.

Hospitalized delirious patients demonstrate higher levels of CRP, IL-6, TNF-α among other pro-inflammatory cytokines [45]. Inflammation leads to changes in CNS microvasculature that predispose to ischemic injury and dysregulated neurotransmitter production. When microglia, the resident macrophages of the CNS, are exposed to the pathologic protein aggregates associated with dementia, they demonstrate greater activation in response to systemic inflammatory signals. Thus, the increased risk of delirium in patients with dementia may be due to a lower threshold for microglial activation in response to systemic pro-inflammatory signals. This heightened inflammatory response, in conjunction with reduced cognitive reserve, may overwhelm the homeostatic mechanisms maintaining normal cognition.

Delirium, through the process described above, may also potentiate the inflammatory response to the neurodegenerative pathology, thereby contributing to accelerated progression of cognitive impairment after an episode of delirium. In a prospective matched controlled cohort study of older adults undergoing hip surgery, postoperative delirium doubled the risk of subsequent MCI or dementia [46].

Cardiovascular

Cardiovascular disease dramatically increases with age and is a major cause of morbidity and mortality in the elderly [47]. Eighty-two percent of all cardiovascular deaths in the United States occur in patients over 65 years old [48]. A high prevalence of hypertension and diabetes mellitus among older adults leads to high rates of coronary artery disease and stroke, which can, in turn, complicate recovery from major surgery. This sequence of events results, in part, from cellular and structural changes in heart and peripheral vasculature, leading to impairment of the body's normal hemodynamic compensatory mechanisms.

Over time, large arteries stiffen and thicken resulting in a critical loss of normal elasticity and a functional decrease in luminal diameter. This phenomenon is a result of accumulated fragmentation in elastin fibers, increased crosslinking of collagen in the subendothelium, and progressive calcification. Arterial wall rigidity leads to an increase in arterial systolic pressure and greater impedance to left ventricular outflow, which over time can stimulate ventricular hypertrophy. Systolic blood pressure increases steadily with age and, along with a leveling or decrease in diastolic blood pressure, results in a widening of the pulse pressure.

Similar to large arteries, the walls of the small arteries thicken and the luminal diameter decreases, causing increased impedance in the periphery and transmission of elevated pressures to end organs. Additionally, in small arteries, advancing age is associated with a decrease in the basal level of nitric oxide as well as a muted response to this intrinsically potent vasodilator [49]. An increase in impedance along with a decrease in vascular conductance leads to greater peripheral vascular resistance. At the capillary level, age-related increased peripheral vascular resistance has been associated with decreased perfusion during times of stress like ischemia, infection or surgery. At the venous level, the age-related decline in response to nitric oxide is thought to be responsible for the inability of older adults to respond to hypovolemic circulatory stress [50].

Like the vasculature, the heart undergoes structural changes with age. Myocytes hypertrophy but decrease in number. In addition, the heart becomes more fibrotic as collagen filaments, fibronectin, and integrins increase. Sympathetic as well as parasympathetic neurons decrease in number with age and valves calcify and stiffen. At rest, these structural changes may be inconsequential. However, under conditions which increase the work demanded of the heart, there can be significant compromise. Worsening fibrosis and hypertrophy impair the heart's ability to comply and contract. Loss of innervation leads to decreased neuromuscular control. Consequently, the heart is unable to meet increased demands needed during times of stress or even routine exercise.

Given the changes described above, fluid shifts associated with surgery present particular difficulty for the older patient. Increases in antidiuretic hormone secretion and renin-angiotensin-aldosterone system activation with stress result in retention of sodium and water with a tendency toward volume overload. Increased fluid retention (often compounded by administration of intravenous fluids and blood products) combined with ventricular hypertrophy and increased vascular resistance can predispose the older patient to increases in systolic blood pressure and a greater tendency for heart failure [51].

In addition to problems with pressure and volume, older adults appear to be uniquely susceptible to atrial arrhythmias in the postoperative period [52]. Estimates of the incidence of postoperative atrial fibrillation range from 15% in noncardiac surgery to over 30% in cardiothoracic procedures. The aging atrium, like the rest of the heart, often enlarges and undergoes fibrotic changes which can result in slowed conduction and a propensity to atrial arrhythmias. In the postoperative period, inflammatory changes and increases in adrenergic stimulation related to pain, fever, and hypovolemia are common triggers. The onset of atrial fibrillation with rapid ventricular response in the acute postoperative period can exacerbate the already tenuous balance of ventricular hypertrophy and decreased end diastolic volume by reducing filling time. This can be an important trigger for heart failure [53].

Gastrointestinal

Aging-related changes in the gastrointestinal tract can have critical implications for preparation for and recovery from surgery. A broad range of biologic factors can have direct bearing on nutrition, hydration, and recovery of bowel function in the postoperative period. This section provides a brief end-to-end overview of these changes. In the mouth, teeth discolor and become more likely to fracture as dental pulp recedes from the crown and the root canal narrows. Muscles of the tongue, like other skeletal muscles, decline in mass. Fat and fibrous tissue replace up to 25% of the secretory parenchyma of the salivary glands [54]. Compensatory mechanisms minimize the impact of these changes such that swallowing and phonation are not clinically diminished in the healthy elderly patient. However, if patients have a comorbid neurologic or muscular illness like Parkinson disease, stroke, diabetic neuropathy, myasthenia gravis, amyotrophic lateral sclerosis or polymyositis, the age-associated oropharyngeal changes predispose to dysphagia, aspiration, and malnutrition. Age-related declines in appetite and thirst can further impede intake as can the tendency for dry mouth, often exacerbated by anticholinergic medications.

Findings associated with "presbyesophagus" include decreased amplitude of peristaltic contractions, incomplete sphincter relaxation, delayed esophageal emptying, frequent tertiary contractions, and esophageal dilatation. These changes seem to be strongly associated with comorbid illness, including neurologic conditions and diabetes mellitus. More likely, esophageal dysmotility is a result of underlying chronic diseases like diabetes mellitus or side effects of medications rather than just normal aging.

Aging-related changes in the stomach include impairments in emptying and acid production. In the stomach, decline in motility and emptying is caused by age-related autonomic nervous system dysfunction and decreased compliance in the gastric wall [54]. In addition, the elderly often take anticholinergic or opioid medications, which further contribute to delayed emptying. This prolongs the "gastric contact time" of noxious agents, like nonsteroidal anti-inflammatory drugs (NSAIDs). Age-related gastric luminal changes include decreased prostaglandin and bicarbonate secretion, slowed mucosal cell proliferation, and impaired gastric blood flow. These changes collectively decrease the gastric mucosal defense against injury. On the other hand, there seems to be a higher incidence of achlorhydria in the elderly, which can impede effective digestion and absorption of nutrients. All these changes can also contribute to slowed emptying which can worsen the anorexia of aging and be particularly difficult to manage in the postoperative period with concurrent administration of medications like anticholinergics and opioids.

The liver, gallbladder, and pancreas all have an age-related decline in organ size, blood flow, and cell proliferation. Between age 70 and 90, the liver decreases from 2.5% of body weight to 1.6% as the overall number of hepatocytes decrease [55]. Cytochrome p450 activity decreases with age, contributing to a slower metabolism of certain drugs. Thus, caution must be used while prescribing hepatically cleared medications in the elderly.

Little evidence exists of major changes in small bowel structure or function with aging. The colon, on the other hand, undergoes changes that have implications for function and quality of life. Colonic transit time increases with age as a result of decreased peristaltic activity. This is likely a result of a decline in number and function of enteric neurons in the colon with a resultant decrease in critical neurotransmitters, particularly acetylcholine and nitric oxide. These changes can have important implications in the postoperative period, with increased rates of constipation. This may be a particular concern in those who remain immobile and dehydrated and on medications that further slow transit time. Eventually, this can also have adverse effects on resumption of oral intake and enteric nutrition [56].

Metabolic and Endocrine

The aging endocrine system presents an intriguing model for the overall changes in homeostatic regulation described earlier [57]. In a normal, unstressed state in the disease-free individual, little change is evident, particularly in the levels and activity of most hormones. However, with illness or surgery, abnormalities become obvious and important. Another key concept is that clinical presentations of endocrine disorders may be atypical, blunted, or even undetectable when compared with those of younger persons. Several examples of these principles are detailed below.

Hypothalamic-pituitary-adrenal axis function appears to be well preserved with normal aging. Prolonged elevation of glucocorticoid secretion with stress may have adverse effects, ultimately, on immune function and glucose metabolism. While primary Cushing syndrome is relatively rare in older adults, chronic administration of exogenous glucocorticoids is common. The ravages that steroids cause to the entire body are particularly severe and debilitating in older adults, including osteoporosis, glucose intolerance, neuropsychiatric symptoms, cataracts, glaucoma, and myopathy. Likewise, the most common cause of adrenal insufficiency in older adults is the suppression of normal adrenal function due to chronic glucocorticoid administration. The presentation of this syndrome can be nonspecific, including generalized weakness, weight loss, dizziness, falls, or overall failure to thrive. In the perioperative setting, systematic reviews of randomized controlled trials demonstrate no advantage to using supplemental (or "stress dose") corticosteroids in the perioperative period for those taking maintenance dose steroids for a medical condition. On the other hand, if a person is taking replacement doses for disorders of the hypothalamic pituitary axis, then supplemental dosing should be given [58].

In terms of the sympathetic nervous system and adrenal medulla, levels of norepinephrine and epinephrine increase with age, primarily due to a rise in secretion. However, the resultant physiologic response is muted due to decreased receptor and postreceptor activation despite increased circulating hormone levels. The clinical implication may be a less pronounced response to stimuli such as hypoglycemia, hypoxia, or systemic infection. The renin-angiotensin-aldosterone system also changes significantly with age. Decreased baseline levels of renin contribute to lower levels of aldosterone, which in turn leads to an increased propensity for salt-wasting among older adults. This phenomenon has important implications. Along with impaired thirst and antidiuretic hormone (ADH) response, older adults may become volume depleted more rapidly and have a greater propensity to develop hyperkalemia. This risk of dehydration and electrolyte imbalance, coupled with the tendency toward volume overload due to the changes in the cardiovascular system described above, illustrates a common "narrow therapeutic margin" in the clinical management of the older adult in the postoperative period. Effective clinical management requires careful continuous assessment and vigilance by all team members.

Decline in growth hormone (GH) is also observed with aging, such that about half of those over age 75 have negligible GH secretion. This may contribute to changes in body composition, including decreased muscle mass and strength, further increasing the risk of falls and fractures. Lower levels of testosterone among older men may contribute to changes in cognition, libido and sexual function, and loss of bone and muscle mass.

With respect to thyroid function, circulating triiodothyronine (T3) and thyroxine (T4) levels remain essentially normal with aging, but with acute illness, the levels of both are lower and, in particular, the conversion of T4 to T3 is impaired and results in a marked decline in the latter – this condition is often referred to as sick euthyroid. Thyroid disorders are common among older adults, but often difficult to diagnose. The presentation can be nonspecific with weight loss, apathy, and weakness as possible clinical manifestations of both hypo- and hyperthyroidism [59].

Alterations in glucose metabolism among older adults are primarily manifested with stress. In normal older adults versus younger controls, glucose tolerance testing reveals a higher elevation in serum glucose levels. Obesity, decreased activity, comorbid illness, and medication may all contribute to the impaired response to endogenous insulin observed with aging. Of course, a critically important consequence is the much higher incidence of diabetes mellitus – found in up to 20% of adults over age 65. The implications of this diagnosis for overall health, including vision, renal function, cardiovascular disease, cognition, and disability, are well described.

Finally, aging results in a number of important changes in calcium metabolism causing reduced bone mass and an increase in fracture risk among older adults. Decreased intake and impaired absorption of calcium and a high prevalence of vitamin D deficiency leads to lower levels of serum calcium in older adults. Most often, the body adjusts by increasing secretion of parathyroid hormone (PTH). This homeostatic mechanism, however, results in an increase in bone demineralization and a resultant reduction in bone mass.

Renal

The prevalence of chronic kidney disease (CKD) rises with age in the USA and may affect up to half of adults over age 70 [60]. Aging of the renal system is characterized by structural changes in the renal vasculature, tubules, and glomeruli. These changes manifest as an age-related decline in renal blood flow and impaired glomerular filtration. With age, the renal arteries undergo wall thickening much like the cardiovascular and pulmonary arteries. The smaller renal arteries become more tortuous, leading to increased vascular resistance. Simultaneously, there is a steady decline in the total number of nephrons starting at age 40. By the fifth decade, light microscopy reveals sclerotic glomeruli with focal sclerosis and partial thickening of the glomerular basement membrane [61]. With the loss of glomeruli, the attached renal tubules degenerate and become replaced by connective tissue.

Along with increased renal vascular resistance in both the afferent and efferent arterioles, there is an overall average decrease in renal blood flow of about 10% [61]. This leads to a decline in renal efficiency for handling fluids and electrolytes. This latter point has particularly important implications for the older adult undergoing surgery. Careful fluid management is warranted in the intraoperative and immediate postoperative period to avoid exacerbating renal function while avoiding fluid overload. Age-related changes in the glomerular filtration rate seem to be variable despite the gradual decline in renal blood flow. A systematic review of longitudinal studies examining changes in renal function with aging revealed heterogeneity in the estimates of age related loss of GFR. The best estimate of average decline in GFR was approximately 0.75 ml/min/year [62]. However, up to one-third of participants had no discernible change in renal function. Comparing and combining these studies was confounded by use of different formulas for estimating GFR. Current choices include those that utilize age, creatinine, and body mass, such as Cockcroft-Gault, the Modification of Diet in Renal Disease (MDRD), and the Chronic Kidney Disease Epidemiology (CKD-EPI) formula.

MDRD and CKD-EPI provide accurate and comparable measures among older adults. The latter may have some advantage in those with normal or near normal values [63]. Newer measures include the use of cystatin C, a protease inhibitor, along with creatinine. The accuracy and utility of this measure, however, may be confounded by the lack of specificity of changes in cystatin C given its association with comorbid conditions, including atherosclerosis, obesity, and inflammation. The variability in glomerular filtration rate also suggests that drug dosing, fluid replacement, or electrolyte correction need careful consideration in the elderly. In particular, health care providers must be cognizant of the route of clearance of medications and familiarize themselves with those drugs eliminated principally or exclusively by the kidneys. Many of these drugs are taken by elderly patients undergoing surgery and present a real risk to the health of the patient.

Summary

Geroscience has advanced beyond the basic biology of aging to provide a useful framework for assessing surgical risk. The conceptual framework of frailty and resilience provides surgeons with an opportunity to individualize the assessment of surgical benefit and risk of complications. Insights from the basic biology of aging are driving the development of biomarkers to assess biologic age and resilience as well as interventions that target the aging process itself. As this work advances, the growing population of geriatric patients will benefit from better informed decision making and surgical outcomes.

Surgery in Centenarians

4

Mark R. Katlic and Joann Coleman

Contents

Abstract

Surgical problems do not cease on a person's centennial, and as our overall population ages, physicians will see increasing numbers of these most senior citizens requiring surgery. All that has been learned about surgery in the elderly – including compulsive preoperative preparation and scrupulous perioperative attention to detail – should be applied to the centenarian. It is not unreasonable, however, to speculate that the 100-year-old who has not already succumbed to a myocardial infarction or pulmonary embolus is unlikely to do so, even during the perioperative period. Survival to the centenary indicates that one has been tested by life and has been found exceptionally fit. Elective surgery should not be deferred nor emergency surgery denied the centenarian on the basis of chronologic age.

Introduction

Ninety years is old, but 100 is news. Belle Boone Beard [1]

The 100th anniversary of an individual's birth still bestows an aura, a mystique, as the centenarian is as close to immortality as a human can be. This special prestige has been afforded the imprimatur of scientific study by Baker [2], who found that centenarians represented a striking exception to the inverted U curve of status across the life-span in Western culture. Baker's data, derived from factorial survey analysis, fit the postulate that there is an "American arc of life" that gives maximum prestige to middle age and least prestige to young and old persons. Centenarians, however, were given unique status nearly equal to that of middle-aged individuals (Fig. 1), because "like four leaf clovers or quintuplets, centenarians are rare."

Even those who care for centenarians are affected. Nishikawa et al. [3] found that family members who care for centenarians had a lower accumulated fatigue level, despite being older themselves and despite their subjects' worse performance status, than those who cared for individuals aged 70–90 years. Webb and Williams described a case of acute tenosynovitis of the right wrist and hand (centenarian hand syndrome) resulting from the congratulatory handshakes of many friends and relatives on a man's 100th birthday [4].

We have an inherent curiosity about our oldest old. What does he eat? What is her secret? Can it be bottled and sold? Decades ago one entrepreneur, Dr. Marie Davenport, became a professional centenarian, offering to teach her secrets of longevity to others for a fee [1]. Jeanne Calment, the world's presumed oldest person when she died at 122 years, was interviewed weekly by the foreign press who sought her out in Arles, France [5]. In 1997 a popular magazine devoted its cover story to "How to Live to 100." [6]

The mystique may wane, however, as more of us reach this milestone. The present paucity

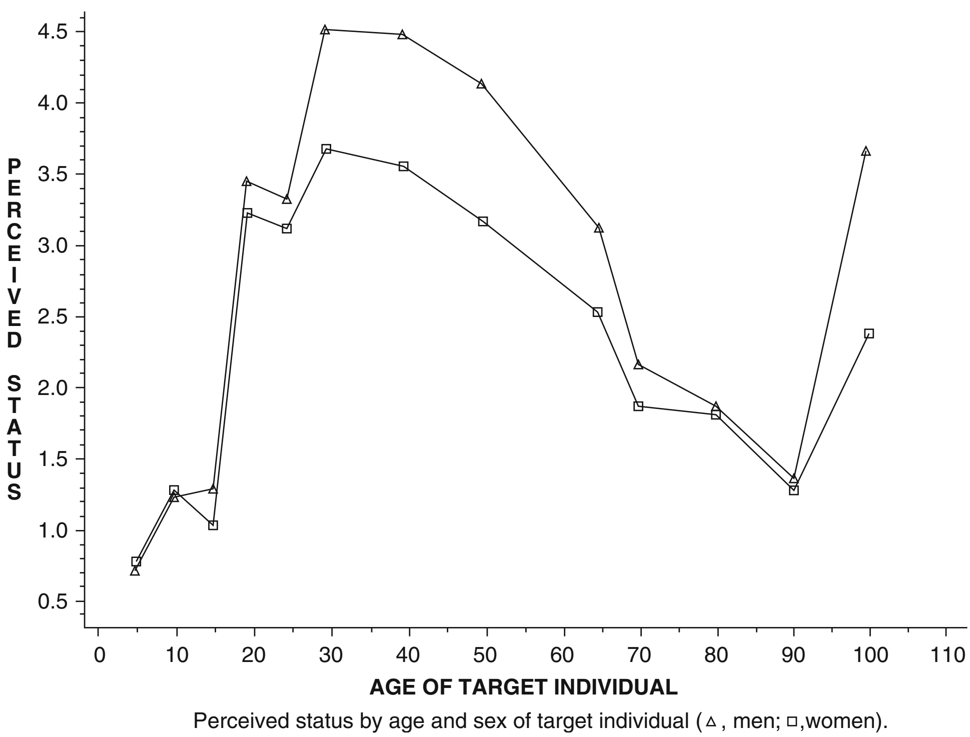

Fig. 1 Perceived status by age and sex of target individual. Triangles, men; squares, women. (From Baker [2], with permission)

of centenarians results from high mortality rates and a much smaller overall population a century ago. Over the past 40–50 years, the number of centenarians has nearly doubled every decade, owing chiefly to improved survival from age 80 to 100 years [7]. When Beard began her monumental, sedulous study of centenarians in 1940, there were 3700 possible subjects living in the United States; when she ended it during the late 1970s, there were at least 14,000 [8]. This number had reached 50,000 by the year 2000 [9], and 72,000 by 2014, an increase of 44% in 14 years [10]. Hallmark sold 85,000 "Happy 100th Birthday" cards in 2008 [11]. Centenarians may number 200,000 in 2020 and 500,000 to 4 million in 2050 [12].

Some authors argue that even these projections are too conservative because they discount the possibility of future baby booms and assume slow rates of mortality decline and low levels of immigration [13]. Vaupel and Gowan calculated that if mortality is reduced 2% per year, by the year 2080 the number of centenarians in the United States would approach 19 million [14].

Surgical problems do not end on a person's centennial. Surgeons will become increasingly familiar with these most senior citizens.

History

Surgeons have written with increasing frequency about operations in the elderly, but the definition of "elderly" has changed. A report in 1907 listed 167 operations performed on patients older than 50 years [15], and even 20 years later, Ochsner taught that "an elective operation for inguinal hernia in a patient older than 50 years was not justified" [16]. Brooks used a limit of 70 years as "advanced age" in his series of 293 operations reported in 1937 [17], and over the next few decades, most authors considered patients above age 60–70 years to be elderly. More recent studies show that good results can be expected in octogenarians and nonagenarians [18, 19], even in those undergoing complex vascular [20, 21], cardiac [22], and cancer operations [23].

An occasional centenarian is included in these series, but most papers devoted to centenarians per se are case reports, some written 50 years ago. Welch and Whittemore [24] in 1954 presented a 100-year-old woman who recovered well from abdominoperineal resection of the rectum for carcinoma. The next year Maycock and Burns [25] discussed prostate surgery in two patents in this age group, and in 1957 Childress [26] successfully treated three femoral fractures under spinal anesthesia. In 1971 isolated cases of pacemaker placement [27] and below-knee amputation [28] were reported. A basket-size ovarian leiomyoma was excised from a 103-year-old woman because of bowel obstruction in 1979, allowing her to live at least two additional years [29]. Six patients aged 100–106 underwent pacemaker procedures with good results in the 1989 report of Cobler et al. [30].

During the 1990s greater numbers of patients were reported. There were three deaths (12.5% mortality) in McCann and Smith's series of 24 patients undergoing a variety of operations, such as colon resection, ruptured aortic aneurysm repair, and hip prosthesis placement [31]. Cogbill et al.'s 1992 series of 16 patients reported perioperative mortality of 6% and a 1-year survival of 69% after a variety of small operations [32].

In 1998 Warner et al. [33] reported 42 procedures in 31 patients aged 100–107 years. There was one major complication (3%) and no mortality within 48 hours of operation; 30-day mortality was 16.1%, none directly related to the operative procedure or perioperative morbidity. Subsequent mortality of these patients equaled that of matched peers from the general population (Fig. 2). Grey and Keggi [34] reported a case of revision total hip arthroplasty, Lath et al. [35] an open abdominal aortic aneurysm repair, and Kent et al. [36] 24 centenary trauma patients. One chapter author (M.R.K.) reported a series of major and minor procedures in 6 patients aged 100–104 years, all of whom survived (Table 1) [37]. The illustrative cases below are from that series.

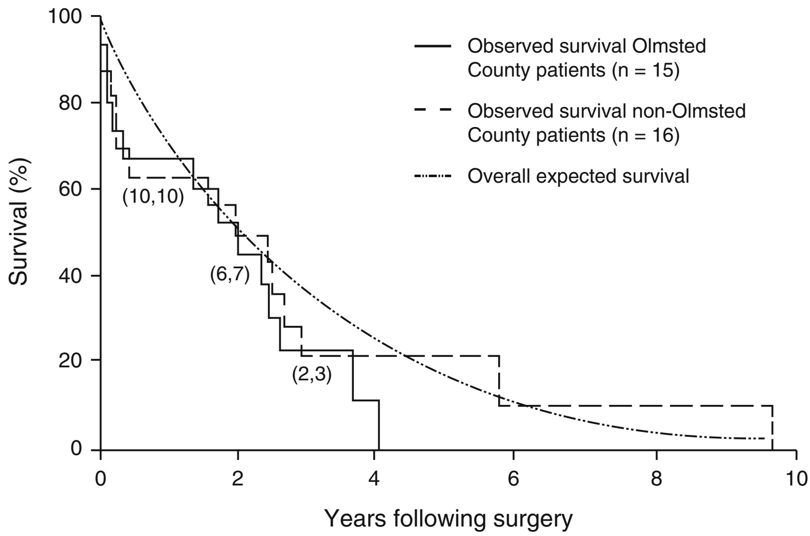

Fig. 2 Survival following surgery for patients ≥100 years of age. Numbers in parentheses represent number of patients alive and followed at yearly intervals during the first 3 years after surgery. (From Warner [33], with permission)

Case Studies

Case 1

A 100-year-old woman fractured her right hip in a nursing home fall. She had a history of myocardial infarction, congestive heart failure, aortic stenosis, arthritis, and hiatal hernia. She had previously undergone cataract surgery, cystocele repair, and open reduction/internal fixation of a left hip fracture. Open reduction/internal fixation of her new fracture was performed under general anesthesia. During her second postoperative week, she developed acute gangrenous cholecystitis, requiring emergency cholecystectomy. This episode was complicated by left lower lobe pneumonia, which resulted in antibiotic treatment, and a localized intraabdominal abscess, successfully treated with percutaneous drainage and antibiotics. Six weeks after admission, she returned to her nursing home. Protruding Enders rod pins in her right leg led to pin removal under local anesthesia 8 months later. At 101 years of age, she underwent elective endoscopic resection of a rectal villous adenoma containing carcinoma in situ. Postoperative bleeding from the resection site mandated suture ligation under general anesthesia. She returned to her nursing home, where she lived for two more years. She died 2 weeks before her 103rd birthday.

Case 2

A 100-year-old retired laborer was ambulatory at his nursing home until his toes became painful. He had a history of hypertension, chronic lung disease, and severe peripheral vascular disease and had undergone prostatectomy. On examination, he had a gangrenous right foot with *Proteus* cellulitis extending to the calf and an absence of leg pulses below the femoral arteries. He underwent amputation of the right leg above the knee while under general anesthesia (spinal anesthesia was aborted because of the patient's agitation) and was discharged 11 days later. He had one later 4-day admission for bronchitis and died at age 101 years of "old age."

Case 3

A 101-year-old woman was ambulatory and independent at home but suffered from a large right inguinal hernia. Her past history included congestive heart failure, atrial fibrillation, type 2 diabetes mellitus, blindness, and a resected basal cell carcinoma of the face. Elective right inguinal herniorrhaphy was completed under local anesthesia in the outpatient surgical unit. Postoperatively, stating that she would "rather wear out than rust out," she took a 3-month cruise around the

Table 1 (continued)

Patient No./sex	Age (years)	Medical problems	Operation	Status	Anesthesia	Complications	Death	Follow-up
	101		Colonoscopic resection of villous adenoma Suture ligation of bleeding rectal polypectomy site	Elective Emergency	Local General	Bleeding at excision site None		
5/F	101	CHF, atrial fibrillation, blind, basal cell carcinoma of face excised, adult-onset diabetes	Right inguinal herniorrhaphy	Elective	Local	None	No	Died, age 102 years of CHF
6/M	104	Squamous cell carcinoma of neck excised, basal cell carcinoma of nose excised and irradiated	Gastroscopy with biopsy	Emergency	Local	None	No	Died, age 105 years of gastric carcinoma

MI myocardial infarction, *CHF* congestive heart failure world and later lectured at a local college geriatric course. On the penultimate day of her life, she completed a political poll. She died of congestive heart failure at age 102.

Discussion

> The first hundred years are the hardest—Wilson Mizner [38]

Centenarians recover surprisingly well from surgery, leading one to speculate that the 100-year-old patient who has not already succumbed to a myocardial infarction or pulmonary embolus is less likely to do so, even in the perioperative milieu. The Mayo Clinic study of surgery in nonagenarians supports this finding, as neither pneumonia nor atherosclerosis with myocardial infarction was a major cause of postoperative death [15].

Longer length of stay and higher costs, however, are likely [39].

Certainly all that has been learned about surgery in the elderly should be applied to the centenarian. Clinical presentation of surgical problems may be subtle, preoperative preparation is essential, and scrupulous attention to detail intraoperatively and perioperatively yields great benefit. Virtually all studies of surgery in the elderly have also shown an almost threefold greater risk for emergency surgery than elective surgery. The worst complications in the author's series, pneumonia and intraabdominal abscess, did occur after emergency surgery, but the patients generally tolerated even urgent operations well.

Centenarians may be considered a natural model of successful aging. What is it about the 100-year-old that allowed him or her to enter this select age group?

Physiologic Changes in Centenarians

The oldest old manifest low frequencies of the E4 form of gene coding for apolipoprotein E, a protein linked to an increased risk of acquiring Alzheimer's disease. Among healthy subjects age 90–103 years, 14% had at least one E4 gene, in contrast to 25% of subjects younger than age 65 [12]. It may be that many of those with E4 suffer early Alzheimer's disease and do not survive to become centenarians. This *cohort effect* may explain some of the other physiologic and pathologic changes in centenarians described below. Silver et al. found that dementia is not inevitable with aging and that dementia in centenarians is often not attributable to Alzheimer's disease [40–42].

Morphologic changes occur in the brain with age – decreased brain weight, atrophy of the cerebral hemispheres, and fall in the number of Purkinje cells in the cerebellum – but healthy aged subjects show little difference from young adults with respect to cerebral blood flow and oxygen uptake [43]. Hubbard et al. studied electroencephalograms in centenarians and found slowing of the posterior dominant rhythm, but there was no evidence of a progressive decrease in frequency between the ages of 80 and 100 years [44]. Well-preserved mucociliary clearance in the lung of a centenarian was documented by Pavia and Thomson despite 80 years of smoking history [45].

An even more paradoxical finding was described by Mari et al. group [46]. They found that a high proportion of 25 healthy centenarians had laboratory evidence of activation of the coagulation system, shown by high levels of enzymes, activation peptides, and enzyme–inhibitor complexes. Levels of factor X activation peptide were equal to those found in patients with disseminated intravascular coagulation. Even procoagulant proteins such as fibrinogen and factor VIII – predictors of cardiovascular disease in young adults – were elevated in centenarians; yet these individuals had no current or past thrombotic events. The authors concluded that significant alterations of these markers are still compatible with health and long life. A more recent study by this group found that the 4G allele and 4G/4G genotype associated with elevated levels of plasminogen activator inhibitor 1 (PAI-1), which predicts recurrence of myocardial infarction in young men, were even more frequent in centenarians than young adults.

The homozygous genotype for the deletion of polymorphism of the angiotensin converting enzymes, which predisposes to coronary artery disease, is also paradoxically more frequent in centenarians than in adults age 20–70 years [47]. Mannucci et al. speculated that occult factors compensate for these putatively unfavorable genotypes in centenarians (e.g., linkage disequilibrium with a locus counteracting the bad effect of elevated PAI-1 levels offsets the risk of hypofibrinolysis). It may be that if an elderly person has already escaped thrombotic disease, it is advantageous to have decreased fibrinolysis [48]. A different genetic finding in centenarians – decreased frequency of the E4 allele of the gene, which encodes apolipoprotein E – would go along with decreased risk of ischemic heart disease [47].

Laboratory values in healthy centenarians may differ even from those of younger elderly adults: widening of the range for sodium levels to 132–146 mmol/L; slightly higher potassium and chloride; decreased total calcium; slight increase in ionized calcium; increased blood glucose; increased alkaline phosphatase and lactate dehydrogenase; slightly decreased bilirubin and total protein; increased amylase likely due to decreased renal function; increased serum urea nitrogen and slightly increased creatinine; increased urinary albumin; elevated urate; decreased albumin; elevated carcinoembryonic antigen; decreased cholesterol and triglycerides; decreased vitamin B_{12}; decreased zinc; slightly decreased thyroxine; increased prolactin; no change in corticotropin; decreased testosterone and estradiol; marked decrease in dehydroepiandrosterone; decreased progesterone; unchanged cortisol; slightly higher gastrin; lower erythrocyte, leukocyte, and platelet counts; and slight decreases in hemoglobin, hematocrit, and iron [49]. Neutrophil function is preserved [50]. Higher functioning centenarians appear to have higher levels of serum albumin [51]. Discussion of possible mechanisms for these findings is beyond the scope of this chapter.

Franceschi et al. asserted that a complex remodeling of the immune system occurs in healthy centenarians in contrast to the presumed progressive deterioration (especially with the T cell branch) [52, 53]. Peripheral blood T cells and major T cell subsets are only slightly decreased despite age-related thymic involution. B lymphocytes are deceased despite data that several immunoglobulin classes are elevated in the serum. Interestingly, peripheral blood lymphocytes in centenarians appear resistant to the oxidative stress that causes irreversible cell damage in younger individuals; such stress may retard entrance into the cell cycle rather than cause permanent damage [54].

Centenarians are more likely to have low body weight [55, 56], possibly due to loss of muscle and fat [57]; a number of investigators have reported short stature even when the effects of aging are considered. Decreased bone mass, however, is not universally present [58]. Both male and female centenarians are more likely to have feminine or androgynous personality traits rather than masculine ones and are more likely to have a type B behavior pattern (easygoing) [59].

Centenarians use fewer drugs than the elderly in general and fewer inappropriate drugs [60].

Pathology in Centenarians

Although atherosclerosis has been found in coronary, cerebral, femoral, and abdominal aortas of centenarians [61], the ascending aorta may be spared [55, 62]. Myocardial fibrosis is located chiefly in the left ventricle and septum, and cardiac amyloid deposition is characteristic [61]. Coronary disease at autopsy is common [63, 64], though perhaps less so in Japanese centenarians [65]. Pneumonia was found in 15 of 23 patients in Ishii and Sternby's series and was also the most common cause of death [61]. Alveolar ectasia and decreased elastic fiber were also seen in the lungs. Interestingly, recent or old thromboembolism in the pulmonary arterial tree was common at autopsy despite the absence of clinical pulmonary emboli during life [61].

In the kidney, chronic pyelonephritis and atherosclerosis are usually pronounced; and the testes, ovaries, and uterus show atrophic changes [66]. In the gastrointestinal tract, the liver also shows atrophy, and colonic diverticula are common. Gallstones are common (13/23 patients), and peptic ulcer is rare [66]. Osteoporosis is common [67], but not universal [58]. Similarly, in the brain, changes of Alzheimer's disease are common but not universal; when present these may not correlate with clinical neurologic findings [68, 69].

Cancer as a cause of death was unusual in Ishii and Sternby's autopsy series [67]; it represented 7.1% of Stanta et al.'s 99 autopsies in centenarians [70], and 31% of Klatt and Meyer's 32 patients [62]. The 7.1% rate in Stanta et al. series was significantly different ($p < 0.001$) from that in age groups 75–90 years (25%) and 95–99 years (9.5%). Metastases in this series were found in 23.5% of the centenarians with cancer and 63.2% of those 75–90 years old; local infiltration did not differ among groups. Many of the cancers in centenarians (70%) were undiagnosed during life, a fact that may explain the exceptionally low incidence of cancer (4%) as a cause of death in epidemiologic studies [71]. Of all the types of cancer, only the prevalence of gallbladder adenocarcinoma was increased in Stanta's series [70]. Germ-line polymorphisms may play a role in the decreased susceptibility of centenarians to cancer [72]. In exploring an animal model of extreme longevity, Cooley found that only 19% of extreme aged dogs died of cancer versus 82% of dogs with usual longevity ($p < 0.0001$) [73] (Fig. 3). In summary, cancer in the oldest old is less frequent and less aggressive.

Centenarians, like younger individuals, die of specific organ failure, not "old age" [74]. Berzlanovich et al. [75] reviewed autopsy records of 40 Austrian centenarians, 60% of whom had been described as healthy before death; all had a specific cause of death, including cardiovascular in 68%, respiratory 25%, gastrointestinal 5%, and cerebrovascular 2%.

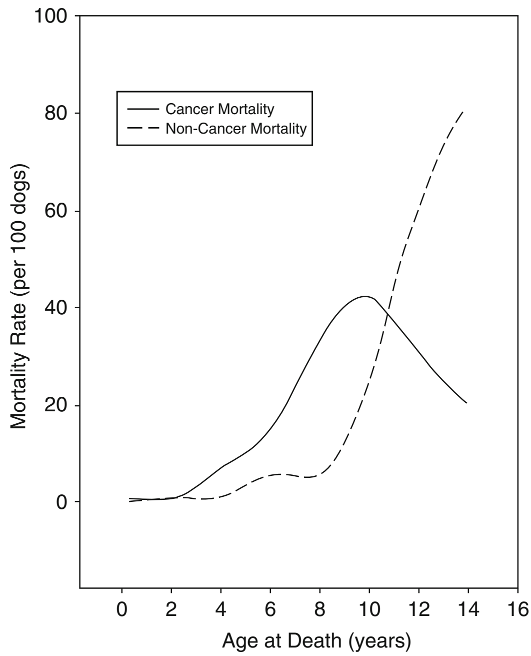

Fig. 3 Comparison of age-specific cancer and noncancer mortality for 345 Rottweiler dogs. Age-specific cancer and noncancer mortality rates were calculated at 2-year intervals from 0–14 years of age and expressed as the number of cancer or noncancer deaths per 100 dogs that entered the interval. (From Cooley [73], with permission)

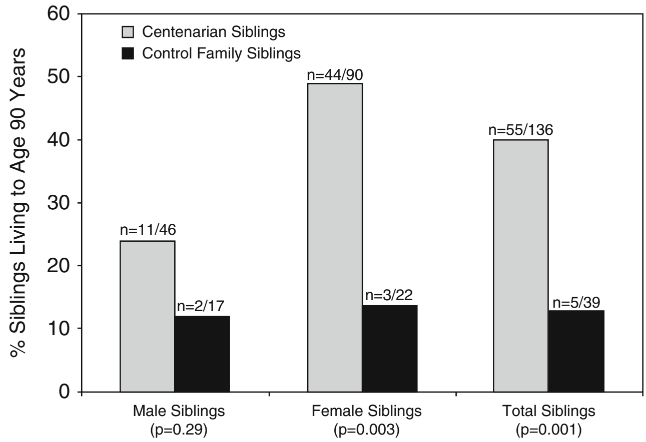
Determinants of Extreme Longevity

Despite our fascination with centenarians, little is known about the influences – genetic, environmental, and medical – on their longevity. Herskind et al., in extensive studies of nearly 3000 Danish twin pairs born during 1870–1900, estimated the heritability of longevity to be 0.26 for men and 0.23 for women; the sex difference resulted from the greater impact of unshared environmental factors in women [76]. Other family studies have shown weak correlations for lifespan between parents and offspring (0.01–0.05) and somewhat higher correlations between siblings (0.15–0.35) [77, 78] (Fig. 4) suggesting either that the genetic factors are nonadditive (genetic intralocus interaction) or there is a higher degree of shared environmental influences among siblings than parents. The offspring of centenarians nevertheless manifest less cardiovascular disease than the general population at similar age [79–81] and, in one study, less cancer-specific mortality [81, 82].

Several specific genetic factors have been associated with extremely long life [83]. In a study of Japanese centenarians, Takata et al. [84] showed a significantly lower frequency of HLA-DRw9 and a higher frequency of HLA-DR1 among centenarians compared to younger adults; these antigens

Fig. 4 Percentage of siblings of centenarians and controls who reached age 90 years, when controlling for extrinsic or unknown causes of mortality. (From Willcox [78], with permission)



are negatively associated with autoimmune diseases in Japan, suggesting mediation of the genetic influence through a lower incidence of disease. The low prevalence of the E4 allele of apolipoprotein E (APOE) and increased prevalence of the DD genotype for angiotensin-converting enzyme (ACE) have been mentioned above [48]; neither of these, however, was associated with longevity in a Korean study [85]. Puca et al. reported evidence for a specific locus (D451564) on chromosome 4 associated with longevity in a sibling pair linkage study [86]. The role of inherited and somatic mutations of mitochondrial DNA (mtDNA) in centenarians remains unclear [87]. Short chromosomal telomeres have been associated with increased mortality in persons over the age of 60 [88], but this has not held true for the oldest old [89, 90]; nevertheless, Terry et al. [91] found healthy centenarians have significantly longer telomeres than unhealthy centenarians (Fig. 5).

Sebastiani et al. [92] studied 1055 centenarians and 1267 controls, building a genetic model which could predict exceptional longevity with 77% accuracy. Their data suggested that enrichment of longevity-associated variants "counter the effect of disease-risk alleles and contribute to the compression of morbidity and/or disability towards the end of very long lives." The model's limitations, however, confirm that lifestyle factors also contribute.

The mediation of genetic influences on longevity via genetic influences on smoking and body mass index – two factors associated with longevity in epidemiologic studies –was disproved by Herschind et al. [93] Even smoking status has shown no definite association with extreme longevity, nor has alcohol consumption, diet, or exercise [94]. Such "lifestyle" factors may, however, influence one's functional status at the age of 100 [51]. Environmental factors such as socioeconomic status and early life nutrition appear to have little influence [95]. Hagberg and Samuelson [96] demonstrated the importance of stochastic determinants (physiological reserve, present health and functional state, and chance) as opposed to programmed factors (family longevity). Although no "fountain of youth" medicine has been discovered, the inverse correlation of blood levels of dehydroepiandrosterone (DHEA) with mortality has prompted ongoing clinical trials of its administration [97], not all of them salutary [98].

Some environments, e.g., Sardinia and Okinawa, appear to be conducive to extreme longevity as do personal factors such as activity, discipline, altruism, spiritual faith [99], musical instruments, and humor. Even personality may be important [100, 101]. In a study of 483 Italian centenarians, 88.6% had never smoked cigarettes [102]. Centenarians themselves attribute their longevity to God, singing, pickled herring, shochu (sugar cane liquor), honey, port, abstinence, boiled onions, whiskey, red wine, fish, luck, chocolates, olive oil, weakness for women (or men), and more. Fifty percent of centenarians walk or hike; nine percent practice yoga or Tai Chi [103].

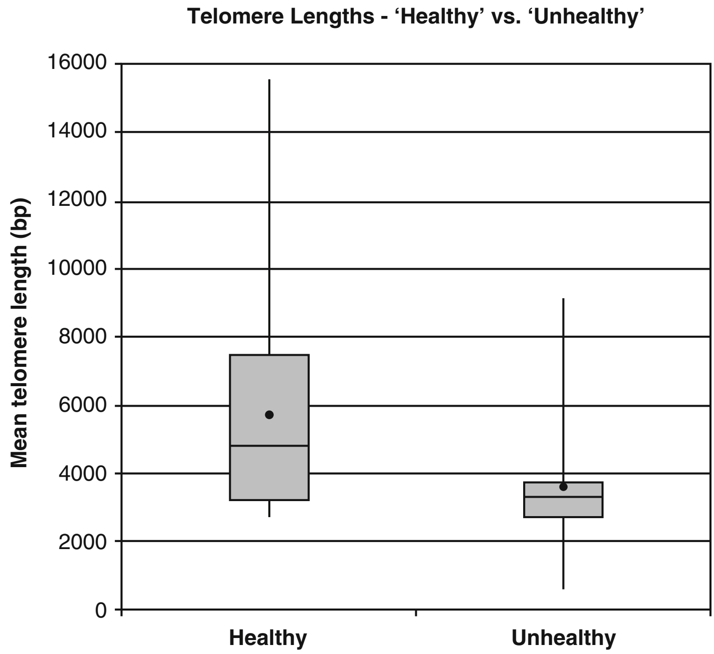


Fig. 5 Mean telomere length measured in base pairs (bp) in 19 healthy versus 19 unhealthy centenarians. Bars, interquartile ranges (Q75%–Q25%) of telomere length. Diamonds, mean; horizontal line within bars, median telomere lengths. Vertical lines, overall range of telomere lengths. (From Terry [91], with permission)

In summary, it is likely a large number of factors interact to determine longevity, three-fourths of them environmental (Table 2). The involvement of a number of genes, each contributing a little, might influence longevity directly or, more likely, through determining susceptibility to disease at different ages. Willcox et al. [104] reviewed the determinants of longevity in 2008.

Selective Survival Hypothesis

> A 100-year-old is as likely to survive surgery as are his sons and daughters, and one may speculate that he is even more likely to do so. The man or woman who has endured ten decades of life's labors enters a select group whose physiological resilience is greater than that of many who are chronologically younger. M.R. Katlic, 1985 [37]

This selective survival concept was discussed by Thomas Perls, principal investigator with the New England Centenarian Study [12]. Perls postulated, supported by his research and that of others, that certain individuals are resistant to the diseases that cripple and kill most people before age 90. These individuals – although 95% have some form of chronic disease [105], including cardiovascular disease [106] – not only live longer lives, they also live relatively free of debilitating infirmities.

Mortality rates for centenarians, for example, are lower than would be anticipated by extrapolating the death rates of younger adults. Mortality can be reasonably predicted up to approximately age 80, but the linear decline in health not only slows at advanced age but varies more among individuals, thus selecting the most fit [107]. Selection is more than sufficient to overcome the effects of aging and is greater in men, probably because of their higher mortality at younger ages [108, 109]. This "gender crossover" resulting from the selection of fit men can be seen as early as age 80 but is more evident in centenarians: men make up 20% of 100-year-olds and 40% of 105-year-olds. Female-to-male ratios, however, may range from 2:1 to 7:1 in different provinces within the same country [110]. Possibly related, there are anatomic and functional gender differences in the heart in centenarians as well [111]. Age 95–97 years appears to be the age at which a person's chance of dying increases in a linear rather than an exponential manner with time (Fig. 6) [12]. Carey et al. [112] found the same phenomenon in medflies.

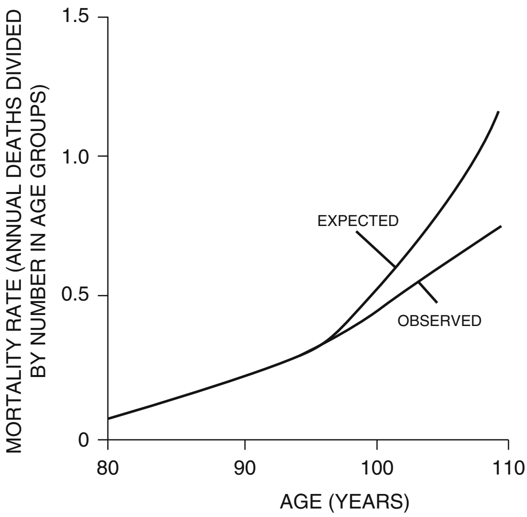

Fig. 6 Observed mortality rate slows after age 97 years compared to the expected mortality rate. (From Perls [12], with permission)

Whether due to compositional change in the cohort (selection of the fittest) or better intrinsic cellular defense mechanisms, the very old have a higher threshold for acquiring disease and a decreased mortality rate, allowing them not only to survive but to do so in relatively good health (Fig. 7). In 1990 the Medicare cost for those who died at age 70 was $6475 during each of the last 5 years of life compared to $1800 per year for those who died at age 100 [113]. In 1995 medical expenses for the last 2 years of life average $22,600 for people who died at age 70 and $8300 for those who died after

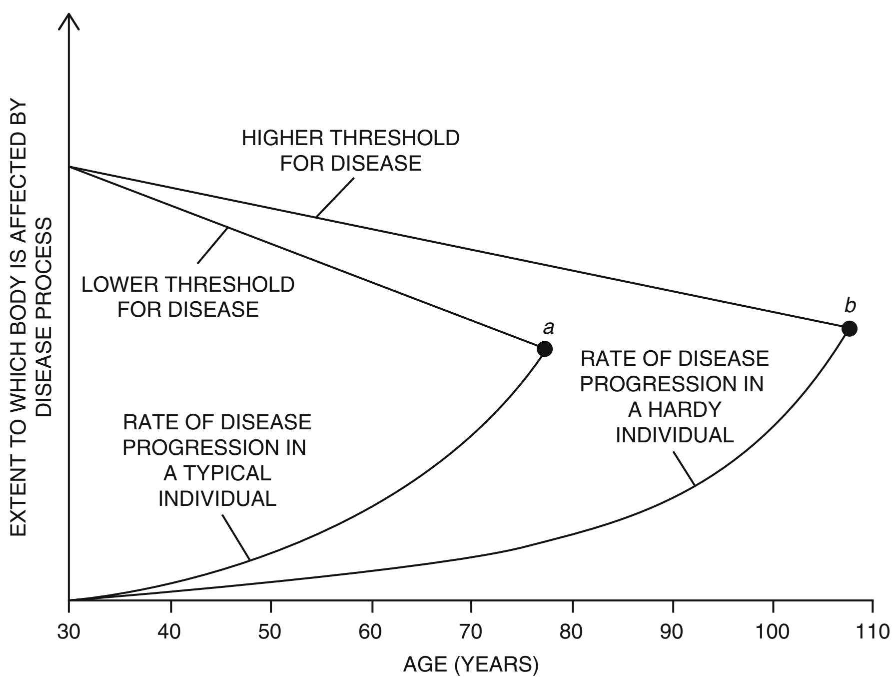

Fig. 7 High threshold for acquiring disease and slow aging process may promote survival because of the good health of centenarians. (From Perls [12], with permission)

age 100 [6]. Caregiver burden does not necessarily increase in this group [114].

Everts et al. have described three morbidity profiles for centenarians [115]. *Survivors* had an age-associated illness prior to age 80 years (24% of men, 43% of women); *Delayers* experienced an age-associated illness after 80 years (44% of men, 42% of women); *Escapers* reached age 100 without a diagnosis of common age-associated illness (32% of men, 15% of women). With respect to the most lethal diseases – heart disease, cancer, stroke – 87% of male centenarians and 83% of female centenarians either delayed or escaped [115]. Motta et al. [116], who studied 602 Italian centenarians, write that even those who are free of disease, autonomous, and bright should not be considered prototypes of "successful aging," as they have not maintained any social or productive activities. Most consider centenarians to be models of healthy aging from which we can learn, in order to improve the health of all elderly [117].

Supercentenarians

Supercentenarians, those aged 110 years or more, likely number less than 500 worldwide; most are women [118]. Schoenhofen et al. [119] studied 32 such individuals, 84% of them are women. Cardiovascular disease and stroke were rare, Parkinson's disease absent, and cancer successfully treated in 25%; 41% were independent or required minimal assistance. In the Okinawa Centenarian Study, supercentenarians had little clinical history of cardiovascular disease and no history of cancer or diabetes (in a different study, even centenarians with diabetes had few clinical problems related to the disease [120]); the authors called this "an elite phenotype" [121]. The parents and siblings of supercentenarians also manifest a survival advantage [122].

Conclusions

All that has been learned about surgery in the elderly should be applied to the centenarian: clinical presentation of surgical problems may be subtle, preoperative preparation is essential, emergency surgery carries high risk compared to elective operation, and scrupulous attention to detail intraoperatively and perioperatively yields great benefit. It is not unreasonable to speculate that the 100-year-old who has not already succumbed to a myocardial infarction or pulmonary embolus is unlikely to do so, even during the perioperative period. Survival to the centenary indicates that one has been tested by life and has been found exceptionally fit. Elective surgery should not be deferred nor emergency surgery denied the centenarian on the basis of chronologic age.

J. Macias and Michael Malone

Contents

Abstract

Older adults are the fastest growing segment in the USA. This aging segment of our population brings a significant number of older adults with multiple comorbidities. Older adults aged 65 and older represent approximately 15% of the total US population and they account for 36% of hospital admissions. They are responsible for approximately 44% of hospital charges [1]. This context has created a need for geriatrics expertise and new challenges for clinicians, hospitals, and health care organizations. Older adults in the USA undergo 20% of all surgical procedures while making up of 15% of the total US population; hence, these statistics suggest how relevant it is to understand the needs of older adults in the perioperative period. It is estimated that by 2030, about

20% of Americans will be older than 65. Twenty-one percent of those over the age of 60 will undergo surgery and anesthesia, as compared with only 12% of those aged 45 to 60 years. These estimates emphasize the importance of identifying and screening geriatric syndromes to lower perioperative complications in older adults [7].

Introduction

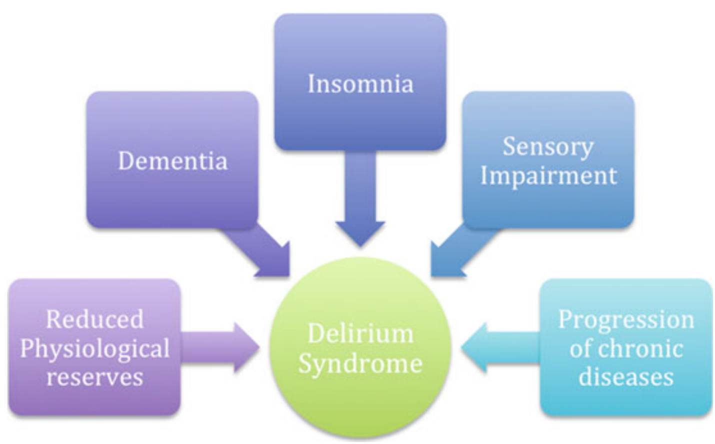
Older adults are at risk for certain adverse events with serious consequences in the acute care setting, including hospitalization-associated disability (HAD), delirium, falls, pressure ulcers, hospital acquired infections, and institutionalization. The increased rates of older adults with complex comorbidities across the care continuum have triggered different initiatives to increase expertise and knowledge in the care of older adults among other specialties. More surgical and related medical specialists are integrating geriatrics principles into their practices to improve their ability to care for vulnerable hospitalized older adults.

There are a number of physiological changes that occurred with aging. Changes in volume of distribution, bioavailability, and receptor sensitivity lead to alterations in the pharmacodynamics of most drugs prescribed to older adults. Poor renal clearance and changes in hepatic function require paying close attention to dosages of medications. Older adults have impairments in thermoregulation. Further, there may be impaired responsiveness in situations of hypotension. Ventilatory responses to hypoxia and hypercarbia are reduced, increasing the risk of postoperative respiratory complications in elderly patients [7]. These biologic changes and the progression of common diseases create a diminished physiological reserve in older adults, which results in a weak compensatory mechanism during stress or an acute illness.

According to the National Institute of Aging, about 80% of seniors have at least one chronic health condition and 50% have at least two chronic health conditions. Arthritis, hypertension, heart disease, diabetes, and respiratory disorders are some of the leading causes of activity limitations among older people. Further, heart disease and cancer are the leading causes of death within this population, with death rates varying by age, sex, and race [8].

In the context of diminished physiological reserves and the progression of common chronic diseases in older adults, the authors frame a discussion of geriatric syndromes. Geriatric syndromes are clinical conditions that share underlying causative factors and involve multiple organ systems [2, 3, 29]. Delirium is an example of a common geriatric syndrome as noted in Fig. 1.

Fig. 1 The interaction of multiple risk factors, which culminates in delirium



Other examples of geriatric syndromes include incontinence, cognitive impairment, falls, pressure ulcers, pain, weight loss, anorexia, frailty, functional decline, depression, and multimorbidity [4]. These geriatric syndromes are more prevalent with advancing age. They are associated with adverse outcomes and increased mortality. Therefore, their recognition and management is key when caring for a vulnerable hospitalized older adult [5]. Geriatric syndromes are often under-recognized in hospitalized older adults and may go unaddressed in the postacute care setting. The challenge in the surgical setting is that the surgical team is often focused on the acute injury and illness of the patient and then the surgical needs of the individual after a procedure. The geriatric syndromes of the patient may have been the context of the patient's acute illness/ injury and may be less apparent in the setting of other acute problems which need to be addressed.

Assessment of the Geriatric Surgical Patient

Hospitalized older adults, despite proper treatments, are prone to hospitalization associated disability (HAD) and other complications with serious consequences – if not identified in the acute care setting. This condition is a common outcome of many complications of medical and surgical care of acutely ill older patients. It appears that surgical patients are more likely to bounce back from their illness than medical patients, as described by a study of the recovery of each cohort of patients. Much of the decline in the function of vulnerable older adults may have to do with our systems of caring for these patients. Strategies that promote early mobilization and efforts to promote functional independence decrease the chances of hospitalization-associated disability. Caring for older patients requires: (1) knowledge of the presentation and management of common diseases in older adults and (2) taking into consideration theories of aging and physiological changes of aging of each organ system to appropriately prescribe and develop treatment plans. This topic has been nicely outlined in the ACS NSQIP/ AGS Best Practice Guidelines: Optimal Perioperative Assessment of the Geriatrics Surgical Patient [30]. Multiple models of care have developed to address the need of hospitalized older adults and minimize potential complication during hospitalization.

The Acute Care for Elders model of care was developed as a multicomponent intervention specially designed to address hospital-acquired dysfunction and systematically identify vulnerable adults. An ACE unit is a medical surgical nursing unit which focuses on improving the management of acutely ill older adults [6].

A model of care for older patients which is *not* unit-based is the Hospital Elder Life Program (HELP). This geriatrics "best-practice" strategy is designed for the prevention of delirium-targeting risk factors for delirium: cognitive impairment, hearing or visual impairment, sleep deprivation, immobility, and dehydration.

Deploying geriatrics models of care in the inpatient setting like the ACE unit or HELP along with geriatric education programs, it is fundamental to improve the care of older patients with geriatric syndromes (Table 1).

Common Geriatric Syndromes in the Setting of Surgical Care

Frailty

Frailty is a syndrome that represents vulnerability in the setting of a stress. Key clinical features include low level of physical activity, self-reported exhaustion, generalized weakness, impaired physical function, and unintentional weight loss. Frailty has been reported to be a predictor of mortality and functional limitations in older adults.

Various measurements exist for assessing frailty. One is the Fried Frailty Index (FFI), [9], which classifies frailty according to the presence of three or more of the following items: unintentional weight loss, low physical activity, low hand grip strength, slow walking speed, and exhaustion. A combination of these findings can

Table 1 Checklist to improve the hospital care of the older surgical patient

Delirium	Screen regularly using the b-CAM or Confusion Assessment Method or similar tools Initiate multicomponent strategies to mitigate delirium risk (Hospital Elder Life program) Minimize medications associated with delirium Remove unnecessary catheters Assess and effectively manage pain
Immobility/ falls	Screen with: Timed up and go test and "Have you fallen in the past year?" Low-bed/ alarms for high-risk patients Early PT/OT assessment Avoid pharmacologic and physical restraints Discontinue IV lines ASAP Use early and regular ambulation strategies
Undernutrition	Screen with Body Mass Index, weight loss, perhaps serum albumin Monitor daily nutritional intake Assist with meals and simplify meal tray where appropriate
Disability	Screen by assessing baseline and current activities of daily living Avoid bed rest unless medically necessary Raise activity level as tolerated

increase the individuals' subsequent risk during an acute injury or acute illness.

Handgrip strength can predict accelerated decline in activities of daily leaving and disability, which can contribute to dependency. In addition, a rapid decline in walking speed has been associated with a high risk of all mortality and impaired mobility. Physical inactivity has been shown to predict dependence and death [10–12]. Unintentional weight loss is a predictor of higher morbidity and mortality. The CSHA Frailty Index Scale, described by Rockwell and his colleagues, is a global clinical assessment of the older individual which defines the patient in one of seven clinical frailty scores. With each increasing scale from 1 to 7, patients had an increasing risk of death within about 6 years or of institutionalization. This CSHA Frailty Index Scale seems very easy to determine. The tool can assist the surgical teams with a global assessment of the older patients' vulnerability.

A screening for frailty should be a core part of the preoperative surgical assessment of an older adult. Understanding such vulnerability can help the surgeon and the patient better understand the risks of the procedure in the context of the overall health of the patient. This will better frame the decision-making and hence the patients' preferences. The management of frailty should include identifying any modifiable precipitating causes. The clinical team should minimize risk factors and stressors that can precipitate complications in hospitalized older adults during the acute illness or in the perioperative period. Likewise, the clinicians should encourage mobility and optimize nutrition. An interdisciplinary approach and comprehensive geriatric assessment is needed to appropriately manage vulnerable older patients with frailty.

Delirium

The most current definition of delirium was recently published in the 5th edition of the DSM and includes a disturbance in attention and awareness; a change in cognition that is not better accounted for by a preexisting, established, or evolving cognitive disorder. The disturbance develops over a short period and tends to fluctuate during the course of the day. The delirium is often a direct physiological consequence of a general medical condition, an intoxicating substance or withdrawal, medication use, or more than one etiology [13].

Delirium is a clinical diagnosis. The Confusion Assessment Method (CAM) is a screening tool commonly used in hospital settings. It provides an overall sensitivity from 94% to 100% with a specificity form 90% to –95% [15]. Recent studies have described a strategy to more easily implement the CAM at the bedside. Many hospitals have started to shift their efforts towards using other tools to screen for delirium, using a RASS score. The main point for the surgical team is to take the time to assess the older patients' ability to shift and sustain their attention. A nice clinical approach is to ask open-ended questions regarding the patient's hospital admission and then to ask the patient (in a reassuring manner) to say the days of the week or the month of the year backwards. Also, the surgical team should define the patients' baseline cognition. Likewise, the surgical team should ask the nursing staff to define any signs or symptoms of delirium.

Delirium is often multifactorial and is the result of the combination of predisposing factors and precipitating factors. Older adults who are admitted to the hospital for a surgical procedure might already have certain factors which increase their risk of delirium. These predisposing factors include cognitive impairment, male, and sensory impairment. The interaction of these vulnerabilities with precipitating factors (sleep deprivation, acute illness, high-risk medication) can result in delirium.

Delirium in older adults has major implications for the patient and the family caregivers. Delirium can be life-threatening. It is the most common postoperative complication in older adults. Delirium occurs in 5% of cases in low-risk patients with low risk procedures and up to 40% in high-risk patients with high-risk operations. Delirium is associated with major postoperative complications such as prolonged hospitalization, loss of functional independence, reduced cognitive function, incomplete recovery, delayed rehabilitation, and death [14]. In short, efforts to help older patients with the most advanced surgical procedures can "fall apart" when the patient develops the complication of delirium.

Delirium is commonly described as hyperactive, hypoactive, or mixed delirium. In the hyperactive type, the patient is agitated and combative. For hypoactive delirium, the patient is usually drowsy, or lethargic. This type of delirium is often unrecognized. The older patient with mixed delirium has a combination of clinical features of both hypoactive delirium and hyperactive delirium. In the hyperactive type, agitation and behavioral disturbances (aggression or combativeness) can be distressing to the patient, their families, and the professional caregivers.

Once delirium is diagnosed, the underlying causes should be treated and target laboratory assessment should be ordered based on clues from a history and physical exam. Neuroimaging should be obtained if the patient has had a history of trauma or if there are clinical findings to suspect a localizing condition. An electroencephalogram is not a part of the initial evaluation, but may be warranted if clinical features are consistent with seizure or if the patient's condition does not improve. Management of an older patient who has delirium includes nonpharmacologic interventions and pharmacologic interventions. This topic has been nicely described in recent guidelines released by the American College of Surgeons and the American Geriatrics Society. Nonpharmacologic interventions focuses on encouraging mobility, avoiding use of physical restraints, addressing sensory impairment ensuring that the patient has glasses, and hearing aids and dentures. Assessment of medications and reduction of psychoactive drugs is essential in the management of delirium [17].

The authors of several high-quality systemic reviews have concluded that the evidence to justify the use of antipsychotics for prevention or treatment of delirium is insufficient [16]. Pharmacologic interventions or use of antipsychotics are reserved for severe agitation, aggression, or combative behaviors that impair essential medical therapy (e.g., intubation). Haloperidol is the most studied of the medications used to treat older patients with delirium. A key clinical point for the surgeon is to use dosages of haloperidol which are low and to carefully reassess the patient's response to the treatment. Use of benzodiazepines in older adults is recommended only in alcohol or benzodiazepine withdrawal. Quetiapine is the drug of choice for patients with Lewy body dementia or Parkinson's disease.

As noted above, American Geriatric Society and the American College of Surgeons recently published clinical practice guidelines for postoperative delirium in older adults. These recommendations were made based on studies that included both surgical and nonsurgical patient cohorts. The guidelines address the prevention and treatment of postoperative delirium.

Key take home messages from these recommendations include: (1) multicomponent nonpharmacologic interventions should be administered to at-risk older adults to prevent delirium; (2) ongoing educational programs regarding delirium are important; (3) medical evaluation should be performed to identify and manage underlying contributors to delirium; (4) pain management (preferably with nonopioid medications) should be optimized to prevent post-operative delirium; and (5) Antipsychotics (e.g., haloperidol, risperidone, olanzapine, quetiapine, or ziprasidone) may be considered, at the lowest effective dose for the shortest possible duration to treat delirious patients who are severely agitated or distressed or who are threatening substantial harm to self and/or others [14].

Previous studies have shown that about 30–40% of delirium is preventable. This understanding is important to a surgical team. The Hospital Elder Life Program (HELP) is an evidence-based medicine program designed to decrease delirium and functional decline in hospitalized older adults. This program is essentially a prevention strategy. The premise of this program is to identify vulnerable older adults with certain risk factors and to deploy delirium prevention strategies.

Dementia

Dementia is a chronic and progressive decline in one or more cognitive domains (learning, memory, complex attention, language, visual-spatial skills, executive function) sufficient to affect daily life. Alzheimer's disease (AD) is the most prevalent cause of dementia (50–75%). Other common types of dementia include vascular dementia (20–30%), dementia with Lewy bodies (10–25%), Parkinson dementia, frontotemporal dementia (10–15%), and mixed dementia [18, 19].

Behavioral and Psychological Symptoms of Dementia (BPSD) is common as dementia progresses [20]. BPSD is present in approximately 60% of community dwelling patients and 80% in long-term care facility residents. Hence, many of the older patients who receive care on hospital surgical units have co-morbid dementia.

In the inpatient setting, it can be difficult to clearly differentiate dementia, delirium, and BPSD. Careful assessment, including obtaining baseline information from the family or the long-term care facility, is important to be able to discern these geriatric syndromes (Table 2) [31]. When evaluating individuals with dementia, it is important to identify reversible or treatable medical conditions such as depression, hypothyroidism, or vitamin B12 deficiency. The Mini-Cog screening tool helps the clinician define those who have cognitive impairment. This five-question screen uses three questions of short term recall and two questions posed to have the older patient draw the face of a clock and place the hands to depict a time (e.g., "ten minutes past ten"). Further assessment tools include the Mini-Mental State Examination (MMSE) or similar more detailed tools, which can assist clinicians to determine changes in cognition over time. The key point is to carefully follow up these patients after their hospital assessments to

Table 2 Discerning dementia from delirium and delirium superimposed on dementia

Features	Dementia	Delirium	Delirium superimposed on dementia
Onset	Insidious	Acute	Abrupt/acute
Course	Gradual deterioration	Fluctuating	Fluctuating
Awareness	Affected in late stages	Impaired	Severely impaired
Attention	Affected in late stages	Disturbed	Disturbed
Memory	Port short-term memory	Affected immediate recall	Impairment in multiple cognitive domains
Delusion	Fixed	Short in duration	Varies
Sleep disturbances	Sleep-wake reversal	Fragmented sleep	Fragmented sleep
Chronic cognitive symptoms	Yes	No	Yes

define if there cognitive assessments improve over time. Physical and neurologic examinations along with functional assessment are important steps in the initial evaluation of dementia. Neuroimaging is warranted in most all cases, especially those with unexplained focal neurologic signs or symptoms. Neuroimaging is particularly deemed necessary in cases of early onset dementia or an abrupt onset or rapid decline in cognition.

The primary goal of treating individuals with dementia is to improve quality of life, maximize function, and improve cognition, optimize mood, and address behavioral challenges. Supporting the family caregiver is likewise essential when delineating a treatment plan for older persons with dementia. Medications used to treat those with dementia (e.g., donepezil, rivastigmine, memantine) have demonstrated to slow cognitive decline and improve quality of life. These medications should be promptly resumed in the older surgical patient.

Recent efforts have been made to improve the management of behavioral and psychological symptoms of dementia (e.g., delusions, visual hallucinations, auditory hallucinations, agitation, irritability, wandering, psychomotor hyperactivity) because in unique situations, antipsychotics are prescribed to manage behavioral disturbances. The United Kingdom's National Institute for Health and Care Excellence (NICE), the American Psychiatry Association, and the American Geriatrics Society all recommend non-pharmacologic behavioral strategies as a first line strategy to manage BSPD.

Pharmacologic treatment of BPSD is considered as adjuvant in certain situations such as depressed mood, anxiety during times of transition, psychosis with potential for self-harm or others [20].

Nonpharmacologic strategies focus on addressing unmet needs like fear, hunger, toilet needs, sensory deficits, and improving communication (e.g., use a calm voice, limit choice, and keep interactions simple). In patients with a history of dementia or cognitive impairment, it is important to determine if the patient has the capacity to make medical decisions. Awareness of the patient's ability to understand information is important when obtaining consent for upcoming procedures. Physicians should assess patient's ability to understand information about treatment, their ability to appreciate how that information applies to their situation, their ability to reason with that information, and their ability to make a choice and express it [21].

Depression

Depression is common in older adults, often under-diagnosed and undertreated. Older adults may complain of lack of energy or pleasure and mistakenly attribute this to concurrent medical conditions. Older patients will neglect to mention such symptoms to healthcare professionals.

Older adults with depression are at an increased risk of functional impairment. Depression can precede cognitive impairment and malnutrition. It increases morbidity and mortality in medical conditions including cancer, diabetes stroke, and myocardial infarction. When depression is suspected in older adults, consider screening with patient health questionnaire (PHQ-2). Those older patients with a positive screen should be assessed by a behavioral health liaison to further evaluate and address their needs.

The DSM-V criteria for major depressive disorder indicate that five or more of the following criteria have to be present during the same 2-week period and represent change from previous functioning, at least one of the symptoms is ether depressed mood or loss of interest. Symptoms are not a direct result of a medical condition. The criteria includes: depressed mood, loss of interest, weight loss, decrease or increase in appetite, insomnia or excessive sleeping, psychomotor agitation or retardation, fatigue or loss of energy, feelings of worthlessness, diminished ability to think or concentrate, and recurrent thoughts of death or suicidal ideation [22].

SSRI antidepressants are usually the first-line agents for the treatment of depression in older adults. Follow-up of the patient for hyponatremia is a part of standard care. Treatment with antidepressant should be continued for at least 6–12 months after remission. Counseling and support is also an effective treatment strategy, alone or in combination with medication management. If remission is not achieved with a first agent, consider switching to a different SSRI or a second-line agent (mirtazapine, duloxetine) or psychiatric consult might be needed. Clinicians should be cautious when combining antidepressants to prevent potential adverse effects.

Falls

Falls are the leading cause of unintentional injury and death in the older adult. Falls are a common problem for older adults. Approximately 30% of people aged 65 and older, and 50% of those aged 80 and older, have fallen at least once during the prior year [23]. Almost a third of older adults who fall experience an injury and some of the consequences of falls can be catastrophic. Accidental and incidental injuries are the fifth leading cause of death in older adults and falls comprise two-thirds of those events. Half of all older adults hospitalized for hip fracture never return to prior level of functional mobility [24]. The best screen for falls in older patients is to simply ask the individual: "Have you fallen in the past year?" The best screening examination tool for assessing ambulatory older patients is the Timed Up and Go Test. Falls in older adults are often multifactorial and are the result of a complex interaction of predisposing factors and precipitating factors. Multiple causes can lead to falls in older adults: for example, poor balance, weakness, sensory impairment, cognitive impairment, and multiple comorbidities. The interaction of these factors with polypharmacy (benzodiazepines, antipsychotics, antihypertensive medications, and skeletal muscle relaxants) and environmental factors can increase vulnerability and hence increase risk of falls in older adults.

Assessment of older patients with history of falls is very important and includes an evaluation of functional gait, balance, and mobility assessment. Assessing risk for falls is key in the acute care setting and usually requires an interdisciplinary approach, (physical therapist, occupational therapist, physicians, nurses, and pharmacist).

Simplifying psychotropic medications is important. Also the clinician must optimize medical treatment of the patients' chronic illnesses like Parkinson's disease, depression, dementia, and orthostatic hypotension. Addressing multiple risk factors by using an interdisciplinary approach is the key message in preventing falls. Other strategies that can assist to improve the risk for falls includes: balance and exercise programs, vitamin D supplementation, home safety evaluations (e.g., lighting, flooring, home adaptive equipment), encouraging the use of ambulatory assistive devices, and treating sensory impairments. Evidence-based falls prevention programs can help as well.

Hearing Impairment

Hearing impairment is common in older adults and increases with advancing age. The consequences of hearing loss in older adults may include: depression, social withdrawal, and decreased quality of life. Hearing impairment is classified as conductive hearing loss, sensorineural hearing loss, retro-cochlear, and mixed hearing loss [25]. Simple whisper test seems to be a clinically feasible screen for busy clinicians. Audiometry assessment can determine the severity of hearing loss as well as the type of impairment.

Mixed hearing disorders are common in older persons. Presbycusis affects about 30–50% of older adults. Some of these individuals have a combined cause of hearing impairment with conductive hearing loss, such as cerumen impaction. The surgical team should be aware of hearing impairment in the context of their instructions during the perioperative care of vulnerable older patients. Voice amplifier devices can help those with hearing impairment in the setting of a hospital nursing unit and in a specialists' office. These inexpensive devices should be a part of the standard tools which a surgical team can use to improve communication with older patients.

Visual Impairment

Visual loss is common in older adults. The Snellen acuity test is the most appropriate screen. The most common causes of visual impairment in an elderly person are: age-related cataracts, age-related macular degeneration, glaucoma, and diabetic retinopathy. Of all persons aged 75 years and over, 52% have advanced cataracts, 25% have nonexudative ARMD, 5% have exudative ARMD, and 2% to 10% have glaucoma [26].

Visual loss is often associated with morbidity in older adults: increase physical dependence, increased risk for falls, depression, and anxiety. Visual impairment may also worsen dementia and has been noted as a predisposing risk for delirium. Visual loss can significantly impact a patient's ability to drive. This fact highlights the importance of appropriate screening and eye evaluation of older adults. Approximately 40% of blindness among elderly persons is either treatable or preventable [26]. A vision assessment is a component of the "Welcome to Medicare examination." Further screening is covered for those at high risk of glaucoma. A full eye exam annually is recommended for people with diabetes mellitus and retinopathy.

It is extremely important for older adults with visual impairment to restore function and maintain independence. Early intervention and visual rehabilitation give this vulnerable population the skills and resources to minimize the effect of this disability. The older surgical patient with serious vision impairment should be seen by an occupational therapist to assure that the patient has a care plan which takes into account her/his needs.

Urinary Incontinence

Urinary incontinence is a common disorder among older adults. The prevalence of urinary incontinence increases with age in both men and woman. UI is defined as the involuntary leakage of urine and like other geriatric syndromes it is multifactorial. Acute UI is may be caused by a number of factors: neurologic conditions, fecal impaction, delirium, or polypharmacy [27].

Chronic urinary incontinence includes stress incontinence, urge incontinence, overflow incontinence, functional incontinence, and mixed patterns. Stress incontinence is caused by a decrease in outlet resistance (urethral hypermobility, intrinsic sphincter dysfunction). Episodes of incontinence may occur with increased intra-abdominal pressure (such as coughing, sneezing, and laughing). Urge incontinence is often associated with neurological disorders and is caused by overactivity of the detrusor muscles in the bladder wall, giving the sensation of urgency and urinary leakage. Overflow incontinence is the inability to completely empty the bladder caused by poor detrusor contractility. This type of incontinence may be associated to diabetes mellitus and some other neurological disorders. A common form of incontinence in frail older adults is the combination of urge and overflow incontinence. Functional incontinence refers to the loss of independent urinary control caused by diminished mobility or cognition. A careful detailed history and evaluation is key to evaluate patients with urinary incontinence.

The following are approaches that have been developed to address urinary incontinence. Behavioral therapies such us scheduled voiding and urge suppression approach are usually the first line of treatment for older adults. Pharmacotherapy has shown efficacy in treating urinary incontinence and they are widely used to treat urge incontinence or mixed incontinence (oxybutynin, tolterodine, mirabegron). These medications are associated with important side effects in older adults; hence, the clinician is encouraged to start a care plan with nonpharmacological strategies. Surgical therapy could be considered for those patients with stress UI that do not respond to other therapies. However, in those frail older adults with multiple comorbidities, surgery may impose a significant risk. Management of UI should focus on conservative therapy with a combination of behavioral therapies, pharmacotherapy, and supportive care (pads and protective garments) [22, 27]. Urine incontinence in the setting of surgical care requires a thoughtful evaluation in the context of the injury and surgical procedures.

Sleep Disorders

Sleep disorders are common in older adults. Sleep disturbances in older adults are the result of the interaction of multiple factors such as psychological and medical comorbidities. Patients with sleep disorders are more likely to develop hypertension, depression, and cardiovascular and cerebrovascular disease. It is important that clinicians routinely ask about sleep and perform initial screenings that may prompt further history and blood work.

Sleep disorders in older adults can be categorized as insomnia, hypersomnia, and movement disorder. Insomnia is defined as difficulty falling asleep or staying asleep. Insomnia is prevalent in older adults and in a study, 42% of participants reported difficulty falling asleep and staying asleep. Insomnia in older adults is often associated with significant morbidity and mortality.

Medical conditions (including chronic pain, chronic obstructive pulmonary disease, congestive heart failure, enlarged prostate, and cerebrovascular disease) have been associated with sleep complaints and insomnia [29]. Medications such as serotonin reuptake inhibitors (SSRIs), beta-blockers, bronchodilators, or diuretics may exacerbate insomnia. Behavioral treatment should be the initial treatment in older adults. Behavioral treatment has shown to be effective in all age groups. Providing nonpharmacologic strategies, sleep education, and encouraging good sleep hygiene are interventions that are frequently included when managing insomnia in older adults. Combining behavioral and pharmacologic therapy may provide better outcomes. For the pharmacologic management of insomnia, non-benzodiazepines (eszopiclone and melatonin receptor agonist) are the safest and most efficacious drugs currently available [28].

Sleep apnea is a condition in which people stop breathing while asleep. There are two types of sleep: obstructive sleep apnea (OSA) and central sleep apnea. Obstructive sleep apnea in older adults occurs in up to 70% of men and 56% of woman. This condition is associated with heart failure, atrial fibrillation, and stroke. Often it is associated with history of hypothyroidism and may be more common in women. Obtaining a detailed history and performing a physical examination that focuses on upper airway, dental structure, and face skeletal structure is important when assessing patients with OSA. Polysomnography will confirm and will determine the severity of the apnea. A CPAP is the best approach and first line of treatment for most patients. General measures such as avoidance of alcohol, hypnotics, opiates, weight loss, and optimizing treatment of chronic diseases like heart failure should be part of the management of OSA.

Sleep-related movement disorder, also known as restless leg syndrome (RLS), is characterized by an unpleasant leg sensation that disrupts sleep. Patients usually report them as creepy-crawly, burning, itching, or painful sensation that will cause insomnia and daytime sleepiness. Certain medications, including tricyclic antidepressant, SSRIs, lithium, and dopamine antagonists, have been reported to exacerbate RLS. A physical examination is usually unremarkable and no specific laboratory tests are required to establish the diagnosis. Serum ferritin is recommended as a part of the assessment because iron deficiency is often associated with RLS. The first line of treatment for RLS is dopaminergic agents (such as ropinirole or pramipexole) are both FDA approved for RLS. Nonpharmacologic approaches are also described for the management of RLS. These approaches include stopping caffeine, stopping offending medications, education, smoking cessation, and exercise.

Conclusion

The biological changes and progression of common chronic illnesses in older adults create a diminished physiological reserve. This in turn results in a weak compensatory mechanism during stress, injury, and acute illness. The interaction of this vulnerability with multiple risk factors associated with age and the insults to multiple organ systems cause the geriatric syndromes.

creening and assessment of geriatric syndromes in older adults may lower perioperative complications and decrease adverse outcomes. Nursing screening tools can be integrated into the electronic health record to systematically detect older adults with geriatric syndromes. Geriatric syndromes are common in older surgical patients. Prevention is important. Early identification and management will improve the care of older adults and provide specific strategies to successfully reduce complications in the acute care setting and subsequently in postacute care setting.

Preoperative Assessment

6 Patient-Centered Surgical Decision Making

Tyler R. Chesney and Margaret L. Schwarze

Contents

Abstract

Populations are aging, and older adults have an increasing need for high-quality surgical care. There are inherent complexities in caring for this group with altered risk and benefit profiles as well as different patient values and goals. Given higher rates of multimorbidity, frailty, and poorer overall prognosis, older patients are at greater risk of nonbeneficial or unwanted care. Surgical interventions can have unintended consequences and unwanted burdens including loss of function, reduced quality of life, multiple transitions of care, and postoperative suffering.

In this setting, standard informed consent is not enough. Decisions need to be made in the face of uncertainty with preference-sensitive choices and a need to avoid making assumptions about patients' goals. A patient-centered

approach using shared decision making integrates patient preferences, values, and goals with their underlying health status to allow patients and their surgeon to make decisions together about treatment strategies. Many barriers exist to patient-centered decision making including system factors, patient and family factors, and standard communication practices including a focus on risk disclosure.

In this chapter, we provide an approach to patient-centered decision making in geriatric surgery. This includes setting the stage to contextualize the surgical diagnosis within the patient's overall prognosis. This requires acknowledging and addressing the uncertainty inherent in prognostic information and in the decisions that need to be made. Surgeons then identify at least two treatment alternatives and emphasize that a choice must be made together. These options may include surgery and no surgery options, medical options, or potentially time-limited trials. A multidisciplinary approach to developing and carrying out treatment options is certainly of great benefit. Information about the different treatment options and potential outcome states should be conveyed narratively to allow visualization of what the experience of various outcomes would be and what the trade-offs are rather than focusing on isolated risk disclosure. Patient's values and preferences must be elicited with care to focus on what is possible and acceptable rather than what is wished for in unrealistic terms. Finally, a surgeon must integrate all of this information to make a treatment recommendation and should demonstrate why the recommendation is being made and that this supports the patient's goals. Indeed, a patient-centered approach to decision making in geriatric surgery is paramount to high-quality care in this complex patient population.

Introduction

With the aging of populations worldwide, the need for older adults to receive high-quality surgical care is increasing, and patient centeredness is a core aim for high-quality care [1]. Older adults have a high burden of surgical disease, and nearly 500,000 older Americans undergo high-risk surgery yearly [2–6]. While many patients experience symptom and survival benefit from surgical intervention, the potential for nonbeneficial care rises in the older population. Older patients can be at higher risk due to poorer underlying prognosis and higher rates of multimorbidity and frailty [7–10].

Indeed, surgical interventions can have unintended consequences and unwanted burdens. Older adults can be at increased risk of serious postoperative complications, reductions in quality of life, and loss of functional status and can experience multiple transitions of care, increased hospital admissions, unwanted interventions, and postoperative suffering [6, 11–15]. Furthermore, the outcomes of importance for older adults may be uniquely different than younger patients with more focus on maintenance of function, time with loved ones, and quality of life and less focus on life extension [16–19].

These factors highlight the added complexity inherent in surgical care and decision making for older adults who face surgical illness. For older adults facing a choice about treatments for a surgical disease, the decision-making paradigm is shifted based on alterations to anticipated benefits and risks as well as patients' preferences and values. While there are many pitfalls that can lead to nonbeneficial care, high-quality surgical care for older adults must incorporate a patient-centered approach to decision making [20]. In this chapter, we will describe how patient-centered decision making in surgery differs from the traditional informed consent process and why this approach is important in geriatric surgery, we will outline barriers to patient-centered decision making, and we will provide a framework for patient-centered decision making in geriatric surgery.

Clinical Vignette

A frail 79-year-old woman with severe emphysema, renal dysfunction, and coronary disease presented to the hospital with a tender aneurysm in her chest and abdomen that could potentially be treated with surgery. Because of her overall fragile health, the operation was very high risk. At best, it would also require prolonged treatment in the ICU and then ongoing care in a nursing home. The patient and surgeon discussed the serious risks of surgery: a 50% chance of kidney failure, a 75% chance of pulmonary failure, and a 50% chance of death. The patient chose to undergo the 10-h invasive procedure, which repaired her aneurysm. However, the patient's family asked her doctors to withdraw all life-supporting treatments just 1 day after her operation, as they recognized that she would not have wanted subsequent burdensome treatments in the ICU or spend the rest of her days in a nursing home.

For this patient, the surgeon complied with current practice standards by obtaining informed consent by accurately disclosing potential surgical risks and benefits plus an alternative nonoperative palliative strategy. Although the patient had an undeniable need for prolonged postoperative ICU care and long-term nursing home care, she was unaware of this information and unable to use it in her decision making. Tragically, the decision started her down a care trajectory she would have avoided had she been better informed. This situation may have been avoided with a patient-centered approach, rather than the traditional informed consent process.

What is Patient-Centered Decision Making?

Patient-centered care focuses on congruence with and responsiveness to patients wants, needs, values, and preferences and has been an aspirational driver of care since the 1960s, though it has more recently been characterized as a quality standard by the Institute of Medicine [1, 21–23]. A patient-centered approach has prompted evolutions in education, research, laws, patient-physician relationships, disclosure, and decision making [21]. For surgical decision making, a patient-centered approach places focus on a broader shared decision-making process than that encompassed in the traditional informed consent process alone. Figure 1 outlines the main components of informed consent and shared decision making along with potential outcomes of each approach.

Most patient-doctor decision making employed by surgeons is grounded by the informed consent process, which is an ethical and legal requirement for surgical treatment and is designed to support self-determination [23]. The informed consent process requires discussion of the nature, purpose, risks, and benefits of a proposed intervention as well as alternatives including consequences of no surgical treatment and must be followed by explicit agreement or refusal by the patient or patient's designated decision-maker [22].

Sadly, informed consent, at least in practice and to some degree in theory, falls short of the goals of patient-centered decision making. Informed consent can assume patients have bought into aggressive postoperative care for potential complications and create the appearance that alternatives to surgery are secondary rather than real options. Informed consent may be perfectly adequate when the patient's best interests and goals are obvious, for example, a young person with colon cancer. Yet, explanation of benefits, disclosure of risk, and noting alternatives (including no surgery) do little to engage the patient in a conversation about preferences, clarify goals, or deliberate about options. For a young person who is likely to do well with surgery and likely values life-prolonging interventions, risk disclosure and presumptions about goals are sufficient. But given the nature and complexity of surgical decision making for older patients, the informed consent approach is not enough. For decision making to be truly patient centered, surgeons need to move beyond the framework of informed consent and embrace shared decision making.

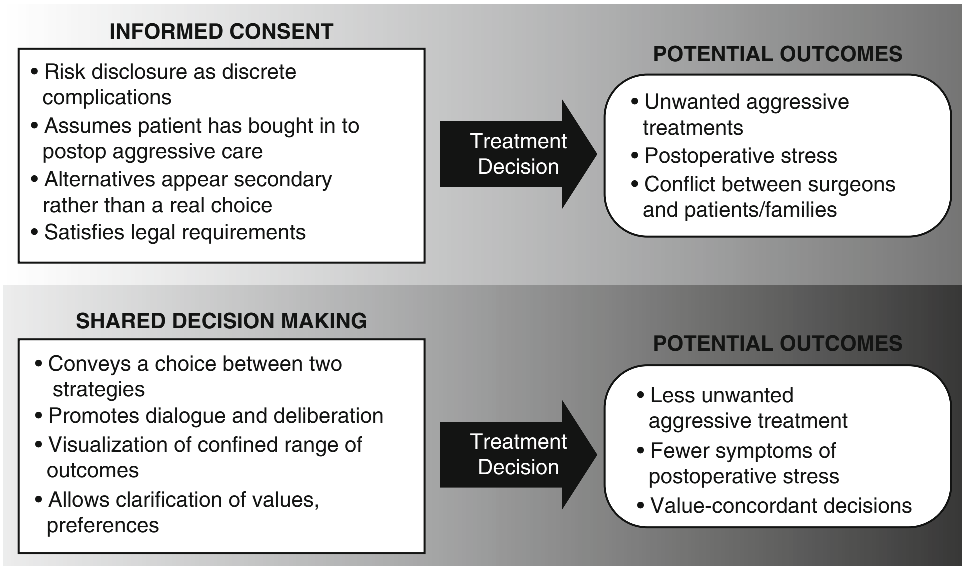

Fig. 1 The main components of informed consent and shared decision making with potential outcomes of each approach

At its heart, shared decision making posits that both surgeon and patient have important information to contribute to the decision-making process [22, 24]. The surgeon has information about outcomes and options, while the patient has knowledge about his/her personal values and goals [25]. For a decision to truly reflect a patient's autonomous wishes, an exchange of knowledge from both sides needs to occur. Thus, shared decision making is a process of information exchange between patient and doctor that leads to a decision, typically a treatment recommendation, which is well aligned with the patient's goals.

As a whole, shared decision making encompasses several components. A choice between at least two treatment strategies is conveyed. A range of outcomes are discussed narratively to allow a visualization of various potential outcome states. Dialogue and deliberation as well as clarification of values and preferences are promoted. Finally, a recommendation for treatment that matches these goals and preferences is made. For many surgical decisions, and certainly for decisions with most geriatric surgical patients, shared decision making is required if the surgeon aims to provide goal-concordant care and support patient autonomy.

Shared decision making is ideal in the setting of high uncertainty or when the outcomes are preference sensitive [22]. Some prototypical examples where shared decision making is required include decision making about prostate cancer (e.g., deciding between surgery, radiotherapy, or active surveillance) or breast cancer treatment (e.g., breast-conserving surgery with radiotherapy or mastectomy). Similarly, decisions about major operations for older patients require a clear evaluation and discussion of the outcomes of both operative and nonoperative treatment options as such interventions may not confer a survival advantage or could significantly change the patient's overall quality of life. Indeed, for older patients, understanding the trade-offs in decision making is essential [26]. Understanding how patients might value these important trade-offs is essential to providing goal-concordant care.

In geriatric surgery, shared decision making may also be important even when there is less uncertainty and more clarity about what surgeons would typically consider to be the "right" treatment in younger patients [16]. Returning to our example of colon cancer for which there are strong notions that cure-driven treatment (surgery) should be employed, this assumption may not hold for a frail older person with dementia and very poor quality of life. Consideration of a comfort-focused strategy in contrast to a survival-focused strategy using the process of shared decision making will help to identify patients for whom an operative intervention will not achieve their goals. Surgical treatment for colon cancer may not actually prolong life in this setting or even ameliorate symptoms. Consideration of the outcomes of treatment and how these outcomes are valued by the patient and family is required to determine the "right" treatment course.

Some patients or their decision-makers may report they want their surgeon to simply do what is best. Many surgeons will find this distressing particularly when the decision is highly preference sensitive or there is "no good option." This is challenging because many surgeons will want to be sure to respect patient autonomy and also have confidence that the patient and family are on board with the treatment plan. Yet the surgeon can assist such patients without fearing paternalism or making the wrong choice for the patient. Shared decision making does not require the patient to decide what to do or even express preferences for a particular treatment. Shared decision making requires that the surgeon learns about what is important to the patient – what the patient hopes for and fears – enough to recommend and support a treatment option that most reflects the patient's goals. Shared decision making helps surgeons figure out "what is best" without abandoning patients to their own autonomy.

Barriers to Patient-Centered Decision Making

Decision making about high-risk surgery is inadequately supported by current communication practices, and there are many barriers to using a patient-centered approach to decision making [27]. A recent Institute of Medicine report noted that although most patients prefer to share in decision making, "they are often not afforded the chance to participate" [28]. Other studies reveal that surgeons rarely employ a cooperative decision-making process, and systematic reviews evaluating informed consent demonstrate a need for improvement in this process which does not meet patients' informational and decisional needs [29–33]. Significant geographic variation in the volume of high-risk surgical treatments suggests clinical uncertainty among surgeons about optimal treatment strategies, further necessitating patient engagement in these high-stakes decisions [6, 34]. These conversations are challenging as surgeons work hard to inform patients about the intricacies of a highly technical procedure, worry about burdening patients with fear of possible complications, and are bound by the structure and language of informed consent.

In observational studies of preoperative decision making, surgeons routinely satisfy the legal requirements of informed consent, yet they do not provide patients the opportunity or the type of information they need to meaningfully participate in decision making [30, 35, 36]. These preoperative conversations follow a robust and consistent pattern which presents opportunities to improve and provide more patient-centered decision making (Fig. 2).

First, there is an explanatory phase that surgeons use to describe the patient's disease and treatment. They describe the patient's disease as an acute abnormality (a valve that is loose, an artery that is blocked, a tumor that is abnormal) and tell how surgery can "fix it" (tighten the valve,

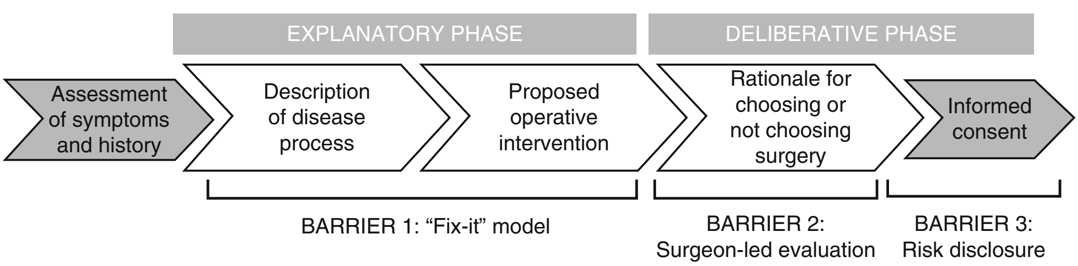

Fig. 2 The structure of usual preoperative conversations and the barriers to patient-centered decision making within them

go around the blockage, remove the tumor) [30]. This model supports an implicit message about the "benefits" of surgery: the reason to operate is to fix what has been identified as broken, and after the problem is "fixed," the patient will return to "normal." The "fix-it" model lacks an explicit description about what surgery might mean more broadly for the patient, for example, whether he or she will feel better or live longer, how surgery will affect other health problems, or what daily life might look like after surgery. Although many surgeons stress that "fix-it" is an overly simplified rationale for surgery, the surgeon's explanation about how disease is "fixed" with surgery makes it hard for patients to understand the need to deliberate about whether surgery is right for them.

Next, surgeons present their own evaluation of the trade-offs and goals of the proposed intervention during the deliberative phase. Although this deliberation occurs in front of patients and families, assumptions about the value of specific outcomes are surgeon-generated and not specifically connected to patient preferences. Typically, surgeons name risks and describe trade-offs, but they struggle to elicit patient preferences. Although surgeons encourage patients to ask questions, the invitation is ineffective as patients regularly respond with logistical or technical concerns. For example [30]:

> Surgeon: *This is an area for vision, smell, for function of legs and bladder. You could even have a stroke...or damage to the vision. You could have an infection or trouble with the healing. . .What questions do you have for me?*
>
> Patient: *Washing my hair was one.*
>
> Surgeon: *I want you to wash your hair with baby shampoo on the third day...Don't scrub the stitches.*
>
> Family: *Stitches or staples?*

Other logistic concerns that patients pose during presentation of surgical risk include the length of the operation, the date or the time of day of surgery, where to go for testing, the need to travel to and from the hospital, the ability to wear pajamas, and rules about visiting hours. While technical and logistic concerns are important to patients, this process does little to inform or engage patients in a discussion about what surgery might mean for them or set expectations for what life might be like after surgery.

Finally, informed consent requires surgeons to disclose risk, but this does not adequately inform patients about possible outcomes. Much attention is paid in the surgical literature to precise risk prediction, which characterizes the overall hazards of surgery as discrete complications for isolated physiologic systems (e.g., a 50% chance of kidney failure) [37–39]. Surgeons use this information to help patients make decisions about whether to have surgery, but they focus on objective quantification and physiologic risk disclosure without describing outcomes in a way that is relevant to patients and families [40]. Although surgeons make significant effort to describe the gravity of surgery, they are often surprised when patients have unrealistic postoperative expectations or have not bought in to the use of prolonged life support [41].

In addition to these communication practices and patterns, there are myriad systems and patient/family factors that add to the challenges of patient-centered decision making (Fig. 3) [20]. The patient-surgeon relationship is often encumbered by the acute nature of surgical illness or lack of a preexisting relationship. While surgeons are typically quite adept at overcoming these challenges, generating trust and attending to the emotional nature of serious illness can be undermined by this lack of preexisting relationship. Furthermore, while many patients live with chronic life-limiting illnesses, their understanding of the impact of these illnesses on their overall health trajectory is often limited. An acute event such as a traumatic injury, abdominal sepsis, or new cancer diagnosis may be very difficult for patients and families to contextualize within the patient's beliefs about their longer-term survival. Finally, while there are many efforts to improve advance care planning, the uptake of such interventions is low [42–44]. Few patients and family members have had conversations among themselves or with their primary care provider to clarify and document goals and values. While surgeons are increasingly asked to navigate this difficult territory with patients, there are few, if any, adjuncts to assist in bridging the gap between unarticulated goals and acute treatment decision making.

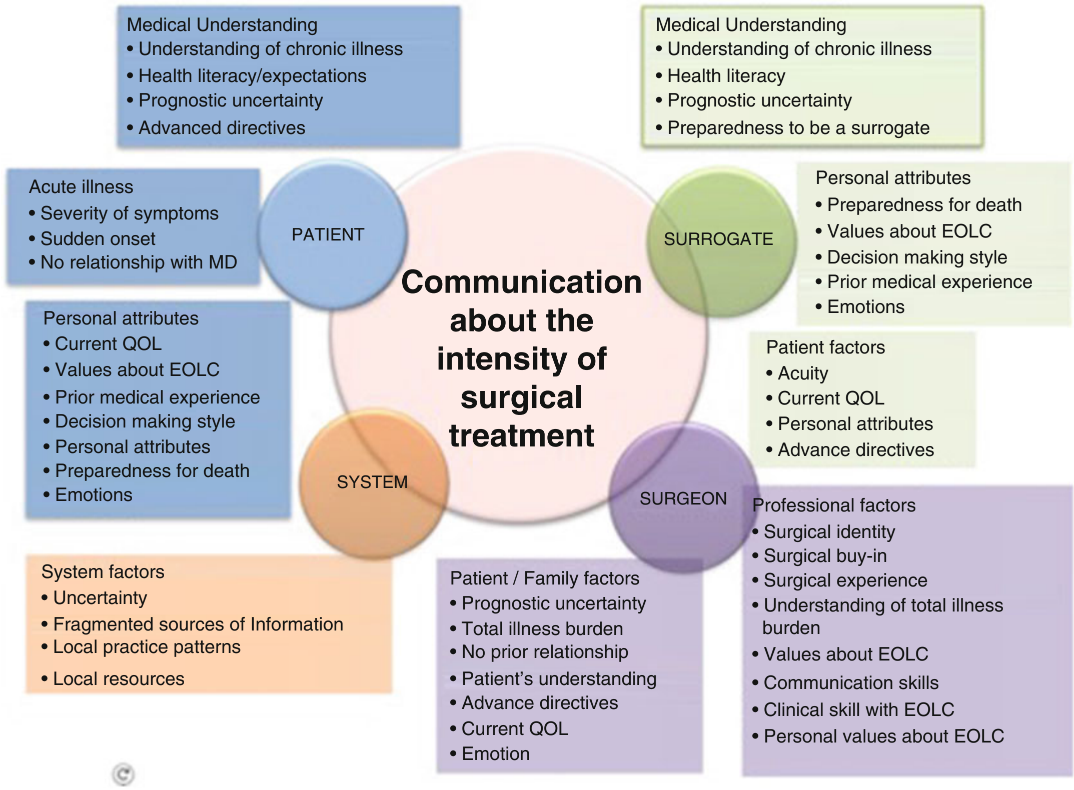

Fig. 3 Factor that may act as barriers to patient-centered communication and lead to nonbeneficial or unwanted care (From Cooper et al. [20])

Indeed, there are implicit advantages to a patient-centered approach to decision making in geriatric surgery given the complexities, uncertainties, and high risk in this population. Nevertheless, there are many barriers to the use of a patient-centered approach including traditional communication practices and training as well as system and patient factors.

Approach to Patient-Centered Decision Making in Geriatric Surgery

To assist in overcoming some of these barriers and promote a patient-centered approach, we propose the following framework for patient-centered decision making in geriatric surgery. This approach combines best practice recommendations as described by Cooper et al. and the domains of shared decision making as codified by Elwyn et al. [45, 46].

Approach to Patient-Centered Decision Making in Geriatric Surgery

1. Set the stage by contextualizing the decision with respect to the patient's overall prognosis, and address the problem of uncertainty.
2. Identify more than one treatment option and the need to make a decision together.
3. Describe the treatment options (at least two treatment strategies with the advantages and disadvantages of each).
4. Elicit patient values and goals.
5. Make a recommendation corresponding to patient values and goals

Setting the Stage: Conveying Overall Prognosis and the Problem of Uncertainty

Many acute surgical decisions are linked to life-changing illnesses. This is particularly true for older patients. Surgeons routinely describe the gravity of the patient's illness, noting treatment might require "big surgery," but often fail to clarify the patient's overall prognosis or how the patient's other illnesses, frailty, or functional status impact the overall outcome of treatment [35]. Without this type of information, patients and families will find it difficult to contextualize treatment options and the relevance of various outcomes and to consider nonsurgical options when this might truly be aligned with their goals [47, 48]. For example, a frail elderly woman might consider undergoing a colectomy if she believes her long-term prognosis is more than 2 years, but she might prefer comfort-focused care if she understood her survival is closer to 6 months due to a constellation of illnesses.

Despite the importance of an understanding of overall prognosis, surgeons may find it difficult to discuss or even raise the topic of overall prognosis because it seems alarming to patients or families [47]. Furthermore, surgeons may feel ill-equipped to estimate overall prognosis or worry about getting it wrong. There are a range of non-disease-specific prognostic indices specifically designed for older adults with multimorbidity [7]. These may be added to clinician judgement and offer a reasonable method to calibrate prognostic estimations. Nevertheless, prognostic estimation is rife with uncertainty [49]. This uncertainty can be uncomfortable and emotionally difficult for surgeons and patients alike. This uncertainty should be acknowledged directly, first by normalizing the uncertainty of prognosis and then attending to the emotional impact of experiencing an uncertain future [49]. Normalizing statements such as "while I wish I could be more certain, like predicting the weather, despite all of our tools, we can never be absolutely certain about the future" can help patients understand that precise prognostication is allusive [49]. We then must acknowledge the emotional experience of uncertainty and help patients focus on making the most of the time they have now with statements like "it is tough not knowing what the future will bring" and "what can we do to help you now, given that we are unsure of exactly what the future will bring" [49].

Most older patients do wish to communicate about prognosis [50]. Evaluating how much explicit information a patient or family wishes to hear can be done by asking a question like "how much do you want to know about the likely course of this illness?" [48]. Even for patients who initially do not want explicit information, there is much that can be done to explore the informational and emotional aspects of this wish [51]. Surgeons often embed prognostic information within their discussion of surgical outcomes: "she may not make it through the operation." Yet, this fails to signal that with or without surgery, this frail 92-year-old woman with colon cancer has life-limiting problems. One strategy to ensure patients and family members have received a signal that the patient's illness is grave is what palliative care physicians often describe as "the shot across the bow." Using phrases, such as "I'm afraid this problem is bad news," at the start of the decision-making conversation can help orient patients and families to trouble ahead and allow them to consider alternative, potentially less invasive strategies, as they understand the implications of their illness.

Identify More than One Treatment Option and the Need to Work Together to Make a Decision

In order to make a preference-sensitive, goal-concordant decision, there must be a choice between at least two options. While many patients struggle to choose between more than two options, at a minimum there must be two different treatment strategies. In surgery, these options are not particularly difficult to generate as there is nearly always a choice between having an operation and not having an operation. Yet sometimes there is a middle ground between surgery and no surgery allowing the patient and family to consider a medical-based intervention.

Another treatment strategy to propose is that of a time-limited trial. Due to the uncertainty outlined above, patients may not want to prematurely forgo treatments that might help, but they do not want to embark on a prolonged trajectory of suffering if things do not go as hoped [52]. A time-limited trial is an agreement between clinicians and a patient or family to use certain interventions, such as surgery followed by ICU care, over a defined period to see if a patient improves or deteriorates [52]. If the patient improves, this treatment strategy is continued; if the patient deteriorates, then the time-trialed treatments are ended and usually a more comfort-based approach is pursued. In this agreement, it is imperative that the time frame, markers for improvement or deterioration, and acceptable actions are agreed upon upfront, and these can be revisited and renegotiated as time passes [53].

By starting a conversation with a statement like "today we have a choice to make...," surgeons can avoid the typical pattern that starts with the surgical problem and the operation to "fix it." Furthermore, noting a patient-doctor partnership by highlighting that the decision needs to be made together can foreshadow the shared aspect of this decision and encourage patient and family participation. Given the complexity of these care needs and this decision making, a multidisciplinary approach to developing and carrying out treatment options is certainly of great benefit [18]. This may include surgical, anesthesia, and geriatric specialists, as well as nursing, physical and occupational therapy, social work, and other disciplines as appropriate.

Describe the Treatment Options

Each treatment option needs to be identified and described noting how the patient might experience each treatment including time in the hospital and recovery. Patients should have some notion about what to expect postoperatively. In addition, the pros and cons of each treatment should be described. Some might conceive of these aspects as risks and benefits, while others might support a discussion of possible outcomes and the trade-offs faced along the way. Ultimately, the patient needs to understand the consequences of each treatment and the degree of uncertainty related to both harms and benefits. When conveying information about various treatment options, as opposed to simply disclosing organ-based and isolated risk estimates, the use of narrative can facilitate conveying the experience of the various potential outcome states following different treatment choices [54].

This contextualizing information allows patients to visualize what it may be like to experience different outcomes and should incorporate the patient's underlying health as described in step 1. This step should aim to acknowledge that unwanted postoperative outcomes typically do not occur in isolation, particularly in older and more vulnerable patients, but instead often cluster together [55]. An initial postoperative complication can lead to a trajectory of further invasive investigations and treatments, prolonged hospitalization, disrupted or prolonged functional recovery, transitions in care, and poorer quality of life and survival [55–58]. Further, there can be a misunderstanding that with a surgical option, the worst outcome is intraoperative death which can be perceived as painless, but this fails to illustrate the more common situation leading to mortality that includes prolonged and aggressive ICU care, further invasive treatments, ongoing complications and declines, and a prolongation of suffering ultimately leading to death without the benefit of engaging with loved ones [59]. Additionally, instead of presenting two treatment options as recommended here, presenting surgery as the primary treatment option and other nonsurgical options as secondary limits discussion of the benefits of comfort-focused options such as time with loved ones, engagement with one's spiritual traditions is applicable, and reductions of suffering [40, 54].

Elicit Patient Values and Goals

This step seems easy, but it is actually the most difficult. Many surgeons will present a range of options and subsequently ask the patient, "what do you want?". In turn, the patient will often respond with a specific treatment preference [60]. Sadly, such information fails to illuminate what is important to the patient about the chosen treatment or reassure the surgeon that the patient's goal for surgery is a possible outcome of surgical intervention. Some patients will respond by saying, "I just want to survive." In turn the surgeon will assume the patient wants to proceed with surgical intervention. While such a decision may or may not be goal concordant, without a follow-up question about what it means to survive (e.g., go home, prolong life for as long as possible even on life-supporting interventions), the surgeon has learned very little about what is important to the patient.

Instead of questions like "what do you want?" or "do you want everything done?" to elicit values and goals, surgeons might consider "how are you thinking about this?", "what are you hoping for?", and "what do you fear?" [60–63]. Indeed, patients want to be well and at home living comfortably, but this does not help to elucidate which treatment option would most align with their goals [60]. Likewise, doing everything has many meanings; assumptions about what this means can lead to nonbeneficial and goal-discordant treatment efforts when these efforts should focus instead on what is possible and how can a patient's goals be achieved within the limits of what is possible [62]. Access to this type of information about how patients appraise specific outcomes or view the burdensome treatments required to get there is critical to ensure the chosen treatment strategy reflects the patient's values and goals.

Make a Recommendation

While eliciting values and goals takes real skill, surgeons may stumble on the step of making a recommendation for fear of being paternalistic. Some surgeons say, "my job is to tell them the options, their job is to choose" [59]. Yet this notion does not support the ideals of relational autonomy inherent in shared decision making. Patients seek out physicians' expert opinion in the same way customers seek advice from car mechanics or financial planners. Part of the presumption of these professional relationships is that the professional will guide the patient or client to an appropriate choice. Failure to make a recommendation and show how such a recommendation supports the patient's goals is abandonment of a professional duty to assist the patient.

Some patients will ask, "what would you do if I were your father?". These patients are asking for a recommendation. An appropriate response to this is not "I don't know, you aren't my father," but rather "it sounds like you are asking for a recommendation." Once the patient or family confirms this is the case, the surgeon should either make a recommendation if confident that the patient's goals and values are understood or say, "I would like to make a recommendation, but first I need to know a bit more about what is important to you." After using the techniques described in step 4, the surgeon can, with confidence, recommend a treatment strategy while revealing to the patient that this strategy supports the patient's goals. By "showing your work," the surgeon avoids a paternalistic stance and confirms that the treatment plan is goal concordant.

Conclusion

There is a growing number of older adults with a need for high-quality surgical care, and the inherent complexities in caring for this group require a patient-centered approach to decision making as there are altered risks and benefits as well as different patient values and goals in this population. Older patients are at greater risk of nonbeneficial or unwanted care given higher rates of multimorbidity, frailty, and poor overall prognosis. Standard informed consent is not enough in this setting given uncertainty, preference-sensitive choices, and the need to avoid making assumptions about patients' goals. A patient-centered approach using shared decision making integrates patient preferences, values, and goals with their underlying health status to allow patients and their surgeon to make decisions together about treatment strategies. Many barriers exist to patient-centered decision making including system factors, patient and family factors, and standard communication practices including a “fix-it” model, surgeon-led deliberation, and a focus on risk disclosure.

There is a better way to approach to patient-centered decision making in geriatric surgery. This includes setting the stage to contextualize the surgical diagnosis with an understanding of the patient’s overall prognosis, while acknowledging and addressing the uncertainty inherent in this type of information and the decisions that need to be made. Surgeons must then identify at least two treatment alternatives and emphasize that a choice must be made together. These options may include surgery and no surgery options, medical options, or potentially time-limited trials. Information about the different treatment options and potential outcome states should be conveyed narratively to allow visualization of what the experience of various outcomes would be and what the trade-offs are. Patient’s values and preferences must be carefully elicited with caution about what is possible and acceptable rather than what is wished for in unrealistic terms. Finally, a surgeon must integrate all of this information to make a treatment recommendation and should “show their work” to demonstrate why the recommendation is being made and that this supports the patient’s goals. Indeed, a patient-centered approach to decision making in geriatric surgery is paramount to high-quality care in this complex patient population.

Abstract

The US older population has been rapidly growing and will constitute a fifth of the total population by 2030. It is the fastest growing subset of the population. This rapid increase in the elderly population has a significant impact on the US healthcare system and, as a result, surgeons will frequently encounter senior patients who often present with unique diagnostic and therapeutic challenges. Aging patients have an increased risk of postoperative complications that result in disability, loss of functional independence, diminished quality of life, and death. Accordingly, the postoperative course of such a patient is of cardinal importance because it plays a critical role in determining recovery to complete functional independence. Increasing age and comorbidities also contribute to frailty, which is defined as a decreased physiological reserve and a decline in the resistance to stressors, which is independently associated with poor short- and long-term outcomes after surgery. Early identification of frail geriatric patients will help to identify those who require a more comprehensive and multidisciplinary approach, necessary to adequately address the significant differences in physiology and outcomes presented by this challenging group. The optimal goal for geriatric patients is not only to reduce mortality rates and complications after surgery, but to maintain and preserve a good quality of life after they are discharged, including increasing their ability to return to their preillness level of function and independence.

Introduction

In the USA, the geriatric population has significantly increased by 21% since 1980 [1]. This is due to aging Baby Boomers as well as increased life expectancy rooted in advances in the standard of living and medical health services. In the USA, those over the age of 65 now account for 14.5% (46.2 million) of the total population – by 2030, this percentage is expected to increase to approximately 20% (72.1 million) [2]. Indeed, geriatric people are the fastest growing subset of the total population. While the total US population has grown by 39% over the past 30 years, for instance, those segments older than 65 and 85 years have grown by almost 89% and 232%, respectively [1, 2].

Aging is a universal biologic process characterized by progressive physiologic and behavioral changes. Inevitably, the gradual accumulation of such transformations over time results in the decrement in performance and impairment of physiologic functions. This, in turn, leads to a diminished capacity to adapt as well as an increased vulnerability to disease and pathologic processes [3]. The rapid increase in the geriatric population has a significant impact on our health care system. It is imperative, therefore, that health care professionals integrate a solid understanding of the physiology of aging in their clinical practice. This is underscored by the increase in the number of older patients presenting to hospitals who require operative intervention. The aging population is, in fact, responsible for more than half of the total number of surgeries performed in the USA [3]. When surgeons operate on older, sicker patients, they are confronted with complex healthcare needs due to, for instance, one or more chronic conditions, polypharmacy, and, oftentimes, functional impairments.

In these typical circumstances, clues about a patient's physiologic reserve, his/her vulnerability to intraoperative or postoperative complications, and his/her short- and long-term prognoses are invaluable. This task is, however, complicated because the rate and the extent of decline in physiologic function among the aged is not uniform [3]. Consequently, regarding older surgical patients, it is challenging to predict who will have an optimal recovery and who will develop a complication that can trigger a cascade of events that may lead to unexpected mortality or permanent disability. The great heterogeneity among such patients is based on each individual's physiologic reserve, that is, the amalgamation of intrinsic host factors (such as age, sex, nutritional status, functional capacity, hormonal balance, and any preexisting medical conditions) that might increase one's morbidity and mortality after stressful events. This insight has given rise to the concept of "frailty," and its operational counterparts: "the frailty index" (FI) and "frailty scores" (FS).

In this chapter, we review the relevance of the concept of frailty in surgery, especially its role in identifying vulnerable surgical patients, improving patient care, and decreasing hospital costs. In addition, we simplify the concept of frailty and FI in order to expand its application.

What Is Frailty?

There is no consensus on a single, precise, and complete definition of frailty. Numerous authors and investigators offer multiple definitions based on their understanding and interpretation of the concept. From a clinical perspective, it can be defined as a syndrome of a decreased physiological reserve (physical and cognitive) and a decline in the resistance to stressors, which, ultimately, result in increased vulnerability to poor health outcomes, worsening mobility and disability, hospitalization, and death (Fig. 1) [4]. Alternatively, it is defined as a geriatric syndrome of increased vulnerability to environmental stressors with underlying inherent pathophysiological mechanisms related to hormonal changes as well as sarcopenia and nutritional deficiencies [5]. Multiple attempts have also been made to identify the different components and criteria for the diagnosis of frailty. Fried et al. defined frailty as the presence of three or more of the following: unintentional weight loss (10 lbs. in the past year), self-reported exhaustion, weakness (assessed by grip strength), slow walking speed, and low physical activity [5].

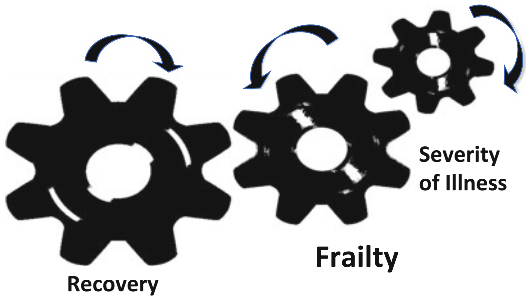

Fig. 1 Frailty "the Lethal Gear"

Somewhat differently, Rockwood and Mitnitski describe it as an accumulation of deficits (assessed via the Rockwood frailty index) that include weight loss; exhaustion or a low level of physical activity, weakness, a low energy and endurance level, and slowness [6, 7]. Clearly, these distinctive definitions of frailty (i.e., as a clinical syndrome, a phenotype, a biologic syndrome, or the accumulation of particular deficits) are the biggest barriers to a standardized application of the concept for surgical practice [8].

Limitations of Age (Superiority of Frailty Measurements)

It is also critical to distinguish between "age" and "frailty." The term "old" does not reflect a clear image of a patient's condition. It only refers to chronological age. Moreover, commonly used tools for the prediction of complications and risk adjustment cannot measure the physiologic reserve of elderly patients – they are mostly subjective and often limited to a single organ system [9]. Furthermore, these tools are rarely feasible in emergency situations because they require trained personnel and a patient's cooperation [10].

Clinically recognizable, frailty syndrome is an increased vulnerability resulting from the age-associated accumulation of deficits in multiple physiological systems, and it is worth highlighting that emerging literature suggests the superiority of frailty measurements over those based on chronological age in order to more accurately predict outcomes. The FI is well established within various disciplines of medicine as an effective assessment tool that is quickly evolving into an important component of the management of elderly surgical patients as well. It easily takes a patient's physiologic, cognitive, social, and psychological deficits into account and then translates them into a quantifiable variable. The FI is clearly superior to assessment techniques that can be cumbersome for emergency surgical patients, such as those based on physical movement and gait speed [11–13].

Pathophysiology

Frailty is also described as a phenotype of a complex proinflammatory condition or as a biologic syndrome occurring during the aging process that causes vulnerability to adverse outcomes [14]. Major factors, including genetic heritability, nutritional status, physical activity, atherosclerosis, hormones, insulin resistance, and pro-inflammatory cytokines, can lead to body compositional changes due to the loss of muscle mass and muscle strength as well as sarcopenia [15]. Likewise, a great deal of literature demonstrates the major impact of body fat on functional capacity in the elderly [16]. An increasing prevalence of high amounts of body fat, coupled with low skeletal muscle mass, is defined as sarcopenic obesity or obesity paradox, and it corresponds with a very high risk of decreased mobility in the elderly [17]. In addition, low-grade inflammation is strongly correlated with both sarcopenia and frailty. Studies on markers related to the inflammaging theory indicate that frail individuals have elevated levels of high sensitivity C-reactive protein (a soluble biomarker of inflammation) and other pro-coagulant factors. Patients with diabetes also have elevated levels of cytokines, such as tumor necrosis factor alpha and interleukin-6, which stimulate proteolysis and apoptosis in muscle cells. Furthermore, different studies show that an imbalance in hormones and nutrients is strongly related to a reduction in physiologic capacity and an increased susceptibility to disability [18, 19]. This includes an imbalance in the levels of anabolic hormones in men (testosterone, adrenal androgen, and growth hormone), an age-related decrease in sex hormones in women (including dehydroepiandrosterone sulfate, growth hormones, and IGF-1), and a loss of nutrients (such as vitamin D).

Sarcopenia: Two Sides of the Same Coin

Entailing a progressive decline in skeletal muscle mass and power, sarcopenia is one of the most serious consequences of the aging process. It accelerates after the age of 60 and, in most cases, leads to functional impairment. Sarcopenia is highly predictive of incident disability, poor quality of life, and all-cause mortality in older adults [14, 20]. Although it is a geriatric syndrome in its own right, it is the key feature of frailty (Fig. 2). As noted earlier, different operational definitions of frailty status exist side-by-side. Each one focuses on specific aspects of the syndrome and detects slightly different risk profiles. Nevertheless, there is an overall agreement about the key role that physical function plays in the determination of the status of extreme vulnerability. Following the Fried et al.'s widely used definition of frailty, a patient is assessed for unintended weight loss, exhaustion, weakness, slow gait speed, and low physical activity [21]. A diagnosis of frailty is supported when three of these features are present. Likewise, because weakness and a slow gait speed are a part of the operational definition of sarcopenia, one can safely posit that a frail individual is more likely to be sarcopenic and vice versa.

Sarcopenia, like many other age-related problems, is a multifactorial condition. Contributing factors include motor units, protein metabolism, hormones, and lifestyle. Properly understanding the impact of aging on the skeletal muscle requires attention to changes in both muscle size and muscle quality. This is particularly important when considering the potential effects of treatments, including improvements not only in muscle mass but also in function and physical performance. Sarcopenia is caused by the simultaneous

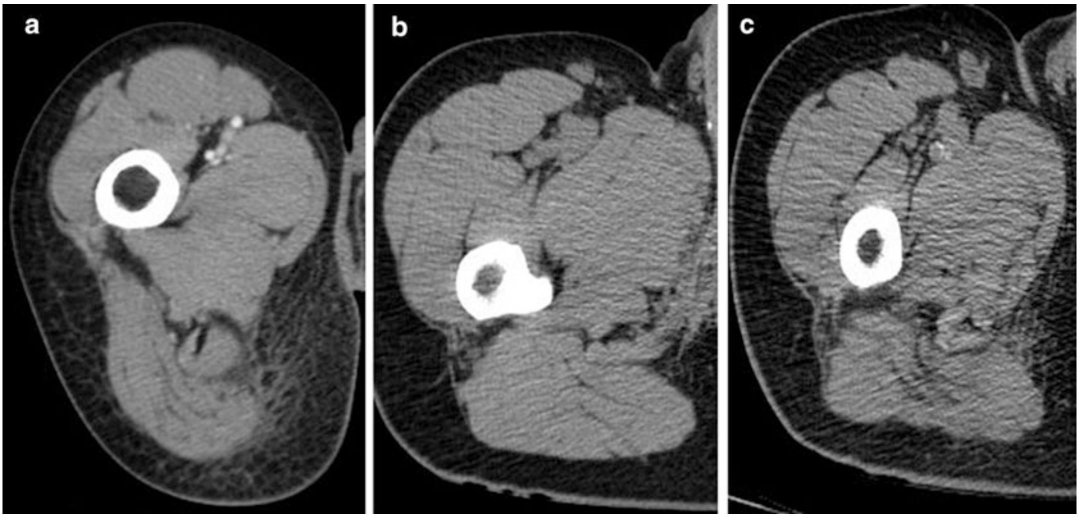

Fig. 2 CT thigh of 15 years' male (**a**) 30 years old male (**b**) and 65 years old (**c**) showing 40% lost in muscle mass in between ages 15 and 65

reduction in the number of muscle fibers and atrophy of remaining myocytes, likely due to a lower rate of myofibrillar protein synthesis and enhanced myonuclear elimination via an apoptosis-like mechanism. These findings reflect a progressive withdrawal of anabolism and an increased catabolism, along with reduced muscle regeneration capacity [22, 23]. Histological sections of aging muscle also show increased infiltration of noncontractile tissue (i.e., collagen and fat). Many factors are responsible for skeletal muscle decline: the aging process itself, genetic susceptibility, behavioral factors (e.g., less-than-optimal diet, prolonged bed rest, sedentary lifestyle), chronic health conditions, and certain drugs. Progressive muscle atrophy directly results in impaired mechanical muscle performance. Of particular importance, there is a nonlinear loss of maximum muscle strength, that is, the ability to produce muscular power is reduced even more than muscular strength [24].

Clinical Implementation of Frailty

Obviously, the usefulness of the concept of frailty in clinical practice necessitates the reliable identification of frailty in patients. Presently, the operational and practical application of the concept is captured via multiple scales composed of several variables. The FI and the FS are the most widely used.

Frailty Index

Identifying the number of health deficits of an individual forms the basis of an FI, which is calculated as a ratio of the total number of deficits (up to 70), as delineated by the Canadian Study of Health and Aging (CSHA), to the actual number of deficits present in an individual [25]. A few variables are dichotomized (yes/no) and the rest have multiple options. The variables include any comorbidity, a lessened ability to perform activities of daily living, a poor nutritional status, an impaired physical status, a lower level of cognition, and a more pessimistic health attitude in general. The greater the numbers of deficits equals a higher FI and, therefore, more extensive frailty. Of the 70 possible deficits delineated by the CSHA, at least 30 should be considered to correctly calculate an FI, which can then accurately predict worsening of health status, hospitalization, and death [6, 21]. Rockwood et al. [13] defined 0.12 as the median FI score for robust individuals, 0.30 for prefrail individuals, and a score greater than 0.40 for frail individuals [26]. Despite variable applications and methods for calculating an FI, it is a highly accurate and reliable way to describe the functional status of an individual.

Frailty Score

Fried et al. use the validated FS (ranging from 0 to 1). They defined an FS of greater than 0.20 as a cutoff-point between frail and robust individuals [21]. Quantification of frailty using the FS is based on five domains: weight loss (10 lbs. in the past year), reduced energy (self-reported exhaustion), reduced grip strength, slow walking speed (time per 15 ft.), and low physical activity (kcal/week). The FS is based on the ability of a patient to perform the activity in the five domains, and a score ranging from 0 to 1 (0 being least frail and 1 being frail) is given to each patient [21].

FI Versus FS

Clearly, a clinical implementation of frailty is impossible without a validated, operational definition [27]. While Fried's definition of frailty (based on the phenotype model) is widely used for research purposes, it can be impractical in clinical settings [27, 28]. In other words, a clinically usable definition of frailty that would allow physicians and surgeons to stratify their patients based on the risks for the treatment (e.g., operative intervention, angiography) is lacking. A wide variability in frailty assessment tools (i.e., FI and FS) makes a comparison of outcomes assessed by them difficult [29]. As a result, there are no studies comparing the FI and Fried's criteria of frailty. Though, a limitation of the FS is that it only focuses on five domains and fails to provide a complete assessment of the patient, which is provided by the FI. Clinical studies assessing frailty have commonly used the FI or a modified FI to predict adverse outcomes, including mortality, complications, and hospital length of stay (LOS), in geriatric patients. In contrast to Fried's phenotype assessment criteria (FS), we believe that the FI can be a reliable predictor of surgical outcomes.

Frailty and Kinesiology

Kinesiology, the scientific study of human movement, is increasingly used to assess the physiologic state of elderly individuals based on their velocity of movement. Alterations in body motion in the upper and lower extremity, for example, have been extensively studied in geriatric patients as a predictor of outcomes [30]. Similarly, assessment of impaired gait and balance by using lower-extremity motion sensors objectively define disease states and the risk of falls in such patients. However, the use of lower-extremity motion sensors is limited and cannot be used in physiologically compromised geriatric patients who are unable to perform gait and balance movements. Likewise, upper-extremity strength and range of motion decline with age, even though upper-extremity motion sensors are used to assess the speed and range of motion in older patients [31]. Studies do show an association between frailty evaluated via the FI or the FS and outcomes from motion sensors. Frailty algorithms use motion sensors to predict outcomes in geriatric patients, but the utility of these sensors in surgical patients to assess the risk of postoperative complications and discharge disposition is still unclear [31, 32].

Preoperative Assessment

A number of preoperative assessment tools, such as the American Society of Anesthesiology (ASA) score, Acute Physiology and Chronic Health Evaluation (APACHE) score, and the Physiologic and Operative Severity Score for the enumeration of Mortality and Morbidity (POSSUM) are used routinely, but each one has limitations. The ASA score is widely used because of its simplicity and suitability for the estimation of operative risk, but it considers only organ-specific diseases and is effective only in determining postoperative survival [33]. The APACHE score (based on age, physiologic variables, and chronic health problems) has limited value because of its complexity and low accuracy. In addition, it is mainly useful only in critically ill patients. While the ASA and the APACHE scores fail to estimate postoperative morbidity in patients, the POSSUM score estimates both morbidity and mortality. However, it can only be used in a limited way because it overestimates morbidity and mortality, and it has low accuracy [34]. Lee et al. and Eagle et al. developed criteria for the preoperative assessment of surgical patients, but it only focuses on a patient's cardiovascular function so it too has minimal utility [34]. Indeed, most scoring systems fail to incorporate the cumulative effect of all of the deficits in an aging individual's health and do not take into account the functional reserve of such an individual [35].

The FI, in contrast, incorporates all the facets of an individual's health that are currently recognized as contributing to postoperative morbidity and mortality. It takes into account the individual's chronologic age, nutritional status, comorbidities, activities of daily living, functional status, and physiologic health. A recent study assessing outcomes in vascular surgery patients demonstrated, for instance, that the FI was superior to the ASA score for predicting outcomes [36]. In another study by Tan et al., the FI was also shown to be superior to the POSSUM score for assessing outcomes in surgical patients [37]. We believe, therefore, that the FI, as a composite score, is superior to the other preoperative assessment tools and that it can be used in the preoperative assessment of patients to dependably evaluate physiologic reserve and risk stratification.

Postoperative Outcomes

Aging patients have an increased risk of postoperative complications that result in disability, loss of functional independence, diminished quality of life, and death. Accordingly, the postoperative course of such a patient is of cardinal importance because it plays a critical role in determining recovery to complete functional independence [38, 39]. Any postoperative complication is not only detrimental to a patient's recovery, it also raises costs by increasing the hospital LOS [40].

Complications

Studies show that patients with one or more postoperative complications have a higher median preoperative FI than those without postoperative complications [41]. Additionally, the median FI progressively increased with an increase in the number of postoperative complications. A median FI less than 0.12 significantly predicted postoperative complications, whereas age, sex, and the number of comorbidities taken individually were not significant predictors of postoperative complications [42]. A prospective analysis of 260 emergency general surgery patients demonstrated that frail patients had higher postoperative complications, including major complications [43]. Kristjansson et al., in a study of patients who underwent colorectal surgery, found that frail patients had a fourfold higher risk of developing postoperative complications [44]. They also found frailty to be a significant predictor of surgical complications (anastomotic leaks, surgical site bleeding, intraabdominal fluid collection) as well as of medical complications (pneumonia, arrhythmia, acute coronary syndrome) after surgery.

In another study by Garonzik-Wang et al. of patients who underwent a kidney transplant, frail patients had a twofold higher risk of developing delayed graft function in comparison with nonfrail patients [45]. Delayed graft function was independent of the chronologic age, but was significantly related to the biologic age and to preexisting deficits. Several studies correlate frailty with the development of postoperative delirium. Pol et al. demonstrated, for example, that frailty was a significant risk factor for the development of delirium after vascular surgery. Likewise, Kristjansson et al. found that the incidence of postoperative delirium was higher among frail patients compared with nonfrail patients after elective colorectal surgery [44, 46]. Assessment of long-term outcomes in elderly patients is of even more importance. The ability to identify elderly patients, who are at an increased risk of hospital readmission, recurrent falls, and mortality, can provide a potential avenue for timely intervention in this group of patients. A study by Joseph et al. that assessed six-months outcomes postdischarge in trauma patients demonstrated that in-hospital frail status as determined by the Trauma Specific Frailty Index (TSFI) was a significant predictor of trauma-related hospital readmission, recurrent falls, and six-month mortality in geriatric trauma patients.

Length of Stay

The FI reliably predicts hospital LOS in patients undergoing surgery. In several studies, for instance, frail patients required significantly longer hospital stays (65% to 89% longer) after minor and major surgical procedures compared to non-frail patients. Kasotakis et al. also found that frail patients required additional postoperative care and support, with a noticeable increase in the intensive care unit LOS, including cardiovascular pressure support, respiratory support, and monitoring. Furthermore, the number of ventilation days was higher for frail patients than non-frail patients [42, 45].

Discharge Disposition

Frailty has a proven efficacy in predicting postoperative morbidity in aging patients as well as in assessing their risk of death [47]. A steady reduction in longevity is noted with increasing FI scores. In contrast with nonfrail patients, Lee et al. demonstrate that frailty correlates with increased mortality among in-hospital frail patients [47]. Of course, the most favorable outcome for patients after surgery is being discharged to home in a state of complete functional independence. And the use of FI scores in predicting a patient's postoperative disposition has yielded positive results. In fact, frailty independently predicts the odds of an unfavorable discharge to a skilled or assisted facility after surgery. Lee et al., for example, showed that frailty was an independent, significant factor in predicting discharge to a rehabilitation institution postoperatively. Joseph et al. also showed that frailty reliably predicts the risk of unfavorable discharge disposition in geriatric trauma patients [39]. Likewise, Rockwood et al. found a significant association between frailty and discharge [26]. Similarly, Robinson et al. confirmed that a low preoperative hematocrit level and the diminished functional ability to walk on stairs were significant factors for discharge to an acute care facility [48].

Hospital Resources

Frailty has also been used as a reliable tool in predicting the costs of operative intervention among aging patients. Increased hospital and intensive care unit LOS among frail patients correspond to higher hospital costs. Robinson et al. demonstrate that the costs of hospitalization and the costs of health care 6 months after surgery were significantly higher for frail patients than for nonfrail patients. In addition, frail patients had increased rates of readmission within 30 days after their initial discharge from the hospital, further adding to costs [49].

Failure to Rescue

Failure to rescue (FTR), death after a major complication, is an important benchmark of patient safety and health care quality. It is a common index of the quality of healthcare delivery and shows how well hospitals perform once a complication arises. Several prior studies found that the in-hospital mortality rate is significantly affected by the variation in the management of complications [11]. Complications following an injury are relatively common among trauma patients, and emerging literature indicates that the majority of these complications may be independent of a hospital's quality of care. Recent evidence suggests that reducing FTR events might be the most appropriate target for quality improvement in geriatric population. A study of trauma patients showed that frail patients have 2.67 higher odds of FTR as compared to nonfrail patients [50]. Although FTR has been considered as an indicator of health care quality, recent literature strongly suggests that frailty status independently contributes to FTR. This needs to be considered in the future development of quality metrics, particularly in the case of geriatric trauma patients.

Successful rescue of patients with complications requires both timely identification of patients experiencing physical decline and the appropriate clinical interventions. Currently, very little surgical literature has reported the usefulness of the frailty index in predicting FTR in geriatric patients. However, there is growing evidence for the correlation between frailty and FTR in geriatric trauma patients. Though, more work can be done to convincingly assess the impact of frailty status on FTR in such patients [50].

Conclusion

An aging individual's frailty, as capsulized in the FI, can have a decisive impact across the spectrum of patient care, including more accurate surgical risk-benefit analysis, preoperative assessment, postoperative outcomes, disposition of discharge from the hospital, and informed clinical decision-making. With the increasing numbers of aging individuals requiring surgery, it has become imperative for the operating surgeon to take frailty into account and to calculate the FI in such patients in order to efficaciously plan patient management.

Abstract

The number of surgical procedures performed in older persons is increasing exponentially. Morbidity and mortality increase with age, rising sharply after the age of 75. After major abdominal surgery, up to 20% of older patients have persistent disabilities in functional status, and a sizable minority never fully recover. Traditionally, efforts to support recovery begin in the postoperative period ("rehabilitation"), but deconditioning related to the metabolic stress of surgery and hospitalization may have already initiated a downward spiral during which the patient may become increasingly inactive, further contributing to complications

R. A. Rosenthal et al. (eds.), *Principles and Practice of Geriatric Surgery*,

and disability. Preoperative physical fitness, physical activity, and nutritional status are predictors of surgical complications and prolonged disability, but may be modifiable. As such, the preoperative period may represent an opportunity to intervene to optimize physiological age (functional capacity) in anticipation of the upcoming stress of surgery, potentially reducing complications and improving recovery. This strategy has been termed "prehabilitation." This chapter will focus on the potential role of prehabilitation to improve functional status in older patients preoperatively, thereby contributing to improved outcomes postoperatively. It will begin with a review of preoperative functional assessment, then summarize the current literature on prehabilitation, focused on the frail and older patient, including recommendations about the duration and intensity of prehabilitation programs in this population.

With the aging of the North American population it is estimated that the annual number of non-cardiac surgical procedures performed in older adults will increase from the present level of six million to approximately 12 million over the next 30 years [1]. As people are living well into their late 70s and early 90s, the prevalence of many conditions requiring surgery is increasing and, as a result of improved perioperative care, a higher number of older patients undergo major surgery [2]. During the last three decades the annual rate of surgical interventions has increased exponentially for men and women 75–84 years of age [3]. This demographic reality creates the need to provide special preoperative and postoperative surgical care to an increasing number of older persons. Over 30% of surgical procedures in North America are performed on persons aged 65 years or older and as a result of advances in surgical and anesthetic techniques, the overall operative mortality has declined significantly during the last 20 years [4]. Nonetheless, morbidity and mortality associated with surgery increase with advancing age and rise sharply after the age of 75 [5, 6]. Furthermore, the prevalence of comorbid diseases rises with increasing age. Over 80% of North Americans aged 65 have at least one chronic condition and 50% have at least two [7]. As the number of associated illnesses increases, so does the rate of perioperative complications. This effect is seen in all age groups but is most pronounced at the extremes of age [8].

While chronological age should not be completely ignored, physiological age (functional status and/or comorbidities) is a better predictor of operative outcome [9–11]. Major abdominal surgery reduces physiological and functional capacity by 40% to 60% [12]. The elderly, persons with cancer, and those with limited protein reserve are the most susceptible to the negative effects of surgery. Risk factors for postoperative complications include history of dementia, low preoperative serum albumin, poor exercise tolerance, and frailty [13–15]. Up to 20% of older patients have persistent disabilities in Instrumental Activities of Daily Living (IADLs) 6 months after major surgery; predictors of prolonged recovery include serious complications, poor physical status at baseline, cognitive impairment, depression and renal impairment [16].

Traditionally, efforts to support recovery begin in the postoperative period ("rehabilitation"), but patients may not be able to fully participate in a structured program because of fatigue and concerns about their prognosis. In addition, deconditioning related to the metabolic stress of surgery and hospitalization may have already initiated a downward spiral during which the patient may become increasingly inactive, further contributing to complications and disability. Preoperative physical fitness, physical activity, and nutritional status are predictors of surgical complications and prolonged disability [17–20], but may be modifiable [21]. As such, the preoperative period may represent an opportunity to intervene to optimize physiological age (functional capacity) in anticipation of the upcoming stress of surgery, potentially reducing complications and improving recovery [22]. This strategy has been termed "prehabilitation" (Fig. 1).

This chapter will focus on the potential role of prehabilitation to improve functional status in older patients preoperatively, thereby contributing to improved outcomes postoperatively. It will begin with a review of preoperative functional

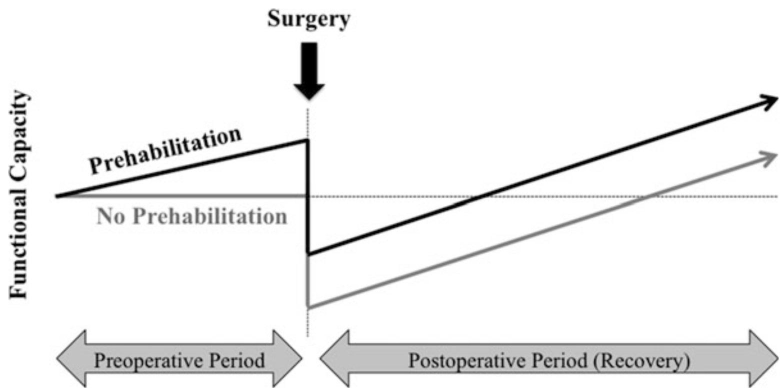

Fig. 1 Trajectory of perioperative functional capacity with and without prehabilitation. (Adapted from Carli et al. [22])

assessment, then summarize the current literature on prehabilitation, focused on the frail and older patient, including recommendations about the duration and intensity of prehabilitation programs in this population.

Preoperative Assessment for Prehabilitation

Functional impairments increase the risk of postoperative immobility, with associated complications such as atelectasis, pneumonia, multisystem deconditioning, increased length of stay, and increased mortality and morbidity [9–11]. Individuals with poor preoperative functional status have longer hospitalizations, more surgical complications, and are more likely to die within 30 days of surgery when compared to individuals with good preoperative functional fitness [22]. Poor baseline physical functioning is also a risk factor for prolonged recovery of IADLs [16]. The general approach to preoperative assessment is directed toward identification of factors that place the patient at increased risk for postoperative complications or functional decline. Although some of these factors are related to the surgical disease itself and to the type of operation required, the most important factors in the determination of risk are related to the overall health, functional status, cognitive abilities and nutritional status of the patient. Preoperative evaluation informed by the concept of prehabilitation suggests that the focus be extended from risk assessment to risk optimization, beginning with evaluation of functional reserve.

Functional reserve is the safety margin required to tolerate the metabolic consequences of major surgery, which include higher cardiac output, oxygen consumption, carbon dioxide excretion and protein synthesis, and the systemic immune response [23]. Functional reserve decreases with age and any organ system dysfunction places the elderly person at additional risk. Before planning any prehabilitation program to improve functional capacity, patients should undergo evaluations of exercise capacity, nutritional and cognitive status performed by a multidisciplinary team that includes a kinesiologist, a nutritionist and a psychologist. Here we focus on the specific assessments performed to design and monitor a prehabilitation program; a review of general and organ-specific preoperative evaluation and optimization for the older patient is outside the scope of this chapter.

Exercise Tolerance

Exercise tolerance, as an indication of functional reserve, is the single most important predictor of cardiac and pulmonary complications following non cardiac surgery [24, 25]. Evaluation begins with patient history, asking for the ability to perform routine physical activities including the maximal level of exercise a patient can achieve, to estimate peak oxygen consumption. One metabolic equivalent (MET) represents the basal oxygen consumption of a 70-kg, 40-year-old man at rest (~ 3.5 ml/kg/min). Estimated energy requirements are available for a wide variety of activities [1]. Patients considering major surgery should be able to achieve >4 METS, representing the ability to climb one flight of stairs. The inability to perform >4 METs is a predictor of increased perioperative cardiac events and long-term risk. The Duke's Activity Status Index is an example of a standardized self-assessment tool that quantifies METs using questions assessing the ability to perform a variety of increasingly strenuous physical activities [26]. However, relying on history is subjective and may overestimate exercise capacity [23].

The gold standard to assess exercise capacity is with cardiopulmonary exercise testing (CPET), which involves measurement of oxygen uptake (VO_{2max}), carbon dioxide production (VCO_2) and ventilatory measures while exercising on a cycle or treadmill to volitional exhaustion. Peak oxygen consumption and anaerobic threshold, defined as the level of oxygen consumption above which circulatory supply does not meet metabolic demand, both correlate with morbidity and mortality. Peak oxygen consumption less than 15 and anaerobic threshold less than 11 ml/min/kg are associated with increased risk of complications after major abdominal, vascular and thoracic surgery. In a classic study, Older demonstrated that in patients over 60 years old, the risk of cardiovascular mortality was less than 1% for those with an anaerobic threshold above 11 ml/min/kg, versus 18% for those with anaerobic threshold below this level [27]. This relationship has since been confirmed in multiple cohort studies [28].

However, while formal exercise testing is the gold standard, it requires additional equipment, involves an exercise effort, and is contraindicated in several cardiac, pulmonary and orthopaedic conditions. Walk tests, such as the 6-minute walk test [6MWT], which measures the distance walked in a 6-minute period in a flat corridor, are simple, objective measures of functional exercise capacity [29] . Predicted values for healthy persons are available, adjusted for age and sex [30]. Mean baseline 6MWT distances in patients undergoing colorectal and other general surgery abdominal procedures is 400–500 m, about 65–75% of predicted values [21, 31, 32]. The 6MWT distance shows moderate correlation with VO2peak in patients undergoing colorectal surgery ($r2 = 0.52$). The risk of postoperative complications is increased in patients with shorter 6MWT distances [33]. As prehabilitation programs are resource-intensive, the focus should be on selection of patients most likely to benefit from prehabilitation. Participants with lower baseline fitness (6MWT distance <400 m) have greater improvements with prehabilitation compared to those with higher fitness [34]. Furthermore, the 6MWT can be monitored throughout the perioperative period to provide a measure of the response to prehabilitation and an assessment of postoperative recovery [31, 35]. Both measurement error [36] and minimal clinically important difference [32] (MCID) for 6MWT distance for patients having colorectal surgery are estimated at around 20 m.

Sarcopenia and Frailty

Baumgartner described the term sarcopenia for age-related loss of muscle mass in elderly men. His index describes relative muscle mass calculated as appendicular skeletal muscle mass measured by dual-energy X-ray absorptiometry (DEXA), divided by the square of stature [37]. According to this index sarcopenia is defined as state of muscle mass two standard deviations below the mean muscle mass of normal for healthy individuals younger than age 30 years. Based on this calculation the prevalence of sarcopenia in people >60 years of age is 7–10%. Etiology of sarcopenia is multifactorial and includes genetic factors [38], physical activity [39], hormonal changes (including insulin resistance, elevated parathyroid hormone, and declines in serum testosterone and growth hormone) [40, 41], nutritional status (protein intake and low vitamin D levels) [42, 43], atherosclerosis, and changes in circulating pro-inflammatory cytokines [44, 45]. Newer definitions of sarcopenia include functional testing since muscle strength does not correlate with volume alone [45, 46]. The European Working Group on Sarcopenia in Older People (EWGSOP) defines sarcopenia as a syndrome characterized by progressive and generalized loss of skeletal muscle mass and strength with a risk of adverse outcomes such as physical disability, poor quality of life, and death [46]. Total psoas mass (TPM) has been proposed as an objective measure of muscle loss and predictor of postoperative outcomes of major abdominal surgery

[47–49]. Psoas muscle measurements are performed at the level of L4 on CT scan. As many patients will have a CT scan prior to undergoing major abdominal surgery, TPM may provide an objective measure of sarcopenia. Lower TPM correlates with longer duration of hospital stay [50], increased cost of major surgery [51], greater complication rates, discharge disposition, and in-hospital mortality in patients with emergency surgery [52].

Sarcopenia is one aspect of frailty, a geriatric syndrome resulting from age-related cumulative declines in multiple systems resulting in impaired capacity to withstand stress and increased vulnerability to adverse health outcomes including falls, hospitalization, and mortality [53]. Phenotypic aspects of frailty and sarcopenia may overlap, including weight loss, exhaustion, weakness, slow gait speed, and low physical activity. However, frailty includes more than physical factors, encompassing psychological and social variables including cognitive status and social support [54]. Patients identified as intermediately frail or frail are at increased risk for postoperative complications [15]. Timed-up-and-go, the time required for a subject to stand from a chair without the aid of their arms, walk 10 feet, return to the chair and sit back down, is a useful screening test for frailty. Slower timed-up-and-go ($\geq$15 sec) is associated with increased complications and one-year mortality after colorectal and cardiac operations [55]. Best practice guidelines recommend evaluation of frailty and documentation of a frailty score (based on unintentional weight loss, decreased hand grip strength, self-reported low energy and slow walking) for all older patients [56]. Patients identified as frail represent an important potential target for tailored prehabilitation.

Cognitive Assessment

Cognitive impairments, either as a presurgical condition or postoperative complication, can interfere with surgical treatment and postsurgical recovery [57, 58]. Patients with dementia and/or delirium have worse perioperative outcomes. Dementia is a major risk factor for delirium, an acute reversible state of confusion, during hospitalization. Therefore, patients are evaluated for cognitive impairment in the preoperative period. The Mini-Cog test is a quick and practical screening tool for cognitive impairment that can be completed in 2–4 min. The Mini-Cog has sensitivity and specificity rates similar to the Folstein Mini Mental Status Examination (MMSE) and a standardized neuropsychological battery [59] . Participants are asked to recall three words and to draw a clock indicating an abstract time such as one forty five (1:45) or ten after 11 (11:10). The three-item word recall assesses short-term memory, while the clock drawing task assesses key features of executive function such as initiation, planning and multistep processing. Evidence of impairments should lead to referral for more in-depth evaluation.

Not all patients who perform poorly on screening examinations will have cognitive impairments. Patients with depressive symptoms may be erroneously perceived to have cognitive impairments as result of lack of effort during testing. Persons who reported more depressive symptoms preoperatively had higher incidence rates and more days of delirium postoperatively [60]. In addition, patients with depressed mood may exhibit less desire to participate in pre- and rehabilitation activities. Patients can be screened for depression using tools such as the Geriatric Depression Scale (GDS), a 15-item questionnaire that can be administered in person or over the telephone [61]. Respondents provide a yes or no response to the questions posed. A score of five indicates depression is a possibility. We have used the Hospital Anxiety and Depression Scale to screen patients for depression and anxiety prior to beginning prehabilitation. While prehabilitation may not improve these symptoms, patients with higher depression and anxiety may be more likely to benefit from the program [9].

Nutritional Assessment

Poor nutritional status is a risk factor for pneumonia, poor wound healing, and other postoperative complications. Malnutrition, defined as a decrease in nutrient reserves, occurs in 35–65% of older patients in acute care hospitals and 25–60% of institutionalized elderly [62]. Physiological changes that occur with aging, such as increased total body fat, loss of lean body mass, decreased bone density, and decreased total body water may all affect nutritional requirements [63]. The assessment of nutritional status begins by understanding the risk factors for nutritional deficiency in older adults. Factors that may lead to inadequate intake and utilization of nutrients include inability to access food (e.g., financial constraints, availability of food, limited mobility), lack of the desire to eat food (e.g., living alone, impaired mental status, chronic illness), inability to eat and/or absorb food (e.g., poor dentition, chronic gastrointestinal problems such as gastroesophageal reflux disease or diarrhea), and medications that interfere with appetite or nutrient metabolism. Nutritional risk can be assessed using the cancer-validated patient-generated subjective global assessment (PG-SGA) tool [64]. The SGA is an easily reproducible tool for assessing nutritional status from the history and physical exam [65]. SGA ratings are most strongly influenced by loss of subcutaneous tissue, muscle wasting, and weight loss. In a study of patients undergoing elective gastrointestinal surgery, both SGA and serum albumin were predictive of postoperative nutrition-related complications [66]. Nutritional assessment can identify chronic and severe protein-energy malnutrition and can also be measured using a standard 24 h dietary recall. The Mini Nutritional Assessment (MNA) is another score that was created to identify older adults at risk for malnutrition [67]. A short form of the MNA has been developed and used preoperatively [68]. Low serum albumin, a strong predictor of outcome in both non-surgical and surgical patients, correlates with increased length of stay, increased rates of readmission, decreased rates of discharge to home, and increased all-cause mortality in elderly patients [69]. In surgical patients, low preoperative serum albumin is correlated with postoperative morbidity and mortality [70, 71].

Summary

The main goal of the preoperative general and organ related assessment is to identify any coexisting disease, or decline in physiologic reserve that can be improved with a structured prehabilitation program. With this information, an accurate risk/benefit determination can be made and a personalized prehabilitation program can be tailored for each patient.

Prehabilitation to Enhance Postoperative Outcome

Prehabilitation to Attenuate Deconditioning

Strategies to minimize postoperative deconditioning in the elderly such as minimally invasive surgery together with enhanced recovery programs have been introduced to facilitate early mobilization and reduce postoperative morbidity [72]. These perioperative care programs focus mainly on the postoperative period (rehabilitation period) as the time for intervention to facilitate the return to the presurgical baseline state (recovery). Exercise, aerobic and resistance, implemented during the rehabilitation period, can improve physical status in the elderly [73]. Nevertheless, there is some realization that the preoperative period may be a very effective time for intervention as patients may be more available and amenable to interventions designed to optimize their physiological conditions in anticipation of the upcoming stress of surgery. This preconditioning period is defined as “surgical prehabilitation,” meaning a process of care that enables patients to better withstand the stress of surgery through the augmentation of functional capacity. Surgical prehabilitation then represents an opportune time for clinical and pharmacological preparation (for example smoking and alcohol cessation, better control of hypertension and of diabetes, treatment of anemia), and holistic interventions (e.g., relaxation, yoga, dietary modification). The role of procedure-specific, evidence based, personalized, structured programs, including physical exercise, nutritional counselling and supplements, and anti-anxiety strategies, together with elements of medical optimization, need to be addressed in the context of a multidisciplinary approach whereby all the stakeholders involved in surgical and medical geriatric care come forward. This concept of prehabilitation is founded on the principle of "marginal gains aggregation" whereby multiple small interventions collectively achieve a far superior effect [74]. Topp and Ditmyer have proposed that, by applying a presurgical exercise program in patients to improve functional ability before a stressor such as surgery, postoperative recovery and achievement of a minimal level of functional ability would occur more rapidly compared to patients who remain inactive throughout the surgical admission (Fig. 1) [75].

Literature on Surgical Prehabilitation

While most of the published literature on surgical prehabilitation incudes patients >60 years of age, few have specifically addressed issues unique to the elderly and frail. Particular attention has been paid to prehabilitation for orthopedic surgery (hip and knee arthroplasty, and spine), however other surgeries studied include cardiac, vascular and abdominal. The primary role of exercise in disease prevention is well recognized, and the benefits of physical activity have been shown in many medical conditions, such as hypertension, stroke, coronary artery disease, diabetes and chronic obstructive pulmonary disease (COPD). Regular exercise has been shown to improve aerobic capacity, to decrease sympathetic over reactivity and insulin resistance, and promote lean body mass. There is an emerging interest in understanding how structured physical exercise can influence postoperative recovery and disease progression. It is thought that by increasing patient's aerobic capacity and muscle strength through increased physical activity before surgery, physiologic reserve would be enhanced, the body would be in better condition to attenuate the negative aspects of surgery, and postoperative recuperation would be facilitated. Three systematic reviews including approximately 400 patients have been published [11, 20, 76]. In the first review, four to eight weeks of preoperative exercise was shown to reduce postoperative complication rates and accelerate hospital discharge in patients undergoing cardiac and abdominal surgery. Conversely, the outcome after joint arthroplasty, and in particularly knee arthroplasty, was not significantly different whether preoperative exercise was used or not [76]. A second systematic review examined 15 studies and concluded that total-body prehabilitation improved postoperative pain, length of stay, and physical function, but was not consistently effective in improving health-related quality of life or aerobic fitness in the few studies that examined these outcomes [20]. Another systematic review of eight studies reported some physiologic improvement with preoperative exercise, but with limited clinical benefit. Overall, there were several limitations with some of the studies, and the exercise regimens were not always structured and were also of different intensity. Finally, adherence to the exercises were not systematically reported. Although some physiologic improvement during the prehabilitation period was achieved in most studies, this change did not consistently translate into improved clinical outcomes [11].

In view of the paucity of studies in abdominal surgery, we performed a randomized trial comparing the impact of a 4-week, home-based, cycle exercise program, based on 75% of VO_2 peak, to a sham intervention to increase walking and breathing exercises on functional walking capacity (6MWT) [77]. While there was no difference in 6 MWT at the end of the prehabilitation period or in the postoperative period, the proportion showing an improvement in walking capacity was unexpectedly greater in the control group than the intense exercise group (47% vs 22%). Full compliance to the intense program was recorded by only 16% of participants, indicating that the prescribed exercise regimen could not be maintained. Predictors of poor surgical outcome included deterioration in functional exercise capacity while waiting for surgery, age greater than 75 years, and high levels of anxiety. These results suggested that an intervention based on intense exercise alone may not have been sufficient to enhance functional capacity in elderly patients, and attention must also be turned to improve nutrition, anxiety and perioperative care processes which might impact exercise performance. Extreme care has to be taken when prescribing physical activity as a single modality to some patients who lack physiological reserve, like frail elderly patients known to have decreased muscle mass and low protein reserve, who may thereby not be able to tolerate an increase in exercise prior to surgery without sufficient protein and energy supplementation. In view of these findings, further studies were conducted using a multidisciplinary approach incorporating nutritional counseling and nutritional supplements and deep-breathing exercises together with a moderate exercise program including aerobic and resistance exercises [19, 78]. In addition, perioperative surgical care was standardized following the Enhanced Recovery After Surgery (ERAS) perioperative care guidelines, which included smoking and alcohol cessation, glycemic control, anemia correction, pharmacological optimization of medical conditions (hypertension, arthritis, coronary heart disease, metabolic disorders), intraoperative control of intravenous fluid administration, normothermia, opioid sparing analgesia, early nutrition and early mobilization [79]. Adherence to this multidisciplinary prehabilitation protocol was 70%, resulting in significant improvements in preoperative functional walking capacity in over 50% of participants and better maintenance of physical activity postoperatively. Over 80% of patients receiving prehabilitation were recovered to their baseline functional capacity by 8 weeks after surgery, compared to 60% of patients who did not receive the prehabilitation plan [21, 78]. There was no difference in clinical outcomes. However, in a recent randomized study of patients scheduled for elective abdominal aortic aneurysm (AAA) repair (mean age 73), a six-week period of preoperative supervised exercise program resulted in reduced complications (42% vs 23%) and shorter duration of hospital stay [80].

A recent consensus opinion by colorectal surgeons addressed exercise prehabilitation in patients undergoing colorectal surgery [81]. It was agreed that physical activity before surgery was to be encouraged in patients with colorectal cancer, however the duration of prehabilitation would have to take into account the type and urgency of surgery. In most studies, the time interval for prehabilitation has been proposed to be between 4 and 8 weeks, with shorter time periods for patients with lung or abdominal cancer, and longer periods for more chronic conditions, such as spine surgery.

Prehabilitation for the Frail Elderly Patient

Many older patients in treatment for cancer are not apparently frail or functionally impaired. Screening to provide timely intervention for the more vulnerable ones who require extra treatment to prevent disability is imperative, in order to preserve function, prevent complications, and generate heath care saving. There is a strong evidence that older adults who are physically inactive, in poor nutritional state and with impaired mental function have low levels of functional health and higher rate of postoperative complications [16]. Patients with low baseline functional capacity have the most to gain from prehabilitation. A recent study [34] reported that elderly patients with low baseline walking capacity (6MWT distance<400 m) improved by 10–15% with a structured multimodal prehabilitation during the preoperative period, and maintained these gains after surgery [34]. It remains to be seen however whether the positive changes in functional status achieved with prehabilitation will result in better postoperative clinical outcomes such as reduced complications and hospital stays after colorectal surgery.

Duration of Prehabilitation

One common question asked by surgeons is about the duration of the preconditioning intervention, in fact some concern has been expressed that enrolling a cancer patient in such a program might put him/her at risk as the disease continues to advance. There is limited published work on preoperative exercise in elderly cancer patients, especially in a time frame dictated by national cancer waiting time limits [81]. The duration of prehabilitation can vary according to the type of surgery, for example chronic conditions such as arthroplasty might require 6–10 week to increase muscle strength and balance. The limitation to exercise and training as a result of pain can reduce the duration of time available to increase the physical reserve. Provision of adequate analgesia in these patients can expedite the physical pre-conditioning and increase muscle strength as illustrated by a recent case report of pre-habilitation of an elderly patient scheduled for total knee arthroplasty who underwent a radio-frequency block 6 weeks before surgery to relieve pain, and who was able to complete the pre-habilitation program with earlier recuperation of her functional capacity in the first 2 months after surgery [82]. For patients with cancer the time is more limited, and 4–6 weeks of prehabilitation is an acceptable duration to increase physiological reserve [83, 84]. The question remains whether those patients with poor physical condition and functional status who need surgery should wait to be optimized before surgery. There is strong evidence that surgery in these patients represents a serious risk leading to postoperative complications and prolonged recovery [85]. The high rate of postoperative complications and the prolonged length of hospital stay make these high risk patients more vulnerable and prone to readmission and higher mortality. The ideal time to design a prehabilitation plan would be at the preoperative clinic, where medical and surgical risk stratification is undertaken and an appropriate window of time is identified to implement the preconditioning.

Preoperative Exercise Activity to Enhance Functional Capacity

A traditional approach to the pre-operative time frame is to encourage rest in order to best prepare the patient for their upcoming surgery, but bed rest has deleterious effects on lean muscle mass, homeostatic mechanism, physical function, lower extremity strength/power, aerobic capacity and insulin sensitivity [86–88] . One of the core features of prehabilitation – besides medical optimization, nutrition counseling and anxiety reduction – is exercise, which not only involves prescribing an effective "dose" to improve physical function but also maximizes patient adherence to the program prescribed. Exercise includes regular physical activity that is incorporated into a planned and structured program for the specific goal of improving fitness. This program results in a certain "dose" of exercise that must be tailored to fit the desired outcomes for the patient. Prescribing exercise requires consideration of intensity, duration, frequency and modality. Adhering to a lower "dose" of physical activity (i.e.,: accumulating 30 min of physical activity over a day) has clear health benefits in the elderly [89]. In addition to cardiovascular exercise, it is equally important to consider resistance and flexibility training as important components of exercise. The exercise program should be safe and of an appropriate intensity to stimulate positive physiological adaptations. As the patient becomes accustomed to the intensity and adapts to the demands of the exercise performed, the intensity must be increased accordingly, although there must be a balance between the "ideal" intensity/amount of exercise, as proposed by existing guidelines/exercise principles, and what is feasible for the patient to perform [90]. This highlights a need for qualified personnel to both prescribe the exercise and supervise the program during the training period in order to achieve maximal benefits and maintain safety. These factors are of particular importance given the proximity of the program to the time of surgery and the physical conditions of many older patients.

Although prehabilitation includes a structured exercise program, the patient should also be encouraged to partake in daily movement and avoid prolonged sitting time. The use of technologies such as pedometers and accelerometers (i.e.,: Fitbit), along with encouraging a certain number of steps per day (i.e.,: 10,000 steps/day), may be an approach that is meaningful and provides immediate feedback to the individual. Replacing sedentary time with standing or light physical activity has positive effects on health related quality of life in the colorectal cancer population. Recent data from our laboratory indicates a wide range of program delivery preferences, ranging between patients who enjoy exercising alone to those who require more social support and group class environment (Ferreira et al., unpublished observations).

The beneficial effects of exercise training, if the stimulus is of sufficient intensity, can occur as rapidly as bed rest negatively impacts physical function. A moderate intensity trimodal prehabilitation program that improved functional walking capacity in the preoperative period was delivered in a median of 24.5 days. Patients undergoing prehabilitation improved by an average of 25 m (SD 50) while the control patients *declined* by an average of 16 m (SD 46) [21]. Patients who deteriorate during prehabilitation may be at increased risk for serious postoperative complications [9]. Not only are ameliorations in preoperative walking capacity achievable in the 4 week time frame, but it is also possible to significantly modulate the intensity and quantity of exercise performed. By participating in prehabilitation, it is possible for patients to increase their physical activity levels to meet current guideline recommendations [91].

Optimizing Prehabilitation with Nutrition

Protein requirements are elevated in stressed states to account for added demands of hepatic acute phase proteins synthesis, and the synthesis of proteins involved in immune function and wound healing. Dietary protein intake should thus be a central focus of nutrition-related anabolic strategies in anticipation of surgery, and should range between 1.2 and 2 g/kg/day. This range permits flexibility to adjust intake based on current nutritional status, physical activity level, presence of comorbid conditions and inflammatory state. Patients are counselled to achieve a total daily protein intake within this range, and the diet has to be adjusted accordingly. Interestingly, available evidence suggests that community-dwelling elderly do not meet current protein recommendations, which is estimated at a minimum of 1 g/kg/day in healthy older adults to promote optimal muscle aging [92]. In fact, the Quebec Longitudinal Study on Nutrition as a Determinant of Successful Aging [93], estimated that half of the cohort of 1793 community-dwelling seniors consumed less than 1 g/kg/day.

Several studies have identified that consuming 25–35 g of protein in a single meal maximally stimulates muscle protein synthesis (MPS). Based on the evidence of this ceiling effect, an equal distribution of daily dietary protein across meals has been proposed [94, 95]. The idea being that the anabolic response to a single dose of amino acids can be compounded when repeated multiple times per day. Given the emerging findings to support an even distribution of daily protein intake in healthy populations, and the evidence that substantive high quality amino acids are required to stimulate a typical anabolic response in elderly patients, it seems reasonable to suggest that daily protein requirements for older surgical patients be met through moderate protein (~25–35 g) consumption at every meal.

The stimulatory effect that amino acids after exercise have on MPS appears to be enhanced. In fact, protein ingestion post-resistance exercise (performed until failure) has been found to stimulate rates of myofibrillar protein synthesis above fasting rates for 24 h [96, 97]. This 24 h period post-resistance exercise has been dubbed the "anabolic window" to reflect what appears to be a period of increased sensitivity of MPS to aminoacidemia, also known as the "muscle full effect." Commercially available post-exercise supplements are usually composed of whey, casein, or soy. According to a recent report from the Food and Agriculture Organization of the United Nations (FAO), protein quality should be assessed using the Digestible Indispensable Amino Acid Score. Using this method to assess protein quality, milk proteins (including casein, milk protein concentrate, whole milk powder, and whey protein isolates) are among the greatest sources of high quality protein [98].

Monitoring Prehabilitation

To monitor the improvement of physiologic reserve and gains in muscular strength with the prehabilitation program, assessments of grip-strength, 6MWT and lean body mass are performed [99]. Ageing is associated with a progressive reduction of muscle tissue volume [100, 101] and a concomitant reduction in strength [102], but it is unclear whether this diminution causes the corresponding age-related decreases in bone mineral density [103]. The reduction in muscle tissue, and thus strength, worsens daily functional ability of elderly persons. However, it has been shown that resistance training can counteract the atrophy and loss of strength in this age group [104–106], potentially improving coordination, balance and perhaps bone mineral density. Relative muscle strength can be increased by 20–200% by weight training [107–113], even after the age of 80 years [103]. This is larger than the corresponding increase in muscle mass. Tracy and colleagues demonstrated that elderly individuals can improve quadriceps muscle strength by 27%, corresponding to a 12% increase in muscle mass, after 9 weeks of weight training [114]. A large part of the improvement in strength is not only from increases in cross-sectional area of muscle, but also due to a neural component. In addition, a recent review has suggested that the magnitude of the exercise-induced muscle response is far greater than the corresponding response in bone mineral density [111]. For example, high-impact weight training only results in about a 1% increase in bone mineral density of femoral neck and spine in postmenopausal women [115].

Exercise capacity can also be measured using maximal oxygen uptake (VO_2). The cardiovascular and musculoskeletal systems are central to achieving and maintaining functional independence, which is a prerequisite for discharge from a health-care facility, as is independent functioning of the individual in the community setting [75]. It has been shown that maximal oxygen uptake (VO2max) can improve by 20–30% in response to 6–12 months' training in previously sedentary older women and men [75, 116–118]. However, there is a heterogeneity of the training response as gains in VO2max can range anywhere from 0 to 1 l/min with a coefficient of variation of about 8% (202 ml/min) [116]. The increase in VO2max correlated with a lower maximal heart rate of 3–7% due to the larger stroke volume at least in part [117, 118]. This is actually independent of age [118].

In elderly males, two-thirds of the increase in VO2max after training is due to a higher maximal cardiac output, while only one-third is due to the wider arteriovenous oxygen difference at maximal exercise [119]. In contrast, in elderly women this improvement has been shown to only result from enhanced arteriovenous oxygen difference at maximal exercise. This suggests that there are no real central adaptations to exercise training in elderly women [119]. It has also been shown that there is moderate increase in aerobic capacity with short-term training. Govindasamy et al. showed that training at 70% of VO2max for 1 h per day, four times per week for 4 weeks improves maximal oxygen uptake by 6.6% and reduce submaximal heart rate by 10 beats per minute [120].

These results could indicate a rapid cardiovascular improvement in elderly people over a short period [121]. Since endurance-trained adults appear to undergo greater rates of decline in VO2max with advancing age compared with sedentary adults [122], one may presume that endurance training throughout the lifespan may not be beneficial. However, endurance-trained older individuals are able to perform physical tasks that cannot be performed by their sedentary peers, at least with the same degree of exertion or effort [122]. This is possible because endurance-trained older individuals possess higher levels of aerobic capacity compared to their sedentary peers of the same age. Since VO2max is a more powerful predictor of mortality than other established risk factors for cardiovascular disease [123], and because age and bed rest contribute to a decrease in VO2max, it is intuitive to have elderly patients perform aerobic exercise training during prehabilitation. Furthermore it has been shown that 1 MET (Metabolic equivalent = 3.5 ml/kg/min) increase in VO2max confers a 12% increase in long-term survival [123]. This further underlines the importance of aerobic exercise training during prehabilitation to improve outcome.

Conclusions

Prehabilitation for older surgical patients is feasible and can improve or maintain preoperative and postoperative functional capacity (see Box 1 for example of a program). It follows that prehabilitation, based on structured, personalized exercise and nutritional supplementation, should be considered an integral part of optimal perioperative care, where appropriate risk stratification, medical optimization, patient education and evidence-based perioperative (e.g., ERAS) care pathways are essential elements. The emerging interest in prehabilitation for the surgical patient is evident from the increasing number of registered clinical trials. Further research on prehabilitation for the elderly surgical patients is needed, specifically addressing the effectiveness and safety of different types of exercise, and the minimum requirement of proteins and other nutrients to complement the exercise in order to enhance muscle strength and increase physiological reserve in the frail older population. Furthermore, there is a need to determine what is the cost-effectiveness of single and multiple modalities, the short and long term impact on clinical outcomes such as length of stay, hospital readmissions, emergency department visits, perioperative complications and time to rehabilitate. Given the aging of population, the number of elderly patients requiring surgery will increase. It is our responsibility to ensure these patients receive the greatest opportunity to return to their preoperative functional status and good quality of life.

Box 1 4-Week Prehabilitation Program for an Elderly Frail Patient Scheduled for Major Abdominal Surgery [22, 124, 125, 126]

1a. Baseline assessment of strength, flexibility, and endurance

• strength: timed up and go (TUG), 2-min step test

• flexibility: chair sit-and-reach test, back scratch test

• endurance: 2-min walk test, 6 min walk test.

Box 1 4-Week Prehabilitation Program for an Elderly Frail Patient Scheduled for Major Abdominal Surgery [22, 124, 125, 126] (continued)

1b. Baseline nutritional assessment to meet protein and energy needs

• 3-day calorie count, PG-SGA, NRS 2000

2. Prehabilitation exercise regime carried out three times per week (home based or supervised by physical therapist or certified trainer; check how safe the exercise is when performed alone; eventually involve caregivers)

Types of exercises; 1–2 sets of each exercise consisting of 10–15 repetitions, 2–3 times per week, alternate with aerobic exercise

Strength (Upper)

- shoulder flexion horizontal abduction
- shoulder blades squeezing
- seated row biceps and triceps curls

Strength (Lower)

- hamstring curls
- ankle pronation
- static quads
- bridging
- hip abduction exercises

Breathing exercise: abdominal breathing, 10–12 deep breaths, three times/day

Cardiovascular ambulation(fast pace for 15–20 min to increase pulse by 10–15%) (3 times per week on alternate days, after 60 min of rest)

2. Evaluation of progression:

(a) Timed up and go (TUG)
(b) 2 min walk test, 6 min walk test
(c) Sit to stand test

Borg scale (The Borg scale assesses the level of perceived exertion in response to

(continued)

Box 1 4-Week Prehabilitation Program for an Elderly Frail Patient Scheduled for Major Abdominal Surgery [22, 124, 125, 126] (continued)

exercise. The scale can be used to monitor improvement of fitness during anexercise program).

Abstract

Cognitive impairment and dementia are common with advancing age. As our population ages a larger number of older adults will undergo surgical procedures requiring anesthesia. While patients with a diagnosis of dementia are less likely to undergo elective surgery and anesthesia, a growing body evidence demonstrates that surgery and anesthesia are more common in older adults when compared to younger adults and children. Interestingly, 20–44% of older patients presenting for elective surgery have undiagnosed probable cognitive impairment that may put them at risk for adverse perioperative outcomes. Accordingly, the detection of probable cognitive impairment is important as it allows for time in the

preoperative period for patient and family counseling, identification of surrogate decision-makers, and potential modification to intraoperative and postoperative care to enhance patient-centered outcomes. There are several tools available to detect probable cognitive impairment in the preoperative period. This chapter describes the prevalence of preoperative cognitive impairment, its relationship to postoperative outcomes, and reviews some of the screening tools that can be used to detect cognitive impairment in older patients.

Introduction

Worldwide the population is aging due to improving social conditions and medical advances leading to an increased average life expectancy. The 2010 Census Bureau reported that almost 13% of the US population was 65 years old or older. By 2050, this age group is expected to comprise 20% of the total population with 19 million of people over the age of 85 [1]. In 1996 more than half of the procedures in cardiothoracic, general surgery, ophthalmology, orthopedics, and urology were performed in patients aged 65 or older [2]. By 2007, nearly 36% of all surgical inpatient procedures in the USA were performed in older adults, and this number is expected to double by 2020 [3]. Therefore, with the aging of the population there are going be an increase in the number of older patients undergoing surgery and anesthesia.

Advances in surgical and anesthetic techniques have reduced perioperative morbidity and mortality in the elderly [4]. Although surgery has potential benefits in older patients, the rate of perioperative morbidity and mortality continues to increase with age [5, 6]. Postoperative delirium and postoperative cognitive dysfunction (currently a research classification rather than a formal diagnosis) are two of the most common perioperative complications in the elderly surgical population and are associated with a higher risk of morbidity and long-term mortality following surgery and anesthesia [7, 8].

The changes that occur in the older brain may be partially responsible for this increased risk of perioperative cognitive morbidity. However, unlike other major organ systems it is rarely evaluated in the preoperative period despite evidence that it should be. In this chapter, we will discuss changes in the aging brain and how baseline cognitive impairment may be a predictor of adverse outcomes.

The Aging Brain

In a recent review, Brown and Purdon [9] dissertate on the neurophysiology and neuroanatomical changes of normal aging. They found evidence for loss of volume and thickness of the prefrontal cortex that play an important role in attention and executive function. Moreover, normal aging is associated with changes in neuronal morphology, synapse number, and a decreased production of the major neurotransmitters. The older brain also has a diminished maintenance capacity making it more vulnerable to oxidative stress and inflammation that may facilitate neural injury. When taken together, these factors may contribute to a decrease in brain plasticity and hinder the old brain's ability to fully recover from the stimulus of surgery, anesthesia, and hospitalization. In patients with baseline preoperative cognitive impairment, this cognitive and neuronal plasticity may be further reduced, which puts these patients at risk for adverse postoperative outcomes including delirium and cognitive dysfunction that may persist for several months following a surgical procedure [10–14].

Cognitive Impairment and Dementia

Cognitive impairment and dementia are common in older adults and there is an increasing incidence with advancing age. Worldwide, approximately 35.6 million people were demented in 2010 and there are expectations that by 2050 there will be 115.4 million people worldwide with dementia [15]. Mild cognitive impairment (MCI) is also common among older adults. The estimated prevalence of mild cognitive impairment in population-based studies ranges from 10% to 20% in persons older than 65 years of age. MCI is defined by the presence of subjective memory complaints in the setting of objective memory impairment in patients with preserved ability to function in daily life. Patients with MCI are at increased risk of dementia but not all go on to develop it. Dementia is diagnosed when there is significant cognitive impairment in at least one cognitive domain (learning and memory, language, executive function, complex attention, perceptual-motor function, and social cognition) that is acquired and represents a significant decline from a previous level of functioning. In dementia, these cognitive deficits interfere with independence in everyday activities, must not occur exclusively during a period of delirium and are not better accounted for by another mental disorder (such as major depressive disorder or schizophrenia) [16, 17].

Undiagnosed preoperative cognitive impairment is common in the geriatric surgical patient. The prevalence of preoperative cognitive impairment in the setting of elective surgical procedures range between 20% and 44% and may be higher in emergency procedures [12, 14, 18, 19]. Without formal screening, cognitive impairment is difficult to detect even in the primary care setting where primary care physicians failed to identify cognitive impairment 20–76% of the time during a routine visit [20, 21]. Not surprisingly, one study demonstrated a prevalence of baseline cognitive impairment or dementia of 68% in patients 60 years of age or older undergoing elective or emergent vascular surgery and the impairment was unrecognized in 88.3% of these patients suggesting that health care providers failed to identify cognitive impairment without formal screening [12].

This is important because individuals with cognitive impairment, advanced age, and functional impairment are at risk for the development of postoperative delirium [7, 22]. In particular, impaired executive function is a predictor of postoperative delirium in patients without impairments in activities of daily living [23]. Delirium is associated with increased medical costs, longer hospital length of stay, higher 30-day readmissions and rates of institutionalization at hospital discharge along with functional and cognitive decline [7, 24]. Traditionally it has been suggested that delirium is associated with an increased mortality rate, but a recent meta-analysis examined the impact of incident postoperative delirium on mortality and concluded that there is insufficient evidence to support an independent association between delirium and mortality after noncardiac surgery [6]. In addition, preoperative cognitive impairment has been associated with increased postoperative complications, including postoperative delirium, longer hospital length of stay, discharge to a higher level of care, persistent postoperative cognitive dysfunction, and mortality after surgery [10, 11, 13, 14, 22].

Preoperative Cognitive Screening

As described above, preoperative cognitive impairment is frequently unrecognized without formal screening yet is associated with significant morbidity and mortality [21, 22].

The American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) and the American Geriatrics Society (AGS) collaborated to create best practices guidelines around optimal perioperative care of the geriatric surgical patients [25]. These guidelines recommend performing a preoperative cognitive screen and if positive to consider referring the patient to a specialist for subsequent evaluation. Similarly, the AGS Expert Panel on Postoperative Delirium in Older Adults elaborated evidence-based recommendations regarding the optimal care of older adults at risk for delirium and recommend screening for cognitive decline prior to a surgical procedure [26]. Additionally, the European Society of Anesthesiologists issued evidence and consensus-based guidelines for the prevention and treatment of postoperative delirium and strongly recommended preoperative cognitive screening [27].

When patients were surveyed in a preoperative anesthesia clinic, one study noted that the majority of individuals believed that a short memory test should be performed prior to having a surgical procedure and that if a memory test could help predict surgical outcomes they would want the test performed on them [19]. Moreover, identifying cognitive impairment preoperatively can help clinicians identify patients who are at risk for adverse postoperative outcomes allowing for a cost-effective way to direct precious health care resources toward their care.

The ideal cognitive screening tool during the preoperative evaluation should be brief, easily administered and scored, with high sensitivity and specificity for cognitive impairment, high inter-rater reliability, and should be validated across multiple languages, cultures, and education levels in older adults [19, 28]. The goal should not be to diagnose dementia or cognitive impairment, but rather to identify those individuals who performed poorly on a preoperative cognitive screening test to direct vigilance, more focused care, and further evaluation.

The Mini Mental State Examination (MMSE) is the most widely studied screening test to measure cognitive impairment [29], but other instruments are as effective, easier to perform, and are freely available [30]. Practical screening tests that can be quickly performed in a preoperative evaluation are shown in Table 1. Here we will discuss those cognitive screening tools that are available for clinical and research purposes that can be completed in 10 min or less that might be suitable in the elective or urgent preoperative setting.

Mini Mental State Examination (MMSE)

The MMSE is a widely used, 30-point cognitive screening tool that is well validated to screen for dementia with high sensitivity and specificity [29, 30]. It consists of 20 questions that cover multiple cognitive domains and has been translated into many languages worldwide. It takes on average 10 min to complete, but it may take longer in demented patients. Each point is given for a correct answer and, traditionally, the cut-off for dementia is <24/30. The MMSE has substantial age, education, and cultural bias and appropriate cut-off scores have been studied to improve its performance [31]. One of the main limitations of this tool is that is copyrighted and not freely available [30]. Moreover, it has a low ceiling effect and MCI patients may score in the normal range. MMSE has been widely used to detect cognitive impairment in the perioperative setting and a poor performance is associated with worse perioperative outcomes [13, 32]. Studies demonstrate that patients with undiagnosed baseline cognitive impairment were at higher risk for developing postoperative delirium and being discharged to a higher level of care [13, 32].

Montreal Cognitive Assessment (MoCA)

The Montreal Cognitive Assessment (MoCA) is a 30-point screening test that takes approximately 10 min to administer. This tool assesses numerous cognitive domains (Table 1) and, when compared to other screening tests, shows a better ability to detect MCI [30]. In a validation study, using a cutoff score of 26, the MoCA detected 90% of mild cognitive impairment and 100% of mild Alzheimer's disease with a specificity of 87% [33]. Time constraints and the complex scoring system are some of the test limitations but when the clinicians have more time and there are pointed concerns from the patient and family member, the MoCA test can be useful as an instrument given that it is more comprehensive and tests a variety of domains. The tool is freely available at the website www.mocatest.org.

One study enrolled patients older than 60 years of age admitted for elective or emergent vascular procedures and used the MoCA to evaluate the prevalence of cognitive impairment (defined as MoCA < 24). In this cohort, the MoCA detected cognitive impairment or dementia in 68% of the patients and this was unrecognized in 88.3% [12]. Preoperative cognitive impairment using the MoCA has demonstrated ability to predict postoperative complications, including postoperative delirium [12, 34].

Mini-Cog

The Mini-Cog is a quick, easily administered, and validated cognitive assessment tool that measures memory with a three-object recall after a distraction test of executive function which utilizes a

Table 1 Cognitive Screening Tools

	Time to administer	Description/ Cutoff	Cognitive domains	Diagnostic accuracy pooled (95% confidence interval) (30)		Advantages	Limitations	Availability	Studied in perioperative setting	Perioperative outcomes
				Sensitivity	Specificity					
Brief < 10 min										
MMSE	8–10 min (up to 15 min if demented patient)	20 questions; 30 points/ Dementia <24/30; age and education norms (different cutoff levels)	Orientation, memory, language, attention, visuospatial	Dementia 0.81 (0.78–0.84); MCI 0.62 (0.52–0.71)	Dementia 0.89 (0.87–0.91); MCI 0.87 (0.80–0.92)	Extensively studied; translated and validated in various languages; often used as a reference for comparative evaluation of other assessment tools; best performance for at least moderate cognitive impairment	Low ceiling (MCI may score 25–30); low sensitivity for MCI; affected by vision, physical and coordination impairment; copyrights; education, cultural language and age bias (not gender)	www4.parinc.com/ Copyright	Yes (13, 32)	POD and discharge to a higher level of care
MoCA	10 min	30 points; designed for those who score <24 on the MMSE/ Dementia <24/30; MCI <26/30	Orientation, memory, language, attention, visuospatial, and executive function, (abstraction, naming)	Dementia 0.91 (0.84–0.95); MCI 0.89 (0.84–0.92)	Dementia 0.81 (0.71–0.88); MCI 0.75 (0.62–0.85)	Validated in many conditions including MCI, AD, and PD dementia; more sensible for MCI than MMSE	Education bias; complex scoring; affected by vision, physical and coordination impairment	www.mocatest.org/Free	Yes (12, 34)	POD and HLOS

	Time to administer	Description/ Cutoff	Cognitive domains	Diagnostic accuracy pooled (95% confidence interval) (30)		Advantages	Limitations	Availability	Studied in perioperative setting	Perioperative outcomes
				Sensitivity	Specificity					
Very brief < 5 min										
Mini-Cog	2–4 min (less if no CI)	3 item recall (3 points for each word) and CDT (0 or 2), maximum 5 points, algorithm for scoring/ CI ≤ 2	Memory, visuospatial, and executive function	Dementia 0.91 (0.8–0.96)	Dementia 0.86 (0.74–0.93)	Validated in multiple languages and cultures; little or no education, language or race bias; tested and feasible in preoperative setting; high inter-rater variability	Use of different word list may affect failure rates; CDT may be challenging if lack of contact with analog clocks, low experience with writing and drawing, and very low levels of educational attainment	www.mini-cog.com/ Free	Yes (11,14,19)	Complications, POD, HLOS, discharge to other place than home, mortality
GPCOG	5 min (4 min cognitive testing and <2 min for the	15 points; 2 steps: step 1 – CDT + questions; if $\leq$4 CI, if 5–8 indeterminate and triggers step 2-	Orientation, memory, language, visuospatial/ executive function, and other living functions	Dementia 0.92 (0.81–0.97)	Dementia 0.87 (0.83–0.90)	Available as a web-tool; translated in various languages; not affected by cultural or linguistic	Studied in primary care setting; necessary informant present	www.gpcog.com.au/ Free	Not extensively	–

	informant section)	informant-based assessment with 6 questions/ CI ≤ 4 or 3 negative answers on step 2				background (not affected by depression, age, gender, years of education, and physical and mental status); combines patient and informant data; quick; easily accepted by clinicians and patients				
Verbal Fluency Test	1 min	List of words (category or letter) in 60 s; 1 point for each word/ CI < 15	Executive function, semantic memory and language	Dementia 0.80 (0.73–0.86)	Dementia 0.82 (0.73–0.88)	Limited training to administer correctly; administer in person or over the phone; no pen or pencil	Education and cultural bias; anxiety	Free	Yes (45, 46)	POD

MMSE Mini Mental State Examination, *MCI* mild cognitive impairment, *POD* postoperative delirium, *MoCA* Montreal Cognitive Assessment, *AD* Alzheimer Disease, *PD* Parkinson disease, *HLOS* hospital length of stay, *CI* cognitive impairment, *CDT* clock drawing test, *GPCOG* General Practitioner Assessment of Cognition clock-drawing task [35]. Although memory loss is a common symptom of dementia, executive function impairment may precede memory decline [36]. One point is award for each correctly recalled word. The clock drawing is scored as normal if the clock has the correct time and is grossly normal. Dementia has been correlated with a score of ≤ 2 [35]. The time for completion of the test averages between 2.5 min and 3.7 min in demented patients in a medical setting [35]. The Mini-Cog can be administered reliably with little practice and the instrument and instructions for its administration can be found at the website www.mini-cog.com. This tool has been translated in various languages and has little or no language and education bias [37]. Nonetheless, the clock drawing may be challenging in those individuals who have very low levels of educational attainment, lack of experience in writing or drawing, or lack regular exposure to analog clocks. The Mini-Cog was first developed for primary care but has been studied in other settings [35, 38]. In a recent systematic review and meta-analysis on cognitive testing, the Mini-Cog was found to have a better diagnostic performance for dementia and to be simpler and shorter than the MMSE [30]. In a review aimed at identifying brief cognitive tools that could be used to detect preoperative cognitive impairment in a clinical setting, the Mini-Cog was considered one of the best screening tools with a 99% sensitivity and 93% specificity for dementia [28].

The Mini-Cog has been endorsed by ACS/AGS guidelines [25] and was found to be a feasible cognitive screening tool with a high inter-rater reliability in the geriatric elective surgical population [19]. The overall incidence of impaired cognition at baseline using the Mini-Cog ranges from 23% to 44% in surgical patients [11, 14, 19]. Poor performance on Mini-Cog has been associated with increased incidence of adverse outcomes including in-hospital complications, postoperative delirium, longer hospital length of stay, higher rate of discharge to an intuitional care facility, and higher 30-day readmission rate and mortality [11, 14]. Interestingly, patients unable to complete the Mini-Cog showed a higher risk of mortality at 1 year [11].

General Practitioner Assessment of Cognition (GPCOG)

The General Practitioner Assessment of Cognition (GPCOG) was developed and validated for primary care and includes both cognitive testing items and informant data [39]. This instrument comprises two sections with the first step including nine items of orientation, memory, and a clock drawing test (4 min) and a second step with six items (2 min) where the informant is asked if the patient is having more trouble with memory and performing other daily tasks including, for example, taking care of his or her medication, A score of 4 or less on the first step defines cognitive impairment. A score of 5 through 8 prompts an informant-based assessment, and a negative response to three of the six items indicates cognitive impairment with a sensitivity of 85% and specificity of 86% [39]. Results suggest that this test might have some utility in detecting patients with MCI as two-fifths of non-demented patients who scored low had sub-threshold cognitive impairment [39]. The GPCOG was found to be reliable and to perform as well as MMSE in detecting dementia [39, 40]. The GPCOG, available as a web-based tool (www.gpcog.com.au), is translated to various languages and, although it has not been extensively studied in the perioperative setting, it is a practical test with a high level of acceptance amongst patients and general practitioners [31]. One of the main limitations of this tool is that requires an informant to be present at the moment of the preoperative evaluation that is willing to participate.

Verbal Fluency Test

Verbal fluency is defined as the capacity to produce a logical and satisfying sequence of spoken words during a given time interval, normally 60 s [41]. The verbal fluency tests assess the ability to produce a list of words that start with a specific letter (phonemic verbal fluency) or within a category (semantic verbal fluency) and relies on the preservation of language, semantic memory, and executive function domains [41]. Impaired verbal fluency is well documented in patients with Alzheimer Disease, and the verbal fluency test (VFT) has been shown to have a high sensitivity in discriminating dementia from normal older controls [42]. In scoring the verbal fluency test, one would count up the total number of animals or words that the individual is able to produce. A score of under 17 indicates concern, although some practitioners use <15 as a cutoff. Semantic fluency has also been shown to be reduced in patients with mild cognitive impairment [43]. Nonetheless, as most rapid cognitive screening tools, education bias and the ceiling and floor effects are some of its limitations. A systematic review concluded that the verbal fluency tests have less predictive power than other more comprehensive instruments [30].

The Animal Fluency Test (AFT) is a simple and very brief cognitive screening tool that assesses semantic fluency by asking patients to name as many animals as they can in 60 s [44]. In this test, each point is given for each animal named and scores under 15 have demonstrated 88% of sensitivity and 96% of specificity in detecting Alzheimer dementia [42]. Besides being very quick and easy, it requires minimal training to administer, does not require pen or paper, and can be performed in patients with motor disability. When the cognitive assessment was performed in patients without recognized dementia or cognitive impairment, the AFT identified cognitive impairment in 52% of patients compared to the 56% identified with the MoCA [44].

One study that evaluated preoperative cognitive function with the AFT tool determined that this is a feasible test in clinical practice and found the prevalence of cognitive impairment to be 29% [45]. Naming fewer animals on this semantic fluency test is associated with a higher risk of developing postoperative delirium [45, 46].

Optimizing Patients with Cognitive Impairment

After identifying cognitive impairment, it is important to ensure patients, and their caregivers are aware of the potential postoperative complications associated with preexisting cognitive impairment to inform clinical decision-making, review postoperative care/instructions, and set expectations. The 2012 ACS/AGS guidelines recommend that if probable cognitive impairment is identified by a cognitive screening test preoperatively, the patient should be referred to a primary care physician, geriatrician, or mental health specialist [25]. While it is helpful to seek care of a professional for medication review and formalized recommendations by a geriatrician, given the prevalence of cognitive impairment this is often not feasible for every patient to see such a specialized provider. However, there are simple nonpharmacological and behavior modifying actions which can be undertaken to decrease the risk of postoperative delirium and other complications such as advising patients to bring sensory assistive devices such as hearing aids and glasses so that they are immediately available in the postoperative period. Additionally, it is helpful to engage families and caregivers in the perioperative setting, have them bring in pictures, familiar items and, if possible, encourage them to stay overnight in the hospital for reorientation [47]. Further interventions include sleep enhancements, i.e., minimizing interruptions overnight once the patient is clinically stable, daily orientation with day/night cycle, and use of large-print clocks. Lastly, prescribing health care providers should modify traditional postoperative prescribing and limit use of benzodiapezines, and anticholinergic medications such as diphenhydramine and scopolamine as these can increase risk of delirium in cognitive impaired patients who are already predisposed.

Formal programs such as the orthopedic co-management [48], Hospital Elder Life Program (HELP) [49], and modified Hospital Elder Life Program (mHELP) [50] have been shown to be beneficial to improve outcomes in individuals with cognitive impairment. In orthopedic co-management programs, individuals are cared for by both geriatricians and orthopedic surgeons that utilize key geriatric friendly principles such as early mobility, minimizing teethers such as Foley catheters and telemetry, standardized protocols to decrease unwarranted variability, and early discharge planning. HELP is an interdisciplinary program mostly run by volunteers which has six interventions targeting cognitive impairment, sleep deprivation, immobility, visual impairment, hearing impairment, and dehydration. Similarly, mHELP has daily programs such as orienting communication, oral and nutritional assistance, and early mobilization have been shown to decrease rates of delirium after abdominal surgery [50]. All of these programs have been shown to decrease the risk of adverse outcomes in elderly patients.

Conclusion

Cognitive impairment is prevalent in older adults. Preoperative cognitive screening is both easily performed and may identify those patients at highest risk so that they may receive more personalized care to enhance postoperative outcomes.

Abstract

The elderly population is particularly vulnerable to malnutrition due to a number of physiologic, psychologic, and socioeconomic changes associated with aging. Diagnosis is challenging and a number of screening modalities have been described. Reliance upon biochemical testing (albumin and prealbumin) alone is not recommended. Multiple screening tools such as Mini Nutritional Assessment (MNA), Nutrition Risk Index (NRI), Malnutrition Universal Screening Tool (MUST), and Nutritional Risk Screening-2002 (NRS-2002) have varying degrees of accuracy. Because malnutrition and "at risk for malnutrition" are strongly predictive of poor clinical outcomes, intervention is recommended, though reversal of malnutrition in the elderly is particularly difficult after significant lean body mass has been lost. Prehabilitation with nutrition and exercise begins in the preoperative stage, continuing through the perioperative period, and continues beyond the immediate postoperative period.

Clinical Vignette

A 72-year-old woman presents to your clinic for evaluation after a routine screening colonoscopy identified a cancerous polyp in the cecum. She lives alone after her husband died 6 months ago. She has had a poor appetite since his death and although she denies significant weight loss, she admits that she hasn't weighed herself recently. Her only medical comorbidities are hypertension (for which she takes atenolol) and hypothyroidism (for which she takes levothyroxine). She weighs 132 lbs (59.9 kg), is 5 ft 7 in, and has a BMI of 20.7.

What tools would you use to screen this patient for malnutrition?
What interventions can you implement to optimize this patient for surgery?

Introduction

By the year 2030, one in five people in the United States will be over the age of 65. The elderly population will continue to increase to 88.5 million by 2050 – more than double what it was at the time of the 2010 census [1]. This change translates into an increase in surgical volume in the elderly as well. In 2007, one-third of all inpatient surgical procedures were performed on elderly patients, and in the next few years, that number is projected to double [2, 3].

The elderly population is particularly vulnerable to malnutrition. The prevalence of malnutrition in the elderly reported in the literature is variable, with rates as high as 60% [4, 5]. This inconsistency can be attributed to a range of geographic locations and varying methods of assessment [6]. Using a pooled analysis of 4,000 elderly patients from 12 countries on five continents treated in multiple settings evaluated with only one assessment tool, the overall prevalence of malnutrition was 23%. When further categorized by treatment setting, the prevalence was highest in rehabilitation centers and hospitals (51% and 39% respectively), and was lower in nursing homes and in the community (14% and 6%) [7]. The prevalence of patients "at risk of malnutrition" was even higher at 46% – meaning two-thirds of the entire study population was either at risk of malnutrition or already identified as malnourished [7].

Malnutrition has serious consequences in the elderly. Malnourished elderly patients (as defined by a body-mass index (BMI) of <20 kg/m^2) have a 1-year mortality rate approaching 50% [8]. In order to improve care, including surgical care of the elderly, it is imperative that malnutrition be recognized and addressed appropriately.

Factors Contributing to Geriatric Malnutrition

Between the ages of 20 and 70, mean energy (calorie) intake decreases by 1,062 kcal/day in men and 481 kcal/day in women [10]. On average, men over age 65 in the USA were shown to lose 0.5% of their body weight each year [11]. There are a number of changes associated with aging – physiologic, psychologic, and socioeconomic – that predispose this population to under-nutrition.

Physiologic

Changes to appetite, taste, olfactory, and visual acuity, chronic disease, physical disability, and dentition can impact food choice and dietary intake. Appetite declines with age, with elderly persons eating smaller meals, eating fewer snacks between meals, and feeling full more rapidly. This trend is referred to as the "anorexia of aging" [4]. The processes present in younger people that impact appetite and correct for over- or undernutrition are not as effective in older people. One study underfed healthy community-dwelling young (mean age 24) and old men (mean age 70) and then documented the responses when they were allowed to eat freely again. The young men over-ate above their baseline consumption to compensate and quickly regained weight, while the older men only returned to their baseline dietary intake and did not regain lost weight [12]. This study suggests an inability among the elderly to quickly rebound from acute undernutrition, similar to the type of acute insult that occurs with a major operation. These patients take longer to regain lost weight and remain malnourished for a prolonged period.

Also contributing to a decline in appetite with aging is deterioration of the senses of taste and smell. The threshold to detect tastes increases with age, with salt being the most difficult to taste; however these changes are variable and the extent of the impact on energy consumption is unproven [13]. The sense of smell is particularly important to stimulate interest in food. This sense, however, deteriorates after age 50 [14], and the consumption of a nutritionally balanced diet is often negatively impacted by removing this stimulus. Additionally, the process of obtaining nutrients from food – from chewing, to slowed absorption – is greatly impaired in the elderly. Dentition alone can change diet and limit the variety and amount of food able to be consumed, particularly protein intake [4].

Even the GI tract itself affects the process of obtaining nutrition. For instance, aging results in impaired gastric emptying and early satiety due to an increase of nitrous oxide in the fundus that occurs with aging [15]. Other comorbidities and chronic medical conditions that occur with aging can also contribute to malnutrition. For instance, diseases that limit mobility either by deformity (such as rheumatoid arthritis), or by limited functional capacity (such as respiratory diseases) can cause malnutrition by impairing feeding, shopping, and food preparation. Chronic medical conditions also require the use of prescription medications, many of which have adverse effects that can limit nutrition. These medications can have a myriad of side effects, including anorexia, nausea, diarrhea, and early satiety among other gastrointestinal symptoms ([16, 17]. Often, with a large number of medications prescribed, it is difficult to parse out symptoms caused by drug interactions.

Body composition changes with age, resulting in an increase in fat and decrease in lean body mass such as skeletal muscle [13]. Up to 3 kg of fat-free muscle mass is lost each decade after 50 years of age [4]. The change in body composition is attributed to several factors, including decreased physical activity, reduced growth hormone and sex hormone levels, and changes in metabolic rate. Testosterone and other androgens decrease with age, contributing to sarcopenia [4]. Additionally, decreases in growth hormone and insulin-like growth factor 1 (IGF-1) affect age-related changes in appetite and food intake [13].

Psychologic

Psychological variables that impact food choice and nutrition include loneliness, bereavement, food likes/dislikes, and mental awareness [5]. Depression occurs in 2–10% of elderly people in the community [18]. In the elderly population, this condition tends to be associated with decreased appetite, loss of body weight, and subsequent malnutrition. While only seen in about 60% of younger adults with depression, weight-loss is noted to be a symptom of depression in nearly all elderly patients [13]. Treating depression has been reported as an effective way of promoting weight gain [4]. Additionally, the elderly tend to live alone and there is an association between loneliness and decreased appetite in the elderly. When not eating alone, older people will eat significantly more [19]. Finally, the prevalence of dementia increases with age, often affecting feeding behaviors and leading to weight loss [16].

Socioeconomic

Socioeconomic factors also impact nutrition in the elderly, as this patient population is often in retirement with a lower or fixed income. Expenses for treatment of the chronic medical conditions associated with aging, such as prescription medication costs, can further limit income available for purchasing nutritious food [20]. Low income can cause "food insecurity," a state where people cannot afford nutritious food, leading to malnutrition [6]. Social factors such as convenience of cooking facilities, distance to food stores, availability of transportation, and access to preferred foods also impact nutrition. When examining activities of daily living, 12% of older persons required help with managing finances, 29% needed help with shopping, and 16% could not prepare food independently [13]. All of these factors contribute to the overall anorexia of aging that makes the elderly population especially vulnerable to malnutrition and its consequences.

Nutritional Assessment of Geriatric Patients

History and Physical Exam

In order to intervene appropriately to optimize nutrition in elderly patients, malnutrition must first be identified. There is a vast array of nutritional assessment strategies that have been employed clinically for this patient population, beginning simply with history and physical exam. These traditional means rely on the patient or caregiver reporting symptoms such as a history of weight loss or changes in diet and detecting physical findings associated with malnutrition such as muscle wasting or edema. The clinician should always begin with history and physical before proceeding to more sophisticated screening tools.

Subjective Global Assessment

One assessment method that formalizes and incorporates the history and physical exam is the subjective global assessment (SGA), introduced by Detsky in 1987 [21]. The SGA includes functional capacity and the clinican's overall impression of the patient's status which they designate as "normal," "mildly malnourished," or "significantly malnourished" [21]. To make that subjective judgment, clinicians assess for a history of weight loss and poor dietary intake and loss of subcutaneous tissue and muscle wasting on physical exam. The

SGA does not include laboratory testing. In validation studies, Detsky et al. demonstrated a sensitivity of 82% and specificity of 72% when using the SGA to predict infection secondary to poor nutritional status – better than six other methods including several laboratory tests and other nutritional indexes [21].

Despite the high level of sensitivity and specificity shown by Detsky, the successful use of the SGA to predict malnutrion is limited by several factors. First, it is most effective when performed by clinicans experienced with the assessment. In additional validity testing in other clinicians, the same level of sensitivity was difficult to replicate. For instance, one study compared the SGA form completed by two independent clinicians to a combination of anthropometry and measurement of serum protein. The two observers had an agreement level of 77.8% and there was significant variability between the two observers in predicting malnutrition (82% vs. 66%) [22]. These studies suggest that SGA is a reliable assessment tool in the hands of experienced clinicians. Similarly, a review of the literature reveals that the SGA performs similarly to traditional methods of determining nutritional status, such as laboratory testing and anthropometry, but concludes that alternative nutritional assessment tools, which will be discussed later in this chapter, are more reliable in detecting malnutrition than the SGA [23]. Another limitation of this method is that the physical signs of muscle wasting and subcutaneous fat loss emphasized by the SGA are often late signs of malnutrition, making the SGA less useful in detecting early malnutrition and also less helpful in re-evaluating progress after interventions for malnutrition [22]. While the SGA does provide a way to translate the history and physical exam into assigning a degree of malnutrition in the hands of an experienced clinician, it is not the ideal assessment tool.

Biochemical Markers

Albumin

In the past, the serum albumin level has been used to define malnutrition under the assumption that albumin level is proportional to the severity of malnutrition. Hypoalbuminemia was presumed to represent a deficit that can be corrected by increasing dietary protein intake. Although this association may be true in a purely protein deficient state, such as Kwashiorkor, in general, the relationship between albumin and malnutrition is far more complex [24]. Albumin levels are affected by many additional factors unrelated to nutrition status. Clinical factors that alter protein anabolism or catabolism including liver cirrhosis and certain drugs (such as steroids) likewise impact albumin levels [25].

Albumin production is limited in the setting of inflammation as protein synthesis shifts toward the production of cytokines and the protein is lost from the intravascular space to the interstitium [22, 27]. In this regard, it behaves as a negative acute phase reactant [26]. Thus, in the inflamed state, the serum albumin level may be low even in well-nourished patients. The half-life of albumin is 18 days, yet the albumin level has been observed to decrease rapidly after hospital admission – too immediate a response to be explained by malnutrition alone.

In addition to the effects of various disease and inflammatory processes, aging itself is associated with a modest decline in serum albumin levels, with a decrease of 0.8 g/L per decade after age 60 [22, 28, 29]. Even recumbent posture has been reported to a decrease in albumin levels [30]. With a multitude of influences, serum albumin lacks the sensitivity and specificity to be an accurate indicator of nutrition. However, albumin has been reported as an accurate predictor of mortality and overall health status [22, 24, 31]. A study of patients in a geriatric rehabilitation unit at a Veterans' Affairs hospital reported that 3 months after discharge, albumin was the strongest predictor of long-term mortality. Patients with albumin less than 35 g/L had 2.6 times greater mortality than those with serum albumin levels above 40 g/L [32]. Subsequent studies from the same group indicate that inflammation at the subclinical level may contribute to the lower albumin levels [26]. At the present time, the body of knowledge suggests that albumin is a valuable biomarker of severity of illness and predictive of perioperative complications, including mortality, prior to elective major surgery [33]. This predictive ability is diminished in the setting of critical illness [34–36]. However, the connection between albumin and nutrition is tenuous at best and likely confounded by comorbid illness [24, 26, 37]. There has been no convincing evidence that aggressive nutritional therapy (independent of treating the comorbid illness) directly increases serum albumin, and that improved serum albumin resulting from nutritional optimization leads to improved outcomes.

Transthyretin (Prealbumin) and C-Reactive Protein

Like albumin, *prealbumin* (also known as transthyretin (TTR)) has been used as a metric of protein malnutrition since the 1970s [38]. Despite its misleading name, prealbumin is not a precursor to albumin. Originally named in reference to its relationship to albumin on a protein electrophoresis plate, prealbumin plays a variety of roles including thyroxin transport and vitamin A transport through formation of a complex with retinol-binding protein [39, 40]. The normal range of prealbumin is reported as 150–350 mg/L and the half-life of prealbumin is 2 days. A consensus statement regarding the use of prealbumin in nutrition evaluation was issued in 1995. Per this statement, a level between 50 and 109 mg/L indicated significant risk of malnutrition and a level of less than 50 mg/L was an indicator of poor prognosis [41]. Furthermore, an increase of less than 40 mg/L within 8 days despite providing 100% of protein need is indicative of need for further intervention and also of poor outcomes [41]. However, factors other than nutrition status alone can also impact prealbumin levels.

Like albumin, the use of serum prealbumin is complicated by the fact that levels also change rapidly when protein synthesis shifts toward acute-phase proteins in the setting of systemic inflammation [42–46]. Because prealbumin also acts as a negative acute phase reactant, there has been a movement toward including *C-reactive protein* (CRP) in acute metabolic panels to assess whether changes in prealbumin are due to an inflammatory process secondary to acute illness or by malnutrition [45, 47].

CRP levels respond quickly to tissue injury – 4–6 h faster than other acute phase reactants, though aging has not been shown to affect measured values [40]. CRP will decrease within 3–5 days after trauma or the resolution of sepsis as other proteins like albumin and prealbumin begin to increase. Based on this relationship, a *Prognostic Inflammatory and Nutritional Index* (PINI) has been created to assess the severity of disease processes and predict survival. In a study of patients in an acute geriatric unit, a PINI score of greater than or equal to 25 was predictive of in-hospital mortality. Hypoalbuminemia, on the other hand (less than or equal to 30 g/L), was associated with disability but did not predict mortality [48].

Additional studies provide similar evidence to support the use of prealbumin combined with CRP to assess for protein-calorie malnutrition. In a study of Belgian geriatric units, prealbumin was measured at the third day of admission and at discharge. A prealbumin level of 170 mg/L was considered to represent increased risk of malnutrition, and patients with a prealbumin concentration of less than 200 mg/L were provided with caloric supplementation. The patients receiving supplementation were admitted with lower prealbumin and higher CRP levels than patients not receiving supplementation. Those patients were then discharged with higher prealbumin and lower CRP levels than the group without supplementation. Although prealbumin levels do appear to reflect dietary repletion, the levels are not specific, as severity of illness and inflammation influence the same markers [49]. Similarly, Mears has reported on the outcomes of a malnutrition screening program that used prealbumin levels for patient assessment at the time of hospital admission and monitoring throughout patients' hospitalization [50]. In that study, patient care improved with early and accurate identification of patients with protein-calorie malnutrition. Less invasive and less expensive methods of nutritional supplementation were required due to the early diagnosis and length of hospital stay and readmission rates were decreased. Not only was patient care improved, but these effects, along with the ability to add the diagnosis as a comorbid condition for Medicare reimbursement, also led to a significant financial benefit to the hospital [50].

Prealbumin-based malnutrition screening has been shown to identify more patients as being malnourished than albumin screening and is able to provide early and correct identification of patients at risk of malnutrition [47, 49, 50]. Another positive aspect of prealbumin-based screening is that it does not change drastically with increasing age in healthy individuals, unlike albumin levels, which change significantly [51]. Although imperfect, the sensitivity of prealbumin in identifying malnutrition and the minimal change with age make it a useful marker in nutritional assessment in the elderly in the uninflamed state. It is important to emphasize, however, that the use of serum protein markers, including albumin and prealbumin, is *not* validated in critical illness and their use in this setting is discouraged by the Society of Critical Care Medicine (SCCM) and the American Society of Parenteral and Enteral Nutrition (A.S.P.E.N.) [52].

Other Biochemical Markers

While not commonly used in clinical practice, there are additional biochemical markers that have been described as indicators of malnutrion. As part of the vitamin A transport complex formed with prealbumin, *retinol-binding protein* (RBP) is also a marker of nutrition [40]. Levels of prealbumin and RBP are comparable except in vitamin A deficiency. RBP remains stored within the liver until vitamin A levels normalize. Like prealbumin, it has a short half-life (12 h) and decreases with liver disease, stress, and inflammation. RBP levels are increased in the setting of renal failure [53]. Also, levels do change with age, and the mean and median levels for healthy nonagenarians and centenarians are overall lower in men and higher in women [54].

Insulin Growth Factor-I (IGF-I), like prealbumin and RBP, is a protein with a short half-life (2–4 h) and was found to fall during periods of protein malnutrition and rise with refeeding [55]. Baseline levels begin to decrease when patients are in their fifth decade and are reduced by 35–60% by their tenth decade. Levels are affected by renal and hepatic failure, autoimmune disease, inflammation, and stress [40]. IGF-I predicts "life-threatening" and "life-threatening infectious" complications in patients over the age of 76 and correlate with other measurements of nutrition [56].

Fibronectin is a glycoprotein produced by endothelial cells, fibroblasts, macrophages, and the liver. It has been explored as a nutritional marker because of its short half-life (4 h). Levels were noted to fall in the setting of starvation within 2 days and return to normal within 5 days of refeeding, prompting the possibility of use as a marker of protein malnutrition [57]. Because it is not produced solely in the liver, fibronectin is less influenced by liver disease. However, fibronectin levels are impacted by burns, infections, and shock as well as the lipid content in some enteral feeding formulas [40]. While plasma fibronectin concentration does increase within a week of nutritional therapy initiation, it does not seem to change significantly thereafter. It also does not correlate with other measures of nutrition and is not predictive of patient outcomes [58].

Total lymphocyte count (TLC) has also been suggested as a marker of malnutriton. Malnutrition was observed to be associated with a decrease in TLC and a TLC of less than 1,500/mm^3 was associated with a four-fold increase in mortality [59]. One study compared TLC to anthropometry measurements, serum albumin, total cholesterol levels, and total score on the mininutritional assessment (MNA) in patients age 65–95. The authors found that there was no difference among the patient groups (grouped as "severely low," "low," or "normal" TLC) in relation to the other measurements of nutrition. TLC did decrease with increased age, but did not change with other nutritional markers [60]. TLC does not appear to be an appropriate or accurate marker of nutrition in the elderly population.

Body Composition and Anthropometric Measures

The 2012 consensus statement on malnutrition from A.S.P.E.N. has included the loss of muscle mass as part of its definition of malnutrition, bringing focus to the assessment of muscle loss

[61]. Physical exam alone to subjectively assess muscle mass and muscle loss is an unreliable method. Methods of body composition and anthropometric measures have therefore been developed to better estimate lean muscle mass and assess nutritional status.

The simplest model to estimate body composition is one that divides the body as a sum of two components: fat mass and fat-free mass (FFM). FFM includes multiple tissues including skeletal and nonskeletal muscle, organs, total body water (TBW), bone, and connective tissue. TBW can be used to estimate FFM by using the following equation that includes a hydration constant:

$$\mathrm{TBW}\ (\mathrm{kg})/0.73 = \mathrm{FFM}\ (\mathrm{kg})$$

The hydration constant is less reliable in the settings where hydration is variable and in obesity. An alternative calculation to TBW involves lean body mass (LBM) or lean soft tissue (LST) which represents all of FFM except bone and is measured by dual-energy X-ray absorptiometry (DXA) [62]. DXA analyzes soft tissue overlying bone in vivo and works best in areas with well-defined bone such as the arms and legs where a sum of the lean soft-tissue mass of the arms and legs is used to define appendicular skeletal muscle [63].

Body cell mass (BCM) is another method of assessing body composition. BCM represents the total mass of oxygen-consuming and work-producing cells in the body, which is assumed to be the non-fat cellular portion of tissues like skeletal muscle, organ tissue, etc. Although BCM cannot be directly measured, there are several methods to estimate this compartment including neutron activation analysis to determine total body nitrogen, total body potassium counting, and intracellular water measured by multiple dilution. All these calculations can be used to assess nutrition and nutrition interventions, though the varying levels of difficulty and expense lead to more common usage in research than clinical practice [62].

While body composition can be estimated mathematically, there are two bedside methods that can also be used estimate lean muscle mass. Bioimpedance and ultrasound assessment have been recommended by A.S.P.E.N. as direct methods of assessing body composition. Bioimpedance is measured by devices that produce an electric current at varying frequencies between electrodes placed in specified locations on the body [64]. The flow of the current through the body is affected by body composition – electrolyte-rich blood and muscle conduct the current while fat and bone do not. The change in voltage as the current passes through the body's tissue – the impedance – is detected by electrodes. This raw data is used to calculate body composition and estimate FFM based on the assumption that the body is comprised of five cylinders with constant cross-sectional area with patient's height representing the length of the conductor [62]. Devices to measure bioimpedance are not interchangeable – the equations used for the body composition calculations are specific to each device. The accuracy of bioimpedance measurements is dependent upon consistency in terms of set up such as electrode placement and body positioning as well as environmental factors such as temperature. Even biological changes in the patient can impact measurements; for instance electrolyte abnormalities or edema can alter resistance values [64].

Ultrasonography

An readily available option to estimate lean tissue at the bedside is ultrasonography. Ultrasound has recently been shown to predict FFM by taking the sum of measurements from several anatomic sites. Muscle thickness is measured and used to estimate total body FFM [65]. This method is limited by operator experience and the subjective nature of interpreting the image and identifying muscle boundaries during measurement of muscle thickness. Also, muscle thickness changes depending on whether or not the muscle is contracted or relaxed. Ideally, measurements should be taken consistently with the patient in the supine position where muscles are more likely to be relaxed and compressible. The amount of pressure to apply while taking muscle thickness measurements has not yet been standardized; some studies advocating for maximal compression and others for no compression [62]. One study reported that ultrasound measurements of the biceps, forearm, and midthigh muscle thickness FFM in patients with multiorgan failure correlated with DXA-determined estimates of FFM [66]. Muscle thickness can also be used to predict outcomes as shown by a study from the University of Vienna in which quadriceps muscle thickness was shown to inversely correlate with length of stay in ICU patients [67]. Despite the potential limitations, ultrasound-measured muscle thickness has been shown to be a low cost, noninvasive, and reliable method of estimating FFM.

Anthropometry

In addition to the multiple direct bedside methods and calculations that exist to estimate body composition, an indirect means is also available in the form of anthropometry. One component of anthropometry is body mass index (BMI), which is calculated by dividing weight (kg) by height squared (m^2). BMI alone, though, is imprecise in estimating lean body mass. Other anthropometric measurements include body circumference, which can be measured in multiple locations including midbrachial, calf, waist (measured midway between the most inferior rib and the iliac crest), and hip circumference (measured at the widest point of the buttock). Using the waist and hip measurements, a waist-to-hip ratio (WHR) can be calculated and used to determine visceral obesity and identify patients with increased mortality risk [68]. However, increased relative risk of mortality is less pronounced in elderly patients over the age of 65 [69]. The *knee-heel length* is also particularly relevant in the elderly population, where patients are often unable to stand upright for traditional height measurements. Stature height can then be predicted using equations developed from the third National Health and Nutrition Examination Survey (NHANES III) from the National Center for Health Statistics [70]. Other measurements include subscapular, triceps, suprailiac, and thigh skinfold thickness measurements; however these require the use of calibrated calipers [68]. Cross-sectional studies in various countries have provided normative reference data for age-, gender-, and disease-specific anthrompometric measurements [68, 71]. Anthropometric measurements can be applied to predict overall level of independence and function, as illustrated by a cross-sectional study of elderly patients receiving home care in Germany showing that patients requiring a higher level of care for their needs had lower anthropometric values [72].

Sarcopenia and Frailty

In 2006, a special interest group on nutrition in geriatrics was created within the European Society for Clinical Nutrition and Metabolism (ESPEN). One of the concepts further defined by this special interest group was age-related sarcopenia – “the loss of muscle mass and muscle strength associated with aging” [73]. Age-related sarcopenia is the result of intrinsic and extrinsic factors. Intrinsic changes with age include a decrease in anabolic hormones, increased muscle cell death, decreased number of alpha-motoneurons innervating skeletal muscle, and increased proinflammatory cytokines. External factors include decreased intake of protein and vitamin D [73].

In its most extreme form, sarcopenia can progress to frailty syndrome. Frailty is a lack of physiological reserve in multiple organ systems leading to increased vulnerability [74]. Frailty is an independent predictor of 30-day morbidity and mortality and institutionalization after surgery and trauma [74, 76–78]. While there are multiple screening tools for frailty, the American Geriatrics Society/National Institute on Aging has adopted the frailty phenotype introduced by Fried et al [75]. Screening for the frailty phenotype is based on five criteria: weight, grip strength, subjective fatigue, physical activity, and walking speed measurements [75].

Functional Assessment

In measures of anthropometrics and body composition, adequate protein nutrition is represented by fat-free mass (muscle). Since muscle mass is associated with muscle function, function is now being examined as an indicator of nutrition. Functional status can be measured in terms of voluntary and involuntary muscle function. The theory behind the use of function as a surrogate for nutrition status is that muscle structure changes with protein undernutrition leading to loss of contractile elements, increased muscle fatigue, and altered contraction patterns [79]. Function measured with hand grip strength and quadriceps strength is also related to mortality, while muscle mass was not [80]. Electrical stimulation testing can test involuntary muscle contraction and provide an objective measure of function, but more practical testing is available to assess voluntary function. Some commonly used measures are hand grip, knee extension, or hip flexion strength. Past studies have shown that handgrip dynamometry can accurately assess muscle function, which can then be correlated with nutritional status [81]. Diminished handgrip strength is included in the A.S.P.E.N. consensus statement as a characteristic of malnutrition [61]. The use of handgrip strength as a surrogate of nutrition is limited by a lack of consensus on measurement. Additionally, small changes in posture or hand position can change measured grip strength [79].

Nutritional Assessment Scoring Systems

The unidimensionality of most of the exams and laboratory values discussed up to this point limits their efficacy in identifying malnutrition in the complex geriatric population. For this reason, multifaceted assessment tools have been introduced into clinical practice.

Mini Nutritional Assessment

The Mini Nutritional Assessment (MNA) was designed specifically as an assessment tool for the elderly, and as such takes into account many age-related risk factors of malnutrition. In particular, it includes an evaluation of both the physical and mental limitations that impact nutrition in geriatric patients [82]. The original version of the MNA, now called the "full MNA," uses a set of 18 questions, with the first six questions serving as a trigger for further assessment. The questions fall within four categories (anthropometric measures, a general assessment, dietary assessment, and subjective/self-assessment) and can be completed in under five minutes. The six screening questions (originally called the Mini Nutritional Assessment Short Form, or MNA-SF) were found to have the same accuracy as the full version, and are thus now used in clinical practice as the MNA [83]. Using this tool, patients are classified as well-nourished, at-risk for malnutrition, or malnourished based on their overall score on the multiple components [84]. The MNA-SF screening questions are included in Fig. 1.

Of note, the MNA does *not* include biochemical markers as part of the assessment. During the development process, the sensitivity and specificity of the MNA without serum testing remained 96% and 98% [85]. Exclusion of blood samples allows minimization of cost and disruption to the patient. Early detection by the MNA of elderly patients at risk of malnutrition allows for interventions prior to clinical deterioration [84]. Risk for malnutrition or malnutrition identified by the MNA is also predictive of adverse outcomes and mortality [82].

GNRI

The *Nutrition Risk Index (NRI)* is an assessment tool that has been used to identify patients at risk of developing postoperative complications [9]. This score, which in theory shows protein nutrition intake and the stress associated with underlying disease, includes albumin concentration and weight loss. However, the NRI is limited by the same factors that limit albumin as a marker of malnutrition – factors other than protein intake affect serum albumin levels [9]. The *Geriatric Nutritional Risk Index (GNRI)* is a similar tool used for elderly patients in the acute care setting

Complete the screen by filling in the boxes with the appropriate numbers. Total the numbers for the final screening score.

Screening

A Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties?
0 = severe decrease in food intake
1 = moderate decrease in food intake
2 = no decrease in food intake ☐

B Weight loss during the last 3 months
0 = weight loss greater than 3 kg (6.6 lbs)
1 = does not know
2 = weight loss between 1 and 3 kg (2.2 and 6.6 lbs)
3 = no weight loss ☐

C Mobility
0 = bed or chair bound
1 = able to get out of bed / chair but does not go out
2 = goes out ☐

D Has suffered psychological stress or acute disease in the past 3 months?
0 = yes 2 = no ☐

E Neuropsychological problems
0 = severe dementia or depression
1 = mild dementia
2 = no psychological problems ☐

F1 Body Mass Index (BMI) (weight in kg) / (height in m)^2
0 = BMI less than 19
1 = BMI 19 to less than 21
2 = BMI 21 to less than 23
3 = BMI 23 or greater ☐

IF BMI IS NOT AVAILABLE, REPLACE QUESTION F1 WITH QUESTION F2.
DO NOT ANSWER QUESTION F2 IF QUESTION F1 IS ALREADY COMPLETED.

F2 Calf circumference (CC) in cm
0 = CC less than 31
3 = CC 31 or greater ☐

Screening score (max. 14 points)

12 - 14 points: Normal nutritional status
8 - 11 points: At risk of malnutrition
0 - 7 points: Malnourished ☐☐

[86] and is calculated using height, weight, BMI, and serum albumin. With those parameters, albumin and actual weight are compared to ideal body weight in the following equation initially described by Bouillanne et al. [86]:

$$\mathrm{GNRI} = [1.489 \times \text{albumin (g/L)}] + [41.7 \times (\text{weight}/\text{ideal body weight})]$$

The calculated GNRI is grouped into four grades, with a score of >98 as no risk and a score of <92 as high risk. Patients with nutritional risk at the time of admission when evaluated with the GNRI are more likely to develop complications and have longer lengths of stay [87].

MUST

The malnutrition universal screening tool (MUST), though not developed specifically for geriatric patients, is another assessment tool available for adult patients of any age group and in any care setting [88]. The premise of the tool was to utilize the association between poor nutrition and impaired function to identify risk factors for which to screen. Subsequent validation studies confirmed the resultant loss of function accompanying varying degrees of weight loss across the spectrum of nutrition status (as represented by BMI) [82]. The MUST consists of three components – BMI score, weight loss score, and acute illness score – which are each given a numerical value ranging from 0 to 2. The weight loss score is determined by evaluating the percentage unintentional weight loss in the preceding 3–6 months and the acute disease effect score is based on poor oral intake for at least the preceding 5 days (or predicted poor intake over the subsequent 5 days). The scores are then combined to determine an overall risk score, which is categorized as low, medium, or high risk of malnutrition. The MUST can be completed within 3–5 minutes [88] and has shown to be a reliable identifier of nutritional risk in both the community and healthcare settings [82]. The components of MUST are shown in Fig. 2.

The tool is easy enough for patients to screen themselves. One study showed that 96% of patients found the MUST assessment easy to understand and there was 90% agreement between the self-screening results and the results obtained by a trained health care professional [89].

NRS 2002

The Nutritional Risk Screening-2002 (NRS-2002) scoring system builds from the MUST assessment. This tool utilizes the same markers of nutrition as MUST to identify patients at risk of malnutrition, but takes into account the fact that disease severity changes nutrition needs by including a fourth component that reflects stress metabolism. ESPEN, therefore, recommends the use of this screening tool in hospitalized patients [82]. Extent of undernutrition is given a score from 0 to 3, while disease severity is given a score on the same scale. These are then added together. The goal is to initiate nutritional support in patients above a certain risk score [90] (Fig. 3).

Like the MNA and GNRI, higher scores on the NRS-2002 assessment correspond with worse clinical outcomes. For instance, patients with moderate or high nutritional risk on this screening were found to have a longer average length of stay than those without nutritional risk [9].

Impact of Nutrition on Outcomes

Once malnutrition is diagnosed in the elderly population, it is important to understand the effects of this state on outcomes, particularly surgical outcomes. In elderly people, malnutrition is an independent predictor of mortality in all settings – the community, nursing home, hospital, or recently discharged from the hospital [4]. A study of malnutrition and risk of complications was performed in patients presenting to University Hospital Zurich's Department of Surgery for elective GI surgery. This group of 200 patients was screened for malnutrition preoperatively within 24 h of admission with three assessment tools (including NRS), then followed longitudinally, monitoring for complications. Complications were graded from 1 to 5, with grade 1 complications as the

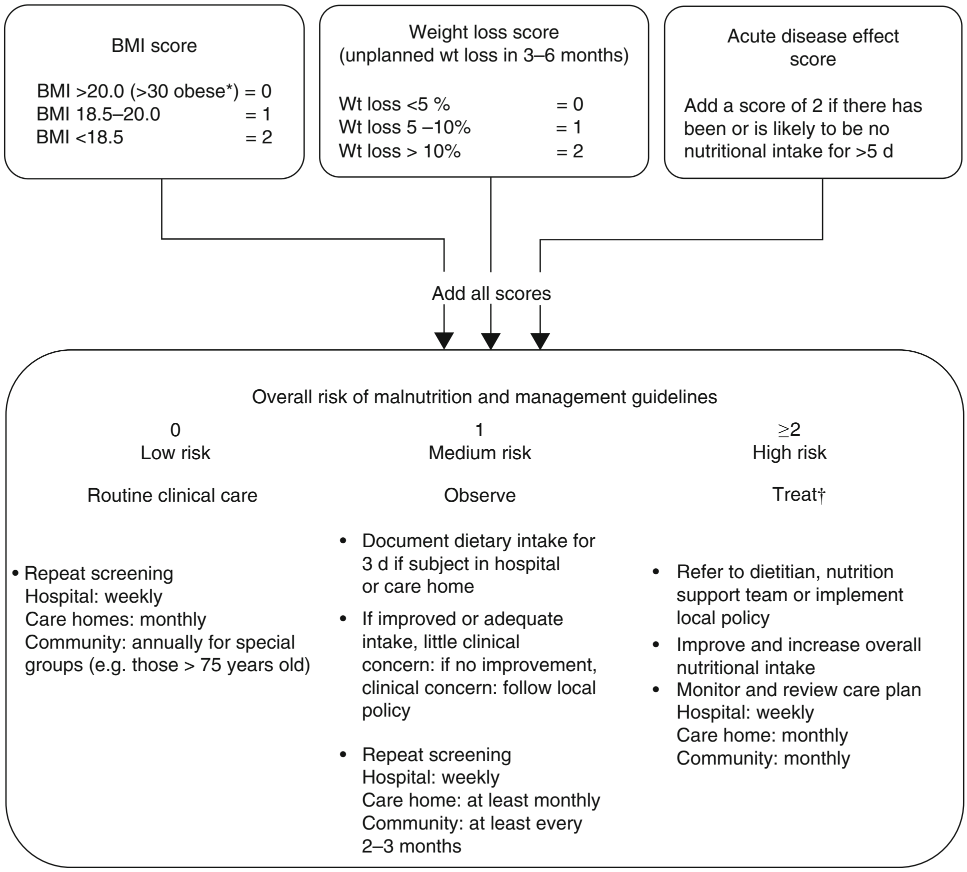

Fig. 2 Malnutrition universal screening tool [88] (Reprinted from British Journal of Nutrition, Volume 92 (5), Stratton RJ, et al. *Malnutrition in hospital outpatients and inpatients: prevalence, concurrent validity and ease of use of the 'malnutrition universal screening tool' (MUST) for adults,* Page 800, Copyright 2004, with permission from Cambridge University Press. The 'Malnutrition Universal Screening Tool' is reproduced here with the kind permission of BAPEN (British Association for Parenteral and Enteral Nutrition). For further information on MUST, see www.bapen.org.uk)

most minor and grade 5 resulting in death of the patient. This study found a correlation between nutritional risk and postoperative complications. In fact, every patient found to be at high risk of malnutrition as defined by the NRS developed a postoperative complication. The complication rate was 64% in patients at nutritional risk, while it was only 20% in patients without nutritional risk. Those patients at risk of malnutrition also had more severe complications, with 45% of patients at nutritional risk developing grade 3–5 complications compared to 7% of patients not at nutritional risk developing the same severity complications [9]. Similarly, a prospective cohort study conducted in 26 hospital departments (including geriatrics) in 12 countries used the NRS-2002 to assess the relationship between nutritional risk and outcomes. In over 5,000 patients studied, patients determined to be at risk of malnutrition had more complications, higher mortality, and increased length of stay compared to patients identified as not at risk [6, 91].

These outcomes were similarly reported in geriatric patients at risk of malnutrition. Data from the University of Alabama at Birmingham's Study of Aging were also used to assess the association between malnutrition and mortality. In this study, 978 elderly patients over age 65 were followed longitudinally over 8.5 years. Patients found to be at high nutritional risk were more

Table 1 Initial screening

		Yes	No
1	Is BMI <20.5?		
2	Has the patient lost weight within the last 3 months?		
3	Has the patient had a reduced dietary intake in the last week?		
4	Is the patient severely ill? (e.g. in intensive therapy)		

Yes: If the answer is 'Yes' to any question, the screening in Table 2 is performed.
No: If the answer is 'No' to all questions, the patient is re-screened at weekly intervals. If the patient e.g. is scheduled for a major operation, a preventive nutritional care plan is considered to avoid the associated risk status.

Table 2 Final screening

Impaired nutritional status		Severity of disease (≈ increase in requirements)	
Absent Score 0	Normal nutritional status	Absent Score 0	Normal nutritional requirements
Mild Score 1	Wt loss > 5% in 3 months or Food intake below 50–75% of normal requirement in preceding week	Mild Score 1	Hip fracture* Chronic patients, in particular with acute complications: cirrhosis*, **COPD***. *Chronic hemodialysis, diabetes, oncology*
Moderate Score 2	Wt loss > 5% in 2 mths or BMI 18.5-20.5 + impaired general condition or Food intake 25–60% of normal requirement in preceding week	Moderate Score 2	Major abdominal surgery* Stroke* *Severe pneumonia, hematologic malignancy*
Severe Score 3	Wt loss > 5% in 1 mth (>15% in 3 mths) or BMI <18.5 + impaired general condition or Food intake 0-25% of normal requirement in preceding week in preceding week.	Severe Score 3	Head injury* Bone marrow transplantation* *Intensive care patients (APACHE>10).*
Score:	+	**Score:**	**= Total score**
Age	if ≥ 70 years: add 1 to total score above	**= age-adjusted total score**	

Score ≥3: the patient is nutritionally at-risk and a nutritional care plan is initiated
Score <3: weekly rescreening of the patient. If the patient e.g. is scheduled for a major operation, a preventive nutritional care plan is considered to avoid the associated risk status.

NRS-2002 is based on an interpre-tation of available randomized clinical trials. *indicates that a trial directly supports the categorization of patients with that diagnosis. Diagnoses shown in *italics* are based on the prototypes given below.
Nutritional risk is defined by the present **nutritional status** and risk of impairment of present status, due to **increased requirements** caused by stress metabolism of the clinical condition.

A nutritional care plan is indicated in all patients who are

(1) severely undernourished (score = 3), or (2) severely ill (score = 3), or (3) moderately undernourished + mildly ill (score 2 + 1), or (4) mildly undernourished + moderately ill (score 1 + 2).

Prototypes for severity of disease
Score = 1: a patient with chronic disease, admitted to hospital due to complications. The patient is weak but out of bed regularly. Protein requirement is increased, but can be covered by oral diet or supplements in most cases.
Score = 2: a patient confined to bed due to illness, e.g. following major abdominal surgery. Protein requirement is substantially increased, but can be covered, although artificial feeding is required in many cases.
Score = 3: a patient in intensive care with assisted ventilation etc. Protein requirement is increased and cannot be covered even by artificial feeding. Protein breakdown and nitrogen loss can be significantly attenuated.

Fig. 3 NRS-2002 score table [90] (Reprinted from Clinical Nutrition Volume 22(4), Kondrop J, et al., *ESPEN Guidelines for Nutrition Screening 2002*, Page 420, Copyright 2003, with permission from Elsevier http://www.sciencedirect.com/science/journal/02615614)

likely to have been hospitalized at each 6 month interval [92]. Another study reviewed geriatric admissions retrospectively over the course of 18 months in Australia. Using the MNA within 72 h of admission, 53.1% of the study population was identified as at risk of malnutrition and 17.3% was malnourished. These patients were less likely to be discharged home and 46% of malnourished patients had a poor outcome, such as admission to a higher level of care or death. They also had a longer length of stay and comparatively higher risk of mortality within the next 18 months. It is estimated that the cost of treating these malnourished or at risk patients is 20% higher than patients with a similar diagnosis but without nutritional risk [93]. Likewise, in another study, 150 elderly patients were recruited and screened with the MUST assessment. Of that group, 58% were identified as at risk for malnutrition and had higher rates of in-hospital and post-discharge mortality and longer hospital stays than low risk patients [94]. The association between clinical outcomes and risk of malnutrition is depicted in Fig. 4.

Considering surgical patients, those with malnutrition have a higher likelihood of developing complications after major surgery [95, 96]. In particular, wound complications such as dehiscence and anastomotic leak, and infectious complications such as surgical site infections, are associated with poor nutrition [97]. Malnutrition also influences overall functional status throughout the perioperative period. To demonstrate the impact of malnutrition on long-term functional status postoperatively, a German group followed 97 elderly patients at a large urban hospital with hip fractures. Patients had been evaluated with the MNA prior to hip fracture and were observed during their hospitalization and for 6 months after discharge. In the patients identified as malnourished or at risk for malnutrition, functional status was worse at all stages of care – prefracture, while inpatient, and at 6 months after discharge [98].

The American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) prioritizes appropriate preoperative assessment of the geriatric surgical patient. In their guidelines released in conjunction with the American Geriatrics Society, the group recommends using a screening tool preoperatively to identify patients at *severe nutritional risk (SNR)* [97]. This tool is comprised of three criteria: BMI <18.5 kg/m^2, serum albumin <3.0 g/dL without renal or hepatic dysfunction, and unintentional weight loss >10–15% in the preceding year and is adapted from criteria set forth by ESPEN. Patients are considered at severe nutritional risk if any of the three criteria are met, and further nutritional assessment is recommended [97]. When utilizing this tool preoperatively in geriatric patients, SNR is associated with poor postoperative outcomes. A study of elderly patients undergoing pancreaticoduodenectomy for benign disease at one institution were screened

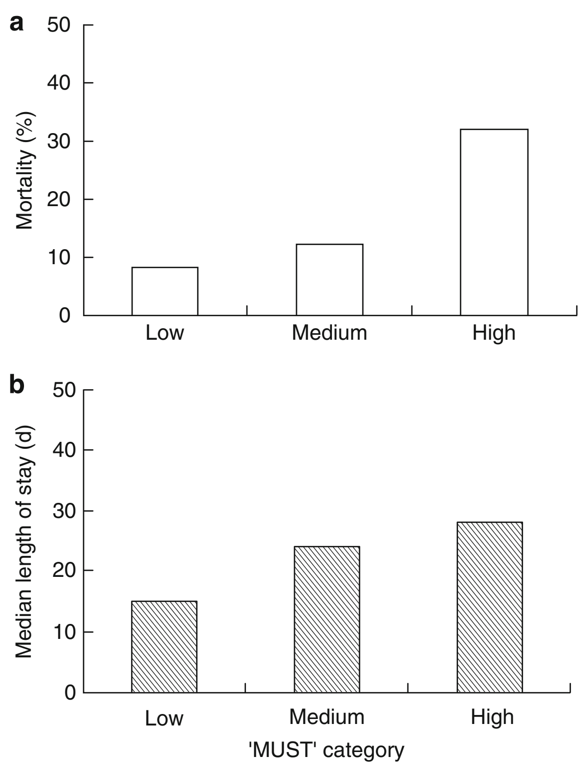

Fig. 4 Outcomes depicted by malnutrition risk, as identified with MUST: (**a**) in-hospital mortality, (**b**) length of hospital stay [94] (Reprinted from British Journal of Nutrition, Volume 95(2), Stratton RJ, et al. *'Malnutrition Universal Screening Tool' predicts mortality and length of hospital stay in acutely ill elderly*, Page 328, Copyright 2006, with permission from Cambridge University Press)

preoperatively for SNR. Those patients identified had a 5-year survival rate of 64.8% compared to 92.5% in patients of the age without SNR [99].

Nutrition Optimization

Energy Requirements in the Elderly

After the diagnosis of malnutrition or nutritional risk has been made in an elderly patient, the next concern that arises is how to address this state. Individualized nutrient balance can be estimated by directly determining nutrient intake compared to calculated energy expenditure/nutrient losses [100]. Alternatively, protein and energy requirements can be estimated for this patient group. At baseline, the recommended energy intake for healthy adults is 25 kcal/kg/day and the recommended intake of protein in adults is 0.8 g/kg/day [17]. This recommendation for protein nutrition was determined by the New Mexico Aging Process Study, a longitudinal study of nutrition in healthy elderly patients that was performed from 1979 to 2003 [101]. Data from 1980 to 1990 of this study shows that women with protein intake greater than 0.8–1.2 g/kg of body weight had fewer health problems over the 10-year study period than women consuming <0.8 g/kg. Similarly, those patients who died or dropped out of the study due to illness had decreased energy intake [102]. This information suggests that protein supplementation can improve outcomes.

Both energy and protein requirements are increased during periods of stress, such as hospitalization or surgical intervention. In order to prevent loss of lean muscle mass, protein intake must account for the increased breakdown in periods of stress and also in the setting of chronic medical conditions that result in protein loss, such as end-stage renal disease. Patients undergoing continuous renal replacement therapy (CCRT) are recommended 2.5 times the typical amount of protein [17]. Similarly, in the severely ill elderly patient, the recommended requirement of protein is at least 1.0–1.2 g protein/kg/day and 20–30 kcal/kg/day of non-protein energy [103]. During acute hospitalization, though, it is difficult to balance energy intake with basal energy expenditure (BEE). In acutely hospitalized elderly men and women (over age 80), the estimated energy expenditure in most patients is higher than energy intake. The resulting negative energy balance leads to a measurable decline in mid-arm muscle circumference during the hospital course [104]. With elderly patients shown to be at risk of undernutrition during hospitalization, some studies even suggest a protein intake of 1.5 g/kg/day in elderly malnourished patients in an attempt to overcome protein losses and to replenish lean body mass [103, 105]. However, in a prospective cohort study, 21% of the included elderly patients were shown to have an average intake of less than 50% of their estimated maintenance energy requirements while hospitalized. These patients were found to have a higher rate of both in-hospital and 90-day mortality [106].

Perioperative Nutrition Management

Early initiation of nutritional intervention is extremely important in elderly patients because it is much more difficult to restore lost muscle mass. Body cell mass is restored at a much slower rate in the elderly as compared to younger patients [107]. When determining etiology for this undernutrition, one common factor was frequent *nil per os* (NPO, nothing by mouth) orders and lack of utilization of oral supplementation, enteral, and parenteral nutrition [106]. Surgery itself is a traumatic event with a significant risk of complications. Even without adverse outcomes, deconditioning and altered muscle mass related to immobility during hopsitalization lead to reduced functional capacity extending for weeks beyond actual discharge. Elderly patients, with their reduced lean muscle mass, are particularly at risk of these consequences [105].

Sometimes, even when patients are identified as being malnourished or at risk of malnourishment, appropriate nutritional therapy is not initiated preoperatively. This phenomena is illustrated by a multicenter Belgian study in which 66% of the patients over 70 years were found to be malnourished but none of those patients had been referred to a dietician or started on supplementation [6]. With evidence of missed opportunities for nutritional intervention, a new focus has been placed on improving nutrition in the perioperative period.

Oral supplementation

As illustrated in the study by Sullivan [106], hospitalization itself increases the risk of malnutrition, as patients are often placed on restrictive diets based on their chronic diseases (such as excluding sweets for diabetics or limiting calories for “heart healthy” diets), or made NPO for tests and interventions [17]. One way to improve perioperative nutrition is to avoid prolonged preoperative fasting. Other than in the setting of emergency surgery or delayed gastric emptying, patients receiving clear liquids within 2–3 h of surgery are at no greater risk of aspiration than those who have been fasting for 12 h. In fact, patients who are loaded with carbohydrate supplementation the night before and 2 h before surgery had lower risk of postoperative insulin resistance and improved muscle mass [108]. Similarly, there is no benefit to routine nasogastric tube decompression or delayed postoperative oral intake. Early oral and enteral nutrition does decrease infectious complications, hospital length of stay, and ICU length of stay [108].

Another simple intervention to encourage oral intake is to allow patients more freedom in their diet to choose foods that appeal to them (like salty foods and sweets) and opt for monitoring chronic conditions closely as opposed to strictly restricting intake of certain foods [17].

In addition to encouragement of ad lib oral intake, oral nutritional supplements (ONS) can also be utilized preoperatively. The question of the value of oral supplementation in improving nutrition and functional status has been evaluated with mixed results. One study showed that, while elderly patients in the community did have increased weight and decreased falls, functional status remained unaffected [109]. In orthopedics in particular, interventions to optimize oral nutrition have been shown in multiple studies to result in improved outcomes. In a study of elderly patients with femoral neck fractures, once daily oral supplementation (250 ml, 20 g protein, 254 kcal) given for 30 days in the intervention group led to decreased mortality and complication rates both in-hospital and at 6 months after the fracture [110].

The results of the study of orthopedic patients contrast with the outcome of another study in which elderly patients with malnutrition were randomized and the intervention group given 8 weeks of supplementation starting at hospital discharge. For the follow-up period of 24 weeks, weight, BMI, anthropometrics, handgrip strength, quality of life, and need for health care professional or social services were documented. The patients receiving supplementation were shown to have a significant improvement nutrition status at 24 weeks compared to their baseline that was not seen in the control group; however the two groups were similar thereafter. Functional capacity as measured by handgrip strength improved in the supplemented group and was significantly improved over the control group until week 8, but then declined again [111]. In this study, there was no clear-cut benefit seen for oral supplemental nutrition after discharge. This study leads to the question of whether or not discharge is too late to initiate nutritional interventions in a population and whether resources should be focused on preventative interventions [111].

To better demonstrate the effects, Milne and colleagues performed a meta-analysis that included 62 trials and 10,187 randomized patients. They found that supplementation does result in small weight gain consistently in most studies. While there was no evidence to support that supplementation improved functional status or decreased mortality in all patients, it did show a beneficial effect on mortality for patients identified as undernourished. Additionally, this review found more evidence to support that supplementation reduces complications, though further investigation is needed in the future, as the studies were deemed to be poor quality [112]. Despite the reported success of some individual studies, based on meta-analysis, outpatient counseling and oral nutritional supplementation of elderly malnourished patients in the community did not show consistent results [113].

In addition to oral supplementation of protein and energy, vitamin supplementation is also necessary in elderly patients. Vitamin D is commonly deficient in this age group and can lead to depression, cognitive changes, and increased fracture risk. Patients over 70 years should receive at least 800–1,000 IU of vitamin D daily. Hospitalized or institutionalized patients have an increased risk of developing vitamin D deficiency due to the lack of sun exposure. Vitamin B12 deficiency is also common and can be seen in patients with prior gastric surgeries or pernicious anemia as well as other neurologic or psychologic conditions. Normally, vitamin B12 and folate are obtained adequately by diet alone, but in some patients oral supplementation may be required. B12 can be supplemented orally at a dose of 1,000 mg/day, but deficiency does not tend to become apparent until after several years of decreased absorption [17, 100]. Calcium can also be depleted in geriatric patients. The recommended dietary intake in this patient population is 1,200 or 1,500 mg/dL to reduce the risk of osteoporosis and impaired functional capacity [108]. Doubling of the daily multivitamin dose can be safely done while nutritional support is ongoing and until normal nutritional status is achieved [100].

Enteral Nutrition

Enteral nutrition (EN) is indicated regardless of risk of malnutrition, and is recommended to start immediately if the patient is not expected to eat for more than 7 days after surgery or if they cannot maintain more than 60% of the recommended oral intake for 10 days or more [108, 114, 115].

Preoperative (EN) has been shown to reduce postoperative complications in cancer patients receiving 3,500–4,000 cal/day (or 150% of calculated basal energy expenditure) when compared to oral diet alone [108]. Both ESPEN and ASPEN guidelines emphasize the importance of preoperative nutritional optimization by recommending that operative interventions be postponed for enteral nutrition in patients with elevated nutritional risk [108]. ESPEN defines severe nutritional risk as weight loss of 10–15% within 6 months, BMI of less than 18.5 kg/m^2, SGA grade C or albumin less than 3.0 g/L in the absense of renal or hepatic dysfunction [115].

Supplementary EN in addition to oral nutrition has not been shown to be particularly beneficial outside of hip fracture patients and are poorly tolerated in the elderly [114]. Patients receiving supplemental nocturnal tube feeds with hip fractures did show improved outcomes. Patients were divided into three groups based on anthropometric measurements. Patients from the “thin” and “very thin” groups were divided into a control and intervention group. Overnight supplementary enteral feeds were given via nasogastric tube (28 g protein,1,000 kcal) to the intervention group in addition to ad lib oral diet during the day. The group receiving supplmental feeds had improved anthropometric measurements and plasma protein levels as well as shortened hospital length of stay and rehabilitation time [116].

There is also less evidence for the benefit of post-operative EN. Gastrointestinal cancer patients receiving preoperative and perioperative enteral feeds only had the same outcomes as patients whose feeds were continued through the postoperative period (though there was an improvement in both groups when compared to patients receiving no enteral nutrition). Oral supplementation has not been shown to improve clinical outcomes or functional capacity [108].

When comparing enteral and parenteral nutrition, EN is preferred unless contraindicated, as in intestinal obstruction, ileus, severe shock, or intestinal ischemia [115]. In a review of 35 clinical trials performed by ESPEN, there is a significant benefit in EN when compared to PN in terms of length of hospital stay, infectious complications, and cost [108]. Tube feeds should not, however, be initiated without careful consideration. For instance, tube feeds should not be given over oral nutrition for ease of care, as elderly patients can typically maintain their nutritional needs with oral nutrition and assisted feeding or oral supplements. Additionally, the decision to start tube feeding in elderly patients requires reflection of the ethics surrounding this intervention, such as considering whether enteral will change outcomes or aid recovery or if the intervention is appropriate in maintaining the patient's expressed wishes and goals of care [114].

In the elderly, enteral feedings via percutaneous endoscopic gastrostomy (PEG) are tolerated much better than feeds via nasogastric (NG) tube. Patients with neurological dysphagia were able to tolerate 93–100% of PEG feeds as opposed to only 55–70% of NG tube feeds [114]. ESPEN does recommend placement of a jejunostomy feeding tube if the patient is already undergoing major abdominal surgery [115]. Regardless of access type, longer-term supplementation beyond 4 weeks is recommended through definitive non-oral access. In terms of tube feed formula, feeds with immune-modulating substrates like argine are recommended for patients undergoing elective surgery for head and neck cancer and major abdominal surgery for cancer. Multiple meta-analyses have shown decreased postoperative complications rates and hospital length of stay in trauma and general surgical patients receiving immune-modulating tube feed formulas [114].

Parenteral Nutrition

Age alone is not a contraindication to parenteral nutrition (PN). In the elderly population, routine postoperative PN is generally not recommended in general surgical patients as they had a 10% greater incidence of complications [108]. A potential complicating factor of using PN in elderly patients is higher rates of insulin resistance leading to hyperglycemia and cardiac and renal dysfunction and may require that lipid content be increased. PN formulas should be adjusted to use higher lipid content [103]. Although there is a higher risk of vascular erosion from central catheters in the elderly age group, parenteral nutrition is still recommended when oral or enteral nutrition is impossible or without sufficient nutrition for >7–10 days [103, 115]. In a review of 13 prospective randomized control trials, moderate to severely malnourished gastrointestinal cancer patients fed for 7–10 days with PN had a pooled reduction in postoperative complications compared to oral nutrition by 10%; however, only one of these studies of preoperative PN showed a statistically significant decrease in mortality [108].

In the geriatric population in particular, it is important to consider the ethical aspects of PN, treating it as an intervention and not routine care. Probability of recovery and goals of care should be weighted in the decision to initiate PN [103].

Refeeding Syndrome

During the initiation of any nutrition regimen in an undernourished elderly patient, attention should be paid to the risk of refeeding syndrome. In this syndrome, phosphate can drop precipitously with introducing glucose rapidly electrolyte shifts also result in lower serum levels of potassium and magnesium. Thiamine levels can similarly drop. All of these changes occurring with rapid refeeding can invoke neurologic symptoms [103]. In patients with delirium at baseline, these symptoms can be significant. It is important to note, however, that most cases of full-blown refeeding syndrome have been reported decades ago and occurred in the setting of *severely* malnourished patients receiving very high caloric loads (up to 75 kcal/kg/day). In modern practice, it is extremely rare to encounter the refeeding syndrome. Isolated refeeding hypophosphatemia is very common, but the clinical significance of this laboratory finding remains to be determined [117]. Electrolyte levels, particularly potassium, magnesium, and phosphate, should be closely monitored (daily or more frequently as necessary) in the first few days of starting nutrition therapy and low levels should be aggressively treated with intravenous replacement. Withholding nutrition in the setting of mild hypokalemia, hypomagnesemia, and hypophosphatemia in the absence of clinical symptoms is not recommended.

"Prehabilitation"

Widening the scope of intervention beyond the immediate preoperative period, the concept of "prehabilitation" emerged from the desire to preemptively counteract the acute stress and negative effects of surgery by improving functional capacity preoperatively. Effective prehabilitation includes both nutrition and exercise interventions and begins preoperatively, continuing through the perioperative period, and continues beyond the immediate postoperative period. One proposed prehabilitation process was tested in colorectal cancer patients prior to colon resection. Patients participating in moderate-intensity exercise and anxiety reduction strategies in addition to the "enhanced recovery after surgery" (ERAS) protocol were more likely to return to their preoperative baseline by 8 weeks after surgery ([105]. Using this same model, the goal of nutritional interventions should be to optimize patients for the stress of surgery as opposed to reacting to and replacing protein loss. Patients at risk of malnutrition can be identified preoperatively using the various assessment tools previously described and interventions initiated [115]. Tools like the MNA not only identify patients with malnutrition but also help target preoperative interventions by reviewing where points are lost in the assessment – simple interventions like supervision during eating for institutionalized patients with functional impairments can improve oral nutrition intake [84]. Similarly, interventions that allow patients to make their own food choices can improve oral nutritional intake. One study changed the food service in a long-term care facility from preplated to cafeteria-like arrangement where patients were able to choose the type of food and amount they'd prefer to eat. This intervention resulted in increased energy intake among residents of the facility at risk of malnutrition [118].

Another example of prehabilitation is found in a multidisciplinary program utilized for elderly orthopedic patients with hip fractures. Patients received either standard nutrition or care from an integrated team that initiated nutritional support during the initial hospitalization and coordinated the transition of care to the outpatient setting for further maintenance. Using multiple measures of nutrition, there was a significant difference in energy intake between the two groups in the first week, with the intervention group taking in more daily energy and more mean protein. When nutrition was reassessed at 3 months, fewer patients in the intervention group were identified as malnourished or at risk of malnutrition [119].

Comprehensive Geriatric Assessment

The Comprehensive Geriatric Assessment (CGA) falls under the umbrella of prehabilitation. Identifying factors that contribute to poor outcomes in the elderly patient population can allow for preoperative interventions to be made. In the traditional model of preoperative assessment, focus is placed on individual systems or subjective assessments. Alternatively, the CGA provides a multidisciplinary approach that offers a complete evaluation of the elderly patient and cohesive plan of care for preoperative optimization that focuses on deficient areas [84]. The original concept of the CGA comprised four major domains – physical health, functional status, psychological health, and socioenvironmental factors [120]. These domains have been further expanded to include a number additional areas that include activities of daily living (ADL), instrumental activities of daily living (IADL), cognition, depression, fall risk, nutrition, polypharmacy, and social support. For purposes of the CGA, the MNA is typically used to evaluate nutrition [84]. CGA has been utilized with success across a variety of clinical services. One study chose to focus specifically on elderly preoperative patients and the usefulness of CGA in predicting outcomes. Patients with impairments in more than five of eight areas were found to be more likely to have an adverse outcome with an event rate of 37.8%. They were also more likely to die while in-hospital, have prolonged lengths of stay, or need to be institutionalized upon discharge [120].

Conclusion

The elderly population in the USA is expected to grow significantly over the next several decades. This group is especially at risk for malnutrition. The anorexia of aging and the physiological, psychological, and socioeconomic factors that contribute to a loss of lean muscle mass have already made undernutrition a prevalent condition in both the community and across all healthcare settings. Malnutrition is a predictor of poor clinical outcomes and contributes significantly to morbidity and mortality. Prompt recognition is therefore required in order to initiate timely interventions. Traditional serum testing, though straight forward, is not accurate in identifying malnourished patients or in monitoring the efficacy of interventions. Multimodal assessments that account for changes in functional capacity and severity of illness are more appropriate. It is now evident that reversal of malnutrition in the elderly is particularly difficult after significant lean body mass has been lost. Current treatment goals have shifted to emphasize the prevention of malnutrition as opposed to reaction to the state, promoting preoperative optimization and prompting initiation of enteral nutrition postoperatively. Looking forward, the future of managing geriatric patients in the surgical setting will continue to build on this foundation of prevention and include a multidisciplinary team and a holistic approach to overall care, including nutrition.

Abstract

Older adults take more medications than any other age group. Evidence suggests polypharmacy increases throughout the last year of life of older adults, fueled not only by symptomatic medications but also by long-term preventive treatments of questionable benefit ([1] too many drugs 2017). The greater the number of medications a patient receives, the greater the likelihood of experiencing a medication-related problem. In the elderly, this can have disastrous repercussions. Surgeons are trained to individually evaluate the risks versus benefits of any given procedure. Equally important, surgeons should evaluate the risks versus benefits of medications they will commonly utilize. As healthcare moves rapidly toward a value-based model of care, understanding medication risks in the elderly becomes every team members' responsibility. Central to a patient's care coordination is the safe transition of their medications between care settings. Disparate data systems, lack of accountability, and interoperable electronic medical records contribute to medication *wreckonciliation*. While the correct term is medication reconciliation, the use of "wreckonciliation" is meant to underscore the difficulties in adequately determining a patient's true medication list. This chapter will focus on common medication-related problems (MRPs) that can result in postoperative complications.

Examples of age-related physiologic changes affecting drug pharmacokinetics

Physiologic change	Direction of change	Drugs affected by this change	Result of change
Serum albumin	↓	Phenytoin, naproxen, valproate, and warfarin	Increased free (active) fraction of drug; increased effects
α_1-Acid glycoprotein	↑	Propranolol, antidepressants, lidocaine, methadone, and quinidine	Decreased free (active) fraction of drug; decreased effects
Body fat	↑	Fat-soluble drugs (e.g., benzodiazepines)	Increased volume of distribution; increased half-life and potential for accumulation
Lean muscle mass	↓	Digoxin	Decreased volume of distribution; increased concentration; lower loading dose is needed
Body water	↓	Water-soluble drugs (e.g., lithium)	Decreased volume of distribution; increased concentration and effects
Hepatic blood flow	↓	High-hepatic extraction ratio drugs (e.g., morphine, meperidine, lidocaine, and isosorbide)	Decreased first-pass metabolism; increased effects
Hepatic metabolism (phase 1: reduction, oxidation, hydroxylation, and demethylation)	↓	Diazepam, alprazolam, triazolam, theophylline, quinidine, propranolol, phenytoin, and imipramine	Decreased metabolism; increased half-life and concentration
Renal function	↓	Aminoglycosides, digoxin, ciprofloxacin, and allopurinol	Decreased clearance; increased effects, toxicity, or both

(continued)

Biology of Aging

With advancing age, organ systems decline at varying rates and independent of each other. An individual's organ reserve capacity helps conceptualize the ability to rebound from illness, injury, or insults. In the absence of disease, an elderly patient's organ system declines may not impair daily function [2, 3]. However, in the setting of illness or advance disease, what might otherwise be considered insignificant in a younger patient becomes a major threat to organ function in the elderly. The ability to withstand even a minor insult can be decreased, and recovery may be delayed. Appreciating medication-related factors that affect an organ system's reserve capacity is an imperfect science. The principles of pharmacokinetics help frame an understanding of how physiologic changes with aging affect medications [4]. Understanding pharmacokinetic changes associated with aging can help surgeons better anticipate MRPs. Pharmacokinetics is defined as the delivery of a drug to its site of action. This includes drug absorption, distribution, metabolism, and excretion. These changes are reviewed here in general terms to provide a background for the discussion of specific drug classes [5] (Table 1).

Table 1 Pharmacokinetic changes with aging

Absorption	Extent not affected
	Rate is reduced or unaltered
	Increased gastric pH
	Unchanged passive diffusion
	Decreased active transport
	Decreased first-pass effect
	Decreased GI blood flow with certain diseases (e.g., HF)
Distribution	Decreased total body water
	Decreased lean body mass
	Decreased serum albumin
	Increased body fat
	Increased or decreased free fraction of highly plasma protein-bound drugs
	Higher concentration of water-soluble drugs
Metabolism	Decreased liver blood flow
	Decreased liver size
	Decreased enzymatic activity
	Variable decreased and increased $t_{1/2}$ for phase 1 oxidation drugs
	Decreased clearance and increased $t_{1/2}$ of drugs with high extraction ratio
Excretion	Decreased GFR
	Decreased renal blood flow
	Decreased tubular function
	Decreased clearance and increased $t_{1/2}$ for drugs eliminated primarily by the kidneys

GI Gastrointestinal, *GFR* Glomerular filtration rate, *HF* Heart failure

Drug Absorption

The amount of oral drug absorption (bioavailability) is dependent on many factors not related to age, including the presence of food, drug ionization, and dosage formulation [6]. Absorption can occur anywhere along the gastrointestinal tract. Oral drug absorption can also include buccal absorption of medications specially designed to disintegrate in patients unable to swallow. Some formulations are designed to release medication in response to changes in intestinal pH or osmolality. In general, older adults tend to have a slight increase in gastric pH. This increase is unlikely to result in altered drug absorption [6, 7].

When the stomach pH is significantly altered, it is possible to impact drug absorption. For example, proton pump inhibitors (PPIs) can reduce the antifungal activity of ketoconazole and itraconazole. It is now recognized that PPIs can reduce the activity of mycophenolate mofetil [117]. Proton pump inhibitors can also affect drug absorption by interacting with adenosine triphosphate-dependent P-glycoprotein (e.g., inhibiting digoxin efflux).

Older adults tend to experience two alterations that can lead to clinically significant changes in the rate of oral drug absorption. First, changes in gastrointestinal blood flow may reduce portal circulation and delay gastric absorption. For example, these changes can be seen in some heart failure or cirrhosis patients with substantial hepatic congestion. And second, decreased gastric emptying, resulting from conditions such as Parkinson's disease or diabetes, may also delay the rate of absorption, but not the extent of drug absorbed [7, 8]. Unless therapeutic failure is observed, no changes in dosing are required to overcome delays in gastric absorption.

Oral bioavailability can be substantially altered in the presence of food, resulting in drug-food interactions. For example, patients who receive calcium supplementation while taking quinolones have a 50% reduction in the absorption of the quinolone due to chelation with calcium. The authors recommend discontinuing most oral calcium supplementation during the postoperative period to prevent potential chelation interactions with antibiotics. Bisphosphonate bioavailability is exceedingly low when taken with anything other than water.

Levodopa absorption is substantially decreased when consumed with a high-protein meal [9]. In addition, certain foods can significantly alter drug levels and actions. Patients on warfarin who alter their intake of vitamin K-containing foods risk changes in their international normalized ratio (INR). Consumption of grapefruit irreversibly inhibits intestinal CYP450 3A4 isoenzyme activity. This results in presystemic decreases in metabolism leading to increases in therapeutic concentrations that can last for up to 72 h. In summary, the rate of absorption may be delayed with aging, but the overall extent of absorption is unlikely to be altered.

Limited information is available about topical drug absorption changes as a result of aging. Topical administration is a way to minimize first-pass metabolism, provide more continuous therapeutic drug concentrations, and potentially improve medication adherence. For example, postoperative pain control may include the use of fentanyl or lidocaine patches. In general, decreases in skin thickness and integrity may alter drug absorption and subsequently peak concentrations. When comparing healthy young volunteers with healthy elderly volunteers receiving transdermal fentanyl patches, the older patients demonstrated higher systemic concentrations of fentanyl and correspondingly greater adverse effects resulting in drug discontinuation [10]. An additional concern when administering medications in patch form is the ability to safely remove the patch without damaging the underlying skin. Finally, all patches utilize adhesives that can cause localized skin irritation. The use of presurgical skin disinfectants and body preparations may contribute to heightened skin sensitivity to patch adhesives.

Distribution

The distribution of drugs is altered by the aging process. Total body and intracellular water decrease, as does muscle mass, whereas body fat increases [2, 3]. These changes have important implications for drug distribution that can affect both the half-life of a compound and the concentration of the drug in various tissues (e.g., lipophilic versus hydrophilic saturation). The volume of distribution of water-soluble drugs is likely decreased because of the decreased total body and intracellular water described above. This results in higher concentrations of hydrophilic substances as they have a smaller volume in which to distribute. Similarly, the volume of distribution for lipid-soluble drugs tends to be higher because of increased fat stores, resulting in prolonged and less predictable half-lives. Changes in protein binding can also alter receptor site activity. When medications exhibit substantial protein binding (generally >90%), the potential for protein-binding interactions due to changes in serum albumin becomes more pronounced. For example, in the case of low albumin levels, the relative proportion of free or unbound drug may be increased, enhancing the pharmacologic and toxic properties of the drug. To further illustrate this point, consider the highly protein-bound drug phenytoin. By convention, when ordering phenytoin levels what is typically reported is the total drug level [11]. In the setting of low albumin, however, the free drug concentration may be high, resulting in toxicity despite a total level in the therapeutic range. In contrast, the carrier protein α-acid glycoprotein may increase with age, as it does with illness, so drugs that bind to this protein may have a lower proportion unbound; an example is propranolol [12]. Another caveat with drug levels is that normal ranges are often established on young persons; therefore targeting lower therapeutic drug levels in older adults may minimize the risk of toxicity. The important exception to this approach is for antibiotic therapy where specific minimum inhibitory concentrations (MIC) are specified. Finally, some evidence suggests that conformational changes in the ability of albumin to bind drugs increase as one ages [11]. Therefore, despite a normal albumin level, the affinity of albumin to bind to medications may be reduced.

Metabolism

First-pass metabolism, liver size, and blood flow tend to decrease with age by 20–30%. Drugs that depend on extensive first-pass metabolism, such as agents with a high-hepatic extraction ratio, may have higher therapeutic levels resulting from decreased hepatic metabolism [9, 13, 14]. Pertinent to a surgeon, it is estimated that morphine exhibits a 33% reduction in clearance in the elderly as a result of decreased first-pass metabolism [14]. Therefore, the effects of morphine may last longer in the elderly. However, this does not constitute a reason to avoid morphine in older patients. Drugs that have high-hepatic extraction ratios also exhibit decreased metabolism and potentially increased therapeutic concentrations. Atorvastatin is a high-hepatic extraction ratio drug with increased serum concentration (40%) and area under the concentration curve (30%) [14]. Therefore, closer attention to liver function tests and potential dose reduction may be warranted. Similar findings occur with simvastatin and lovastatin.

Pharmacogenomics and the Cytochrome P450 Enzymes

The field of pharmacogenomics continues to develop rapidly. It is postulated that much of the variability in drug response can be explained through pharmacogenomic changes in drug metabolism. However, drug metabolism can also be affected by diet, smoking, alcohol intake, and medication adherence [4, 14, 15]. Polymorphisms in the drug-metabolizing enzymes influence drug safety and efficacy. Patients may have genetic polymorphisms that result in extensive or poor metabolism. Pharmacogenomics refers to the influence of genes in determining drug metabolism, safety, and efficacy. As most drugs are metabolized by the liver and involve one or more enzymatic pathways, the ability to prescreen a patient for potential genetic variants that affect drug response has clinical utility. Individualizing medication therapy based on a patient's specific metabolic genotype is available for selected medications. The ability for surgeons to easily interpret these results, the clinical utility of genomic findings, and the application to clinical practice all warrant careful consideration before ordering any pharmacogenomic study. The single greatest variable to drug response remains patient adherence.

Appreciating potential changes in drug metabolism with aging and the influence of genetic factors that alter metabolic functions is central to the field of pharmacogenomics. For example, genetic polymorphism and changes in hepatic blood flow can explain interpatient variability to medications commonly used in the surgical intensive care unit [15]. The use of codeine in patients deficient in cytochrome (CYP) 2D6 results in poor conversion of codeine to morphine (the active metabolite) [14, 15]. Therefore, switching to an equianalgesic dose of morphine based on the failed codeine regimen can result in drug toxicity. Patients who are extensive metabolizers may experience poor pain control from oxycodone. Additionally, the use of clopidogrel in CYP2C19 poor metabolizers results in decreased antiplatelet activity.

The influence of age on the CYP450 system is variable. While some drugs metabolized via pathways involving microsomal oxidation are slowed with aging and may have active metabolites, broader probes for hepatic microsomal activity have shown inconsistent results [14–17]. For example, early studies of diazepam and chlordiazepoxide in the elderly demonstrated longer and less predictable half-lives. However, both these drugs are highly lipophilic and therefore have a larger volume of distribution given the increase in adipose tissue common in aging. Changes in drug distribution are now thought to account more for the prolonged and erratic half-life than decreases in metabolism [18, 19]. Regardless, neither agent is recommended for elderly patients.

Metabolism via glucuronide conjugation is minimally changed with advancing age, and metabolites tend to be inactive [14, 15]. Thus, drugs metabolized through these pathways, including benzodiazepines such as lorazepam, oxazepam, and temazepam, have shorter, more predictable half-lives. Therefore if a benzodiazepine is needed, these will be shorter acting in elderly patients (Table 2) [8, 18, 19]. Drug inhibition of enzymatic pathways typically occurs at a faster rate than induction of the same pathways. The ability to induce hepatic enzymes to the same extent as in younger individuals is unclear. Some agents commonly associated with enzyme induction include phenytoin, carbamazepine, phenobarbital, and chronic alcohol use. An example of a potent inhibitor is valproic acid.

Table 2 Half-life of common benzodiazepines

Drug	Half-life in adults <65 years (h)	Half-life in adults ≥65 years (h)
Lorazepam	12.7	14.4
Alprazolam	11.7	15
Diazepam	M[a] 35.0–44.5	M 61.7–71.5
	F[b] 44.0–45.5	F 79.4–101
Chlordiazepoxide	10.1	18.2

[b]Female patients

Renal Elimination

The kidney is the main route of elimination for most drugs. On average, there are declines in glomerular filtration rate and renal blood flow with advancing age, although up to one-third of elderly persons have no substantial changes in renal function [20, 21]. Because of decreases in muscle mass and therefore creatinine production, serum creatinine levels may not accurately reflect renal function. Therefore, it is strongly recommended that creatinine clearance be calculated for every elderly patient. Even patients with seemingly normal serum creatinine levels may have a decreased creatinine clearance [22, 23]. Renal function can be represented in a variety of formats and is often calculated for clinicians in the EMR (e.g., eGFR, MDRD, Cockcroft and Gault) [24–26]. It is important to recognize that all the available methods have limitations [27, 28]. The most widely used method is the Cockcroft and Gault equation:

The Cockcroft and Gault formula (1973)

$CCr=\{((140-\text{age}) \times \text{weight})/(72\times SCr)\}\times 0.85$ (if female)

Abbreviations/ Units

CCr (creatinine clearance) = mL/minute

Age = years

Weight = kg

SCr (serum creatinine) = mg/dL

This equation is valid when serum creatinine is at steady state. It is the authors' approach to use the resulting creatinine clearance to determine a range of possible renal function by adding and subtracting five points to the calculation. Many medications have specific dosing guidance based on creatinine clearance. Therefore, knowing the range of a patient's creatinine clearance allows for more conservative dosing if necessary and compensates for patient variability in serum creatinine. When renal dose adjustments are necessary, surgeons should reduce the dosage or extend the dosing interval of primarily renally excreted drugs. This also applies to drugs with active metabolites that may have prolonged durations of action during renal insufficiency. For example, glyburide should not be used in patients with a creatinine clearance <50 mL/min because of reduced elimination of a renally active metabolite leading to greater hypoglycemia. The Veterans Health Administration (VHA) Pharmacy Benefits Management (PBM) Services, Medical Advisory Panel (MAP), and VA Center for Medication Safety (VA MedSAFE) issued a national bulletin advising providers to switch all patients with a calculated creatinine clearance of <50 mL/min to glipizide [29]. Glyburide is also included on the Beers Criteria for this very reason.

Medication-Related Problems in the Elderly

Polypharmacy, Potentially Inappropriate Medications, and the Surgeon

Surgeons are often in the difficult position of operating on an older patient with complex comorbidities and equally complex medication regimens. While in the surgeon's care, decisions must be made about discontinuing certain medications, placing others on hold, and when/who should restart any medications that were changed. While surgeons don't typically start chronic maintenance medications, they must coordinate and reconcile existing mediation regimens as patients transition their care to/from the surgeon to post-operative services. This is a critical period that results in significant medication errors.

Polypharmacy is more than the absolute number of medications a patient receives; importantly it includes any medication that is inappropriate. Polypharmacy is a significant problem for many older adults. Medications that are medically not necessary, including those not indicated, not effective, or constituting a therapeutic duplication, would be considered polypharmacy. Polypharmacy is common across care settings and increases in prevalence as patients transition from community settings to skilled nursing homes.

In a nationally representative probability sample of community-dwelling adults aged 57–84 years old, Qato et al. found that more than half of older adults used five or more prescription medications, over-the-counter medications, or dietary supplements [35]. Almost one-third of this study population used five or more prescription medications, and the prevalence of the use of five or more prescription medications increased steadily with age. Data from the Centers for Medicare and Medicaid Services (CMS) estimate that 58% of community-dwelling elderly are taking three or more different acute and chronic medications in a year. Additionally, polypharmacy has been shown to increase within the last year of life [1].

Medication reconciliation is foundational to ensuring safe and appropriate medication use and is the responsibility of every team member. A 2014 Medicare Payment Advisory Commission report to congress noted that Medicare Part D enrollees' medical problems may be "caused or exacerbated by their heavy use of medications (polypharmacy), and they are at increased risk of adverse drug events, drug-drug interactions, and use of inappropriate medications."

Potentially inappropriate medications (PIM) in the elderly are associated with poor quality of life, falls, physical disability, high healthcare use increased costs, increased risk for adverse drug events, delirium and mortality [30–32]. PIMs in the elderly can lead to increased hospitalization [152]. For example, older veterans taking more than five medications were almost four times as likely to be hospitalized from an ADE [15]. Common drug classes associated with ADEs include anticoagulants, NSAIDs, cardiovascular medications, diuretics, antibiotics, anticonvulsants, benzodiazepines, and hypoglycemic medications [13, 15, 16]. Use of specific PIMs such as sedative hypnotics and anticholinergics can result in falls, fracture, delirium, and hallucinations [153].

In a study of health outcomes, 40% of individuals 65 and older filled at least one PIM prescription and 13% filled two or more [154]. Drug-related problems occurred in 14.3% of this population who had at least one PIM, whereas only 4.7% of those with no PIMs had a drug-related problem.

Preoperative Medication Therapy Management

The increased emphasis on guideline-based medicine often results in patients receiving multiple agents for a condition in order to conform to "best practices." Patients with heart failure, hypertension, and diabetes can easily exceed six or more medications based on current clinical practice guidelines [36]. In this example, all six medications may be appropriate while still increasing the risk for potential ADEs.

Medication management in elderly patients is more complex than in younger patients, and each added medication increases the potential for interactions, adverse events, and therapeutic competition (i.e., when treatment for one condition may adversely affect a coexisting condition). For example, clinically significant drug interactions are more likely to occur when a patient takes five or more medications, and the likelihood for falls increases when an older adult takes four or more medications. Additionally, 75% of older adults have multiple chronic conditions, and within this population, one-fifth of older adults receive medications that may adversely affect coexisting conditions [37].

Lack of coordinated prescribing between primary care providers and specialists remains a critical issue, despite advances in interoperability of health information systems. Furthermore, patients may fill prescriptions from multiple pharmacies thereby circumventing the pharmacist's ability to screen for drug-drug interactions. Collectively, there is a loss of control over ensuring medication safety and appropriateness.

As healthcare payment reform models evolve from "volume to value," more episodes of care are bundled (i.e., comprehensive care for joint replacement and cardiac care), more risk is assumed by providers, and greater accountability is required in coordinating medications across care settings.

Medication Selection in Older Adults

The general approach to prescribing in older adults must also take into account the selection of medications. Beginning in 1991, geriatric experts have developed recommendations for potentially inappropriate medication use in older adults (defined as age 65 years and over) [118]. Originally published by Mark Beers, MD, MPH, the recommendations became known as the "Beers Criteria of Potentially Inappropriate Medication" and have been updated every 6–7 years, with the most recent update slated for 2019 [119]. These recommendations have been developed and adopted by the American Geriatrics Society and are intended to identify medications that should not be used or used with caution in older adults due to higher rates of adverse events than in younger populations, which compromises the risk-benefit ratio for these medications. The recommendations are intended for use by clinicians, however, and have also been widely adopted in research and as a quality measure for monitoring and comparing quality of prescribing.

The Beers Criteria are constructed in five different domains: the first identifies medications that should generally be avoided for all older adults; the second identifies medications that should be avoided in older adults with specific diseases; the third identifies medications that may be used, but with caution; the fourth identifies clinically relevant (non-antibiotic) drug interactions in older adults, and the fifth identifies medications (non-antibiotic) that should be avoided or reduced in those with renal insufficiency. The authors suggest clinicians become familiar with these recommendations and incorporate them into clinical practice, perhaps through electronic reminders or decision aids, to optimize patient care patterns and quality metrics.

The majority of research identifying potentially inappropriate prescribing utilizes the Beers Criteria as a gold standard for identifying inappropriate medications. However, a European tool has also been developed to aid in optimizing medication use in older adults [120]. Named the STOPP/START criteria (Screening Tool of Older Person's Prescriptions and Screening Tool to Alert doctors to Right Treatment), these tools share a number of similarities. The STOPP/START criteria offer recommendations not only for medications to avoid but also indications for certain medications in older adults (i.e., annual influenza vaccination or ACE inhibitors in systolic heart failure). Of note that the Beers Criteria have also published a list of alternatives to potentially inappropriate medications with the 2015 update [121].

The preoperative evaluation is an opportunity for surgeons to significantly improve medication use by identifying and de-prescribing potentially inappropriate medications. When evaluating medications, surgeons should utilize the Beers Criteria as a resource in avoiding potentially inappropriate or high-risk medications in the elderly. Explicit lists of high-risk medications are also incorporated into HEDIS quality measures established by the National Committee for Quality Assurance (NCQA). These quality measures are important factors in determining an organizations overall quality scores and influence reimbursement rates.

An often repeated saying in geriatrics is that any new symptom in an elderly patient should be considered a drug side effect until proven otherwise. During the course of treatment, the patient should be monitored closely and regularly for adverse effects. Regardless of age, 95% of all adverse drug reactions (ADRs) are predictable extensions of the pharmacology of the drug. Proper dosage adjustment based on renal and hepatic function can reduce the likelihood of experiencing an ADR. Once the desired effect is achieved and maintained, or the inciting event has passed, taper and discontinue the medication.

Medication Review and Reconciliation

The maxim of geriatric prescribing is to "start low, go slow, and sometimes say no." While perhaps overly simplistic and not applicable to all medications (i.e., antibiotics), the message is clear – medications are potentially dangerous in the elderly and should be used with caution [38–40]. Furthering the maxim, if starting low, it follows that you should also discontinue slowly (if possible). While many drugs can be discontinued quickly, others (e.g., benzodiazepines, beta-blockers, and clonidine) should be tapered to avoid adverse drug withdrawal effects. With this background in mind, several underlying principles can help minimize the occurrence of MRPs and maximize adherence to prescribed drug regimens. Although they may seem rudimentary, they are nonetheless helpful to review (Table 4).

The Joint Commission requires medication reconciliation upon each transition into, within, or out of a healthcare organization as a part of its National Patient Safety Goals. The standards apply to both inpatient and ambulatory care settings. The medication reconciliation process requires that organizations interview the patient (or an appropriate representative) to document a complete list of the patient's current medications upon admission to the organization and communicate a complete list of medications to the next provider of service when a patient is referred or transferred to another setting, service, practitioner, or level of care within or outside the organization. This step is extremely important in both reducing potential harms from medication errors and identifying potential adverse effects from a current (prescribed, over-the-counter, or even illicit) medication.

Discrepancies between what patients think they should be taking, what they are actually taking, and what is recorded in the medical record are common [122]. Medication reconciliation can prevent medication-related problems resulting from forced adherence, a common occurrence resulting from a medication being restarted in a patient who stopped or changed their medication without notifying their primary provider. Elderly patients are often reluctant to admit they have stopped a medication or altered the dose.

Many institutions incorporate pharmacist and/or pharmacy technicians to conduct the medication reconciliation process. In most instances, pharmacists or technicians will interview patients to generate a medication list and then confirm the list from pharmacy dispensing records or review of prescription bottles, allowing for a measure of adherence. This list generated from patient report (subjective measure) and confirmed with dispensing information or review of prescription bottles (objective measure) is then compared with the medication list within the institution. Discrepancies are then corrected or justified (reconciliation) and repeated prior to discharge or transfer of care to the next institution. The intent of this safety goal is to improve the safety of medication use within all healthcare institutions.

When obtaining a full medication history, it is ideal to have the patient or a family member bring all medications with them. The authors recommend instructing patients to bring all prescription and active nonprescription bottles to their presurgical screening visit. Examining the pill bottles can provide valuable information about the individual's medication management abilities. For example, you might be able to determine the number of providers following the patient, if they use only one pharmacy (important for drug interaction screening) and if there is duplication of medications from multiple providers, and the physical appearance of the bottles (recently filled prescription bottles that are filthy may be indicative of the individual's home environment), if the refills are on time, the pills are in the right bottles, the pills are mixed together, and the pill counts are accurate. Given that many drugs with potential toxicity and interactions are available without a prescription, every patient should also be asked about the use of OTC, herbal, or alternative medications.

Pharmacist interventions with inpatients may decrease subsequent hospital and emergency visits and medication-related readmissions [43, 44]. Inclusion of pharmacists on daily rounds in the intensive care units is encouraged to help improve overall prescribing [45]. Utilization of computerized provider order entry can further reduce medication errors [46]. When preparing discharge prescriptions, keep medication regimens simple. Once-daily dosing substantially improves adherence. If a complicated regimen is necessary, the hospital pharmacist may be able to arrange for the patient's community pharmacy to dispense the medication in a pill box or have them blister packed. These approaches may enhance adherence to the regimen. Providing the patients with a *legible* list of their medications with directions written in lay terms is perhaps the single most important strategy to prevent medication-related problems. Many hospitals have pharmacists available for comprehensive medication counseling and to assist in streamlining regimens.

De-prescribing

As noted at the beginning of the chapter, the problem of polypharmacy increases with age and the presence of comorbid disease. In the current healthcare environment, new complaints presented by patients are quickly addressed by adding new medications, perpetuating the polypharmacy problem in older adults. De-prescribing is the practice of reducing potentially inappropriate or ineffective medications and has achieved important successes through improved perception of well-being and reduced medication costs.

De-prescribing can be defined as: “the systematic process of identifying and discontinuing drugs in which existing or potential harms outweigh existing or potential benefits within the context of an individual patient’s care goals, current level of functioning, life expectancy, values, and preferences. . . . De-prescribing is not about denying effective treatment. It is a positive, patient-centered intervention. . .and requires the same good prescribing principles that apply when drug therapy is initiated” [123].

A number of barriers exist to de-prescribing: clinical complexity among those with polypharmacy paired with limited time in patient-provider interactions, fragmented care among multiple providers, incomplete information on indications and prior experience with alternative modes of therapy, ambiguity in and changing care goals, uncertainty in risks and benefits of continuing vs. discontinuing a medication, and the social/community expectations of more rather than fewer medications to manage symptoms [124, 125].

Table 3 Drugs/combinations to watch carefully in the elderly

Warfarin-NSAIDs[a]
Warfarin-quinolones[b]
ACE inhibitors-potassium supplements
ACE inhibitors-spironolactone
Anticholinergics (such as oxybutynin, amitriptyline, and meclizine)
Anticoagulants
Digoxin-amiodarone
Insulin

[a]NSAID class does not include COX-2 inhibitors
[b]Quinolones that interact include ciprofloxacin, enoxacin, norfloxacin, and ofloxacin

Despite such barriers, a number of successful de-prescribing trials have shown improvements in meaningful patient outcomes as reductions in emergency room visits [126], unplanned hospitalizations in heart failure patients [127], as well as patient-reported outcomes such as quality of life [128]. A study targeting chronic users of benzodiazepines, traditionally difficult to discontinue because of physical and psychological dependence, found a nearly fivefold increase in rates of discontinuation or dose reduction among those receiving a simple de-prescribing intervention [129]. This study found no safety concerns (seizures or withdrawal effects) as a result of the intervention; however other studies have shown adverse drug withdrawal events may occur in up to 30% when consistent taper schedules are absent [130] (Tables 3, 4, and 5).

Specific Prescribing Issues

Delirium

Delirium is a significant concern in older surgical patients because of its prevalence and relationship with detrimental acute and chronic outcomes. Delirium occurs in up to 70% of postoperative older adults and can increase morbidity and mortality and among survivors has been associated with postoperative cognitive dysfunction and dementia [132–134]. Our emphasis in this chapter is limited to a discussion of the pharmacologic management in older adults, whereas a more

Table 4 Principles of safe geriatric prescribing

Take a detailed medication history (including over-the-counter and herbal/alternative preparations)
Establish clear, feasible therapeutic endpoints
Know the clinical pharmacology of drugs prescribed; use a few drugs well; balance safety with efficacy
Begin with a low dose of a drug and titrate up to achieve the desired response
Keep the regimen as simple as possible
Review medications regularly and discontinue those no longer needed
Remember that new symptoms (and illness) can be caused by a drug as well as by a new illness
Select the least costly alternative whenever possible
Encourage compliance. Utilize available pharmacy resources for counseling, written information, special packaging, and other reminder devices

Source: Steinman and Hanlon [131]

thorough discussion of predisposing and precipitating risk factors and diagnosis is discussed elsewhere in the book.

Risk factors can be thought of as "predisposing factors," making one vulnerable to developing delirium and "precipitating factors," which directly or indirectly lead to it. Among the predisposing factors are cognitive impairment, visual impairment, severe illness, and renal insufficiency [48]. Precipitating factors include the use of physical restraints, malnutrition, bladder catheterization, iatrogenic events, and the number and type of medications [49]. Certain medications have been linked to a particular risk of postoperative delirium (e.g., meperidine and benzodiazepines) [50, 135]. Anticholinergic medications may also increase the risk of delirium and include diphenhydramine which is commonly used in hospital settings for sleep and prophylaxis of allergic reactions during transfusions [136, 137]. One study noted that the simultaneous addition of three or more medications to a drug regimen in the hospital was a significant contributing factor to delirium, suggesting that the sheer volume of new medications in certain hospitalized patients may be sufficient to overwhelm their reserve capacity (it should be noted that as the number of prescribed medications increased, there was a greater likelihood of at least one of the medications being psychoactive) [49].

A number of strategies may be employed to decrease the risk of delirium; however these efforts should be focused on identifying and managing the underlying illness and normalizing sleep and activity patterns. The hospital setting is notorious for scheduling medications or monitoring around the clock that interrupts normal sleep-wake cycles. Although it may be necessary for acutely or severely ill patients or during the immediate postoperative period, these interventions should be minimized as soon as possible. These nonpharmacologic interventions may reduce delirium incidence by 35–40% [51, 52]. Holding, reducing, or discontinuing medications thought to increase the risk of delirium is warranted, though this should be done with attention to the indication, duration of use, and with respect to the potential for adverse drug withdrawal effects.

Pharmacologic prevention and treatment is not recommended in routine clinical care [138–140]. Two systematic reviews of pharmacologic management of delirium in surgical populations failed to recommend any medication, found mixed results for medications in the prevention of delirium (antipsychotics, ketamine, dexmedetomidine, and morphine), and insufficient data to make a recommendation for pharmacologic treatment of delirium in postoperative populations [139]. The authors did, however, identify that reducing perioperative sedation levels through targeted bispectral index monitoring reduced delirium incidence and duration. However, the preferred choice of agent used for anesthesia and optimal sedation target have yet to be determined.

Because of potential serious side effects (all antipsychotics hold a black box warning for increased risk of stroke and death in older adults with dementia) [56–58], they should not be used to treat insomnia or other minor complaints. It is important to look for delirium as the potential cause of a new-onset behavioral disturbance or thought disorder, so the underlying etiology can be determined and treatment of the primary process initiated.

As noted above, use of antipsychotics in postoperative delirium is not routinely recommended due to insufficient evidence at this time. However, studies have been conducted that suggest antipsychotics may have a future role in preventing postoperative delirium; the dose, frequency, and duration have yet to be determined before this practice is adopted. Antipsychotics may be employed if delirious patients experience agitation that interrupts care or has the potential to cause harm to the patient or staff. No agent has proven superior efficacy or tolerability in short-term delirium trials. The older, "typical" agents, such as haloperidol (starting dose 0.25–0.5 mg, maximum daily dose 2.0 mg), are inexpensive and are available in oral, intramuscular, and intravenous preparations. Parenteral preparations (intravenous and intramuscular) of antipsychotics may be particularly helpful in the setting of acute agitation or if the patient is unable to take oral medications. Haloperidol is more likely to produce extrapyramidal side effects with prolonged use, but less likely to cause sedation, orthostasis, and anticholinergic effects than lower-potency agents. Among the extrapyramidal effects are parkinsonian.

Antipsychotics

Antipsychotics are used to treat hallucinations, delusions, paranoia, and extreme agitation or physical violence [53]. They tend to not be useful for pacing or wandering, behaviors sometimes seen in older adults with dementia.

Tardive dyskinesia is a potential serious side effect of neuroleptic use and one of the reasons their use should be limited to severe agitation and restricted to short periods of time. Tardive

Table 5 Strategies for Improving Medication Adherence and Reconciliation

Barrier	Talking points
Cost	*Diagnose barrier: copay requirements too high, overall medication spend too high, income insufficient to meet medication costs* • Switch to 90-day Rx for maintenance meds • Maximize generic medication prescribing • Switching to mail order often results in lower copay • Review insurance formulary to ensure med is lowest tiered, clinically appropriate agent in that class • Look for extraneous med spending – e.g., herbals/vitamins/minerals • Check for low-income subsidy for Medicaid recipients • Consider patient assistance programs (*not manufacturer coupons*): typically for specialty agents only and provided by a foundation (The Assistance Fund)
Difficulty refilling meds	*Diagnose barrier: transportation issue, cost issue, confusion/complexity of refill process?* • Have pharmacist attempt Rx synchronization so that all meds filled simultaneously • Switch to local pharmacy with delivery service and/or pillbox-prefill option • Enlist surrogate to oversee refills • See if pharmacy has a refill app • Consider auto-refill programs
Forgetfulness/confusion	*Diagnose barrier: underlying cognitive disorder, overly complicated regimen, lack of medication education, level of education, health literacy, conflicting information from providers, psychosocial environment overwhelming, no med management system, hoarding?* • Screen for memory disorder – TICS/MiniCog/MMSE/MOCA/SLUMS • Medicare eligible can receive annual comprehensive medication review (CMR) – contact your local pharmacist • Direct pt back to local pharmacist for a scheduled medication therapy management session (some pharmacists will schedule these visits) • Ensure medication list identifies indications/goals of care • Identify pt's source(s) of medication information – may listen to neighbors, believe what is on TV or internet. Stress that what is advertised can be misleading. Talk to pharmacist or provider • Empower patients to review medications with providers at each office visit

(continued)

Table 5 (continued)

Barrier	Talking points
	• Encourage the use of a pill box or reminder system: ○ Set an alarm on phone ○ Link taking medication to a daily routine like brushing teeth/eating meals ○ Free phone apps to remind and track meds such as Mango Health and Round Health by Circadian Design • Refer to behavioral health for hoarding/psychosocial stressors
Overly complex med regimen	*Diagnose barrier: functional limitation in dexterity, vision, hearing, swallowing, cognition or challenge to lifestyle, polypharmacy* • Consolidate to less frequent dosing • Identify opportunities for deprescribing • Consider alternative dosage formulations if swallowing barrier exists • Review if pill splitting is a barrier • Look for complex med directions (e.g., every other day, restrictions on food/meals) • Use pillbox/auto prefill systems • If discontinuing med, alert pharmacy to deactivate the discontinued prescription to prevent an accidental refilling of discontinued medication
Tablet splitting	*Diagnose barrier: functional limitation in dexterity, vision, cognition or challenge to lifestyle, polypharmacy, time consuming* • Advise against as this increases the likelihood of med errors during hospital admissions • Advise against as this makes pts appear suboptimally adherent even if taking as instructed by provider • Contact provider for new Rx reflecting the correct dose
Side effects	*Diagnose barrier: new onset of signs or symptoms temporally related to medication administration, fear of side effects, used as an excuse to stop medications* • Obtain side-effect history – is this an actual SE or perceived SE? • Notify provider of side effects and reconnect with the patient with instructions. In many cases, the provider may decide that the benefit outweighs the risk • Is the side-effect in response to what was seen on TV/internet? Talk to MD or PharmD • Is there an FDA-issued recall/alert for this issue? Follow FDA advice • Has this person experienced prior side effects/appears "hypersensitive" to medications? If so, is this affecting pt's ability to take current medications?
Goals of care not aligned with medication use	*Diagnose barrier: no immediate result from new Rx, lack of perceived benefit from chronic Rx, patient beliefs, condition resolved* • Review pts beliefs to identify cultural, religious, moral, ethical reasons for not taking Rx • Many patients being treated for chronic conditions fail to see immediate results and prematurely discontinue therapy. Talk about expectations of taking the medication and the prevention of a worse outcome and preservation of quality of life • When a new therapy is started, check-in on the patient to ensure that they are taking the medication as directed and do not have any barriers with taking the medication (rather than waiting for the next visit for the pt to talk about the issue) • Did pt appropriately discontinue med? Did condition resolve? Was provider alerted?

Medication Review Checklist

Step One: Chart Review

Prepare care medication list for review with patient. Consider new starts, changes in therapy, discontinuations from hospital discharge instructions or provider office visits. Use the following sources:

- Discharge Summary
- Provider notes
- Claims data

Step Two: Patient Interview

With medication list prepared from sourced documents above, interview patient and obtain best-possible medication history. Goals of interview are to determine overall medication management strategy, potential non-adherence, and accuracy of medication list. Use the following questions to guide your interview:

Confirm Medication Changes

1. **Did any doctor start a new medication recently?**
2. **Did any doctor stop a medication recently?**
3. **Did any doctor change the dose of your medications recently?**

Identify Patient Discrepancies

4. **Have *YOU* recently started any new medications?**
5. **Have *YOU* changed the dose or stopped any of your medications recently?**
6. **Do you take any over-the-counter meds, vitamins, minerals, herbals?**

Identify Barriers to Adherence

(Refer to Adherence Strategies Document)

7. **Have any of your medications been causing side effects?**
8. **Do you ever forget to take your medicine?**
9. ***If applicable*: Your profile indicates that you may have run out of some medications. Is that correct?**

Medication Management Issues

10. **Please describe how you manage your medications? Can prompt with the following:**
    a. **Do they use a pillbox?**
    b. **Do they receive help in taking medications?**
    c. **Do they order their own refills?**
    d. **Do they have difficulty obtaining their refills?**
    e. **Do they combine it with any previously dispensed medication?**
    f. **Do they require reminders to take medications?**
    g. **Do they feel confident in your ability to manage your medications?**
    h. **Can they read the label on a medication bottle?**
    i. **Do they have a medication list? Is it up to date?**

Step Three: Documentation

Created by Christina Polomoff, PharmD & Sean Jeffery, PharmD

Having completed steps 1 – 3 now you can document the medication review. Based on your patient interview, update any changes to the medication regimen. Note any discrepancies between the medication list and the patient interview.

1. Medication Changes

- Medication(s) Started:
- Medication(s) Changed:
- Medication(s) Discontinued:

2. Medication Discrepancies identified from patient interview

3. Adherence and Medication Management Issues – list barriers and recommendations

dyskinesia starts as fine movement of the tongue, a facial tic, or lip smacking but may progress in the extreme to affect speech, eating, and breathing. Additional features include tremor, bradykinesia, and masked facies. Akathisia may also be manifested as motor restlessness, pacing, or disturbed sleep and may be reported as discomfort or anxiety. A danger is that these features may be misinterpreted as increasing psychosis, with the neuroleptic dose then being increased, resulting in worsened symptoms. As a result, it is often better to decrease the dose as an initial response to such symptoms to see if they are alleviated.

Furthermore, it may be irreversible. Older adults and women are most likely to develop tardive dyskinesia, and it is more likely to be severe and less likely to be reversible in the older adults. It is less clear that treatment duration and type of agent are important contributors to risk [54, 55]. The primary treatment is to taper and discontinue the drug.

"Atypical" agents, such as risperidone (starting dose 0.25–0.5 mg, maximum daily dose 2.5 mg) and olanzapine (starting dose 2.5–5 mg, maximum daily dose 20 mg), have been touted as having fewer extrapyramidal side effects, although the risk does increase with increasing dosage. These agents have not been proven more effective or safe in short-term trials in critical care or postoperative settings [139, 140]. Olanzapine or quetiapine (starting dose 25 mg, maximum daily dose 200 mg) may be helpful in individuals who have insomnia in addition to psychosis, although these effects may be problematic with longer-term use and are off-label.

Many of the problems with neuroleptic use result from patients being left on the drug long after the inciting event has resolved and after discharge from the hospital. Three studies have shown that approximately 30% of patients receiving a new antipsychotic during a critical illness continue to receive the antipsychotic at discharge [141–143]. If agents are prescribed on an as-needed, or pro re nata (PRN), basis, the indication for use and maximum daily dose should be clearly stated in the orders. The maximum daily doses provided for agents outlined above are guidelines; while they may be exceeded, this should be done cautiously and under close supervision because of the increased risk of side effects.

Of note, antipsychotics are included in the Beers Criteria as potentially inappropriate medications for older adults due to the lack of proven evidence in efficacy and their severe adverse event profile. These effects add to the importance of judiciously using these medications only for the appropriate indications (psychosis and agitation where the health and safety of the patient or caregivers is threatened) and at as low a dose and for as short a duration as is clinically necessary.

Antidepressants

The cardinal features of depression are the "vegetative" or depressive signs and symptoms, including increased or decreased sleep, decreased activity level, fatigue, decreased concentration, increased or decreased appetite or weight, motor slowing or agitation, guilt, suicidality, chronic somatic complaints, and pain [59]. Although standardized instruments, such as the Geriatric Depression Scale, can be useful adjuncts, diagnosis still relies on the recognition of depressive signs and symptoms [60]. As described above in the description of delirium, onset of depressive symptoms in the acute/post-procedural period should be carefully weighed against a diagnosis of delirium. It is important to rule out underlying medical illnesses contributing to depression, such as stroke, myocardial infarction, congestive heart failure, thyroid disorders, uremia, and certain cancers. Medications may contribute as well, including central-acting antihypertensives and b-blockers, narcotics, antipsychotics, benzodiazepines, antihistamines, and sedative/hypnotics [61].

Once these contributing factors have been ruled out and target signs or symptoms identified, the choice of agent again depends in part on the characteristics or features of the patient and the desired side effect profile [59, 62, 63]. Pharmacologic treatment of depression should be offered in conjunction with nonpharmacologic behavioral and support strategies (such as problem solving therapies, social support, etc.), since pharmacologic strategies alone are often not sufficient to result in remission. Treatment success is similar across the wide range of therapeutic options to treat depression; however adverse event profiles prioritize certain classes in older adults.

Both the Beer's and the STOPP/START criteria offer strong recommendations to avoid tricyclic antidepressants (e.g., amitriptyline, nortriptyline, imipramine, and doxepin) due to poorly tolerated adverse events in older adults (Beer's ref). These adverse events include sedation, orthostasis, and a host of anticholinergic-related adverse events including dry mouth, urinary retention, and constipation. Several studies have also shown a relationship between chronic use of these medications and irreversible cognitive impairment (Fox SER, Gray JAMA Int Med, Campbell Pharmacotherapy). Monoamine oxidase (MAO) inhibitors are another class identified by Beer's as potentially inappropriate in older adults because of their potential serious interactions with certain medications and tyramine-containing foods. Therefore preferred antidepressants in older adults begin with selective serotonin reuptake inhibitors (SSRI) or serotonin norepinephrine reuptake inhibitors (SNRI) for those with certain indications.

Because of their enhanced safety and tolerability profiles, selective serotonin and norepinephrine reuptake inhibitors are the current preferred agents for treating depression in older patients [63, 65]. In general, citalopram/escitalopram and sertraline are safe, effective, low cost, and well-tolerated by older patients and are reasonable initial choices. Second-line therapy can include venlafaxine or duloxetine as monotherapy or combination therapy with SSRI and a medication with complementary mechanisms, such as mirtazapine or bupropion. For patients with poor sleep, poor intake, and anxiety as features of their depression, mirtazapine would be an option. For patients with neuropathic pain and depression, duloxetine is an alternative. The latter options may minimize the number of medications by treating multiple symptoms with a single agent. Most agents take several weeks to have an effect on mood, but beneficial effects on sleep or appetite may be seen sooner. Remission is achieved in approximately one-third of new antidepressant users; therefore it is important to monitor for improvement in symptoms and adjust or discontinue therapy to optimize efficacy and minimize polypharmacy. Treatment with an antidepressant should not be considered a failure until 4–6 weeks of use are confirmed (through some measure of adherence) with a therapeutic dose.

Class-wide side effects of SSRI/SNRI include gastrointestinal upset, headaches, dizziness, and sexual dysfunction. Because serotonin receptors are present in platelets, this class may also increase bleeding risk, though bleeding events are only increased when an SSRI/SNRI is used in conjunction with other antiplatelets or antithrombotics (such as aspirin, clopidogrel, warfarin) (add ref). Antidepressants have also been correlated with an increased risk of falls, due to their central site of activity, and represent a significant concern in both community-dwelling older adults and those residing in assisted living or advanced care facilities.

In addition to adverse events related to medication use, potential adverse withdrawal events may also arise from intentionally or unintentionally stopping antidepressants (along with all other centrally acting medications) too quickly. Included in this risk are narcotics or other habit-forming scheduled medications. Adverse withdrawal events for antidepressants may include neurological, psychological, cardiovascular, gastrointestinal, and flu-like symptoms and usually occur within 3 days of abrupt discontinuation [144]. The medication reconciliation process should be sensitive to all sources of medications and prescription and recreational drugs, throughout each transition to avoid untoward effects of adverse drug withdrawal of centrally acting medications.

Anxiolytics

Pharmacologic intervention for anxiety is warranted if symptoms are sufficiently severe to interfere with daily coping or enjoyment of life. In general, treatment should be short term: for a grief reaction or as an adjunct to supportive therapy to develop coping strategies. It is again important to rule out contributing disorders such as congestive heart failure and chronic obstructive pulmonary disease.

Historically, anxiolytic therapy relied heavily on the use of benzodiazepines [53, 67]. However, given the metabolic changes that occur with aging, potential for dependency, cognitive impairment in older adults, and increased risk for falls, benzodiazepines have fallen out of favor as preferred agents for anxiety. Those that are still used are most often short-acting agents such as lorazepam (starting dose 0.5 mg/day) and oxazepam (starting dose 7.5 mg/day). These are preferred because of their more predictable half-lives and duration of action. All benzodiazepines share potential side effects, including sedation, dizziness, depression, confusion, agitation, and disinhibition. Dependence can develop, and tolerance to their effects often occurs after 2–4 weeks of continuous use. Consequently, it is best to use these agents short term. Many anxiolytics are not recommended for use longer than 4 weeks.

Because a withdrawal reaction or "rebound" characterized by tremor and agitation can occur after abrupt withdrawal, benzodiazepines should be tapered prior to discontinuing. Tannenbaum and colleagues have shown that benzodiazepines can be successfully withdrawn, even in patients with decades of use. While this approach requires preplanning a taper regimen, it is an option for some elective surgery patients and may help reduce postoperative delirium by removing offending agents. Excellent patient and provider resources on how to successfully taper and discontinue benzodiazepines are available at www.deprescribing.org.

As treatment of anxiety has gravitated away from benzodiazepines, other agents like SSRIs, SNRIs, and buspirone (starting dose 5 mg twice a day) have increased in use. Buspirone is a non-benzodiazepine anxiolytic that is less likely to cause dependence, sedation, or psychomotor retardation. However, it has a delayed onset of action (several weeks) and lacks the soporific and muscle relaxant effects of benzodiazepines. Its primary side effects are dizziness and nausea. Barbiturates should be avoided because they are less effective and have greater addictive potential than other available agents [67, 68].

Sedative/Hypnotics

Disturbed sleep is a common complaint among older persons, particularly in the hospital [53, 69]. Part of this is due to changes that occur in sleep patterns with aging, including a phase shift (falling asleep and waking up earlier than in prior years) and more disruptions to sleep. Poor sleep is often a proxy marker to other underlying medical factors that contribute to sleep difficulties, including anxiety, depression, pain, itching, nocturia, and congestive heart failure. Disturbed sleep may manifest as difficulty falling asleep, difficulty staying asleep, or early morning awakening. Medications that may contribute include amphetamines, steroids, selegiline, decongestants, caffeine, and alcohol. A number of other factors may play a role among hospitalized patients, including daytime naps, intravenous lines, catheters, traction, and frequent wakings for medications or treatments. After establishing by history if sleep is disturbed, the mainstay of treatment should be nonpharmacologic interventions directed at potential contributing factors. For example, cognitive behavioral therapy has been proven effective as a long-term strategy improving sleep.

Any decision to use sedative/hypnotics must carefully balance the risks and benefits of this class of medications. There are no safe sleeping pills as they are all variously associated with increased risk of falls, confusion, and daytime sleepiness. Overall evidence of efficacy is limited with this class of medications; in general they increase sleep time in aggregate by approximately 20 min. If drug treatment is indicated, short-term use (suggested maximum duration of use is 7–10 days) is advised. Among the benzodiazepines, short-acting agents are preferred because they are less likely to cause carryover sedation the following day. Temazepam (starting dose 7.5 mg) has a reasonable duration of action but a delayed onset of action and so must be given approximately 1–2 h before bedtime. Nonbenzodiazepine hypnotics, such as zolpidem, zaleplon, and eszopiclone, are alternatives that, while commonly used, are still identified as high-risk medications in the elderly and appear on the Beers Criteria [70]. If the primary problem is difficulty falling asleep, ramelteon is another option. If persons are depressed and have sleep difficulties, treatment with a sedating antidepressant is preferable to separate treatment with two different medications.

Trazodone (25–100 mg p.o. within 1 h of desired sleep time) is commonly used for its sedating properties; however there is limited evidence of long-term benefits, and given its long half-life, some patients report excessive daytime sleepiness.

Many patients will obtain over-the-counter (OTC) sleep aids such as diphenhydramine or melatonin. It is therefore important to screen for OTC sleep aids. Melatonin has a cult-like following in the community where it is widely touted as a natural sleep aid. However, overall evidence of efficacy is very limited and generally related to circadian disorders. As the pineal gland secretes melatonin in response to exposure to AM bright light, a nonpharmacologic recommendation to improve circadian rhythm sleep is to encourage patients to be exposed to sunshine between 9 and 11 am for at least 30 min.

Comorbid behavioral health problems can significantly impact sleep. If someone has a thought disorder and disturbed sleep, a sedating neuroleptic is preferred, but neuroleptics should not be used for sleep alone as these carry black box warnings.

Pain Management

Pain is a common complaint among elderly persons and can have a substantial impact on quality of life and physical functioning. It is beyond the scope of this chapter to review in detail the pharmacologic management of pain in surgical patients. Instead, this section will highlight common concerns regarding frequently used pain medication. Pain management guidelines are undergoing significant scrutiny for safety, efficacy, and contributions to the broader public health crisis of opioid abuse. Overuse of opioid prescriptions has contributed to an epidemic of abuse and significantly increased the number of overdose deaths annually. The elderly are especially at risk as pain management guidelines have advocated opioids as first-line agents. A generation of seniors have significant amounts of unused opioids in their possession, potentially serving as a point source for addicts. Moreover, use of opioids in the elderly can contribute to cognitive impairment, falls, and other troublesome side effects. Adequate treatment is thus important, but caution must be exercised because of the strong potential for adverse effects with many of these agents. As such, it is helpful to follow the stepwise approach for assessing the nature and extent of pain, determining its etiology, and starting with lower doses of less-potent agents. A variety of instruments are available to help gage the current severity of pain and the effectiveness of treatment [71, 72].

The first line of therapy often consists of acetaminophen, tramadol, or topical nonsteroidal anti-inflammatory agents (NSAIDs) [74]. Most guidelines now recommend acetaminophen rather than nonsteroidals for the first-line treatment of pain because of their side effect profiles in older adults [NEW]. Acetaminophen lacks the anti-inflammatory properties of NSAIDs; however acetaminophen is safe, effective, inexpensive, and well tolerated by older persons with mild to moderate pain. Caution should be exercised in the setting of liver disease or alcohol use. Given acetaminophens' ubiquity in over 600 commercially available products, unintentional acetaminophen overdose is the main contributor to acetaminophen-induced hepatotoxicity [75]. Caution must be taken to ensure that patients avoid compound medications that include acetaminophen, which may contribute to their unknowingly exceeding recommended daily limits (3 g/day).

Aspirin and the nonsteroidals can cause gastrointestinal bleeding and renal insufficiency, worsen hypertension, and can interfere with platelet function. A variety of central nervous system (CNS) side effects may also be seen with nonsteroidals, and therefore they are no longer recommended for long-term pain management in older adults. Topical NSAIDs are generally well tolerated given the lower systemic absorption from these agents. Because these are applied topically, they are of most benefit to localized pain. Additionally, brand-name topical agents are often very high cost and restricted. Generically available topical NSAIDs exist and are equally analgesic.

If pain is not controlled with these agents, a trial of topical lidocaine may also be reasonable if the pain is localized and neuropathic in nature. Topical lidocaine (ointment, cream, or patch) is generally well tolerated with the most common adverse effect being headache [73, 74]. However, lidocaine patches are very expensive and typically require prior authorization approval.

Tramadol (50 mg every night, then 25–50 mg immediate release every 6 h; maximum daily dose 400 mg) is modestly effective for mild to moderate pain. Common side effects include constipation, nausea/vomiting, dizziness, headache, and somnolence. Tramadol can also increase the risk of seizures or serotonin syndrome when used with antidepressants or monoamine oxidase inhibitors (MAO), serotonin reuptake inhibitors, and tricyclic antidepressants [74].

Opioid analgesics are the next line of treatment [72–74]. Use of the lowest effective dose for the shortest period of time can help prevent abuse and misuse of opioids. Common opioids, such as codeine, oxycodone, and hydrocodone, may provide relief alone or are available in conjunction with nonopioid analgesics like acetaminophen. All opioids have similar potential side effects, among which are respiratory depression, constipation, urinary retention, nausea and vomiting, delirium, and myoclonus. The patient should be monitored closely and appropriate dose adjustments made when these side effects appear. Prophylactic bowel regimens are often necessary and should be initiated when the narcotic is started. Stool softeners will result in all "mush and no push," and therefore stimulant laxatives are necessary. Tolerance to some of the effects may appear and may require continuous, rather than as-needed, administration schedules. For respiratory depression, the opiate antagonist naloxone may be helpful. Meperidine should be avoided in the elderly, as it must be used with caution in patients with renal insufficiency and its metabolite, normeperidine, may cause seizures.

Topical analgesics such as capsaicin may be helpful for conditions such as herpes zoster. Nonpharmacologic modalities such as heat, cold, massage, biofeedback, and transcutaneous electrical nerve stimulation (TENS) help in certain situations. Nerve blocks are another potential option for certain types of refractory pain. A recent trial of an interdisciplinary analgesic program in orthopedic patients found that intervention participants had less pain postoperatively at 6 months and better physical performance [76].

Antihistamines

Histamine H_1 receptor blockers are commonly used for the treatment of allergies and allergic reactions; occasionally they are used as sedative/hypnotics. Antihistamines such as diphenhydramine should not be used as sleep medications as they can cause confusion and acute urinary retention. First-generation antihistamines have prominent anticholinergic properties and should be used cautiously in the elderly. Newer agents with relatively low anticholinergic properties, such as loratadine, are preferred to treat allergy symptoms.

Histamine H_2 receptor blockers, used to inhibit gastric acid secretion, can be safely used in elderly persons. Histamine H_2 receptor blockers, used to inhibit gastric acid secretion, can be used safely in the elderly provided the dose and duration of therapy are kept to a minimum and adjusted for renal function. If used prophylactically during the perioperative period, the dose should be decreased and ultimately discontinued as soon as possible. All of these agents can cause alterations in mental status if not carefully dosed.

Antibiotics

There are two major clinical categories of antibiotic usage among surgical inpatients:

perioperative prophylaxis and the treatment of postoperative infections. Aging-related changes in pharmacokinetics of antibiotics will have limited impact on prophylactic use of antibiotics and a more significant impact on dose and scheduling of treatment regimens. Although this chapter does not focus on specific antibiotic recommendations for procedures or site infections, it addresses the general principles of antibiotic choice, dosing, and specific side effects in the geriatric patient.

Given changes expected in payment systems (see earlier comments), surgeons will become increasingly responsible for prevention and treatment of infections both in the acute care setting and possibly extended care and rehabilitation settings. Growth of clinical pharmacy services, along with partnership of infectious disease physicians and antimicrobial stewardship programs, is available to surgeons in both inpatient and extended care or rehabilitation facilities. These local programs are specifically charged with optimizing use of antibiotics with attention to treatment success, resistance, and cost and are supported by a number of organizations, including the Centers for Disease Control and Prevention and Infectious Diseases Society of America. Important to the long-term care setting, in 2016 the Centers for Medicare and Medicaid Services' "Mega-Rule" is requiring facilities to develop an Infection Prevention and Control Program (IPCP) that includes an Antibiotic Stewardship Program and designate at least one infection preventionist on-site.

It is important to consider technologic devices (grafts, stents, pacemakers, transplanted organs, and dialysis catheters) as important factors in the selection of antibiotics in the elderly surgical patient. Both the devices themselves and the medications (immunosuppressive drugs and anticoagulants) that patients may be on as a result need to be taken into consideration when choosing an antibiotic regimen. With increasing antibiotic resistance constricting options for care, and new antibiotic development lagging, it is imperative that the proper choice of antibiotic be made by taking into account possible drug interactions (Table 6), the side effect profile of a particular drug, the appropriate dose in a given patient, the antibiogram, and whether this is empiric or targeted treatment based on cultures and sensitivities [78].

Selection of an antibiotic for surgical prophylaxis should be (1) active against the pathogens most likely to contaminate the surgical site, (2) given in an appropriate dose and time that ensures adequate serum and tissue concentrations during the period of potential contamination, (3) safe, and (4) administered for the shortest effective period to minimize adverse effects, the development of resistance, and costs. Prophylactic antibiotic regimens in acute care settings often include first- or second-generation cephalosporins, such as cefazolin or cefuroxime rather than broad-spectrum antibiotics [145]. A single dose of cefazolin 2 g or cefuroxime 1.5 g is recommended for most patients and may be readministered depending on details of the procedure. Depending on the specific type of surgical procedure, vancomycin has been recommended as either a primary or as an adjuvant agent for patients who are presumed or known to have *S. aureus* colonization, in institutions where a "high" prevalence of MRSA exists and when a surgical procedure involves a prosthetic joint insertion, sternotomy, or vascular graft insertion. The recommended dose of vancomycin for prophylaxis is a fixed dose of 1000–1500 mg or a weight-adjusted dose of 10–15 mg/kg.

While the maxim of geriatric prescribing, "start low, go slow," is true for most classes of drugs, this practice is not advisable with antibiotic use. This is especially true in the critically ill surgical patient and may in fact contribute to the problem of antimicrobial resistance. Understanding when pharmacokinetic changes in the elderly are important and call for dose adjustments is imperative [80]. Proper dosing of antibiotics and other drugs in older adults reduces the incidence of ADRs. This point is especially important in light of the fact that the incidence of ADRs increases with advancing age and the effects are more serious in frail elderly patients than in their younger counterparts [81]. In general, improper dosing is a more frequent cause of error in therapy than is the use of an inappropriate drug [82].

Judicious clinical practice requires the prescribing physician to be aware of age-related

Table 6 Selected antibiotics and their drug interactions

Antibiotic	Other drugs	Effect
Ampicillin	Anticoagulants	Anticoagulation
Aminoglycosides	Amphotericin B	Nephrotoxicity
	Cyclosporine	Nephrotoxicity
	Loop diuretics	Ototoxicity
	Neuromuscular blockers	Respiratory paralysis
	NSAIDs	Nephrotoxicity
	Vancomycin	Nephrotoxicity
Cefoperazone, cefotetan	Anticoagulants	Anticoagulation
Clindamycin	Muscle relaxants	Frequency of respiratory paralysis
Ciprofloxacin	Antacids/sucralfate/cations (vitamins and calcium supplements)	Absorption of ciprofloxacin if taken within 2 h
	NSAIDs	CNS stimulation/seizures
	Anticoagulants	Anticoagulation
Fluconazole	Tacrolimus	Tacrolimus level with toxicity
	Cyclosporine	Cyclosporine level, nephrotoxicity
	Ca channel blockers	Ca channel blocker level
	Anticoagulants	Anticoagulation
	Theophylline	Theophylline level
Metronidazole	Alcohol	Disulfiram-like reaction
	Oral anticoagulants	Anticoagulation
Imipenem-cilastatin	Cyclosporine	Cyclosporine level
Trimethoprim-sulfamethoxazole	Anticoagulants	Anticoagulation

Source: Data from [78]

changes in drug absorption, distribution, metabolism, and elimination. These have been described earlier in this chapter. Of these factors, the one with the most direct clinical relevance to antibiotic dosing is the decline in renal function. Most clinicians are aware of the need to decrease the dose of certain nephrotoxic antibiotics, such as aminoglycosides, in the setting of acute renal insufficiency or decreased creatinine clearance. However, other commonly used drugs such as quinolones and most cephalosporins need to be dose-adjusted for a creatinine clearance of less than 30 ml/min [83]. Table 7 lists selected antibiotics whose dosages need to be adjusted [84, 85].

Although aminoglycosides remain important drugs for treating serious infections, alone or in combination with other drugs, the availability of quinolones, monobactams, and carbapenems, agents with broad-spectrum coverage and less nephrotoxicity, makes the use of aminoglycosides less common in elderly persons. Risk factors for the development of aminoglycoside-induced nephrotoxicity include diabetes mellitus, dehydration, advanced age, and duration of treatment [86]. In addition to nephrotoxicity, aminoglycosides may also cause ototoxicity. This is more likely to occur in elderly patients especially if given in high dose or for prolonged periods because ototoxicity is cumulative. Furthermore, the risk of ototoxicity is greater in patients concomitantly taking a loop diuretic [87–89]. Appropriate monitoring of trough aminoglycoside levels can minimize potential adverse events. Several analyses of pooled data from randomized controlled studies in adults found that once-daily aminoglycoside dosing may be associated with less nephrotoxicity and no greater ototoxicity than with multiple daily doses [90–93]. Keep in mind, however, that once-daily aminoglycoside dosing is not appropriate for, or recommended in, any patient with a creatinine clearance <30 ml/min.

Table 7 Selected antibiotics requiring dose adjustment when used for treatment in those with renal insufficiency

Antibiotic	Usual dose	Dose for CrCl 10–50 ml/min	Dose for CrCl <10 ml/min
Cefazolin	1–2 g q8 h	1–2 g q12 h	1–2 g q24–48 h
Cefuroxime	0.75–1.50 g q8 h	0.75–1.50 g q12 h	0.75–1.50 g q24 h
Ceftazidime	2 g q8 h	2 g q12–24 h	2 g q24–48 h
Cefotaxime	2 g q8 h	2 g q12–24 h	2 g q24 h
Penicillin G	0.5–4.0 million units q4 h	75% of dose	20–50% of dose
Ampicillin	1–2 g q6 h	1–2 g q6–12 h	1–2 g q12–24 h
Piperacillin-tazobactam	3.375–4.5 g q6–8 h	2.25 g q6 h	2.25 g q8 h
Piperacillin	3–4 g q4–6 h	3–4 g q6–8 h	3–4 g q 8 h
Ticarcillin-clavulanate	3.1 g q4 h	3.1 g q8–12 h	2 g q12 h
Aztreonam	2 g q8 h	50–75% of dose	25% of dose
Ertapenem	1 g q24 h	0.5 g q24 h	0.5 g q24 h
Imipenem-cilastatin	0.5 g q6 h	0.25 g q6–12 h	0.125–0.25 g q12 h
Metronidazole	7.5 mg/kg q6 h	7.5 mg/kg q6 h	50% of dose
Vancomycin	1 g q12 h	1 g q 24–96 h	1 g q4–7 days
Gentamicin	1.7 mg/kg q8 h	1.7 mg/kg q12–24 h	1.7 mg/kg q48 h
Amikacin	7.5 mg/kg q12 h	7.5 mg/kg q24 h	7.5 mg/kg q48 h
Amphotericin B	0.4–1 mg/kg q24 h	0.4–1 mg/kg q24 h	0.4–1 mg/kg q24 h
Fluconazole	100–400 mg q24 h	50% of dose	50% of dose
Ciprofloxacin (IV)	400 mg q12 h	400 mg q12–24 h	400 mg q18–24 h

CrCl creatinine clearance

Regarding hepatic metabolism of antibiotics, although liver size and blood flow tend to decrease with age, in the absence of serious liver disease and subsequent hepatic dysfunction, antibiotic dosages do not need to be adjusted. Drug-induced hepatitis in patients treated with antituberculous agents, especially isoniazid, increases in incidence from 2.8/1000 in patients <35 years old to 7.7/1000 in patients 55 years old [87, 94]. Therefore, liver function tests must be performed frequently prior to and during the course of antituberculous therapy. Antibiotics that require dose adjustments in patients with hepatic dysfunction include cefoperazone, clindamycin, erythromycin, isoniazid, ketoconazole, nafcillin, and rifampin (Table 8). Beta-Lactam antibiotics (penicillins, cephalosporins, cephamycins, carbapenems, and monobactams) have varying characteristics of absorption, peak concentration, bioavailability, and metabolism. These topics are described in detail in standard texts and are not covered here. In general, bioavailability is relatively poor after oral administration, which has implications for the switch from intravenous to oral preparations, and pharmacokinetics are similar after intramuscular or intravenous administration [84].

Table 8 Selected antibiotics requiring dose adjustment in the presence of severe hepatic dysfunction

Nafcillin
Cefoperazone
Clindamycin
Erythromycin
Ketoconazole
Isoniazid
Rifampin

Cephalosporins are relatively safe drugs to use in older persons. Dosages for certain cephalosporins need adjustment for renal insufficiency (Table 7). The broad spectrum of activity of ceftriaxone together with its convenient once-daily dosing makes it an ideal drug for empiric use in a variety of clinical infections in the older adults [95, 96]. In addition, it has both renal and biliary excretion and as a result needs little adjustment for renal insufficiency. A lesser known side effect of ceftriaxone is the formation of biliary sludge with prolonged use [97].

Carbapenems (imipenem-cilastatin, meropenem, and ertapenem) are occasionally used in the postoperative patient because of their broad spectrum of activity. Their pharmacokinetics are similar to that of cephalosporins, and they require dose adjustment for renal insufficiency because they are excreted renally. The cilastatin component of imipenem-cilastatin has no antibacterial activity, but is used to inhibit renal tubular metabolism of imipenem, thereby increasing the urinary concentration of the active drug. Major adverse effects of the carbapenems, especially imipenem-cilastatin, are related to the CNS, including seizures, somnolence, and confusion and are dose-related [103]. This is more likely to occur in the elderly with a history of a CNS lesion, prior seizure disorder, or renal insufficiency.

Aztreonam is a monobactam that has only aerobic gram-negative bacterial coverage. Its pharmacokinetics are similar to that of the cephalosporins. It is frequently used in patients with renal insufficiency as a substitute for aminoglycosides, although it too needs dose adjustment in such patients. It lacks cross-reactivity with other b-lactam antibiotics and can be used safely in patients with severe allergy to penicillin or cephalosporins [104, 105].

The fluorinated quinolones are widely used. Compared with the first-generation fluoroquinolones (norfloxacin and ciprofloxacin), subsequent fluoroquinolones (ofloxacin, levofloxacin, and moxifloxacin) have a broad spectrum of aerobic gram-positive and gram-negative bacterial activity along with the same excellent pharmacokinetic profile. The gram-positive coverage, especially in vitro activity against *Streptococcus pneumoniae*, of the earlier quinolones (ciprofloxacin) is not as good as that of the new generation of quinolones. In addition, they are active against intracellular organisms such as *Legionella*, *Mycoplasma*, *Chlamydia*, and *Mycobacterium*. They are well absorbed orally, with a high degree of bioavailability that makes them especially useful drugs in the transition from intravenous to oral dosing. They also have excellent tissue penetration. Care should be taken with the oral administration of these drugs to ensure that they are administered 2 h before or after antacids, sucralfate, or other multivalent metallic cations as their absorption can be severely impaired, leading to therapeutic failure [106, 107]. Renally eliminated fluoroquinolones (ofloxacin and levofloxacin) need to be dose-adjusted when the creatinine clearance is $<$50 ml/min.

Along with the increased usage of this class of antibiotics, there have been reports of specific side effects when prescribing these drugs in older adults. Certain quinolones can cause QT interval prolongation. They should be avoided in patients with known prolongation of the QT interval, patients with uncorrected hypokalemia or hypomagnesemia, and patients receiving class I or class II antiarrhythmic drugs [108]. Elderly patients on corticosteroids, especially in the setting of chronic renal insufficiency, are also at risk for Achilles tendon rupture [109].

An important and well-documented drug interaction of quinolones with warfarin is particularly noteworthy in the postsurgical patient. The prothrombin time (PT) and INR need to be closely monitored to prevent bleeding complications [110, 111]. Lastly, fluoroquinolones have been associated with CNS toxicity in older adults. These reactions take the form of confusion, psychosis, or seizures and may be dose-dependent, with higher likelihood in those with existing neurologic disease or a compromised blood-brain barrier [2, 146, 147].

With the increase in the number of infections due to methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant enterococci, alternatives to vancomycin are needed. Linezolid, a fluorinated oxazolidinone active against gram-positive organisms and most commonly used vancomycin alternative, is a nonselective inhibitor of monoamine oxidase (MAOI). In the elderly patient with the potential for polypharmacy as discussed above, drug interactions need to be kept in mind when using this antibiotic. Linezolid is on the list of drugs with serotonergic activity that may cause serotonin syndrome. The most common drug combinations associated with serotonin syndrome are MAOIs with selective serotonin reuptake inhibitors (SSRIs). Since SSRIs are frequently used for the treatment of depression, this is an important drug interaction to keep in mind [112–114].

No discussion of antibiotic use is complete without mention of *Clostridium difficile*-associated diarrhea (CDAD) – a challenge in the care of all hospitalized patients, particularly older ones. Surgical patients comprise 55–75% of all patients with CDAD [115]. Initial treatment regimens remain the same in this population and include oral metronidazole (cheap and generally effective) for mild-moderate infections or oral vancomycin (expensive and concern for antibiotic resistance) for severe infections; however, there is an increased frequency of treatment failure and CDAD recurrence among elderly persons. Prolonged tapering course of antibiotic treatment with anion-exchange resins, oral lactobacillus, or nonpathogenic yeast such as *Saccharomyces boulardii* and fecal transplants (enema with feces from healthy donors) or combinations of the above may need to be considered [148]. Risk factors for CDAD include prolonged use of proton pump inhibitors, highlighting yet another reason to deprescribe this class of medications if not clearly indicated.

Summary

A number of factors can potentially influence the risk-benefit equation for drug use in an older population, including age-related physiologic changes in organ system function, increased likelihood of comorbid diseases affecting organ systems that are the intended site of drug action or are responsible for the metabolism or clearance of a drug, and increased likelihood of multiple chronic medications, which may increase the possibility of drug interactions. It is prudent for surgeons to be mindful of medication-related problems in older adults and be an active medication management steward when selecting, dosing, administering, and monitoring drug effects and side effects.

Abstract

The management of cancer, often considered a disease of the elderly, is becoming an increasingly common challenge for surgeons and oncologists caring for older adults. As the geriatric population has grown, so too have opinions and standards as to what constitutes an appropriate treatment approach in the elderly cancer patient. Not surprisingly, oncology treatment regimens in elderly populations have become increasingly individualized. When applying these tailored treatment paradigms to elderly cancer patients, a crucial consideration is whether the benefits of a proposed cancer treatment outweigh their perceived risks within the context of patients' residual life expectancy. In some circumstances, optimal implementation of these tailored approaches may require deviation from treatments that would otherwise constitute standard of care in younger patients of similar cancer and stage. As such, a strong working knowledge of the nuances involved in the preoperative assessment of the elderly cancer patient, as well as alternative treatment strategies, is crucial for surgeons caring for these patients to ensure optimal perioperative and postoperative decision-making, care, and outcomes.

Introduction

Americans aged 65 years and older now comprise approximately 13% of the total population [1]. As the population of the United States (USA) continues to age and Americans live longer, the US Census Bureau estimates that this figure will eclipse 20% by 2030. As such, it is not surprising that the management of cancer, often considered a disease of the elderly, is becoming an increasingly common challenge for surgeons and oncologists caring for older adults [2]. As of 2016, cancer and its complications were the most common cause of death in persons aged 60–79 years [3].

Just as the geriatric population has grown, so too have opinions and standards as to what constitutes an appropriate treatment approach in the elderly cancer patient. In decades past, it was routinely accepted that reasonable postoperative outcomes could be expected in the hands of technically seasoned surgeons adopting strict selection criteria. Given the continued shift in the US healthcare system away from surgical paternalism and toward patient-centered, value-based care, the traditional assumptions and approaches toward operative geriatric oncology may also no longer be valid [4, 5].

Numerous clinical studies have stressed the importance of focusing on patients' physiologic age, rather than simply their chronological age; in turn, oncology treatment regimens in elderly populations have become increasingly individualized. When applying these tailored, treatment paradigms to elderly cancer patients, perhaps the most important consideration is whether the benefits of a proposed cancer treatment outweigh their perceived risks within the context of patients' residual life expectancy. In some circumstances, optimal implementation of these tailored approaches may require deviation from treatments that would otherwise constitute standard of care in younger patients of similar cancer and stage (e.g., substitution of chemoradiation with or without local excision for neoadjuvant chemoradiation and abdominoperineal resection in an elderly patient with a low, locally invasive rectal adenocarcinoma). As such, a strong working knowledge of the nuances involved in the preoperative assessment of the elderly cancer, as well as alternative treatment strategies, is crucial for surgeons caring for these patients to ensure optimal perioperative and postoperative decision-making, care, and outcomes [3].

Preoperative Considerations

Life Expectancy

Typical considerations when developing a treatment plan for an oncologic condition involve the natural history of that condition, the patient's tumor stage and its perceived "biologic aggressiveness," the efficacy and risks of the proposed treatments, and the risks of cancer recurrence and death. As noted above, responsible oncologic planning in older cancer patients must also acknowledge residual life expectancy as a fundamental component of the decision-making process. Although life expectancy in the USA continues to increase (Fig. 1), likely as a consequence of advances in diagnostic capabilities and increasingly efficacious interventions and pharmaceutical agents, it is important to remember that most life expectancy calculators do not incorporate a patient's specific cancer diagnosis into their algorithms. These estimations must instead be completed within the clinical arena and require a realistic appraisal of the patient's cancer prognosis, as well as their current and future quality of life (both without cancer treatment and after treatment) [3, 6]. A growing body of literature suggests that a significant gap exists between oncologists' assessments of future life expectancy and patients' comprehension of the quantity and quality of that life. To truly honor the informed consent process, the treating surgeon/oncologist must consider the patient's cancer within the context of their projected life expectancy to optimize communication and patient-centered decision-making [7].

Decision-Making Capacity

Also inherent in the proper implementation of the informed consent (and subsequent discussion of proposed treatments) is a patient's ability to process information and make decisions independently. A patient's decision-making capacity should ideally be determined shortly after cancer diagnosis but before initiation of cancer treatment [3]. In accordance with accepted legal criteria for demonstrating decision-making capacity, a patient must understand the relevant information communicated by the physician; acknowledge his or her

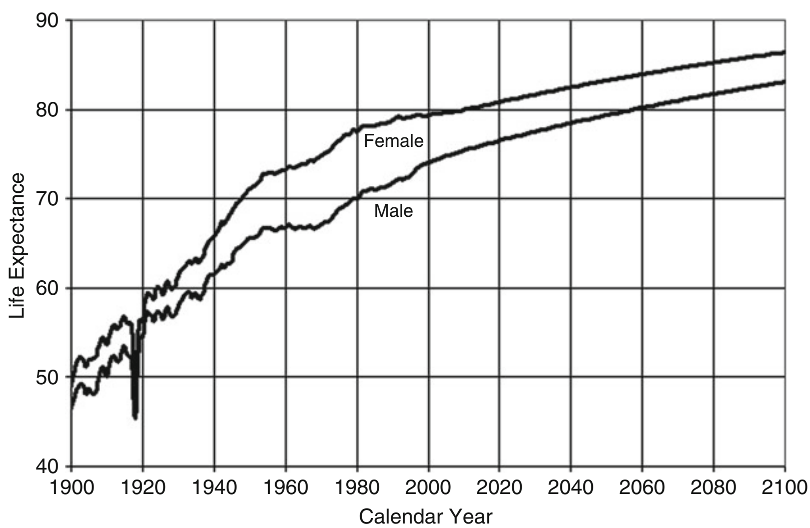

Fig. 1 Life expectancy at birth by sex and calendar year (1900–2100). Line graph illustrating average life expectancy by the year of birth (Adapted from the US Social Security Administration, Actuarial Study 120, August 2005 https://www.ssa.gov/OACT/NOTES/actstud.html)

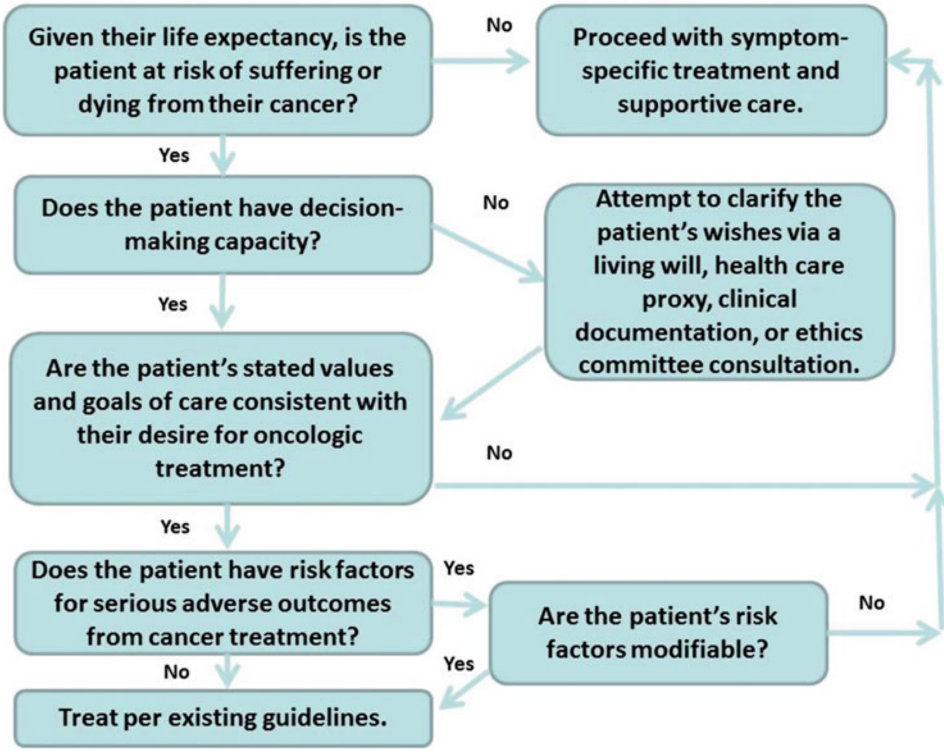

Fig. 2 Decision-making algorithm in the elderly cancer patient. Proposed algorithm to assist in the evaluation and treatment planning of the elderly cancer patient (Adapted from NCCN. Older Adult Oncology (Version 2.2016) http://www.nccn.org/professionals/physician_gls/pdf/senior.pdf)

medical condition, treatment options, and likely outcomes; engage in a rational discussion regarding treatment options; and be able to indicate his or her treatment choice [2]. Although the specifics of how best to assess decision-making capacity fall within the purview of the surgeon/oncologist's usual practice, a proposed algorithm is shown in Fig. 2 [3].

Goals of Care

Another crucial step when crafting a treatment plan in elderly cancer patients is an explicit discussion of the physician and patient's goals of care. Surgery, radiation therapy, and systemic therapy can be deployed for attempted cure or simply to palliate a patient's cancer and ideally improve quality of remaining life [6]. Previous studies suggest that despite extensive and repeated counseling by oncologists regarding the rationale and intent of a specific treatment, a significant proportion of patients remain unaware that their treatment is not curative [7]. As such, it is imperative to discuss the patient's prognosis and chances for "cure" at the time of the initial oncologic evaluation before eliciting the patient's goals of care. Furthermore, this discussion may need to be repeated at various intervals during the patient's care, particularly in the setting of serious toxicity/complications, changes in treatment plan, or disease progression. Although of particular importance to the older cancer patient, adherence to this approach is widely considered best practice irrespective of a cancer patient's age.

Comprehensive Geriatric Assessment

Another tool that should be utilized to better estimate an elderly patient's fitness for oncologic intervention is comprehensive geriatric assessment

(CGA). CGA is a validated, detail-oriented method by which a patient's overall physical, mental, and emotional suitability for surgery can be evaluated through a multidisciplinary assessment of comorbidity, "geriatric syndromes," and existing support systems [3, 6, 8]. A full CGA is outlined in the first column of Table 1.

Comorbidities requiring careful preoperative assessment include cardiopulmonary disease, liver disease, and renal insufficiency. In accordance with current American College of Cardiology and American Heart Association recommendations, all patients undergoing major non-cardiac surgery should be evaluated for perioperative cardiac risk [9]. Postoperative myocardial infarction (MI) is associated with hospital mortality rates of 15–25%, and patients experiencing nonfatal perioperative MI are at significantly increased risk for cardiovascular death and additional nonfatal MIs during the 6 months after surgery [10]. Identification of elderly patients with higher cardiac risk profiles is critical since these patients are more vulnerable to perioperative cardiac adverse events during the perioperative period, as well as during neoadjuvant/adjuvant therapy [2].

Similarly, postoperative pulmonary complications are common and contribute considerably to overall morbidity and mortality. Some degree of pulmonary compromise is often associated with postsurgical recovery, regardless of age. Elderly oncology patients, many of whom may require large thoracic/abdominal incisions for tumor extirpation, are no exception. As such, older patients should be carefully evaluated to assess their risk of developing postoperative pulmonary complications. Patient-related factors, such as history of chronic obstructive pulmonary disease, cigarette use, and functional status, must be considered. In patients deemed to be at increased risk, the implementation of preoperative prevention strategies (e.g., smoking cessation, pulmonary

Table 1 Comparison of a CGA, G-8 screening tool, and CARG

1. *Functional status* ADL – activity of daily living IADL – instrumental activity of daily living performance status (ECOG) 2. *Comorbid medical conditions* Charlson comorbidity index, polypharmacy 3. *Cognitive function* Mini-Mental State Examination 4. *Psychological state* Geriatric Depression Scale 5. *Social support* Living conditions, caregivers, access to care 6. *Nutritional status* Mini Nutritional Assessment 7. *Geriatric syndrome* Dementia, depression, delirium, falls, osteoporosis, neglect or abuse, failure to thrive, nutritional deficiency	1. Has food intake declined over the past 3 months due to loss of appetite, digestive problems, and chewing or swallowing difficulties? 2. Weight loss during the last 3 months 3. Mobility (bed bound, does not go out, goes out) 4. Neuropsychological problems (none, mild–severe dementia) 5. Body mass index 6. Takes more than three medications per day 7. In comparison with other people of the same age, how does the patient consider his/her health status? 8. Age: < 80, 80–85, > 85	1. Age ≥ 72 2. Type of cancer (GI/GU) 3. Number of chemotherapy drugs (one vs. multiple) 4. Chemotherapy dosing (standard vs. reduced) 5. Hemoglobin <11 g/dL in male and <10 g/dL in female 6. Creatinine clearance <34 mL/min 7. Hearing fair or worse 8. Number of falls in the last 6 months ≥ 1 9. IADL: taking medication with some help/unable 10. Limitation in walking one block 11. Decreased social activity at least sometimes

CARG Cancer and Aging Research Group, *ECOG* Eastern Cooperative Oncology Group, *GI/GU* gastrointestinal/genitourinary function testing, perioperative intensive inspiratory muscle training, etc.) may be appropriate and beneficial [2].

Many elderly oncologic patients are afflicted with varying degrees of hepatic dysfunction and renal insufficiency. For those with known disease, preoperative coordination with the patient's primary care physician, gastroenterologist/hepatologist, and/or nephrologist is strongly recommended. A serum comprehensive metabolic panel should be obtained prior to surgery, and liver function tests, glomerular filtration rate, and albumin/creatinine values should be reviewed to identify patients with subclinical hepatic dysfunction/renal insufficiency who may require additional medical evaluation and/or intervention prior to surgery. All medications should be reviewed, and appropriate agents should be dosed in accordance with patient's creatinine clearance (instead of serum creatinine alone) [2].

In addition to the aforementioned comorbidities, various geriatric syndromes proven to increase perioperative morbidity and mortality can also afflict elderly surgical patients. The incidence of dementia, among the most prevalent of age-related disorders within this population, rises exponentially with increasing age over 65 years [11]. In elderly patients without a known history of cognitive impairment, a detailed history and cognitive assessment (e.g., Mini-Cog) are indicated [2, 12]. Depending on the results, additional specialty referral may be needed. Careful documentation of preoperative, baseline cognitive status is required, and surveying knowledgeable family members about recent functional decline is highly recommended. Ideally, these cognitive assessments should be completed during the preoperative evaluation, since presence of dementia may adversely affect the accuracy/validity of subsequent preoperative assessments [2].

Similarly, clinical depression is not uncommon among elderly surgical patients and among patients older than 71 years and has an estimated prevalence of 11% [13]. Established risk factors include female sex, disability, bereavement, sleep disturbance, and prior history of depression. A new diagnosis of cancer can often exacerbate subclinical depression, if already present. Clinical depression can adversely impact the evaluation, treatment, and recovery processes; as such, preoperative depression screening is advised. Available, validated screening tools, such as the Patient Health Questionnaire-2, can prompt additional referral for specialty consultation, if necessary [2, 14].

Alcohol and substance abuse can dramatically increase the risk of postoperative morbidity and mortality and adversely impact the ability to successfully administer neoadjuvant/adjuvant chemotherapy in elderly surgical patients. Routine screening via the CAGE or another similar questionnaire is recommended [2, 15, 16]. Patients identified to be at high risk for alcohol/substance abuse should ideally be referred to a substance abuse specialist for preoperative abstinence or medical detoxification; at a minimum, perioperative withdrawal prophylaxis should be utilized [2].

Postoperative delirium is a common complication in elderly surgical patients, with an estimated incidence ranging from 5.1% to 52.2% [17]. It is associated with higher hospital utilization/costs, perioperative morbidity mortality and complications, longer lengths of stay, higher rates of post-discharge institutionalization, and slower functional recovery [18–20]. Proper screening and documentation (in the outpatient setting) can in turn optimize perioperative management, including avoidance of use of antihistamines, benzodiazepines, drugs with strong anticholinergic side effects, and meperidine for analgesia during the inpatient, postoperative period [2].

Frailty, a syndrome of decreased physiologic reserve and resistance to stressors clinically distinct from comorbidity or disability, increases elderly patient vulnerabilities to various poor health outcomes, including worsening mobility, falls, hospitalization, and death [21, 22]. Frailty has also been shown to be a powerful independent predictor of postoperative adverse events, including increased lengths of stay, morbidity/mortality, and post-discharge institutionalization [23]. Several, "user-friendly" frailty measures exist which can be implemented in the clinical setting to optimize and streamline care during the perioperative period. One example, developed by Robinson

Table 2 Geriatric assessment markers for frailty, disability, and comorbidity

Criteria	Definition	Points
Cognition	Mini-Cog ≤ 3	1
Nutrition	Albumin ≤ 3.3 g/dL	1
Physical Stability	Falls ≥ 1 in past 6 months	1
Anemia	Hematocrit $< 35\%$	1
Disability	Dependence ≥ 1 ADLs[a]	1
Comorbidity	Charlson index ≥ 3	1

[a]Activities of daily living
Adapted from Robinson TN, et al. *Ann Surg*. 2009 Sep;250 (3):449–55

et al., is shown in Table 2; a total patient score greater than or equal to 4 is predictive of 6-month mortality with sensitivity of 81% and specificity of 86% [2, 24, 25].

An important related factor, functional dependence, was the strongest predictor of postoperative 6-month mortality in a recent prospective study of elderly patients undergoing major operations with subsequent intensive care unit admission [24]. In the setting of likely postoperative stomas and/or drains, patient independence and agility may be crucial. Outpatient screening should measure the patient's ability to independently perform daily activities (i.e., functional status) and should inquire about any history of falls. Deficits in hearing, vision, and swallowing should be documented, and limitations of gait and ambulatory mobility should be objectively quantified using the Timed Up and Go test or another similarly validated technique [25]. Based on these assessments, preoperative occupational/physical therapy can be considered, and proactive discharge planning can be implemented [2].

Another common geriatric syndrome, malnutrition, is also associated with increased risk of adverse postoperative events and, in particular, infectious and wound complications [26]. Previous studies have documented significant rates of malnutrition among elderly patients, with prevalence estimates ranging from 5.8% in the community to 13.8% in nursing homes, 38.7% in hospitals, and 50.5% in rehabilitation settings [27]. Attention paid to preoperative nutritional status is especially important in patients scheduled for procedures that may put them at risk for postoperative malnutrition (e.g., esophagectomy, total gastrectomy, pancreaticoduodenectomy, etc.). As such, nutritional status should be routinely assessed in the preoperative setting and should include calculation of body mass index (BMI), measurement of serum albumin and prealbumin, and documentation of unintentional weight loss within the previous 6 months. Patients with a BMI less than or equal to 18.5 kg/m2, serum albumin less than or equal to 3.0 g/dL, or reported unintentional weight loss of more than 10% within the previous 6 months are considered to be at high risk for malnutrition; these patients should undergo a full, preoperative nutritional assessment by a dietician and have a formal perioperative nutritional plan developed to address any anticipated deficits [2].

Polypharmacy, a common problem in elderly patients that has been associated with increased risk of cognitive impairment, morbidity, and mortality, should be routinely assessed in this population. As such, surgeons caring for elderly cancer patients should carefully review and document each patient's complete medication list, including the use of non-prescription agents and herbal supplements – particularly if neoadjuvant therapy is planned to minimize the risk of adverse drug reactions. In accordance with existing national guidelines, medications proven to reduce perioperative risks of adverse events (e.g., cardiac, etc.) should be started or continued. The addition of new medications should be minimized, and potentially inappropriate agents that may increase the risk of adverse drug reactions should be discontinued preoperatively [2].

Assessment of the patient's socioeconomic status (SES) and degree of social support is an important but often overlooked element of the CGA. Low SES and lack of social support can severely limit the elderly patient's ability to adhere with planned neoadjuvant and/or adjuvant therapy and comply with preoperative instructions (e.g., pre-habilitation, bowel preparation, etc.). Furthermore, lack of social support has been shown to be associated with increased treatment-related mortality [3, 28]. When developing a complex, multidisciplinary treatment plan for an elderly cancer patient, the oncology care provider must ascertain the patient's ability to comply with the logistics and cover the costs of the various required therapeutic elements. Otherwise, financial limitations, travel restrictions, and care obligations to an infirm spouse/partner may jeopardize care that could have been potentially mitigated via upfront referral to the treating institution's social worker and/or financial counselors [3].

Treatment Approaches

Planning and Sequencing of Care

Regardless of patient age, optimal oncologic care requires careful planning, collaborative multidisciplinary care, and adherence (whenever possible) to the most up-to-date clinical guidelines. Among elderly populations, consideration of the patient's expectations and goals of care are an integral part of this process, as modifications or omissions of specific treatment paradigms may be appropriate or required. For example, in an octogenarian woman with significant comorbidities and marginal functional outcome, it may be appropriate to treat her newly diagnosed breast carcinoma via surgical extirpation without adjuvant therapy. Proper planning should also consider the patient's ability to comply with scheduled treatments and tolerate potential toxicities/complications that may ensue [3, 6]. Elderly patients with cognitive deficiency, polypharmacy, and limited social support are more likely to become non-compliant over the duration of their cancer care [3]. Potential non-compliance can range from failure to complete a bowel preparation prior to colorectal surgery to outright refusal to take oral chemotherapeutic agents.

Surgical Therapy

Given the scope and complexity of many oncologic surgical procedures, postoperative morbidity and mortality are not uncommon, particularly in elderly patients. In an effort to preemptively mitigate these risks, the role of nutritional and/or physical pre-habilitation is increasingly being explored. A growing body of evidence supports the use of pre-habilitation programs focusing on increased pulmonary fitness and physical activity levels, particularly prior to cardiopulmonary surgery [6, 29]. In a 2016 systematic review by Moran et al., a pre-habilitation regimen encompassing aerobic activity, resistance training, and inspiratory spirometry was associated with reduced postoperative morbidity following abdominal surgery [29]. Given that many elderly cancer patients present with frailty and/or impaired functional status, further work to define the benefits of pre-habilitation in these populations is especially important [3, 29].

Among elderly cancer patients, particularly those with advanced age, advanced comorbidity, and/or marginal functional status, perhaps the most critical decision facing the surgical oncologist is whether to proceed with a curative surgical resection or a palliative procedure. Irrespective of patient age, a definitive curative procedure should be strongly considered in fit elderly patients with good performance status if a negative margin (i.e., R0) resection is technically feasible. In more frail patients with significant comorbidities and/or limited life expectancy (e.g., an 88 year old man with a metastatic, near-obstructive right colon cancer), modified extirpative procedures or palliative procedures may be more appropriate. Whenever possible, the least invasive and morbid palliative option that will reduce symptoms and optimize patient quality of life should always be implemented first. Palliative surgical interventions, however, play an important role in the treatment of the elderly cancer patients and should be included in the surgical oncologist's armamentarium [30, 31].

Although its benefit has been well established, postoperative rehabilitation is often underutilized, even among elderly cancer patients [32]. Clear advantages of rehabilitation after cancer surgery include improved physical fitness (and associated activity levels), increased quality of life, decreased costs of care, and decreased missed work days and rates of early retirement [33]. Given the physical and functional challenges often faced by geriatric surgical cancer patients, surgical oncologists should assign the same degree of importance to referral to and compliance with rehabilitation as they do to the other aspect of the patient's multidisciplinary care [32].

Radiation Therapy

While radiation may be applied in curative, adjuvant, or palliative settings in the elderly, there are more opportunities to consider radiotherapy as a curative mode of therapy in elderly cancer patients who are not deemed to be candidates for attempted curative resection. As such, a broad familiarity with radiation fractionation schedules (with or without radiosensitizing chemotherapy) is useful in presenting elderly patient with viable treatment options that may be better tolerated. As frequent travel to and from radiation therapy facilities is often challenging in elderly patients, shorter hypofractionated schedules are frequently advantageous from a logistical perspective [34]. Setup for radiation for elderly patients may sometimes require deviation from the most optimal position due to decreased mobility. The incorporation of advanced technologies, with more focused dose delivery and image guidance to decrease setup error, has made these "nonstandard" treatments more feasible [35].

While data exist describing increasing cellular radiosensitivity with age, the clinical response to radiotherapy is not always so clear [36]. In practice, while some elderly patients are quite sensitive to radiation, there are others who tolerate treatment better than their younger counterparts. Most retrospective series analyzing this topic have reported that age alone is not a good predictor of toxicity and that elderly patients often tolerate treatment quite well [37–40]. However, a more holistic approach to radiation toxicity allows one to make pretreatment predictions that can be valuable in treating elderly patients.

Smith et al. have proposed a framework for conceptualizing radiotherapy in the elderly [41]. This structure incorporates four factors to be considered when determining the risk/benefit ratio of radiotherapy in the elderly: locoregional tumor behavior, competing cancer and non-cancer morbidity and mortality risks, functional reserve, and palliative requirements. Of note, while it is important to avoid overtreatment of elderly patients, the authors also warn against undertreatment that may stem from underestimating the patient's true life expectancy or the aggressiveness of the cancer. Consideration of these factors in the context of a multidisciplinary evaluation is thus crucial to the optimal care of elderly cancer patients.

Systemic Therapy

While the surgical and radiation oncology care may be limited to a defined time, the medical oncologist often follows patients through the disease continuum from diagnosis through the late stages of palliative care. Supporting an older patient through this journey is often a very challenging and involved task that requires attention to multiple factors that affect the patient's care. These challenges are encountered daily by medical oncologists around the world and will become more prevalent in the future [42]. Medical oncologists are becoming more comfortable in caring for these older patients and prescribing anticancer therapy. This was well demonstrated by Vijayvergia et al. who reported an increase in the number of older patients and patients with multiple comorbidities that received multi-agent therapy for metastatic colon cancer over the last two decades [43]. Despite this trend older patients continue to be underrepresented in clinical trials, and high evidence data to guide treatment approach is lacking in many circumstances [44–46]. In recent years a few studies have been published demonstrating the feasibility of conducting elderly specific clinical trials and the utility of these data in guiding the management of older patients. One such example is the AVEX study which set the stage for front-line therapy with 5-fluorouracil and bevacizumab in older metastatic cancer patients who are not candidate for standard multidrug regimens [47].

As with cancer surgery, chronological age alone should not be used as a sole factor to determine the patient's ability to undergo anticancer systemic therapy. This is especially important when considering chemotherapy treatments that are often prolonged and carry significant toxicity risks. The medical oncologist is tasked with the difficult duty of differentiating between those older adults who are fit and would benefit from chemotherapy and those who are frail and would derive little benefit from this approach. Furthermore, many older adults may appear somewhat fit prior to starting treatment but are at high risk of development of side effects that will affect their function, quality of life, and longevity. These treatment decisions must be made through a shared discussion with the patient and caregivers since patient's goals and values would weigh highly on the final treatment plan. Studies have shown that older patients would value quality of life over length of life in the setting of cancer therapy [48].

Specific Chemotherapy-Related Challenges

Older patients have an altered response to chemotherapy as compared to their younger counterparts, mainly due to physiologic changes related to the aging process. These changes in organ function are often underestimated and remain undetected without a thorough evaluation. Decrements in renal and hepatic function, altered GI motility, loss of cardiac and marrow reserves, changes in cognition, and decrements in bone and muscle mass may increase the risk for treatment-related toxicity. Furthermore, the high incidence of comorbidities adds additional challenges to the planned therapy. The Centers for Disease Control and Prevention estimates that 80% of older adults have at least one chronic condition and 50% have two or more conditions that affect their care [49]. The presence of multiple comorbidities results in patients receiving additional medications and often dealing with the challenges of polypharmacy. The reported rate of polypharmacy among older cancer patients varies in the literature [50]. One study reported up to 63% of these patients have the potential for adverse drug interaction, with majority of these patients receiving an average of eight medications [51]. The definition of polypharmacy among cancer patients continues to be debated. A recent study of 385 patients over the age of 70 with cancer reported that an average of 6.5 medications predicted for frailty and an average of 5.5 medications predicted for falls. In this single institution study, the proposed cutoff was five medications or more that would define polypharmacy in an older cancer patient [52]. Delivering chemotherapy along with multiple other medications can clearly alter the activity of the anticancer therapy and result in drug-drug interactions that can affect toxicity rates and efficacy. Careful review of the medication list and elimination of unnecessary agents are necessary to decrease these interactions and maximize the efficacy and tolerance.

As noted above, changes in normal organ function are prevalent among older patients and heavily affect treatment tolerance and efficacy (Table 3). Effects of these changes in the gastrointestinal tract especially affect the older patient's ability to tolerate chemotherapy. Nausea, vomiting, and diarrhea that are commonly induced by chemotherapy can be very debilitating and result in dehydration and significant morbidity in an older patient with limited reserve. Multiple medications are available today for management of chemotherapy-induced nausea and vomiting. Serotonin (5-HT3) receptor antagonists, neurokinin-1 receptor antagonist, and corticosteroids are most commonly used and are quite effective in controlling these symptoms. These drugs, however, carry additional toxicities such as QTc prolongation, constipation, fatigue, and confusions. Thus careful selection of these agents based on the emetogenic potential of the regimen must be undertaken [62].

Glomerular filtration rate (GFR) also decreases with age and results in delayed renal excretion of many agents and increase in rate of toxicities as a result. As serum creatinine measurement may not be a good indicator of GFR in older patients, calculation of the creatinine clearance to assess the true renal function is required for all patients prior to chemotherapy initiation. A study by Peterson et al. reported an increase of about 12% in the odds for chemotherapy-related toxicity with every decrease of 10 mL/min in creatinine clearance. The study also confirmed the lack of predictive value of serum creatinine alone as a predictor of chemotherapy toxicity [53].

Table 3 Physiologic changes of aging and their effect on chemotherapy tolerance

System	Changes	Impact on chemotherapy tolerance	Recommended intervention
Cardiovascular	Decreased ventricular compliance Valvular thickening Increased vessel wall thickness Diastolic dysfunction Decreased cardiac reserve	Increased risk for heart failure Increased risk for arrhythmias Increased risk for blood pressure changes – which may lead to falls	Monitor use of cardiotoxic drugs Monitor polypharmacy EKG/ECHO monitoring based on recommended guidelines when using cardiotoxic drugs
Gastrointestinal	Decreased acid production Decrease in protective mechanisms Decreased motility and absorption Decreased hepatic drug clearance	Increased risk for mucositis and diarrhea which can lead to dehydration Decreased medication absorption Increased risk for drug overdose due to slow hepatic metabolism	Close monitor for GI-related adverse events Support with anti-nausea and antidiarrheal agents Monitor for drug interaction Consider dose reduction
Pulmonary	Decreased lung compliance Decreased FEV1 and vital capacity Increased residual volume Decreased respiratory center sensitivity Decreased mucociliary function	Increased work of breathing Decreased pulmonary capacity/ reserve Increased risk for pulmonary infections	Pulmonary evaluation prior to surgery or radiation Influenza/pneumonia vaccination Smoking cessation
Renal	Decreased GFR Tubular renal function Dysregulation of renin angiotensin system Impaired vitamin D metabolism	Drug-related nephrotoxicity – need for dose reduction Increased risk for electrolyte abnormalities	GFR/CrCL calculation for each patient + appropriate dose reductions Avoid nephrotoxic drug Evaluate for polypharmacy Monitor electrolytes
Hematologic	Increased risk for myelosuppression Increased risk for anemia Increased risk for thrombocytopenia	Increased risk of febrile neutropenia and infections Increased risk for fatigue Increased risk for bleeding	Prophylactic use of G-CSF Close monitoring of blood counts Monitor for additional medications that increase risk of bleeding, i.e., anticoagulation

EKG electrocardiogram, *ECHO* echocardiogram, *GI* gastrointestinal, *FEV1* forced expiratory volume 1, *GFR* glomerular filtration rate, *CrCl* creatinine clearance, *G-CSF* granulocyte colony-stimulating factor

Myelosuppression is the most common adverse event encountered by older patients receiving chemotherapy, and its incidence increases dramatically with aging [54–56]. For example, the risk of severe neutropenia in studies of elderly patients with non-Hodgkin's lymphoma ranged between 15% and 89% depending on the regimen used and averaging at 50% [57]. Similar data was reported among breast cancer patients with increase in the rate of dose reductions due to myelosuppresion among patients over the age of 65 [58]. The prophylactic use of granulocyte colony-stimulating factors (G-CSF) is effective in reducing the risk of febrile neutropenia and documented injections that are associated with dose-intensive chemotherapy regimens [59]. Many guidelines recommend the prophylactic use of G-CSF for patients who are at high risk based on age and when the risk of febrile neutropenia is expected to exceed 20% [60, 61]. Despite these recommendations, a recent study by Choi et al. reported a low percentage of older patients that receive this therapy despite undergoing therapy with high-risk regimens.

Additional examples of physiologic changes that are encountered with aging and directly affect anticancer therapy are outlined in Table 3. These highlight the importance of through evaluation of the patient's comorbid conditions, physical health, and other medications. Furthermore, personalization of therapy based on the patient's individual assessment is necessary to ensure the desired benefit and least toxicities possible.

Targeted Therapy and Immunotherapy

In recent years multiple new agents have been added to the treatment arsenal of various cancers. These drugs include monoclonal antibodies such as bevacizumab and trastuzumab, tyrosine kinase inhibitors such as sorafenib and sunitinib, and finally immunotherapies such as ipilimumab and pembrolizumab. As with other modalities of therapy, older patients comprised a small portion of the subjects who took part in the studies leading to approval of these agents, and thus data is limited with regard to their tolerance of these drugs. Those studies that included older patients overall demonstrated a similar efficacy in older and younger patients treated with these agents [62]. Nevertheless, there are still concerns about increased toxicities with these agents among older patients. Some of these agents have now been used for a significant time to allow post-marketing information regarding the tolerance in older patients. For example, the use of bevacizumab in older patients with metastatic colon cancer has been found to be safe, without any significant increase in toxicities in comparison to younger patients [47]. Conversely, older patients were found to have similar efficacy but higher rates of grade 3 or higher toxicities with erlotinib therapies in the advanced lung cancer [63]. Similarly, the benefit associated with trastuzumab in the treatment of HER2-positive breast cancer is equivalent in older and younger patients, yet the risk of trastuzumab-induced cardiotoxicity seems to be increased in the older patient population [64]. As oncologists become more comfortable using these agents, additional research is needed to clarify the specific considerations that are required when using them in the older patient population.

The use of monoclonal antibodies targeting immune checkpoint molecules (CTLA-4, PD-1, PD-L1) has emerged as a novel treatment approach in recent years. Currently these drugs are approved for use in multiple cancers including melanoma, non-small cell lung cancer, and renal cancer. Studies are ongoing that will likely result in approval of these agents in other cancers as well. However, data regarding their use in older patients is sparse. In addition, there are concerns regarding "immune-senescence phenomenon" – age associated impairments in the immune system that could affect efficacy of these agents [65]. These drugs can lead to prolonged antitumor response yet carry the risk of immune-related adverse events and toxicities that are distinct from the typical chemotherapy-related toxicities. A recent meta-analysis of over 5,000 patients treated with these agents demonstrated similar efficacy and survival benefit among older and younger patients [66]. Most studies to date also demonstrated similar toxicity profile among older and younger patients receiving these agents [67, 68]. Nevertheless, older patients must be monitored closely while on these agents for early detection and initiation of therapy should an immune-related adverse event arise.

Many of the targeted agents are orally administered and thus are thought to be a good choice for an older adult with cancer. However, the use of oral medication raises concerns for compliance and adherence to prescribed therapy. Studies have shown that nonadherence to oral anticancer regimen is common among older patients [69]. Factors associated with nonadherence include poor communication, disease/treatment complexity, co-payment, motivation, social support, and patient's perception. These factors must be taken into consideration when determining the treatment approach for each individual patient. Furthermore, close follow-up to ensure the drug is used appropriately and reiteration of the instructions will likely improve compliance and efficacy of the therapy.

Evaluation Prior to Systemic Therapy

Comprehensive geriatric assessment is recommended as the gold standard tool for a thorough assessment of an older patient prior to chemotherapy initiation [70]. A full CGA will evaluate all important domains that could affect the patient during the therapy (Table 1). In a study by Kenis et al., 70% of 967 patients over the age of 70 years had an abnormal screening assessment at diagnosis or disease progression. A subsequent CGA unmasked geriatric issues in 51% of participants. These observations resulted in planned interventions and changes in cancer-directed therapy in 25% of these patients [71]. Similar findings were documented in a trial of 937 patients aged $\geq$70 years, the majority of whom had an Eastern Cooperative Oncology Group performance status (ECOG PS) $\leq$ 1 (72%). CGA detected 73% of patients to be "at risk" (57% with instrumental activities of daily living (IADL) and 51% with ADL deficits) [71]. Despite the extensive data supporting the incorporation of a geriatric assessment into clinical oncology practice, time and personnel constraints have resulted in limited uptake of this approach.

Multiple screening tools (i.e., VES-13, G-8 scale, etc.) have been developed that could identify patients who could benefit from a full geriatric assessment and referral to a geriatrician (Table 1) [72, 73]. A recent study identified the G-8 scale as the best screening tool for identification of patients that would benefit from a geriatric assessment and found it to be independently prognostic of 1-year overall survival [73]. Recently several elderly specific tools for predicting chemotherapy-associated toxicity, using CGA factors, have been developed [46, 74, 75]. These models aim at providing the treating physician with a quick tool that will identify patients who are at risks of chemotherapy toxicities in a busy oncology practice. The model developed and validated by Hurria et al. and the Cancer and Aging Research Group (CARG) includes an evaluation of multiple domains that have been found to directly correlate with the risks of chemotherapy-related toxicities [46, 74, 76, 77]. Completion of this questionnaire is quite simple, and feasibility studies showed the ability to incorporate these data in a clinical practice and research setting [74, 78]. This tool has been found to have significantly higher predictive ability when compared to evaluation by ECOG PS. It allows the oncologist to assess the risks of chemotherapy toxicity to the older patient and enables the physician to have an informed discussion with the patient prior to initiating therapy. Ideally these types of evaluations should be repeated multiple times throughout the disease course. This knowledge will assist the physician in monitoring the patient through therapy and management of treatment-related toxicities, identify areas of frailty that could be improved, and aid in having goals of care discussions.

The use of chemotherapy and other antineoplastic agents for the treatment of older patients with cancer carries significant challenges and high risks for toxicities. As oncologists continue to increase the number of older adults that are under their care, available tools must be incorporated into routine practice to ensure proper evaluation and personalization of therapy. The old "eye ball" test that many physicians use is likely to lack the ability to detect all the active issues and result in less optimal care. Additional research to further define the best treatment approach, recommended dosing, and supportive care measures for older patients in different types of cancer will further enhance our care of this growing patient population.

Disease-Specific Treatment Recommendations in Elderly Cancer Patients

As emphasized throughout this review, cancer care in elderly patients should be tailored to carefully account for both patient and cancer characteristics. Whenever possible, basic cancer treatment paradigms should be adhered to. As outlined below, however, adjustments to various components of care (made within a multidisciplinary context) should also be considered and, often, may be more appropriate.

Breast Cancer

Unlike their younger counterparts, elderly women with invasive breast cancer have a distinctly improved, stage-adjusted prognosis. Invasive breast cancers in older women are more likely to be estrogen and progesterone receptor-positive receptors and less likely to harbor HER2 mutations [79]. Surgical treatment of elderly patients mirrors that of younger individuals and may include mastectomy or breast conservation therapy in combination with sentinel lymph node biopsy. In accordance with the results of the ACOSOG Z0011 trial, women of all ages may not require completion axillary lymphadenectomy if they have early-stage breast cancer (T1-T2), undergo breast conservation therapy with subsequent chemotherapy, and have limited nodal involvement [80]. In geriatric patients who do not meet these criteria, it may still be reasonable to omit axillary lymphadenectomy in patients with significant comorbidity, less biologically aggressive tumors, or if it will not influence the choice of adjuvant systemic therapy [3].

The extent of radiation therapy can also be tailored to the individual elderly breast cancer patient. As suggested by the results of the PRIME II study, it may be reasonable to omit the radiation component of breast conservation therapy for early-stage tumors (T1-T2) with benign histopathologic features (i.e., estrogen receptor-positive, node-negative) in women aged 65 years or older [81]. Furthermore, expert opinion also endorses the exclusion of radiation therapy in women aged 70 years or older who undergo margin-negative breast conservation therapy, have stage I receptor-positive disease, and who will complete 5 years of endocrine treatment [3, 81]. For the aforementioned reasons, the recommendation regarding use of adjuvant endocrine therapy in geriatric women is unchanged [3].

Unfortunately, the significance of adjuvant chemotherapy in this population is less clear. Although some studies suggest a decreased benefit among patients of advancing age treated with systemic therapy, others studies have demonstrated that geriatric patients with aggressive or metastatic carcinomas do obtain the same benefits from first-line systemic therapy as younger patients [82, 83]. As noted above, however, older women are more susceptible to toxicity from chemotherapeutic agents and should be closely monitored for required dose reductions or treatment changes [3].

Lung Cancer

Surgical therapy in geriatric patients with non-small cell lung cancer (NSCLC) largely mirrors recommendations in younger patients. Fit patients with early-stage disease should undergo operative extirpation and mediastinal lymphadenectomy, regardless of age [84]. Among elderly patients with early-stage NSCLC and significant comorbidities (including limited pulmonary reserve), stereotactic body radiation therapy (SBRT) represents a reasonable treatment alternative with similar overall and recurrence-free survival [85]. In patients with larger tumors requiring more extensive resections, pneumonectomy is associated with a significantly higher risk of mortality risk among elderly patients and should only be performed following serious consideration [3, 86].

Recommendations for adjuvant systemic therapy are similar in younger and older patients with early-stage NSCLC. In geriatric patients with unresectable locally advanced disease, definitive chemoradiation also confers similar overall survival, regardless of patient age [87]. However, associated toxicities were more severe in elderly patients and should be anticipated in patients with impaired fitness. In elderly patients with advanced/metastatic NSCLC, multiple phase III studies have confirmed that single- or double-agent chemotherapy is superior to supportive care alone in terms of overall survival and quality of life [88–90]. Again, however, toxicity remains a concern and should be closely monitored for, especially in elderly patients with decreased performance status [3].

Geriatric patients with early-stage small cell lung cancer should undergo concomitant multimodality therapy, including surgical resection if complete extirpation is possible [91, 92]. In the setting of extensive disease, elderly patients, like their younger counterparts, should receive systemic chemotherapy alone [93]. Both cisplatin- and carboplatin-based regimens have been shown to be equivalent with regard to overall survival [3, 94].

Colorectal Cancer

As with other malignancies, the surgical treatment of colorectal cancer should be guided by location and stage, not patient age. Even in patients with isolated hepatic metastases, studies demonstrate similar survival outcomes following liver resection in elderly patients compared to their younger counterparts [95]. In patients with rectal cancer, it is well established that elderly patients have a higher frequency of treatment complications, both during the neoadjuvant and postoperative settings [96]. This observation highlights the importance of optimal patient selection and an individualized approach to cancer care but should not discourage use of stage-based neoadjuvant treatment protocols or extirpation procedures, as deemed appropriate [3]. In patients with significant comorbidity and/or impaired functional status, less morbid surgical procedures (i.e., local excision combined with neoadjuvant radiotherapy with or without adjuvant systemic therapy) or a "watch and wait" strategy (following complete clinical response after neoadjuvant therapy) can be considered [97, 98]. In patients who refuse surgical resection (and/or are not surgical candidates), definitive chemoradiation alone (with or without adjuvant systemic therapy) is a viable treatment option [99].

5-Fluorouracil-based chemotherapy remains the standard of care for adjuvant therapy (or palliative care in the metastatic setting), irrespective of age [100]. Although the majority of studies of systemic therapy for colorectal cancer have not identified an increased incidence of chemotherapy-related toxicities among elderly patients, treating oncologists should practice close surveillance during therapy [3]. Limited data are available regarding the use of newer systemic agents and combinations among elderly patients. In addition to traditional chemotherapy, bevacizumab and anti-epidermal growth factor receptor (EGFR) antibodies (e.g., cetuximab, panitumumab, etc.) have shown much promise in the metastatic setting among geriatric patients and should be considered [3, 101–103].

Liver Cancer

Surgical treatment options for elderly patients diagnosed with hepatocellular carcinoma (HCC) include both liver resection and transplantation (although patients with more advanced age are often no longer considered for transplantation by many programs). Although surgical approaches to resection (e.g., non-anatomic versus anatomic resection) are consistent among age groups, special attention to underlying liver function at presentation and planned future liver remnant (which predicts risk of postoperative liver dysfunction/failure) is of particular importance in elderly patients. Although prospective data are limited, retrospective studies have confirmed that, when properly selected, outcomes of surgery for liver cancer in older patients are similar to those in younger patients [104]. In elderly patients with significant comorbidity and/or impaired functional status, liver-directed therapy, such as percutaneous radiofrequency or microwave ablation, trans-arterial chemoembolization, and SBRT, should be strongly considered [3].

Among elderly patients with advanced/metastatic HCC, standard systemic therapy largely consists of therapy with sorafenib. Although overall survival among HCC patients treated with sorafenib has been shown to be equivalent among both older and younger cohorts, agent-induced toxicities are more common in patients aged 70 years and older [105]. If prescribed within this age group, caution should be observed and close surveillance maintained [3].

Prostate Cancer

Regardless of age, the treatment of prostate cancer should be based on the patient's life expectancy, their tumor's stage and biologic aggressiveness, and the presence or absence of symptoms. While watchful waiting is a viable option in elderly men with low-risk prostate cancer, the combination of radiation therapy and androgen deprivation therapy (ADT) of variable duration has also been proven to be an effective treatment strategy in men with localized high-risk prostate cancer who do not wish to pursue surgical resection and/or are not viable surgical candidates [3, 106]. Side effects associated with long-term use of ADT (28–36 months) are commonly reported among elderly men (e.g., osteoporosis, thromboembolism, sarcopenia, etc.), and thus, close monitoring is warranted [107]. Short course ADT (4–6 months) has also been shown to be efficacious in patients with locally advanced prostatic cancer and is associated with less treatment-related toxicity [3, 108].

Bladder Cancer

Standard care for patients with locally advanced bladder cancer, irrespective of age, includes radical cystectomy and pelvic lymphadenectomy [3]. Population-based data have demonstrated that definitive surgical therapy is equally effective in both elderly and younger patients with bladder cancer [109]. Improved survival was similarly observed across age groups with administration of neoadjuvant chemotherapy in patients with muscle-invasive disease [110]. In contrast, multiple studies have demonstrated that intravesical administration of Bacillus Calmette-Guerin immunotherapy is less effective in elderly patients with bladder cancer [3, 111].

Ovarian Cancer

Although the use intraoperative staging, surgical cytoreduction, and adjuvant systemic therapy remains the standard of care in women with ovarian carcinoma, population-based studies have unfortunately demonstrated underutilization in elderly patients [112, 113]. Reasons for underuse include lack of access to optimal surgical care, distance to treatment facility, and existing comorbidities. Lower enrollment rates of elderly women in prospective clinical trials for ovarian cancer have resulted in the paucity of level I data in this population. Although individualized care should be emphasized, special attention should be paid to the primary roles of surgery and chemotherapy in this patient cohort. Regarding selection of systemic agents, retrospective studies demonstrate that platinum-based doublet chemotherapy is reasonable for patients 70 years or older, as is intraperitoneal chemotherapy [114, 115]. Not surprisingly, however, agent-specific dose modifications and associated toxicities are more common among older women [3].

Melanoma

Despite recent advances in the care of melanoma, surgical excision remains the keystone of curative therapy. As in younger patients, elderly patients with melanoma should undergo wide local excision of the primary site with nodal evaluation/excision performed as per current guidelines [116]. Should significant comorbidity and/or poor functional status make surgery under general anesthesia prohibitive, a reasonable alternative is wide local excision under local anesthesia and omission of nodal evaluation/excision. For primary lesions which cannot be completely resected, adjuvant radiation therapy should be considered [3].

As with younger patients, elderly patients with locally advanced or metastatic melanoma have enjoyed treatment success with newer immunotherapy agents. Ipilimumab, perhaps the most well-known monoclonal antibody used in the treatment of melanoma, has been shown to increase overall survival in previously treated patients afflicted with metastatic melanoma. Multiple studies have confirmed that this survival benefit is consistent in patients above the age of 65 [117, 118]. Similarly, increased overall survival among elderly metastatic melanoma patients has also been confirmed with the use of the BRAF kinase inhibitor vemurafenib and the selective MEK1/MEK2 inhibitor trametinib [119, 120]. Systemic therapy with immunotherapy agents represents the standard of care for all patients with unresectable disease, regardless of age [3].

Conclusion

Optimal care of the elderly cancer patient requires careful consideration of patient- and tumor-related factors and thoughtful deployment of curative surgery or palliative procedures within a multidisciplinary context. A patient-centered CGA is absolutely essential and must consider patients' life expectancy, goals of care, comorbidities, functional status, and socioeconomic/social context, rather than simply patients' chronological age. Whenever possible, preoperative interventions to address various geriatric syndromes and optimize emotional/physical fitness for surgery – as well as neoadjuvant and/or adjuvant multimodal therapy – should be considered and utilized. Although advanced age can be associated with increased rates of treatment-related toxicity, an individualized, methodical, coordinated approach to surgical care in elderly cancer patients can result in excellent short- and long-term perioperative, functional, and oncologic outcomes.

13 Diabetes in Older Adults

Margo S. Hudson and Nadine E. Palermo

Contents

Abstract

Diabetes mellitus is a complex and chronic illness which affects patients of all ages. Recent estimates predict increased prevalence in the aging population as well as worldwide. Older adults are at increased risk of both acute and chronic diabetes-related complications with adverse consequences on overall health and mortality. Several important factors distinguish inpatient and outpatient management in this patient population.

Diabetes mellitus type 1 · Diabetes mellitus type 2 · Older adult · DKA · Hypoglycemia · Insulin · Cardiovascular disease · Microvascular complications

Introduction

According to the latest estimates from the International Diabetes Federation (IDF), the number of individuals with diabetes worldwide now exceeds 415 million [1]. The Center for Disease Control (CDC) predicts continued rise in diabetes prevalence in the United States with estimated projections affecting one in three adults by 2050 [2]. More than 25% of patients age 65 and older have diabetes which is among the highest

https://doi.org/10.1007/978-3-319-47771-8_14

proportion of any age group [3]. The cost of diabetes care shows a similar increase with a 40% rise seen in the last decade, now over $176 billion dollars, with approximately 59% spent on patients over age 64 [4]. In recent years, there has been a tremendous focus on individualizing treatment and ongoing interest for a consensus to address recommendations for older adults with diabetes. In this chapter, we will review the pathophysiology of diabetes and special considerations and challenges in the management of diabetes in older adults.

Epidemiology, Pathophysiology, and Diagnosis of Diabetes

Diabetes mellitus is a common metabolic disorder which results from complete or partial deficiency in insulin. The most prevalent forms of diabetes are type 1 and type 2, which account for approximately 5–10% and 90–95%, respectively. While in the past it has been suggested that the age at diagnosis determines the subtype, the landscape of diabetes is more complicated, and these traditional paradigms have changed. This is particularly important to consider in older adults. While type 2 diabetes is the predominant subtype, patients may be diagnosed with type 1 diabetes at any age. Patients with type 1 diabetes are also living longer [5]; therefore, this phenotype will be seen in older adults. This distinction in identifying the subtype is essential to understand as the underlying etiology governs the most appropriate and effective treatment strategy.

Classical type 1 diabetes is due to autoimmune-mediated destruction of pancreatic beta cells, which over time results in complete insulin deficiency. In this subtype of diabetes, there are often positive autoimmune antibodies or "biochemical markers" present. The most commonly detected antibodies include islet cell antibodies, glutamic acid decarboxylase 65 (GAD 65), anti-insulin, anti-IA-2, and zinc transporter 8 (ZNT8). Classical type 1a diabetes is defined as the presence of one or more of the aforementioned antibodies. However, some patients with type 1 diabetes do not display the common "biochemical markers" which reflect beta cell immunity, yet these patients have insulin deficiency. Regardless of the etiology, patients with type 1 diabetes must be considered insulin deficient and should not be without exogenous insulin.

Type 2 diabetes results from impaired insulin secretion often in the setting of insulin resistance rendering the patient relatively insulin deficient. Some of the key functions of insulin occur in the muscle (increasing glucose transport into the cells), liver (inhibiting glucose release and promoting glycogen storage), and adipose tissue (forming triglycerides and inhibiting lipolysis). In insulin resistance, insulin is less effective at producing these results, and more insulin must be produced to maintain normal glucose levels. Insulin resistance is increased in states of inflammation, in excess nutrition, and from glucocorticoids to name a few causes [6]. When insulin secretion cannot keep up with insulin needs, type 2 diabetes will result. A myriad of factors including age-related beta cell decline [7], decreased insulin secretion [8], increased adiposity, and changes in physical activity [9] contribute to the pathogenesis of type 2 diabetes. For most patients with type 2 diabetes, in contrast to type 1 diabetes, non-insulin agents may be used initially, and over time insulin replacement may or may not be required. It should be noted that there are many other atypical forms of diabetes such as monogenic diabetes syndromes, maturity-onset diabetes of the young (MODY), cystic fibrosis-related diabetes (CFRD), pancreatic diabetes due to pancreatitis or surgery, and new-onset diabetes after organ transplant (NODAT) [10]. Treatment strategies should be matched to the underlying etiology.

Older adults are at increased risk for both diabetes and prediabetes, and the American Diabetes Association (ADA) recommends all adults age 45 years or older be screened every 1–3 years and at younger ages with other risk factors for dysglycemia [10]. Diabetes mellitus may be diagnosed based on plasma glucose levels (fasting, 2-h postprandial following 75 g oral glucose tolerance test (OGTT)) or hemoglobin A1c (A1c). In the setting of symptomatic hyperglycemia or

Table 1 Diagnostic categories for hyperglycemic disorders

Diagnostic criteria for diabetes mellitus
FPG≥126 mg/dL (7.0 mmol/L)
2 h post prandial glucose ≥ 200 mg/dL dining OGTT
A1c ≥ 6.5% (48 mmol/mol)
Random PG ≥ 200 mg/dL, symptoms of hyperglycemia or hyperglycemic crisis
Diagnostic criteria for pre-diabetes
FPG 100–125 mg/dL "impaired fasting glucose" (IFG)
2 h post prandial glucose 140–199 mg/dL during OGTT "impaired glucose tolerance" (IGT)
A1c 5.7–6.4%

Modified from American Diabetes Association [10]
A1c hemoglobin A1c, *FPG* fasting plasma glucose as defined as no caloric intake for minimum 8 h, *PG* plasma glucose, *OGTT* oral glucose tolerance test (following 75 g anhydrous glucose dissolved in water)

hyperglycemic crisis, the diagnosis of diabetes mellitus is clear. In all other cases, a confirmatory test should be done to formally establish a diagnosis of diabetes (see Table 1).

The same biochemical testing used to screen for diabetes may be used to detect prediabetes, impaired fasting glucose (IFG), or impaired glucose tolerance (IGT). See Table 1 for criteria for these categories [10–12]. Identifying patients with prediabetes is important because progression to diabetes can be prevented [13], and when these patients have other acute illnesses, glucose tolerance can quickly deteriorate leading to hyperglycemia.

It is important to note that A1c results should be interpreted in the setting of other factors that may affect the glycation of hemoglobin such as hemoglobinopathies, anemia, hemodialysis, recent transfusions, medications (erythropoietin), and splenectomy. One may consider using fructosamine and 1,5-anhydroglucitol (1,5-AG) to assess glycemic control.

Acute and Chronic Complications

Type 1 and type 2 diabetes are associated with higher mortality at all ages, and deaths are largely due to cardiovascular disease complications. In a large Canadian study, mortality was 70% higher in patients with diabetes age 65–74 compared to nondiabetic peers [14]. It has been estimated that men with type 2 diabetes will lose nearly 12 years of life and women lose 14 years [15] from complications of diabetes. Importantly, recent efforts at better control of glucose, blood pressure, and lipids have led to a decrease in complication rates and improved mortality [16, 17] giving cause for optimism.

Acute Complications

Acute complications of diabetes include hypoglycemic and hyperglycemic emergencies. Hypoglycemia occurs when glucose levels are below 70 mg/dL and severe hypoglycemia when glucose is below 40 mg/dL [18]. Severe hypoglycemia can lead to arrhythmias, seizures, coma, and death. In the hospital, any hypoglycemia is associated with higher mortality [19]. For patients on insulin with hypoglycemia in the hospital, mortality was four times greater than patients on insulin who did not have hypoglycemia. Lower BMI, renal dysfunction, hepatic dysfunction, and cognitive decline put patients at higher risk for hypoglycemia. Patients at particular risk are those with unpredictable eating patterns especially in the hospital or skilled nursing facility. Patients with recurrent episodes of hypoglycemia will often lose symptoms of hypoglycemia, a phenomenon called hypoglycemia unawareness [20]. This can only be treated with vigorous avoidance of hypoglycemia. Many of the newer medications for type 2 diabetes do not lead to hypoglycemia which can have significant benefit for older patients.

Hyperglycemic crises include diabetic ketoacidosis (DKA), hyperglycemic hyperosmolar syndrome (HHS), and the overlap syndrome that has been called hyperosmolar ketoacidosis (HK). These syndromes are characterized by hyperglycemia, dehydration, and severe electrolyte depletion. Their natural histories and associated mortality risk vary. DKA has the lowest mortality, reported now to be <5% across institutions in the United States and <1% in several reported institutions. HHS, however, is associated with mortality over 15% in several studies, and the concomitant presence of

Table 2 Classification of hyperglycemic crisis

	Mild DKA	Moderate DKA	Severe DKA	HHS
Blood glucose (mg/dL)	>250	>250	>250	>600
PH	<7.30	7.12–7.24	<7.15	>7.30
HCO3	15–18	10 to<15	<10	>18
Urine/serum ketones	+	+	+	+/−
Serum Osm (Osm_{eff})				> 320
AG	>10	>12	>12	Variable
Mental status	Alert	Alert/Drowsy	Stupor/Coma	Stupor/Coma

Serum effective osm (Osm_{eff})=2[Na] + Glucose/18
AG anion gap, *Osm* osmolality

ketoacidosis yields mortality rates as high as 30% for HK. Precipitants for hyperglycemic crises include noncompliance with medication, introduction of a new medication such as glucocorticoids, or development of an intercurrent illness such as infection or myocardial infarction. Diagnostic criteria for hyperglycemic crises [21] are listed below (see Table 2).

Prompt recognition and aggressive treatment are necessary for good outcomes in the older population. Primary treatment requires insulin, fluids, and electrolyte replacement and should be done in the hospital in a setting based on severity and usual hospital practice. Algorithms for management of hyperglycemic crisis are available [21], and a simplified outline is shown here (Fig. 1).

Chronic Complications

Landmark studies such as the United Kingdom Prospective Diabetes Study (UKPDS) looking at type 2 diabetes [22] and the Diabetes Control and Complications Trial (DCCT) looking at type 1 diabetes [23] demonstrated the direct relationship of hyperglycemia to microvascular (retinopathy, nephropathy, and neuropathy) and macrovascular (cardiovascular, cerebrovascular, and peripheral vascular disease) diabetes complications. We are now starting to understand the pathophysiology of complications. One recently recognized pathway is the irreversible glycation of proteins which then form cross-linked macroprotein derivatives known as AGEs (advanced glycation end products). AGEs bind to their receptor RAGE (receptor for AGE) and damage endothelium, nerve tissue, glomerular podocytes, and many of the other tissues we commonly consider to be impacted by diabetes [24]. Our understanding of the mechanisms of glucose-induced tissue damage may lead to targeted treatments in the future. However, we also know the central importance of hypertension and hyperlipidemia to development of complications.

Diabetes is the leading cause of blindness and end-stage renal disease (ESRD) in the United States and a major contributor to amputation. The main risk factors for the development of microvascular complications include duration of diabetes as well as glucose control. The figure below shows the direct impact of A1c on complication rates in type 1 diabetes [25, 25] (see Fig. 2). For each 1% drop in A1c that a patient can achieve, risk for retinopathy decreases by 45%! In type 2 diabetes, each 1% drop in A1c reduces risk of microvascular complications by 37% [26]. Newly recognized diabetic complications include soft tissue damage (diabetic cheiropathy, tendon contractures, and adhesive capsulitis) [27] and diabetic bone disease which can lead to increased fractures and Charcot foot deformity.

Patients with diabetes also have two to four times the rate of macrovascular complications compared to controls [28, 29]. Long-term follow-up studies of UKPDS and DCCT have shown that improved glucose control improves cardiovascular outcomes [30, 31]. Every 1% drop in A1c results in a 14% risk reduction for myocardial infarction. In both the DCCT and the UKPDS trials, intensive treatment was only maintained for 6–10 years during the active trial, and then A1c levels converged to remain at

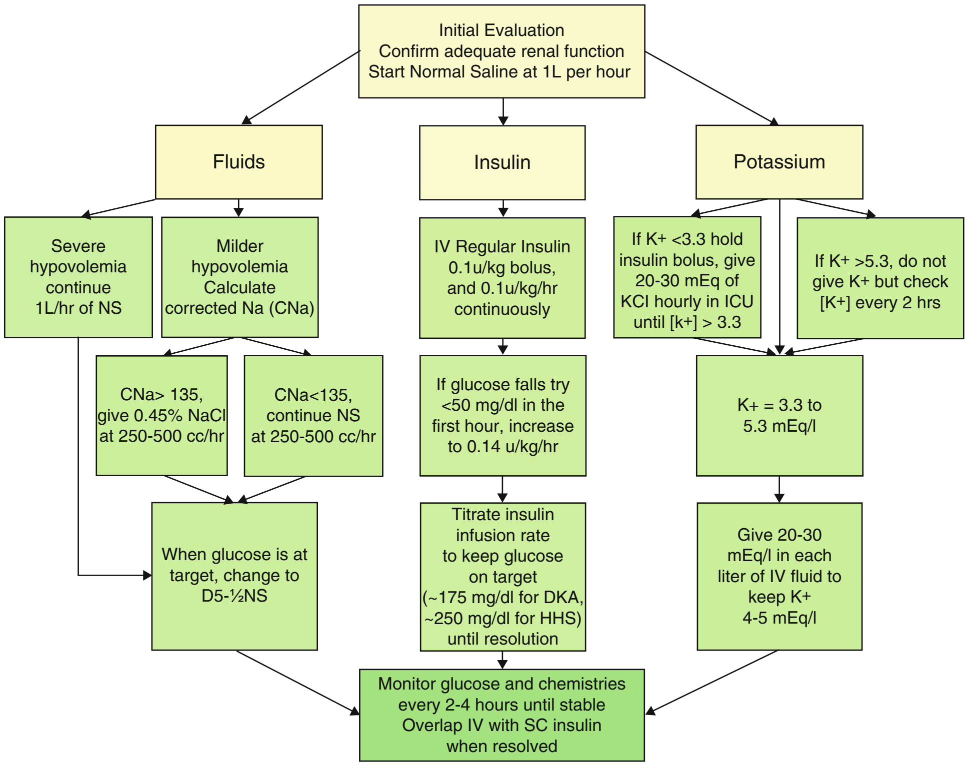

Fig. 1 Schemata for the management of diabetic ketoacidosis (Used with permission [21])

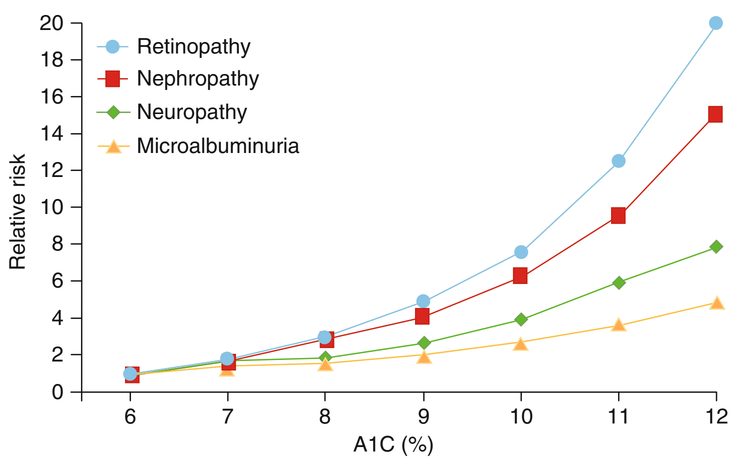
Fig. 2 DCCT A1C levels and the risk of complications in type 1 diabetes [23]



approximately 7.5–8% for up to an additional 20 years. Yet risk reduction for microvascular and macrovascular disease has remained at 25–50% and 13–40% [30, 31]. This phenomenon of lifelong benefit from good glucose control early on in diabetes is now termed "metabolic memory" and has helped change practice.

Some of the newer agents for diabetes such as the SGLT-2 inhibitor empagliflozin and the GLP-1 receptor agonist liraglutide may also lower cardiovascular risk through mechanisms beyond glucose control [33, 34] since benefits can be seen within months of initiating therapy. Cardiovascular event risk reduction in the range of 13–38% has been reported.

Treatment approaches beyond glucose control have also demonstrated improvement in diabetic complications. Blood pressure control can lower microvascular complication rate by up to 37% [32] and macrovascular risk by up to 50%. ACE-Is, and ARBs have had particular success in preventing progression of nephropathy [35, 36]. Lower blood pressure control is not always better as the ACCORD (Action to Control Cardiovascular Risk in Diabetes) trial showed. This was a large randomized study looking at cardiovascular outcomes in type 2 diabetes patients at high risk for cardiovascular disease. The trial looked at achieving systolic blood pressure below 120 mmHg versus 140 mmHg and found no overall benefit though there was lower stroke rate with the more intense BP control [37]. Lowering LDL cholesterol levels with statin therapy has been very effective at primary prevention of macrovascular complications [38]. Statin therapy is now recommended for all patients with diabetes over age 40 [39] unless contraindicated. Moderate- or high-intensity statin therapy (equivalent to 40–80 mg of atorvastatin) is considered beneficial for patients with diabetes over the age of 75 with higher dose for those with known cardiovascular disease.

Diabetes doubles the risk for cognitive impairment and dementia, adversely affecting quality of life [40]. This is multifactorial and includes a 100–150% higher rate of vascular dementia and a 45–90% higher rate of Alzheimer's disease. Hypertension and hyperlipidemia as well as hyperglycemia play a role. More rapid cognitive decline is associated with higher A1c and longer duration of diabetes. There is a strong correlation between microvascular complications and cognitive impairment [41]. However, intensive control of diabetes was not shown to improve cognitive outcomes in older patients with type 2 diabetes [42]. Intensive control may even be hazardous in older patients because episodes of severe hypoglycemia may double the risk of dementia. The relationship is complex since patients with dementia also have higher rates of hypoglycemia [43, 44]. Depression is also an independent contributing factor to dementia in patients with type 2 diabetes [45].

Goals of Treatment in Older Adults

While several studies have demonstrated the importance of achieving and maintaining glycemic control, it is noteworthy to mention that many of the larger trials were not designed for patients age 75 or over and there is limited evidence in this patient population. Based on the available data, attempts to achieve near-normal glycemic control have not always been favorable in older adults. The glucose arm of the ACCORD study which looked at achieving A1c levels below 6.0% versus below 8.0% was terminated early as intensive glycemic control was associated with increase in death and higher rates of hypoglycemia in older adults [37]. It is because of this that the ADA position statement suggests patients with "longer duration of diabetes, known history of hypoglycemia, advanced atherosclerosis, and advanced age / frailty" may not benefit from intense or "tight" glycemic control [46]. As older adults with diabetes often have other medical comorbidities and substantial variability in their overall health status, goals of diabetes treatment should be individualized with emphasis on preventing significant hyperglycemia and clinically relevant hypoglycemia. There are several challenges in this patient population including irregular nutrition, decline in renal function, cognitive and functional impairment, polypharmacy, and costs of medication, all of which can contribute to barriers in care of older adults with diabetes. It is equally important to consider caregivers in treatment plans, and regimens are often designed with this in mind.

Blaum et al. sought to develop a framework to assist with determining appropriate diabetes treatment strategies for older adults [47]. In this study, they defined three health status groups: relatively healthy, patients who may have difficulty with diabetes self-management, and a limited benefit group due to coexisting conditions. The relatively healthy group had fewer than three chronic illnesses and no significant cognitive or visual impairment and was fairly independent with activities of daily living (ADLs). The second group was comprised of patients with one or more of the following: three or more chronic illnesses in addition to diabetes, mild cognitive impairment, severe vision impairment, and two or more dependent ADLs. The third group, limited benefit group, represented those patients with the poorest overall health status with moderate to severe cognitive impairment, two or more dependent ADLs, and/or residence in a long-term care facility. In this study, a large proportion of older adults had clinically complex comorbidities and a spectrum of health status which can make self-management of diabetes challenging. It was estimated that approximately 22% of patients over age 51 with diabetes have health challenges that could make self-care of diabetes difficult. Therefore, careful considerations in determining individualized glycemic targets are needed [47]. It is now widely accepted that less stringent A1c goals may be appropriate in some patient populations especially older adults at risk for hypoglycemia and limited life expectancy with multiple comorbidities. Below is a graphical depiction considering these factors to assist with determining glycemic targets [48] (Fig. 3).

Tools of Glucose Management

As noted above, treatment goals for diabetes should always be individualized but especially so in the older adult. For patients who are frail, have heart disease or dementia or hypoglycemia unawareness, and are at high risk of hypoglycemia and its deleterious consequences, higher glucose levels may be appropriate, and the goal of using "hypoglycemia-free" medications may be indicated.

Likewise, patients with shortened life expectancy may not benefit from risk reduction for chronic complications, and treatment goals may be limited to preventing symptoms of hyperglycemia and hypoglycemia. On the other hand, many older adults are quite vigorous, and there is no reason to modify goals from those of younger patients (Table 3).

Treatment of hyperglycemia in type 2 diabetes should start with medical nutrition therapy and lifestyle intervention. For obese or overweight patients, weight loss in the range of just 5–10% can markedly improve glucose control [49] especially when combined with increased activity. Recent data on best macronutrient mix for weight loss has not been consistent with an earlier trial showing no greater success with low-carbohydrate versus low-fat diets [50] and a more recent trial showing better outcomes with low-carbohydrate diets [51]. Even when weight loss is not a goal,

Fig. 3 Considerations for treatment in older adults with diabetes

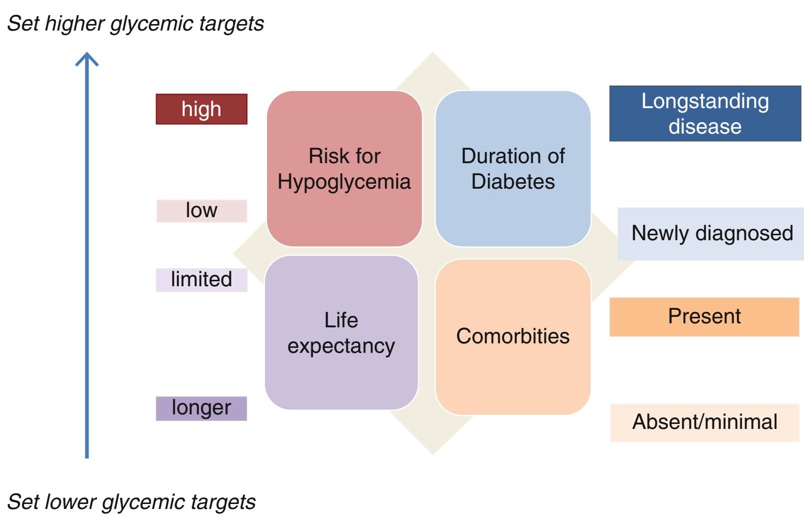


Table 3 Recommendations for glucose, blood pressure, and lipids in older adults with diabetes

Health status	A1c goal	Pre-meal glucose target (mg/dL)	Bedtime glucose (mg/dL)	BP target (mmHg)	Statin use
Healthy	< 7.5%	90–130	90–150	<140/90	Yes if tolerated
Intermediate: multiple co-existing illnesses, moderate cognitive dysfunction	< 8.0%	90–150	100–180	<140/90	Yes if tolerated
Poor: end-stage co-morbidities, severe cognitive decline	< 8.5%	100–180	110–200	<150/90	Only if benefit can be expected

Modified from Diabetes Care 2017:40(supp 1):s99–104

adherence to diet modification is important. Diet recommendations can be compatible with patient preference and culturally sensitive but should include suggestions for monounsaturated fats over saturated fats, whole grain, high-fiber foods over refined grains, and avoidance of sugar-sweetened beverages. For patients on prandial insulin, insulin doses and carbohydrate content need to be coordinated [52].

For most patients with type 2 diabetes, however, diet and exercise alone are not sufficient for glucose management. There are many classes of drugs available now for treatment, and choosing which one or which combination is appropriate for each patient can be confusing. The main considerations in choosing a drug are efficacy at lowering glucose, risk for hypoglycemia, cost, side effects, contraindications, and whether the drug is oral or injectable. The main mechanisms of action (MOA) are increasing insulin release, improving insulin action, increasing glucose excretion, blocking glucose absorption, or replacing insulin. Table 4 lists non-insulin-based medications and MOA. Many new drugs are being developed, and many existing ones are available in fixed dose combinations which are not included here.

Insulin-sensitizing agents improve insulin action but do not work in the absence of insulin. Biguanides are insulin sensitizers and have been used for many years. Currently the only available member of this class is metformin. The exact mechanism of action of metformin is not well established, but its primary effect is to lower liver production of glucose. Some newer studies implicate an effect on the intestine as well. Metformin has enjoyed a wide acceptance as first-line therapy for type 2 diabetes. It is oral, comes in once-a-day formulations, is low cost, and, because it is a sensitizer, it does not cause hypoglycemia. It has been associated with improved cardiovascular outcomes. Common side effects include nausea and diarrhea. Because a previously available drug in this class, phenformin, had been associated with lactic acidosis, the FDA has been quite cautious in the use of metformin in renal insufficiency. But there is good evidence that metformin can be safely used even with eGFR down to 30–45 ml/min/1.73m^2 with some dose modifications [53]. Age should not be a reason to avoid use of metformin.

Thiazolidinediones are another class of drugs that work by improving insulin action. The primary effect is improved postprandial glucose levels due to increased glucose uptake by muscle and adipose tissue. These drugs are PPARγ (peroxisome proliferator-activated receptor gamma) nuclear activators. They promote adipose tissue differentiation and production of the hormone adiponectin which improves insulin signaling. The two available drugs in this class include pioglitazone and rosiglitazone. Rosiglitazone has been implicated in worse cardiovascular outcomes which has decreased its use. These drugs are oral, available as generics, and do not cause hypoglycemia. They also lower hepatic fat content. But they cause weight gain, fluid retention, increase heart failure rates, and increase fracture risk. In general they are not recommended for use in most older patients.

Sulfonylurea agents have been available for longer than the other classes of non-insulin-based drugs. They work by binding to the SUR

Table 4 Treatments for diabetes

Drug class	Generic name	Mechanism of action
Insulin sensitizers:		
Biguanide	Metformin	Lowers hepatic glucose output, may also work through gut
Thiazolidenedione	Pioglitazone Rosiglitazone	Increase glucose uptake in muscle and fat cells, decreases hepatic steatosis
Insulin secretogogues:		
Sulfonylurea agent	Glimepiride Glipizide Glyburide	Increase insulin secretion independent of glucose level(high hypoglycemia risk)
Meglitinide	Repaglinide Nateglinide	Increase insulin secretion with some glucose dependence(less hypoglycemia risk)
Incretin agents: DPP4 inhibitors	Sitagliptin Linagliptin Vildagliptin Saxagliptin Alogliptin	Prolong naturally produced GLP-1 increasing insulin and decreasing glucagon in a glucose dependent manner
Incretin based agents: GLP-1RA	Liraglutide Dulaglutide Exenatide Lixisenatide Albiglutide	Long-acting agonist for GLP-1 receptor, increase insulin secretion, decrease glucagon secretion, decrease appetite, prolong gastric emptying, glucose level dependent
Glycosuric agents:		
SGLT-2 inhibitor	Empagliflozin Canagliflozain Dapagliflozin	Decrease glucose reabsorption in the kidney
Lesser used agents:		
α-glucosidase inhibitor	Acarbose Miglitol	Decrease glucose uptake in the gut
Dopamine agonist	Bromocriptine	Modulates hypothalamic control of metabolism
Bile acid sequestrant	Colesevelam	Binds bile acid
Amylin analog	Pramlintide	Approved for use in type 1 DM, decreases glucagon and gastric emptying

receptor on the ATP-dependent K channel in the beta cell which leads to insulin secretion. This effect happens regardless of glucose levels, so it is important to note the risk of hypoglycemia. Three drugs in this class ("second-generation" sulfonylureas) are primarily in use: glyburide, glimepiride, and glipizide. They are all available as generics and are oral. Glyburide has been associated with the highest rates of hypoglycemia and should not be used in older adults [54]. Mitiglinides, repaglinide, and nateglinide also bind to the ATP-dependent K channel in the beta cell. They have a short duration of action and do not contain sulfur which may be helpful in some cases of allergy. Repaglinide can cause hypoglycemia, but it is rare with nateglinide.

The incretin system has recently become a target of drug development. When food enters the gut, it triggers the release of the incretin hormones, GIP and GLP-1. These hormones "prime" the beta cells to secrete more insulin in response to rising glucose levels. They also suppress glucagon, slow gastric emptying, and decrease appetite, all designed to limit postprandial glucose rise. In type 2 diabetes, GLP-1 is deficient. Two strategies are available to increase GLP-1 effect. Degradation of GLP-1 can be limited by inhibiting DPP-4, the enzyme that breaks down GLP-1. This class of drugs is known as DPP-4 inhibitors. The other strategy is to develop agonists that bind to the GLP-1 receptor but are resistant to DPP-4, the GLP-1 RA class of drugs.

There are currently several available DPP-4 inhibitors. They are oral and with glucose-dependent reduction have less risk for hypoglycemia. They are well tolerated and can be used in renal insufficiency and even ESRD (some require dose modification). Their efficacy at lowering A1c is limited, averaging 0.5–0.8%, and they are not available as generics at this time. Most cardiovascular outcome studies of DPP-4 inhibitors have been neutral [55]. They have a favorable side-effect profile. Pancreatitis may be increased, but overall risk is quite low. A recent meta-analysis found rates of 0.28% versus 0.15% with placebo [56]. They are an excellent choice for frail elders who do not require significant lowering of A1c.

GLP-1 RA therapy is becoming widely used. A1c lowering can equal or exceed 1%. Weight loss of 4–5 kg is also a significant benefit. All drugs in this class are currently available as injectables only, but several are available as weekly preparations. There are no generics and cost can be substantial. Side effects include nausea and nodules at the site of injections. Use is contraindicated in patients with gastroparesis or in patients with high risk of medullary thyroid cancer (due to animal studies that have not been replicated in humans). Two recent cardiovascular outcome studies have shown modest benefit [34, 57]. As with the DPP-4 inhibitors, pancreatitis risk may be increased but is still at a low rate.

The newest class of drugs is the SGLT-2 inhibitor class. These drugs inhibit glucose and sodium uptake in the proximal renal tubule causing a glucose and sodium diuresis. A1c lowering is in the range of 0.7% on average. They are oral and are associated with modest weight loss. Side effects include genitourinary infections, dehydration leading to worsening renal function, increased rate of DKA (sometimes with lower glucose values or "euglycemic" DKA), and possible increase in fracture risk. In a recent large trial of empagliflozin, cardiovascular outcomes including mortality were improved by over 30%, and empagliflozin recently became the first glucose-lowering agent to receive FDA approval for lowering cardiovascular risk [33]. Interestingly, renal outcomes were also better [58].

Other available classes used less frequently because of cost, lack of efficacy, or side effects. α-Glucosidase inhibitors, acarbose and miglitol, are oral and work by inhibiting intestinal glucose absorption. Because glucose is delivered to the colon, side effects such as gas, bloating, and diarrhea are frequent, limiting patient acceptance. The dopamine agonist bromocriptine is available in a rapid release formulation for type 2 diabetes. It has a novel mechanism, working centrally to perhaps reset the sympathetic nervous system. It is expensive and lowers A1c on average less than 0.5%, but there has been one cardiovascular outcome study that showed benefit [59]. Colesevelam is a bile acid sequestrant that is generally used to lower cholesterol but in combination with metformin can lower A1c by 0.6%. Constipation and flatulence are limiting side effects. Finally pramlintide is an injectable analog of the naturally occurring peptide amylin. Amylin is co-secreted with insulin and slows gastric emptying as well as suppresses glucagon. It must be given with each meal and causes significant nausea limiting its use. It is the only non-insulin-based drug approved for use with type 1 diabetes.

Insulin use should not be avoided in older patients with diabetes. Insulin must be used for patients with absolute insulin deficiency such as type 1 diabetes and pancreatic-based diabetes from cystic fibrosis, recurrent pancreatitis, or pancreatectomy. In type 2 diabetes, insulin should be used regardless of age when combinations of non-insulin-based medications do not reach glycemic targets. Insulin dosing complexity requires that the patient and/or caretaker fully understands how to administer insulin and how to recognize when adjustments are indicated. Ability to monitor glucose values by using point-of-care glucose testing is crucial for the safe use of insulin.

There are many different types of insulin currently available, and many more are being developed [60]. Pharmacokinetics including onset of action, time-to-peak action, and duration of action are the main differences between insulins. Insulin is naturally secreted in two patterns, continuously in low doses to suppress hepatic glucose output (basal) and in short bursts to cover postprandial glucose spikes (bolus). The goal of treatment is to mimic these normal physiologic patterns. Insulin can structurally be identical to natural human insulin or can have various amino acids or other

Table 5 Summary of insulin pharmacokinetics

Category	Name	Human or analog	Onset of action	Peak action	Duration of action
Rapid acting	Lispro U-100	A	10–15 min	1 h	4 h
	Lispro U-200	A			
	Aspart U-100	A			
	Glulisine U-100	A			
Fast acting	Regular U-100	H	15–30 min	2 h	6 h
Intermediate	NPH U-100	H	1 h	5–6 h	10–12 h
	Regular U-500	H	1 h	4 h	6–8 h
Long acting	Detemir	A	90 min	Minimal peak effect	20 h
	Glargine	A	90 min	No peak	24 h

	Lispro 75/25	A			

substitutions and additions (termed analog insulin). Adding protamine to insulin was the earliest way to prolong action, and the insulin can be completely protaminated (NPH) or partially so (premixed). Insulin can also vary by concentration. Most standard concentrations are U-100 (100 units/cc), but U-200, U-300, and U-500 concentrations are available. Table 5 lists current insulins.

In type 1 diabetes, basal and bolus insulin must be combined, or the patient can use rapid-acting insulin continuously infused by a pump. In type 2 diabetes, most patients started on insulin begin with basal once a day or premixed twice a day, and bolus insulin is added as needed [61]. Insulin can be used in combination with most oral agents, but combinations must make "sense." An algorithm for combining all available agents is shown below [48] (see Fig. 4).

With appropriate use of the many available glucose-lowering agents, most older patients can reach glucose targets safely.

Management of Glucose in the Hospital

The current definition of hyperglycemia in the hospital is any glucose over 140 mg/dL [18]. Hyperglycemia is a very common problem in the hospital with 26% of patients admitted having known diabetes and another 12% with hyperglycemia from undiagnosed diabetes or acute physiologic stress [62]. In the ICU, up to 70% of all patients develop hyperglycemia. Stress hyperglycemia is a transient hyperglycemia in patients without diabetes which resolves after the illness resolves. Recent ADA recommendations for defining clinically significant hypoglycemia in the hospital is a BG <54 mg/dL and severe hypoglycemia is a glucose associated with cognitive changes [10]. However, previously, hypoglycemia had been defined as any glucose below 70 mg/dL, and severe hypoglycemia is a glucose below 40 mg/dL.

Patients with diabetes have long been recognized to have worse outcomes than nondiabetic peers. During surgery, in particular, patients with diabetes have higher rates of MI, renal failure, and postoperative infections [63]. This may be due in part to comorbidities of vascular disease and kidney disease, but hyperglycemia itself has long been felt to contribute. In patients with myocardial infarction and diabetes, sustained hyperglycemia is correlated with an increase in mortality by 25–50%. To demonstrate the importance of stress hyperglycemia on outcomes, in this same study of MI, in patients with stress hyperglycemia, mortality is increased by 200–400% [64]!

The key management question is whether controlling hyperglycemia will improve outcomes, and there have been many trials looking at

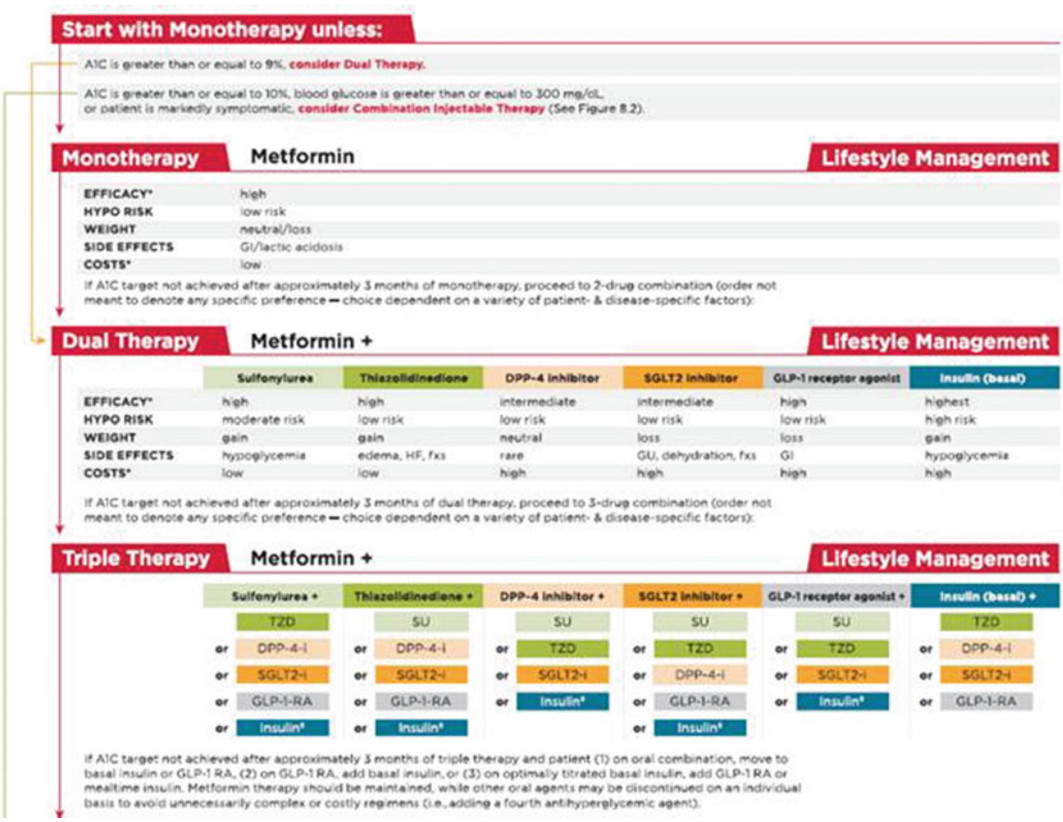

Fig. 4 Treatment algorithm [48]

inpatient outcomes and glucose control. One of the first nonrandomized demonstrations was in cardiac surgery patients. Using IV insulin infusion for 72 h postoperatively in patients with known diabetes, glucose was maintained in well-defined target ranges which were lowered over time, from below 200 mg/dL to 175 mg/dL to 150 mg/dL, and the team was able to reduce sternal wound infection rates and mortality to levels comparable to those without diabetes [65]. In a single center study, Van den Berghe then expanded the concept using IV insulin infusion in the ICU setting for all surgical patients. All patients (not just known diabetes) were randomized to a trial of maintaining glucose in the 80–110 mg/dL range with IV insulin or to conventional treatment of insulin to maintain glucose around 200 mg/dL. She demonstrated improved mortality and other outcomes with this technique [66]. However, when used in a medical ICU setting, there was no benefit for maintaining glucose in this "euglycemic" range, and rates of severe hypoglycemia were six times higher [67]. The definitive randomized, multicenter medical, and ICU trial was NICE-SUGAR (The Normoglycemia in Intensive Care Evaluation-Survival Using Glucose Algorithm Regulation). Of note, this trial excluded cardiac surgery patients. It tested two glucose target ranges 80–110 mg/dL and 140–180 mg/dL maintained by IV insulin infusion. Surprisingly mortality was better in the group with the higher glucose goals. Severe hypoglycemia occurred less frequently in these patients, and this may have contributed to the mortality differences [68].

Outside of the ICU, there are very few randomized trials of glucose control. The RABBIT-2 surgery trial [69] looked at patients with known diabetes undergoing elective surgery and randomized them to two groups, those managed with short-acting correctional insulin only (sliding scale) and those with scheduled weight-based insulin using long-acting and short-acting insulin (basal bolus). Mean glucose levels were 145 mg/dL in the basal-bolus group and 172 mg/dL in the sliding-scale-only group. Composite outcomes of adverse events including postoperative infections and renal failure were 24% in the sliding-scale group compared to 8.6% ($p < 0.003$) in the basal-bolus group. But the basal-bolus group had higher rates of hypoglycemia with 3.8% having severe hypoglycemia in the basal-bolus group compared to none in the sliding-scale group ($p = 0.057$).

Hypoglycemia has been associated with adverse outcomes in several inpatient studies, and the elderly are especially vulnerable [70]. Hypoglycemia is the major factor limiting management of hyperglycemia in hospitalized patients. Current management recommendations for inpatients are essentially a compromise between risks of hypoglycemia and benefits of treating hyperglycemia.

Glucose goals for treatment are based on results of these and similar studies. For most patients in the ICU, if glucose is greater than 180 mg/dL, an IV insulin infusion protocol should be initiated. Glucose should be maintained in the 140–180 mg/dL range with lower goals of 110–140 mg/dL appropriate for some patients, such as cardiac surgery patients, with the caveat that it can be achieved without hypoglycemia. There are many IV insulin infusion protocols published [71]. They all involve using regular insulin mixed in a standard solution (usually 1 unit/cc) and infused at a rate that is adjusted at least hourly based on current glucose level and rate of change from prior level. There are even commercial computer programs [72] to assist with this. IV insulin drips using the ranges suggested here are quite safe and effective if the nursing staff is familiar with them, but they are quite labor-intensive.

Because the drip rate is dependent on rapid and accurate determination of glucose, providers should understand the limits of the methods used. Arterial glucose values are higher than capillary which are higher than venous values, independent of method used. Glucose testing sent to the lab has long turnaround times and is not practical for adjusting the infusion. Glucose values done with a blood gas analyzer are probably most accurate for "point-of-care" testing but may not be readily available. Glucose meter testing with meters developed for outpatient use may not be accurate in settings of extremes of hematocrit, hypothermia, acetaminophen overdose, and other conditions [73]. The Centers for Medicare and Medicaid Services (CMS) has raised the issue of accuracy of using outpatient meters for ICU patients, but at this time, using them remains the standard of care [74].

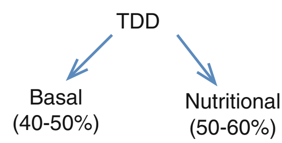
On the general medical floors, the use of oral agents to control glucose is discouraged because of the issues of potential fluctuating renal function (metformin), unpredictable eating, and risk of hypoglycemia (sulfonylureas) and fluid retention (thiazolidinediones), and the use of basal-bolus insulin regimens has become the standard practice. The three components of basal-bolus insulin therapy include the basal dose (a long-acting analog insulin daily or intermediate-acting human insulin twice daily) and the prandial dose (usually a short-acting human or analog insulin) combined with the correctional dose of a short-acting insulin. Analog insulins are preferred in most institutions because of better action profiles, but human regular and NPH can be effectively used [18]. The key to writing safe and effective insulin orders, especially for insulin-naive patients, is the use of order sets [69]. The main determinant of insulin dosing is weight, but elderly patients require lower weight-based dosing than younger ones. Renal insufficiency will also decrease insulin needs, and the use of high-dose glucocorticoids will increase insulin dose. Once initial insulin orders are written, the inpatient team should review and adjust on a daily basis. A guideline for writing insulin orders is in Fig. 5. Usually 50% of the initial calculated daily dose (total daily dose or TDD) is given as basal insulin such as glargine daily or NPH BID. The other 50% of the dose is given in equal amounts before meals usually with a rapid-acting insulin analog such as lispro or aspart. For patients on continuous enteral feedings, giving the prandial dose as regular insulin

Fig. 5 Approach to initiation and titration of insulin

Step 1

Baseline TDD estimate	0.5 unit/kg/day
Age > 70 years	-0.1 unit/kg/day
Renal insufficiency (eGFR < 45)	-0.1 unit/kg/day
Advanced Cirrhosis	-0.1 unit/kg/day
Pancreatic deficiency (chronic pancreatitis, cystic fibrosis,s/p pancreatectomy,)	-0.1 unit/kg/day
HbA1c > 10%	+0.1 unit/kg/day
Currently on glucocorticoids with equivalent of prednisone 40 mg/day or greater	+0.1 unit/kg/day
FINAL TDD estimate	=

Step 2: Components of insulin program
basal, nutritional, correctional



Example: 60 kg patient with TDD estimate 0.5 unit/kg/day
0.5 x 60=30 units TDD with 50% basal and 50% nutritional
30/2=15 units basal and 15 units prandial (5 units AC)

Step 3: Access *frequently* (at least daily) and titrate to goal by 10-20%

Increase by 10% for glucose values 140-180 mg/dL
Increase by 20% for glucose values over 180 mg/dL
Decrease by 10% for glucose values 70-99 mg/dL
Decrease by 20% for glucose values <70 mg/dL

divided into four equal doses every 6 h can be effective. Correctional scales can be ordered based on the calculated total daily dose (TDD). Generally for TDD below 40 units, the correctional scale would be 1 unit for every 50 mg/dL glucose above goal. If the calculated TDD is 40 units, higher correctional scale should be 2 units for every 50 mg/dL glucose increment above goal. Glucose target goals are "fasting" glucose levels below 140 mg/dL and "random" glucose target below 180 mg/dl, and glucose values below 70 mg/dL require adjustment of insulin dosing [75].

Managing glucose at the time of a procedure is difficult and not well studied. In this setting it is very important to identify those patients with absolute insulin deficiency (type 1 diabetes) if at all possible so that they are never without basal insulin, even when NPO. These patients are at risk for rapidly developing DKA if insulin is withheld even for as little as 4–6 h. For patients on oral agents, they are usually told to take them the day before surgery but not the day of surgery. For those on insulin, a simple approach is for patients to take their full dose of basal insulin the evening before unless they are prone to hypoglycemia in which case they can take 80% of their dose. For those patients who take basal insulin in the morning, one approach is to have them take half their dose, especially if patient is using NPH. Patients should not take rapid-acting insulin prior to their procedure. During the procedure and immediately afterward, it is important to check point-of-care glucose at least every 4 h to identify and treat significant hyperglycemia or hypoglycemia. Some patients may require IV insulin during the procedure and immediately postoperatively. After a procedure it is very important to restart basal insulin. If dose determination is unclear, use weight-based insulin order set as described above for assistance.

For patients who use insulin pumps, a discussion should be initiated prior to any elective procedure about whether the patient will continue to use the pump during and after the procedures. Well-informed patients can continue to use pumps during and after a procedure. The patient should follow the advice of their physician, but in general the pump can be used at normal rates until day of procedure. If glucose values are well controlled, pump can be continued at a "basal" rate of about 80% of usual throughout a procedure with anesthesia checking glucose frequently. For procedures lasting longer than 4 h, transitioning to IV insulin infusion can be considered. After the procedure, the patient can resume the use of the pump once recovered from anesthesia unless the patient is too sedated. In the event that a patient is unable to manage postoperatively, the pump should be removed and the patient placed on basal-bolus insulin as above.

Conclusion

Diabetes is a common chronic illness. With increased prevalence of approximately 25% in older adults, special considerations in management are needed. Focus on individualizing treatment will help match therapy to patient needs. Algorithmic approach to inpatient and outpatient dysglycemia can assist in achieving goals and preventing acute and chronic complications.

14 Cardiac Disease in Older Adults

Wilbert S. Aronow and William H. Frishman

Contents

Abstract
Cardiovascular function in older persons is significantly affected by the aging process itself and by those acquired diseases of the cardiovascular system that are more prevalent with age. Some of the cardiovascular disorders that are more prevalent in older persons include systemic hypertension, left ventricular hypertrophy, left atrial enlargement, an abnormal left ventricular ejection fraction, atrial fibrillation, congestive heart failure (especially with a normal left ventricular

ejection fraction), coronary artery disease, ischemic and thromboembolic stroke, peripheral arterial disease, extracranial carotid arterial disease, aortic stenosis, aortic regurgitation, mitral regurgitation, mitral annular calcium, hypertrophic cardiomyopathy, and pacemaker rhythm. These physiologic and pathologic changes of the aging cardiovascular system must be taken into consideration during the clinical assessment and management of older patients who need to undergo surgical procedures and general anesthesia.

Introduction

Age-related changes in the cardiovascular system, overt and occult cardiovascular disease, and reduced physical activity affect cardiovascular function in older persons. With aging, there is a loss of myocytes in both the left and right ventricles with a progressive increase in myocyte cell volume per nucleus in both ventricles [1] and an inability to regenerate new myocytes [2]. There is also a progressive reduction in the number of pacemaker cells in the sinus node, with only 10% of the number of cells present at age 20 remaining at age 75 [3]. Wall thickening and dilatation are structural changes that occur within large elastic arteries during aging [4].

Gonzalez et al. have demonstrated in an animal model that chronologic age also leads to telomeric shortening in cardiac progenitor cells [5]. Aging affects the growth and differential potential of cardiac stem cells, interfering not only with their ability to sustain physiologic cell turnover but also with their capacity to adapt to increases in pressure and volume loads [6, 7].

Afterload

Resistance to the ejection of blood by the left ventricle is called afterload. There are two components to afterload: peripheral vascular resistance and characteristic aortic impedance. Peripheral vascular resistance is the steady-state component and provides opposition to steady blood flow. Characteristic aortic impedance is the dynamic component and opposes pulsatile blood flow. Peripheral vascular resistance is measured by dividing the mean arterial pressure by the cardiac output; it is inversely proportional to the cross-sectional area of the peripheral vascular beds. Characteristic aortic impedance is measured as the time variation in mean arterial pressure/flow through the aorta; it is inversely proportional to the arterial compliance (the distensibility of the arterial wall). An indirect measurement of afterload is the pulse wave velocity, which measures the propagation speed of pressure waves traveling from proximal to distal arterial segments; it increases as arteries become less compliant.

With aging, the large elastic arteries become dilated with a reduction in compliance [8]. Progressive thickening of the aortic media and intima is associated with aortic enlargement [9]. There is an age-associated increase in arterial stiffness resulting from changes in the arterial media, such as thickening of the smooth muscle layers, increased fragmentation of elastin, an increase in the amount and characteristics of collagen, and increased calcification [10]. These structural changes are associated with a reduction in aortic distensibility due to increased aortic stiffness with an increase in pulse wave velocity [10]. The structural changes in the arterial wall are independent of coexisting atherosclerosis. Avolio et al. [11] showed an increase in pulse wave velocity with age in farmers from Guangzhou Province in southern China despite a low prevalence of atherosclerosis in this population. The age-associated increase in stiffness and decrease in distensibility of large elastic arteries are not found in distal arteries [12].

The increase in arterial wall thickening and decrease in endothelial function with aging are associated with an increase in arterial stiffness and a decrease in compliance [13]. Age-associated structural changes in the arterial media that increase vascular stiffness include increased collagen content, covalent cross-linking of the collagen, decreased elastin content, elastin fracture, and calcification [14, 15].

Impedance spectral patterns have shown an age-related increase in characteristic aortic impedance and peripheral vascular resistance [16]. The reduction in arterial compliance contributes more to the age-related increase in afterload than does the loss of peripheral vascular beds [16]. Peripheral vascular resistance was not age-related in healthy persons screened for occult coronary artery disease in the Baltimore Longitudinal Study of Aging [17] but increased with age in persons not screened for occult coronary artery disease [18]. Arterial stiffening appearing as an increase in pulse wave velocity is associated with degeneration of the vascular media independent of atherosclerosis. Arterial stiffening causes earlier occurrence of wave reflection from peripheral sites to the ascending aorta during left ventricular ejection. Therefore aortic and carotid phasic pressures increase to a greater magnitude at a later time during left ventricular ejection, causing an increase in systolic and pulse pressures and a delayed peak in the aortic pressure pulse contour.

Circulating levels of catecholamines increase with age, especially with stress, although beta-adrenergic vasodilation of vascular smooth muscle decreases [19]. α-Adrenergic vasoconstriction of vascular smooth muscle does not change with age [20]. The impaired vasodilator response to β-adrenergic stimulation with age is most important during exercise and contributes to the increased afterload associated with aging.

Increased afterload causes an increase in blood pressure. With aging, there is an increase in systolic blood pressure and a widened pulse pressure. A slight decrease in diastolic blood pressure occurs after the sixth decade [21, 22]. The increase in systolic blood pressure is due to interactions of aging, cardiovascular disease, and lifestyle factors, such as dietary sodium intake, body weight, and level of physical activity [22]. An age-associated increase in the index of aortic stiffening was not found in normotensive persons on a low sodium chloride diet [23]. The increase in carotid augmentation index (an index of aortic stiffening) in highly trained older men was half of that expected on the basis of age alone [24]. The prevalence of abnormal aortic stiffness increases steeply in the community with advancing age, especially in the presence of diabetes mellitus and obesity [25].

As aortic compliance decreases with aging, the transfer of kinetic energy from the blood ejected during left ventricular systole to potential energy stored in the elasticity of the aortic wall is decreased. Consequently, return of the potential energy stored in the elasticity of the aortic wall back to the kinetic energy of blood flow during diastole also is decreased. Therefore the left ventricle must eject its stroke volume into a less compliant aorta with greater pressure and force to achieve adequate cardiac output. The increased pulse wave velocity also causes the pressure in the aorta to increase and peak later during systole, contributing to the increased systolic blood pressure and widened pulse pressure.

Posterior left ventricular wall thickness increased with increasing age in normotensive men and women screened for occult coronary artery disease in the Baltimore Longitudinal Study of Aging [26]. Data from persons in this study suggested that the increase in left ventricular wall thickness associated with aging is mediated by an increase in systolic blood pressure [26]. Aging is also associated with an increase in the prevalence of hypertension and cardiovascular disease and, therefore, with the left ventricular hypertrophy seen by echocardiography.

Age-associated left ventricular hypertrophy is caused by an increase in the volume but not in the number of cardiac myocytes. Fibroblasts undergo hyperplasia, and collagen is deposited in the myocardial interstitium. Increased afterload results in an increase in left ventricular systolic stress and the addition of sarcomeres, in parallel, which causes increased left ventricular wall thickness with a normal or reduced left ventricular chamber size and an increased relative wall thickness.

In the Framingham Heart Study, echocardiographic left ventricular hypertrophy was observed in 33% of men and 49% of women older than 70 years [27]. In our older population, echocardiographic left ventricular hypertrophy was found in 226 of 554 men (41%) with a mean age of 80 years and in 539 of 1243 women (43%) with a mean age of 82 years [28].

In our older population, systolic or diastolic hypertension was present in 255 of 664 men (38%) with a mean age of 80 years and in 651 of 1488 women (44%) with a mean age of 82 years [29]. In another study of our older population, systolic or diastolic hypertension occurred in 108 of 215 Blacks (50%) with a mean age of 81 years, in 411 of 1140 Whites (36%) with a mean age of 82 years, and in 19 of 54 Hispanics (35%) with mean age 81 years [30]. Echocardiographically diagnosed left ventricular hypertrophy occurred in 66 of 92 hypertensive Blacks (72%), in 194 of 346 hypertensive Whites (56%), and in 8 of 15 hypertensive Hispanics (53%) [30]. However, it was observed in only 2 of our 88 older persons (2%) without hypertension or overt cardiac disease [31].

Regular aerobic endurance exercise attenuates age-related reductions in central arterial compliance and restores levels in previously sedentary healthy middle-aged and older men [32]. Regular aerobic endurance exercise also can prevent the age-associated loss in endothelium-dependent vasodilation and restore levels in previously sedentary middle-aged and older healthy men [33]. These are mechanisms by which regular aerobic endurance exercise contributes to a decreased risk of cardiovascular disease in older persons [32, 33].

Preload

Preload is the filling volume of the left ventricle. Preload is determined by many factors that influence blood return to the heart and by the mechanical properties of the heart during diastolic filling of the left ventricle.

Resting left ventricular end-diastolic volume, measured by radionuclide ventriculography using multiple gated pool acquisition imaging or by echocardiography, is not age-related in healthy persons, indicating that the resting preload does not change with age [8, 17, 34]. Although resting preload does not change with age, left ventricular early diastolic filling decreases with age.

Passive filling of the left ventricle occurs during the rapid filling and diastasis phases of early diastole. With age, left ventricular stiffness is increased, left ventricular compliance decreased, left ventricular wall thickness increased, left ventricular relaxation impaired, and left ventricular early diastolic filling decreased. This may result in hypotension if preload is reduced. An age-related increase in systolic blood pressure also reduces left ventricular early diastolic filling, leading to hypotension if preload is reduced. Left ventricular filling during early diastole is decreased 50% from age 20 to age 80 [8, 35, 36].

Despite the reduction in early diastolic filling of the left ventricle with age, preload is maintained because left atrial contraction becomes more vigorous to increase late diastolic filling of the left ventricle [8, 34–40]. Augmentation of late diastolic filling of the left ventricle prevents a decrease in left ventricular end-diastolic volume. The ratio of late diastolic Doppler peak transmitral velocity (peak atrial, or A wave, velocity) to early diastolic Doppler peak transmitral velocity (peak rapid filling, or E wave, velocity) increases from approximately 0.6 at 30 years of age to 1.2 at 70 years of age [41]. A reduction in the E/A wave ratio with age reflects a reduction in left ventricular compliance. An age-related increase in left atrial size resulting from increased wall stress due to increased left atrial pressure counteracts the effects of decreased left ventricular compliance with age. In our older population, 619 of 1797 older persons (34%) had echocardiographic left atrial enlargement [28].

Age was the most powerful independent variable for left ventricular filling in healthy persons in the Framingham Heart Study [42]. Age was inversely associated with the E wave (peak early diastolic filling velocity) and was directly associated with the A wave (peak late diastolic filling velocity). Other independent variables that contribute to a lesser degree to left ventricular filling were heart rate, PR interval measured from the electrocardiogram (ECG), gender, left ventricular systolic function, and systolic blood pressure. Increasing the heart rate reduces peak early diastolic filling and increases peak late diastolic filling velocity. The PR interval on the ECG is inversely associated with peak early diastolic filling velocity. Women have slightly higher peak early diastolic filling velocities than men. Left ventricular systolic function is directly associated with peak early diastolic filling velocity. Increasing the systolic blood pressure increases the peak late diastolic filling velocity [42, 43]. Age-associated abnormalities in Doppler measures of myocardial filling and relaxation are only partially minimized by lifelong endurance training [44].

A decrease in preload is not well tolerated in older persons. Reduced intravascular volume, reduced venous return to the heart, vasodilation by drugs or disease states, and the use of drugs such as nitrates or diuretics reduce preload and may cause reduced cardiac output and hypotension in older persons. Decreased compliance of the left ventricle and decreased cardiac and vascular responsiveness to β-adrenergic stimulation [45] cause older persons to be highly dependent on the Frank-Starling mechanism to increase cardiac output. Older persons are more susceptible to developing orthostatic hypotension [46–48]. Impaired baroreceptor reflex sensitivity [49], decreased cardiac responsiveness to β-adrenergic stimulation [45], loss of arterial compliance, decreased venous return due to increased venous distensibility, impaired compensatory mechanisms for maintenance of fluid volume and electrolyte balance, increased incidence of common precipitating diseases and disorders, and the use of multiple drugs contribute to orthostatic hypotension. Older persons are also more susceptible to developing postprandial hypotension [45–48].

Marked reductions in postprandial systolic blood pressure in older persons may predispose them to symptomatic hypotension and to falls, syncope, angina pectoris, and transient cerebral ischemic attacks [50–54]. At 29-month follow-up, a marked decrease in postprandial systolic blood pressure in older persons was associated with an increased incidence of falls, syncope, new coronary events, new stroke, and total mortality [54]. Whether therapeutic interventions to prevent a marked reduction in postprandial systolic blood pressure in older persons can reduce the incidence of falls, syncope, new coronary events, new stroke, and total mortality at long-term follow-up must be investigated.

Because left atrial contraction can contribute up to 50% of left ventricular filling in a poorly compliant left ventricle, the development of atrial fibrillation may result in a marked reduction in cardiac output because of loss of the left atrial contribution to left ventricular late diastolic filling. A rapid ventricular rate associated with atrial fibrillation also reduces the time for diastolic filling of the left ventricle, resulting in a marked decrease in cardiac output.

The incidence of atrial fibrillation also is increased with age [55, 56]. In 2101 older persons in a nursing home, the prevalence of chronic atrial fibrillation was 5% in persons aged 60–70 years, 13–14% in persons aged 71–90 years, and 22% in persons 91 years and older [56]. Atrial fibrillation in older persons is associated with an increased incidence of new thromboembolic stroke [55, 56] and new coronary events [57, 58].

Cardiac output increases during exercise in healthy older persons owing to an increase in venous return to the heart, increasing the diastolic filling of the left ventricle and allowing an increased stroke volume to be ejected during exercise [59]. This is the Frank-Starling mechanism. The maximal heart rate response to exercise decreased with age in healthy persons in the Baltimore Longitudinal Study of Aging [17], whereas exercise stroke volume increased with age to maintain the exercise cardiac output [17]. The increase in exercise stroke volume resulted from an increase in left ventricular end-diastolic volume (preload) via the Frank-Starling mechanism. In contrast, healthy non-older persons achieved an increase in exercise cardiac output primarily by an increase in heart rate. Exercise stroke volume increased in non-elderly healthy persons owing to a slight increase in the left ventricular end-diastolic volume and a large decrease in the left ventricular end-systolic volume. The exercise-induced increase in heart rate and reduction in left ventricular end-systolic volume in nonolder persons are probably mediated by β-adrenergic stimulation. The increase in left ventricular end-diastolic volume during exercise in healthy older persons suggests that the age-associated reduction in resting early diastolic filling of the left ventricle does not persist during exercise.

Contractility

The intrinsic ability of the heart to generate force does not change with age in healthy persons, although the duration of contraction and relaxation is prolonged in senescent animals [60, 61]. Prolongation of the left ventricular ejection time [62] and the preejection period [63] with age in healthy persons indicates that prolongation of contraction occurs with age. Prolongation of the duration of contraction in senescent animals is associated with increased muscle stiffness and prolongation of the action potential duration [64]. These age-related changes are associated with cellular changes in the excitation-contraction coupling mechanism [65] and are an adaptive response to preserve contractile function in response to an age-induced increase in afterload.

There is no reduction in resting left ventricular ejection fraction (LVEF) or circumferential fiber shortening in old persons with no evidence of heart disease [8, 17, 34, 66, 67]. However, systolic function with exercise decreases with age. In the Baltimore Longitudinal Study of Aging, old persons showed less exercise-induced increase in LVEF than did younger persons because of an age-related increase in left ventricular end-systolic volume [17]. However, the absolute values of LVEF at maximal exercise in healthy old persons rarely decrease from basal values [17]. Age-associated reductions in maximal heart rate and left ventricular contractility during maximal exercise are manifestations of decreased β-adrenergic responsiveness, with aging partially offset by exercise-induced dilation of the left ventricle [68].

Diastolic Function

Aging is associated with prolongation of the isovolumic relaxation time, reduced early diastolic filling of the left ventricle, and augmented late diastolic filling of the left ventricle [35, 38, 41]. Normal aging changes that affect the left ventricular diastolic function include increased systolic blood pressure, increased left ventricular wall thickness, decreased left ventricular early diastolic filling, prolonged left ventricular diastolic relaxation, increased left atrial size, and increased left ventricular late diastolic filling [69].

With aging occurs slowing of the rate at which calcium is sequestered by the sarcoplasmic reticulum following myocardial excitation, which causes reduced relaxation of the left ventricle [65, 70, 71]. Accumulation of calcium at the onset of diastole may reduce left ventricular diastolic relaxation and early diastolic filling [70]. Reduced oxidative phosphorylation and cumulative mitochondrial peroxidation occurring with age may also reduce the left ventricular diastolic function [72, 73].

Increased left ventricular stiffness with age due to increased interstitial fibrosis and cross-linking of collagen in the heart impairs left ventricular diastolic relaxation and filling [1, 74–76]. Myocardial ischemia in the absence of coronary artery disease caused by decreases in capillary density and coronary reserve with age may further decrease left ventricular diastolic function in older persons [1, 77].

In addition to a reduction in left ventricular diastolic relaxation and early diastolic filling caused by age, older persons are more likely to have left ventricular diastolic dysfunction because they have an increased prevalence of hypertension, myocardial ischemia due to coronary artery disease, and left ventricular hypertrophy due to hypertension, coronary artery disease, valvular aortic stenosis, hypertrophic cardiomyopathy, and other cardiac disorders. The increased stiffness of the left ventricle and prolonged left ventricular relaxation time decrease left ventricular early diastolic filling and cause higher left ventricular end-diastolic pressures at rest and during exercise in elderly persons [78, 79].

In patients with congestive heart failure (CHF) associated with left ventricular systolic dysfunction, the LVEF is less than 50%. There is a reduced amount of myocardial fiber shortening, the stroke volume is reduced, the left ventricle is dilated, and the patient is symptomatic.

With CHF due to left ventricular diastolic dysfunction with normal left ventricular systolic function, the LVEF is normal. Kitzman et al. [80] demonstrated that during exercise, persons with CHF and normal left ventricular systolic function but abnormal left ventricular diastolic function were unable to increase stroke volume normally, even in the presence of increased left ventricular filling pressure. Myocardial hypertrophy, ischemia, or fibrosis causes slow or incomplete left ventricular filling at normal left atrial pressures. The left atrial pressure increases to augment left ventricular filling, resulting in pulmonary and systemic venous congestion. The development of atrial fibrillation may also cause a reduction in cardiac output and the development of pulmonary and systemic venous congestion because of loss of the left atrial contribution to left ventricular late diastolic filling and decreased diastolic filling time due to a rapid ventricular rate.

In a prospective study of 2535 persons older than 60 years (mean 82 years), CHF developed in 677 (27%) [81]. In a prospective study of 1160 men and 2464 women older than 60 years, mean age 81 years, CHF developed in 29% of older men and in 26% of older women [82]. Older persons are more likely than nonolder persons to develop CHF because of abnormal left ventricular diastolic dysfunction with normal left ventricular systolic function. Table 1 shows that the prevalence of normal LVEF in older persons with CHF ranges from 34% to 52% [81, 83–88]. The prevalence of normal LVEF with CHF is also higher in older women than in older men [81, 83–88].

A normal LVEF was present in older persons with CHF in 44% of 55 African-American men versus 58% of 110 African-American women, in 46% of 24 Hispanic men versus 56% of 34 Hispanic women, in 35% of 148 White men versus 57% of 303 White women, and in 38% of 227 older men versus 57% of 447 older women [88]. Table 2 shows the prevalence of a normal LVEF in 572 older persons with CHF in men and in women of different age groups [81]. In the community, advancing age and female gender are associated with increases in vascular and ventricular systolic and diastolic stiffness even in the absence of cardiovascular disease [89]. This contributes to the increased prevalence of CHF with a normal LVEF in older persons, especially in older women.

LVEF should be measured in all patients with CHF in order that appropriate therapy may be given [90–94]. For example, digoxin should not be used to treat persons with CHF and normal left ventricular ejection fraction if sinus rhythm is present [69, 95–99]. By increasing contractility

Table 1 Prevalence of normal left ventricular ejection fraction in older patients with congestive heart failure

Study	Results for patients with CHF and normal LVEF
Wong [83]	41% of 54 persons, mean age 80 years
Aronow [84]	47% of 247 persons, mean age 82 years
Cardiovascular Health Study [85]	63% of 269 persons, mean age 74 years
Framingham Heart Study [86]	51% of 73 persons, mean age 73 years
Pernenkil [87]	34% of 501 persons, mean age 81 years
Aronow [81]	50% of 572 persons, mean age 82 years
Aronow [88]	51% of 674 persons, mean age 81 years

LVEF, left ventricular ejection fraction; CHF, congestive heart failure

Table 2 Association of congestive heart failure with normal left ventricular ejection fraction with gender and age in 572 older patients

Age (years)	Normal left ventricular ejection fraction
60–69	22% of 18 men and 37% of 38 women
70–79	33% of 54 men and 44% of 79 women
80–89	41% of 86 men and 59% of 219 women
≥90	47% of 19 men and 73% of 59 women
All ages	37% of 177 men and 56% of 395 women with congestive heart failure

Adapted from Aronow et al. [81]

through increasing intracellular calcium ion concentration, digoxin may increase left ventricular stiffness, increasing left ventricular filling pressure and adversely affecting CHF due to left ventricular diastolic dysfunction. Patients with CHF due to abnormal LVEF tolerate higher doses of diuretics than do patients with CHF and normal LVEF. Patients with CHF due to left ventricular diastolic dysfunction and normal LVEF need high left ventricular filling pressures to maintain an adequate stroke volume and cardiac output and cannot tolerate intravascular depletion. These patients should be treated with a low-salt diet with cautious use of diuretics rather than with large doses of diuretics. Patients with abnormal LVEF should not be treated with calcium channel blockers [100, 101].

Table 3 Cardiovascular responses to exercise in healthy older persons

Maximal heart rate is decreased with age
Exercise stroke volume is increased with age to maintain cardiac output
Increased exercise stroke volume with age results primarily from increase in left ventricular end-diastolic volume by Frank-Starling mechanism
Decrease in muscle mass with age plays a role in age-associated decreases in systemic arteriovenous oxygen difference and in VO_2max at peak exercise
Left ventricular end-diastolic and end-systolic volumes are increased during peak exercise with age
Peak exercise left ventricular ejection fraction is reduced with age
Exercise-induced decrease in the left ventricular end-systolic volume index and increases in the cardiac index, stroke volume index, and left ventricular ejection fraction from the rest are greater in older men than in older women

Cardiovascular Response to Exercise

The maximal oxygen consumption (VO_2max) is the best overall measurement of cardiovascular fitness [102]. VO_2max is the product of cardiac output and the systemic arteriovenous oxygen difference at peak exercise. Maximal cardiac output – the heart rate multiplied by the stroke volume at peak exercise – is a more direct measurement of cardiovascular reserve than is VO_2max [102]. VO_2max is decreased with age [103, 104]. The degree of decrease of VO_2max with age is affected by physical conditioning, subclinical coronary artery disease, smoking, and body weight. Table 3 lists the cardiovascular responses to exercise in healthy older persons and clinical implications.

In the Baltimore Longitudinal Study of Aging, older male athletes had a higher peak exercise VO_2max than older sedentary men [105]. The greater peak exercise VO_2max in older male athletes than in older sedentary men was achieved by a higher cardiac index and a greater systemic arteriovenous oxygen difference. The higher peak exercise cardiac index in older male athletes than in older sedentary men was due to a higher stroke volume index with similar maximal heart rates. Long-term endurance training also is associated with enhanced ventricular diastolic filling indices [106]. Older age is associated with a decreased exercise efficiency and an increase in the oxygen cost of exercise, which contributes to a decreased exercise capacity. These age-related changes are reversed with exercise training [107].

A decrease in maximal systemic arteriovenous oxygen difference occurs with age [108]. The decrease in muscle mass with age may play a major role in the reduction in systemic arteriovenous oxygen difference at peak exercise and in VO_2max [109].

Fleg et al. [110] also investigated the effect of age on peak upright cycle exercise in healthy sedentary men and women aged 22–86 years in the Baltimore Longitudinal Study of Aging. Peak cycle work rate was reduced with age in both men and women but was greater in men than in women at any age. Both men and women had peak exercise reductions in heart rate, cardiac index, and LVEF and increases in the left ventricular end-diastolic volume index and end-systolic volume index with age. Peak exercise stroke volume index did not vary with age in men or women. The exercise-induced reduction in left ventricular end-systolic volume index and the increases in cardiac index, stroke volume index, and LVEF from rest were greater in older men than in older women.

Age-Related Changes in Cardiovascular Function

Table 4 lists some age-related changes in cardiovascular function in healthy older persons and clinical implications. Contractility at rest does not change with age, but the duration of left ventricular contraction and relaxation is prolonged. Age-associated decreases in maximal heart rate and in left ventricular contractility during maximal exercise are manifestations of reduced β-adrenergic responsiveness with age partially offset by exercise-induced dilation of the left ventricle.

Decreased arterial compliance contributes more to the age-related increase in afterload than does the loss of peripheral vascular beds. The impaired vasodilator response to β-adrenergic stimulation with age is most important during exercise and contributes to the increased afterload associated with age. Resting preload does not change with age. Left ventricular early diastolic filling is decreased with age. Augmentation of late diastolic filling of the left ventricle prevents a reduction in left ventricular end-diastolic volume with age. The maximal heart rate response to exercise is decreased with age. Exercise stroke volume is increased with age to maintain the exercise cardiac output, resulting from an increase in preload by the Frank-Starling mechanism. VO_2max and the systemic arteriovenous oxygen difference at peak exercise are decreased with age. Aging also selectively impairs endothelium-dependent function [111].

In addition to age-related changes in cardiovascular function and deconditioning due to a sedentary life style, older persons also have a higher prevalence and incidence of cardiovascular disorders that impair cardiovascular performance than do nonolder persons. Older persons are more likely than nonolder persons to develop CHF secondary to abnormal left ventricular diastolic dysfunction with normal left ventricular systolic function. There is also an age-related increase in pulmonary artery systolic pressure [112].

Table 4 Some age-related changes in cardiovascular function in healthy elderly persons

Contractility at rest does not change with age
Duration of left ventricular contraction and relaxation is prolonged with age
Decrease in arterial compliance contributes more to age-related changes Increase in afterload than does loss of peripheral vascular beds
Resting preload does not change with age
Left ventricular early diastolic filling is decreased with age
Augmentation of late diastolic filling of the left ventricle prevents a reduction in left ventricular end-diastolic volume with age
Cardiovascular responses to exercise with age are noted in Table 3
Age-associated reductions in maximal heart rate and left ventricular contractility during maximal exercise are manifestations of decreased β-adrenergic responsiveness with age partially offset by exercise-induced dilation of the left ventricle
Aging selectively impairs endothelium-dependent function

Treatment of Congestive Heart Failure

The LVEF should be measured in all persons with CHF in order for appropriate therapy to be given [90–94]. For example, digoxin should not be used to treat persons with CHF and normal LVEF if a sinus rhythm is present [69, 95–99]. Large doses of diuretics and nitrates should also be used cautiously in persons with CHF and a normal LVEF [100].

Calcium channel blockers such as diltiazem, nifedipine, and verapamil exacerbate CHF in persons with CHF associated with abnormal LVEF [113]. Diltiazem increased mortality in patients with pulmonary congestion associated with abnormal LVEF after myocardial infarction [114]. The Multicenter Diltiazem Postinfarction Trial showed, in persons with a LVEF less than 40%, that late CHF at follow-up was increased in patients randomized to diltiazem (21%) versus those randomized to placebo (12%) [115]. Prospective studies have demonstrated that the vasoselective calcium channel blockers amlodipine [116] and felodipine [117] did not significantly affect survival compared with placebo in patients with CHF associated with an abnormal LVEF. There was a significantly higher incidence of pulmonary edema in the persons treated with amlodipine (15%) than in those treated with placebo (10%) [116]. The American College of Cardiology Foundation (ACCF)/American Heart Association (AHA) guidelines recommend that calcium channel blockers should not be given to persons with CHF associated with abnormal LVEF [101].

Abnormal Left Ventricular Ejection Fraction

Table 5 shows the ACCF/AHA class I recommendations for treating patients with current or prior symptoms of CHF with reduced LVEF [101]. Older persons with CHF associated with abnormal LVEF should be treated with a low-sodium diet and with diuretics plus an angiotensin-converting enzyme (ACE) inhibitor [118, 119] plus a beta-blocker such as metoprolol CR/XL [120], carvedilol [121], bisoprolol [122], or nebivolol [123]. An angiotensin receptor blocker should be used if the patient is intolerant to an ACE inhibitor because of cough or angioneurotic edema [124]. Regular physical activity such as walking should be encouraged in patients with mild to moderate HF to improve functional status and to decrease symptoms. Patients with CHF who are dyspneic at rest at a low work level may benefit from a formal cardiac rehabilitation program [125].

An implantable cardioverter-defibrillator (ICD) and cardiac resynchronization therapy (CRT) should be used according to ACC/AHA guidelines [101, 126–130]. Statins should also be used in these patients to reduce appropriate

Table 5 Class I recommendations for treating patients with current or prior symptoms of heart failure with reduced left ventricular ejection fraction

1.Treat underlying and precipitating causes of heart failure
2. Use diuretics and salt restriction in persons with fluid retention
3. Use angiotensin-converting enzyme inhibitors
4. Use beta-blockers
5. Use angiotensin II receptor blockers if intolerant to angiotensin-converting enzyme inhibitors because of cough or angioneurotic edema
6. Sacubitril/valsartan may be used instead of an angiotensin-converting enzyme inhibitor or angiotensin II receptor blocker in patients with chronic symptomatic heart failure and reduced left ventricular ejection fraction class II or III to further reduce morbidity and mortality
7. Avoid or withdraw nonsteroidal anti-inflammatory drugs, most antiarrhythmic drugs, and calcium channel blockers
8. Recommend exercise training
9. Implant cardioverter-defibrillator in persons with a history of cardiac arrest, ventricular fibrillation, or hemodynamically unstable ventricular tachycardia
10. Implant cardioverter-defibrillator in persons with ischemic heart disease $\geq$40 days post-myocardial infarction or nonischemic cardiomyopathy, a left ventricular ejection fraction $\leq$30%, New York Heart Association class II or III symptoms on optimal medical therapy, and an expectation of survival of $\geq$1 year
11. Implant cardioverter-defibrillator in selected patients with heart failure at least 40 days after acute myocardial infarction or nonischemic cardiomyopathy with a LVEF of 30% or less and New York Heart Association class I symptoms on chronic guided directed medical therapy with a reasonable expectation of meaningful survival for more than 1 year
12. Use cardiac resynchronization therapy in persons with a LVEF $\leq$35%; New York Heart Association class II, III, or ambulatory IV symptoms on guided directed medical therapy; sinus rhythm; and left bundle branch block with a QRS duration of 150 msec or greater with or without a cardioverter-defibrillator
13. Add an aldosterone antagonist in selected patients with moderately severe to severe symptoms of heart failure who can be carefully monitored for renal function and potassium concentration (serum creatinine should be $\leq$2.5 mg/dl in men and $\leq$2.0 mg/dl in women; serum potassium should be $<$5.0 mEq/l)
14. Use hydralazine plus nitrates in patients self-described as African Americans with moderate to severe symptoms on optimal therapy with angiotensin-converting enzyme inhibitors, beta-blockers, and diuretics

Adapted from Yancy et al. [101]

cardioverter-defibrillator shocks and mortality [131, 132]. An aldosterone antagonist such as spironolactone [133] or eplerenone [134, 135] should be used according to ACC/AHA guidelines [101]. Isosorbide dinitrate plus hydralazine was very effective in treating Blacks with CHF in the African-American Heart Failure Trial [136, 137] and is now recommended in Blacks with New York Heart Association class II or IV symptoms on optimal medical therapy with a class I indication [136, 137].

ICD therapy has a class I indication in selected patients with CHF at least 40 days after acute myocardial infarction or nonischemic cardiomyopathy with a LVEF of 35% or less and New York Heart Association class II or III symptoms on chronic guided directed medical therapy with a reasonable expectation of meaningful survival for more than 1 year [101, 126]. ICD therapy also has a class I indication in selected patients with HF at least 40 days after acute MI or nonischemic cardiomyopathy with a LV ejection fraction of 30% or less and New York Heart Association class I symptoms on chronic guided directed medical therapy with a reasonable expectation of meaningful survival for more than 1 year [101, 129]. CRT has a class I indication for patients with CHF; a LVEF of 35% or less; class II, III, or ambulatory IV symptoms on guided directed medical therapy; sinus rhythm; and left bundle branch block (LBBB) with a QRS duration of 150 ms or greater [101, 127–130].

Since the 2013 ACC/AHA heart failure guidelines have been published, the PARADIGM-HF (Prospective Comparison of Angiotensin Receptor Neprilysin Inhibitor (ARNI) with Angiotensin-Converting Enzyme Inhibitors (ACEI) to Determine Impact on Global Mortality and Morbidity in Heart Failure) was reported [138]. This study showed that in 8442 patients with class II-IV CHF and a LVEF of $\leq$40% (later amended to $\leq$35%) at 27-month follow-up that compared to enalapril 10 mg daily, patients randomized to receive twice daily dosing of 200 mg of sacubitril (a neprilysin inhibitor) or valsartan in addition to standard medical therapy for CHF had a 20% reduction in death from cardiovascular causes or hospitalization for CHF [138]. Major limitations to this study include the following: (1) sacubitril has not been tested by itself in the treatment of CHF with a reduced LVEF and (2) the maximum recommended dose of valsartan for the treatment of CHF with a reduced LVEF was not used [139].

Table 6 shows the ACC/AHA class IIa recommendations for treating patients with current or prior symptoms of CHF with a reduced LVEF [101]. The serum digoxin level should be maintained between 0.5 and 0.8 ng/ml to avoid an increase in mortality [101, 140, 141]. CRT has a class IIa indication for patients with CHF, a LVEF of 35% or less, class III or ambulatory IV

Table 6 Class IIa recommendations for treating persons with current or prior symptoms of heart failure with decreased left ventricular ejection fraction

1. Angiotensin II receptor blockers may be used instead of angiotensin-converting enzyme inhibitors if patients are already taking them for other reasons
2. Hydralazine plus nitrates may be used if symptoms of heart failure persist despite angiotensin-converting enzyme inhibitors and beta-blockers
3. Implant cardioverter-defibrillator in patients with left ventricular ejection fraction (LVEF) of 30% to 35% of any origin with New York Heart Association class II or III symptoms on optimal medical therapy with a life expectancy of >1 year
4. Digoxin can be used in patients with persistent symptoms to reduce hospitalization for heart failure
5. Cardiac resynchronization therapy (CRT) can be used in patients with heart failure, a LVEF of 35% or less, class III or ambulatory IV symptoms on guided directed medical therapy, sinus rhythm, and a non-left bundle branch block (LBBB) pattern with a QRS duration of 150 ms or greater
6. CRT can be used in patients with heart failure; a LVEF of 35% or less; class II, III, or ambulatory IV symptoms on guided directed medical therapy; sinus rhythm; and a LBBB pattern with a QRS duration of 120 to 149 ms
7. CRT can be used in patients with heart failure, atrial fibrillation, and a LVEF of 35% or less on guided directed medical therapy if (a) the patient needs ventricular pacing or otherwise meets CRT criteria and (b) atrioventricular nodal ablation or pharmacological rate control will allow near 100% ventricular pacing with CRT
8. CRT can be used in patients with heart failure on guided directed medical therapy, a LVEF of 35% or less, and are undergoing placement of a new or replacement device with anticipated need for more than 40% ventricular pacing

Adapted from Yancy et al. [101]

symptoms on guided directed medical therapy, sinus rhythm, and a non-LBBB pattern with a QRS duration of 150 ms or greater [101, 128, 130]. CRT has a class IIa indication for patients with CHF; a LVEF of 35% or less; class II, III, or ambulatory IV symptoms on guided directed medical therapy; sinus rhythm; and a LBBB pattern with a QRS duration of 120 to 149 ms [101, 128–130, 142]. CRT has a class IIa indication in patients with CHF, atrial fibrillation, and a LVEF of 35% or less on guided directed medical therapy if a) the patient needs ventricular pacing or otherwise meets CRT criteria and b) atrioventricular nodal ablation or pharmacological rate control will allow near 100% ventricular pacing with CRT [101, 143]. CRT also has a class IIa indication in patients with CHF on guided directed medical therapy, a LVEF of 35% or less, and are undergoing placement of a new or replacement device with anticipated need for more than 40% ventricular pacing [101, 144].

In experimental studies, the recognition of factors enhancing the activation of the cardiac stem cell pool, their mobilization, and translocation, however, suggests that the detrimental effects of aging on the heart might be prevented in the future by the local stimulation of cardiac stem cells or the intramyocardial delivery of cardiac stem cells following their expansion and rejuvenation in vitro [2, 5, 7]. Cardiac stem cell therapy may possibly become a novel strategy for the devastating problem of CHF in the older population. The use of stem cell therapy in patients with ischemic heart disease is discussed elsewhere [145].

Normal Left Ventricular Ejection Fraction

Table 7 shows the therapy for older persons with CHF associated with a normal LVEF. Beta-blockers [123, 146], ACE inhibitors [147, 148], angiotensin receptor blockers [149], and aldosterone antagonists [150, 151] are efficacious in the treatment of these patients.

In older persons with CHF associated with a normal LVEF, pulmonary congestion is reduced by a low-sodium diet, diuretics, and nitrates.

Table 7 Therapy of patients with heart failure and normal left ventricular ejection fraction

1. Treat underlying and precipitating causes of heart failure
2. Avoid use of inappropriate drugs such as nonsteroidal anti-inflammatory drugs
3. Treat hypertension, especially systolic hypertension, hyperlipidemia, myocardial ischemia, anemia, obesity, and other comorbidities
4. Treat with cautious use of diuretics
5. Treat with beta-blockers
6. Treat with aldosterone antagonists
7. Treat with angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker if patient cannot tolerate ACE inhibitor because of cough, angioneurotic edema, rash, or altered taste sensation
8. Add isosorbide dinitrate plus hydralazine if heart failure persists
9. Avoid digoxin if sinus rhythm is present
10. Exercise training as an adjunctive approach to improve clinical status in ambulatory patients
11. Control ventricular rate in patients with atrial fibrillation

Sinus rhythm is maintained to increase the left ventricular filling time. The ventricular rate is slowed below 90 beats per minute by a β-blocker to increase left ventricular filling time. Myocardial ischemia should be decreased and is best achieved by giving a β-blocker. Elevated systolic blood pressure is decreased by diuretics and an ACE inhibitor. The left ventricular mass is reduced by an ACE inhibitor. Left ventricular relaxation should be improved by ACE inhibitors or β-blockers.

The Treatment of Preserved Cardiac Function Heart Failure with an Aldosterone Antagonist (TOPCAT) trial randomized 3445 older patients with symptomatic CHF and a LVEF of 45% or more to spironolactone 15 mg to 45 mg daily or placebo [150–153]. Of these patients, 1767 patients were enrolled from the Americas, and 1, 678 patients were enrolled from Russia and Georgia. The primary outcome was a composite of death from cardiovascular causes, aborted cardiac arrest, or hospitalization for treatment of CHF. The mean follow-up was 3.3 years. In the Americas group, compared with placebo, spironolactone reduced the primary outcome by 18%, cardiovascular mortality 26%, hospitalization for CHF 18%, recurrent CHF 25%, and all-cause mortality 17%; increased the incidence of doubling of serum creatinine by 60%; increased the incidence of hyperkalemia ($\geq$ 5.5 mmol/L) 3.46 times; and reduced hypokalemia (serum potassium <3.5 mmol/L) by 49% [151]. In the Russia and Georgia group, all of these outcomes were similar for patients treated with spironolactone or placebo [151]. On the basis of these data, we recommend treating patients with CHF with a normal LVEF with an aldosterone antagonist.

Other Cardiovascular Disorders

In addition to age-related changes in cardiovascular function and deconditioning due to a sedentary life style, older persons also have a higher prevalence and incidence of cardiovascular disorders, which impair cardiovascular performance, than non-older persons. Table 8 lists the prevalence of some cardiovascular disorders in an older population in a long-term health-care facility [82, 154, 155].

Aortic Valvular Disease

Valvular aortic stenosis in older persons is usually due to stiffening, scarring, and calcification of aortic valve leaflets. Calcific deposits in the aortic valve are common and may lead to valvular aortic stenosis [28, 156–158]. Calcific deposits in the aortic valve were present in 22 of 40 necropsied patients (55%) aged 90–103 years [157]. Aortic cuspal calcium was present in 295 of 752 men (36%), mean age 80 years, and in 672 of 1,663 women (40%), mean age 82 years [158].

Calcific valvular aortic stenosis was present at autopsy in 18% of 366 octogenarians [159]. Valvular aortic stenosis was diagnosed by continuous-wave Doppler echocardiography in 463 of 2805 older persons (17%) with mean age 81 years [82]. Severe aortic stenosis was present in 2% of these 2805 older persons [82]. Severe aortic stenosis was also diagnosed in 3% of 501 persons aged 75–86 years in the Helsinki Ageing Study [160].

Aortic valve calcium, mitral annular calcium, and coronary artery disease in older persons have

Table 8 Prevalence of cardiovascular disorders in older persons in a long-term health-care facility

	Mean age	Prevalence	
Cardiovascular disorder	(years)	No.	%
Coronary artery disease [82]	81	1521/3624	42
Thromboembolic stroke [82]	81	1131/3624	31
Peripheral arterial disease [82]	81	1011/3624	28
40–100% Extracranial carotid arterial disease [154]	81	281/1846	19
Congestive heart failure [82]	81	978/3624	27
Hypertension [82]	81	2136/3624	59
Aortic stenosis [155]	81	463/2805	17
Mitral annular calcium [155]	81	1321/2805	47
$\geq$1 + Mitral regurgitation [155]	81	928/2805	33
$\geq$1 + Aortic regurgitation [155]	81	824/2805	29
Rheumatic mitral stenosis [155]	81	37/2805	1
Hypertrophic cardiomyopathy [155]	81	108/2805	4
Idiopathic dilated Cardiomyopathy [155]	81	29/2805	1
Atrial fibrillation [82]	81	495/3624	14
Pacemaker rhythm [82]	81	186/3624	5
Abnormal left ventricular ejection Fraction [155]	81	687/2805	24
Left ventricular hypertrophy [155]	81	1224/2805	44
Left atrial enlargement [155]	81	987/2805	35

similar predisposing factors for atherosclerosis [158, 160–166]. Older persons with extracranial carotid arterial disease [161] and with peripheral arterial disease [162] have an increased prevalence of aortic stenosis. Older persons with aortic stenosis [167–169] and with valvular aortic sclerosis [169, 170] have an increased incidence of new coronary events.

Many older persons with symptomatic severe aortic stenosis and comorbidities at high risk for mortality from surgical aortic valve replacement can now undergo transcatheter aortic valve replacement [171–175].

The prevalence of aortic regurgitation also increases with age [28, 176, 177]. Aortic regurgitation was diagnosed by pulsed Doppler recordings of the aortic valve in 526 of 1797 elderly persons (29%) with a mean age of 81 years [82]. Severe or moderate aortic regurgitation was diagnosed by pulsed Doppler recordings of the aortic valve in 74 of 450 elderly persons with a mean age of 82 years [178]. Margonato et al. [176] linked the increased prevalence of aortic regurgitation with age to aortic valve thickening.

Mitral Valvular Disease

Two degenerative aging processes – mitral annular calcification and mucoid (or myxomatous) degeneration of the mitral valve leaflets and chordae tendineae – can cause significant mitral valvular dysfunction [179–181]. Mitral annular calcification was diagnosed by two-dimensional echocardiography in 36% of 924 older men and in 52% of 1881 older women, mean age 81 years [82]. Mitral annular calcium was present in 11 of 57 persons (19%) 62–70 years of age, in 53 of 158 persons (34%) 71–80 years of age, in 190 of 301 persons (63%) 81–90 years of age, in 75 of 85 persons (88%) 91–100 years of age, and in 3 of 3 persons (100%) 101–103 years of age [182].

The breakdown of lipid deposits on the ventricular surface of the posterior mitral leaflet at or below the mitral annulus and on the aortic surfaces of the aortic valve cusps is probably responsible for the calcification [183]. Older men and women with mitral annular calcium have a higher prevalence of coronary artery disease [184–186], of peripheral arterial disease [186, 187], of extracranial carotid arterial disease [186, 188, 189], and of aortic atherosclerotic disease [186] than older men and women without mitral annular calcium.

Conduction Defects

The increased prevalence of conduction defects in older persons is due to age-related degeneration of the conduction system and to the development of cardiovascular disease. Aging is associated with regional conduction slowing, an anatomically determined conduction delay at the crista, and structural changes including areas of low voltage [190]. Impairment of sinus node function and an increase in atrial refractoriness occur with aging, predisposing to atrial fibrillation [190]. Table 9 lists the prevalence of conduction defects in 1153 older persons, mean age 82 years [191]. At a 45-month follow-up, older persons with second-degree atrioventricular block, left bundle branch block, an intraventricular conduction defect, and pacemaker rhythm had an increased incidence of new coronary events [191]. At a 45-month follow-up, elderly persons with first-degree atrioventricular block, left anterior fascicular block, or right bundle branch block did not have an increased incidence of new coronary events [191].

Table 9 Prevalence of conduction defects in 1153 older persons

Defect	Prevalence (%)
First-degree atrioventricular block	6
Left anterior fascicular block	8
Right bundle branch block	10
Left bundle branch block	4
Intraventricular conduction defect	3
Second-degree atrioventricular block	1
Pacemaker rhythm	4

Source: Adapted from Aronow [191]

Conclusions

Cardiovascular function in older persons is significantly affected by the aging process itself and by those acquired diseases of the cardiovascular system that are more prevalent with age. These physiologic and pathologic changes of the aging cardiovascular system must be taken into consideration during the clinical assessment and management of older patients who need to undergo surgical procedures and general anesthesia.

Abstract
A substantial proportion of the excess operative risk among elderly patients is attributable to respiratory complications. The excess risk is explained in part by structural and functional changes in the respiratory system associated with aging. These changes are progressive even in individuals who enjoy apparently good health and are most marked beyond 60 years of age.

Physiologic changes with age: pulmonary

Parameter	Change with age	Functional impact of change
Chest shape	↑ AP diameter	No significant impact
	Mild-mod kyphosis	
Conducting airways	Calcification	Insignificant ↑ deadspace
	Mild ↑ size	
	Mucus gland hypertrophy	Minimal significance
Lung parenchyma	Enlarged alveolar ducts	Similar to mild emphysema
	V/Q mismatch	**Decreased reserve**
	↓ Elastic recoil	
Bellows apparatus	↑ Chest wall rigidity	Increased work of breathing
	↓ Respiratory muscle strength	Highly individual
Ventilatory control	↓↓ **Response to hypercapnia and hypoxemia**	Impaired homeostasis under stress Signs of distress subtle

Most important messages in bold
AP anteroposterior, *V/Q* ventilation/perfusion

A substantial proportion of the excess operative risk among elderly patients is attributable to respiratory complications. The excess risk is explained in part by structural and functional changes in the respiratory system associated with aging. These changes are progressive even in individuals who enjoy apparently good health and are most marked beyond 60 years of age.

In youth, healthy individuals have a physiologic reserve (a marked excess of functional capacity over the amount needed to meet metabolic needs at rest or with stress). The respiratory system draws on this reserve as its function declines with age. Aged individuals thus become vulnerable to the stress, disease, and injuries that are weathered much more easily by the young.

The routine activities of healthy elderly persons are not limited by this decreasing respiratory system function. Thus, the effects of age may not be apparent until they need to draw on their physiologic reserves during stress, such as postoperative recovery or complications. An awareness of the inevitable, but possibly hidden, age-related changes in the respiratory system helps the surgeon anticipate and treat respiratory complications in elderly patients.

The purely age-related changes in the respiratory system are complicated by other accompaniments of aging. The lungs are exposed to a lifetime of environmental stresses, including tobacco smoke, respiratory infections, air pollutants, and occupational exposures to dusts and fumes. Elderly individuals also often have increasingly sedentary lifestyles and decreasing fitness.

As an introduction to the topics to be reviewed in this chapter, the various components of the respiratory system are shown in Table 1. Table 1 also contains introductory comments about structural and functional changes with age.

Airways and Lung Parenchyma Lung Shape

The lungs are closely applied to the chest wall, and their overall shape is determined by the chest wall shape. The increases in anteroposterior diameter of the lungs with age and the more rounded shape that results are presumably due to changes in the shape of the surrounding thoracic cage. These changes are not thought to have functional consequences.

Conducting Airways

The conducting airways consist of the air passages from the mouth to the level of the respiratory bronchioles. The volume of the conducting airways determines the anatomic dead space. Their size, shape, and branching pattern are the major

Table 1 Respiratory system and changes with aging

Functional division	Components	Function	Change(s) with aging
Conducting airways	Airways not involved in gas exchange	Transport gas to and from lung parenchyma	Calcification and other minor changes
Lung parenchyma	Respiratory bronchioles through alveoli and supporting structures	Exchanges gas between alveoli and pulmonary capillaries	Enlarged alveolar ducts; ventilation–perfusion mismatching
Bellows apparatus	Chest wall and respiratory muscles	Provides support for lung structure and applies force to lung	Increased rigidity of chest wall, some decrease in respiratory muscle strength
Ventilatory control	Respiratory control center; carotid and aortic bodies	Alters ventilation to match metabolic needs	Markedly decreased responses to hypoxemia and hypercapnia

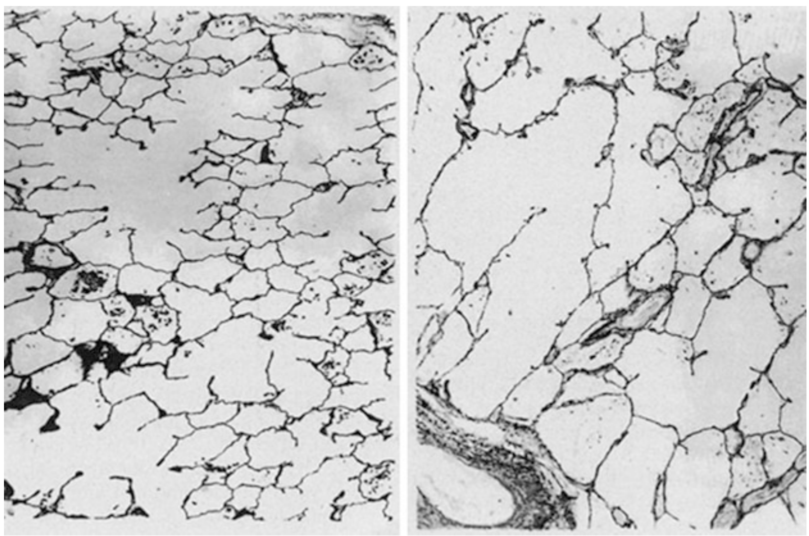

Fig. 1 Histologic changes in the aging lung. Normal lung of a 36-year-old woman (left). Lung of a 93-year-old woman (right). Alveolar ducts are dilated, and shortening of interalveolear septa is observed. (Photomicrographs courtesy of Charles Kuhn III, MD, with permission of the Mayo Foundation)

determinants of airway resistance. The large cartilaginous airways show a modest increase in size with age, resulting in slight but probably functionally insignificant increases in anatomic dead space [1]. Calcification of cartilage in the walls of the central airways and hypertrophy of bronchial mucous glands are seen during advanced age, but these and other changes in the extraparenchymal conducting airways appear to have little or no physiologic significance.

Lung Parenchyma

The respiratory bronchioles and alveolar ducts undergo progressive enlargement with age, beginning as early as age 30 or 40 but observable most prominently after the age of 60 (Fig. 1). The proportion of the lung made up of alveolar ducts increases, and alveolar septa become shortened, leading to a flattened appearance of the alveoli. The proportion of alveolar air decreases as the volume of air in alveolar ducts increases [2]. The distance between alveolar walls (the mean linear intercept, or MLI) increases, whereas the surface/volume ratio of the lung decreases. As a result of these changes, the alveolar surface area decreases by approximately 15% by age 70.

Superficially, the morphologic changes in the lung with aging are similar to those observed with mild pulmonary emphysema. To be classified as emphysema, however, the anatomic changes must consist of airspace enlargement in the gas-exchanging zone of the lung (distal to the terminal bronchioles) and must show evidence that the airspace enlargement is due to alveolar wall destruction, with fusion of adjacent airspaces [3]. For a time, there was considerable debate as to the cause and classification of the airspace enlargement seen with advanced age. Debate centered on whether the airspace enlargement was a "senile" form of emphysema.

Pump [4] and several early authors thought they could identify "emphysematous" lesions in aged lungs. However, Pump studied only two lungs (from 78- to 80-year-old men), one of whom had been a heavy smoker. Ryan and colleagues resisted the term "emphysema" and called the age-related structural changes "ductectasia" because of the prominent finding of enlarged alveolar ducts [5]. Significant alveolar wall destruction as a cause of emphysema appears to be unlikely, as Thurlbeck and Angus have shown that the number of alveoli per unit area remains constant in mature lungs [2]. The latter authors considered the changes to be a "rearrangement of the geometry of the lung." A National Heart, Lung, and Blood Institute Workshop on the definition of emphysema weighed the available evidence and decided not to include age-related changes in the lung parenchyma under the definition of emphysema [3]. To avoid confusion and to simplify the nomenclature, they recommended use of the term "aging lung" to apply to the uniform airspace enlargement that develops with increasing age.

Mechanical Properties of the Lungs

The lungs exert an inward force in the intact thoracic cage. The retractile force of the lungs, or "elastic recoil," can be measured during life by estimating the pleural pressure with an esophageal balloon. Measurements are taken at progressively decreasing lung volumes from total lung capacity (TLC) to functional residual capacity (FRC), when the airways are open and there is no airflow. The negative pleural pressure is generated by the lungs' elastic recoil forces.

Figure 2 compares the elastic recoil pressures of a young man, a normal elderly adult, and a patient with emphysema. The normal elderly individual and the patient with emphysema have a greater decrease in elastic recoil pressure than does a young person. This is reflected in the leftward shift of their pressure–volume curves [7, 8]. Emphysema produces a much greater loss of elastic recoil than is caused by aging alone.

There has been some disagreement as to whether aging changes lung compliance (the slope of the curve in Fig. 2) or, alternatively, is accompanied by a parallel leftward shift of the pressure–volume curve with aging (no change in compliance). There is general agreement if small changes in lung compliance do occur, they are not physiologically significant.

Changes in Lung Recoil Due to Surface Forces

The loss of surface area with age reduces the area of gas–liquid interface, resulting in a decrease in the surface tension forces. This ultimately causes a decrease in the lung elastic recoil. This change has important effects on lung function (especially on the function of small airways and expiratory flow).

Changes in Structural Macromolecules

Elastic fibers consist in large part of an extremely hydrophobic, highly cross-linked, and highly elastic macromolecule (elastin). They form a continuous skeleton that follows the airways and pulmonary vessels and extends to a fine mesh-work in the alveolar septa [9]. These fibers are thought to contribute substantially to lung elasticity. The amount of elastin in the lungs has been studied in an attempt to determine the cause of decreasing lung elastic recoil with age. Analysis of whole lungs has revealed that the elastin content actually increases (rather than decreases) with age [10]. More recent evidence indicates that the increase in lung elastin with age is accounted for by an increase in pleural elastin; parenchymal elastin does not change [9].

Careful studies of the elastic fibers in the lung parenchyma by two independent methods have

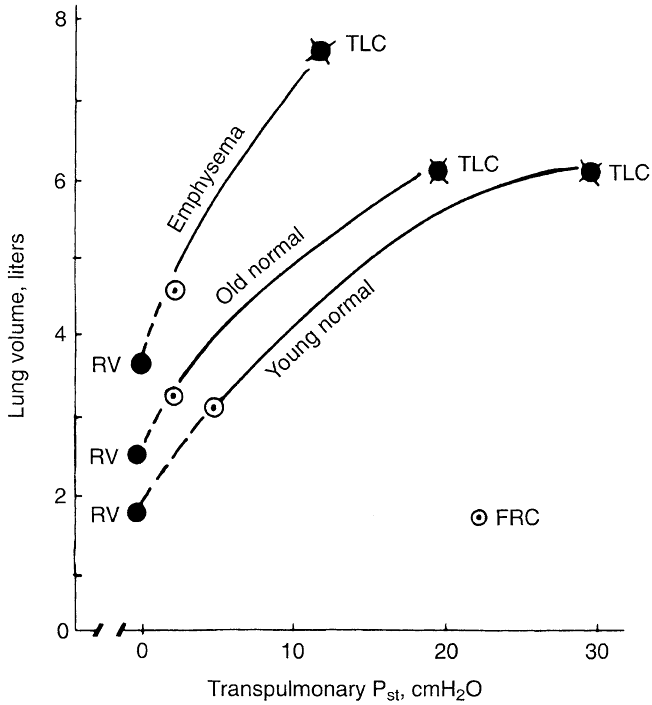

Fig. 2 Static pressure–volume curves of the lungs illustrating elastic recoil forces and compliance. To generate these data, transpulmonary pressure (which reflects lung elastic recoil) is measured at various lung volumes with an esophageal balloon. At any lung volume, the recoil pressure is less in the aged than in the young individual. This results in a pressure-volume relation that is shifted upward and to the left. A curve for a patient with emphysema is shown for comparison. With emphysema, recoil pressures are much less than in normal elderly individuals, and lung compliance (the slope of the curve) is markedly abnormal. (From Pride [6], with permission)

shown that they are remarkably stable following postnatal lung growth. Modeling of radiocarbon data [11] indicates that the "mean carbon residence time" in elastin is 74 years (Fig. 3). It is correct to consider that lung parenchymal elastin is stable over the human life span. These elastic fibers probably provide a metabolically inert scaffold for the structure of the lung. Thus, there are no age-related changes in lung elastin that provide an explanation for the decrease in elastic recoil forces observed in the elderly.

Although human studies have not been done, studies in rodents and birds suggest that lung collagen fibers, like elastic fibers, are long-lived. Finally, although some qualitative changes in collagen during aging have been described (decreases in solubility and increases in intermolecular cross-links), they appear to have no relation to changes in lung elastic recoil.

Chest Wall

The chest wall becomes more rigid with advancing age [8, 12]. As can be seen in Fig. 4, the static pressure–volume curve of the chest wall is shifted to the right and is less steep (indicating decreased compliance) with increasing age [13]. It is known that the articulations of the ribs with the sternum and the spinal column may become calcified, and the compliance of the rib articulations decreases with age. The changes in rib articulations may be compounded by the development of kyphosis due to osteoporosis. The decreasing compliance of the chest wall demands more work from the respiratory muscles. For example, in a 70-year-old person, approximately 70% of the total elastic work of breathing is expended on the chest wall, whereas this value is 40% in a 20-year-old.

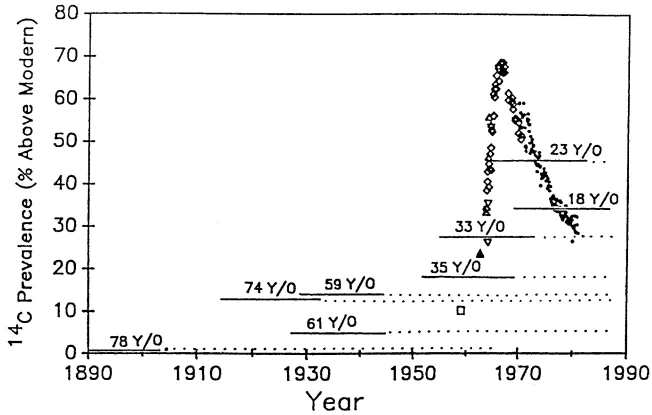

Fig. 3 Turnover of elastic fibers in human lung parenchyma. Radiocarbon (^{14}C) prevalence in lung elastin is shown on the ordinate, with zero being the level before atmospheric nuclear weapons testing began. Levels above zero reflect protein synthesis that has occurred since the 1960s (% Above Modern). The symbols are data from human tissues that exhibit rapid turnover, sampled during the years shown [11]. Each horizontal line represents an analysis of human lung parenchymal elastin from a single individual. The age at time of death is shown for each subject. The lengths and positioning of the solid portions of the lines correspond to timing and duration of fetal and postnatal lung growth, and the interrupted portions of the lines represent the remainder of the individuals' life spans. The vertical position of each line represents the ^{14}C prevalence measured in that sample. Note that the ^{14}C prevalence measured in the elastin samples reflects the ^{14}C prevalence in the biosphere during the period of lung growth. Individuals whose lungs had ceased growing before the nuclear weapons age had little nuclear weapons-related ^{14}C in their lung elastin, demonstrating that minimal lung elastin turnover occurred during adulthood. (From Shapiro et al. [11], with permission)

Muscles of Respiration

Age-related changes in nonrespiratory skeletal muscle include decreased work capacity owing to alterations in the efficiency of muscle energy metabolism, atrophy of motor units, and electromyographic abnormalities. Based on lessons learned with other skeletal muscles, it, at first, appeared likely that age-related abnormalities in respiratory muscles would also be found.

An early study by Black and Hyatt [14] appeared to confirm age-related decrements in respiratory muscle function by measuring maximal inspiratory pressure (PI_{max}) and maximal expiratory pressure (PE_{max}) in 120 normal individuals (both smokers and nonsmokers) between the ages 20 and 70. Maximal respiratory pressures in women were 65–70% of those in men. No significant age-related changes were observed in individuals under the age of 55. Trends toward reduced maximal respiratory pressure with age were seen for both sexes and with both PI_{max} and PE_{max} With the numbers of men studied, the change with age in PI_{max} was not statistically significant for the male gender.

More recently, McElvaney and coworkers [15] have come to a different conclusion in a similar study of 104 healthy individuals over the age of 55. They found large variation in maximal respiratory pressures from individual to individual (as had Black and Hyatt) but no significant correlation with age. In contrast, in a third population of 160 healthy individuals who ranged in age from 16 to 75 years, Chen and Kuo found significant gender differences in maximal respiratory pressures as well as trends toward decrements with age for both PI_{max} and PE_{max} in both genders [16]. The age-related change in PE_{max} in the male subjects was not statistically significant with the sample size studied. When the 40 individuals of both genders in the youngest age group (16–30 years) were compared with the 40 individuals in the oldest group (61–75 years), the decrement in PI_{max} was 32–36%, and the decrement in P^{e}max was 13–23%. Representative findings for maximal respiratory pressures in women are illustrated in Fig. 5.

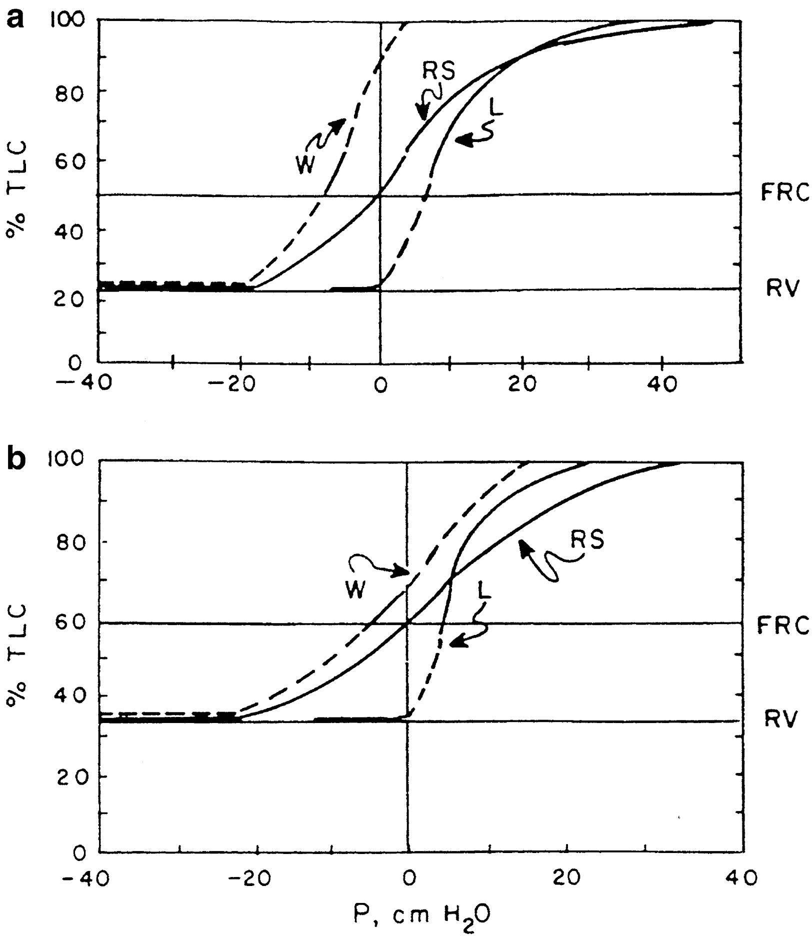

Fig. 4 Static compliance relations of the components of the respiratory system. *L* lungs, *W* chest wall, *RS* total respiratory system, *TLC* total lung capacity, *FRC* functional reserve capacity, *RV* residual volume, *P* pressure gradient, (**a**) A 20-year-old man; (**b**) A 60-year-old man. Note that the static compliance of the chest wall is substantially decreased (reduced slope) in the older individual, whereas FRC (resting volume of the respiratory system, or the point at which the pressure gradient across the respiratory system is zero) increases somewhat. Note again (compare with Fig. 2 of Chap. 35, "Parathyroid Disease in the Elderly") that the static recoil pressure of the lungs is reduced in the older subject

Chen and Kuo measured inspiratory muscle endurance against a resistive load and found significant decrements with age [16]. Physically active men had greater inspiratory muscle endurance than sedentary men.

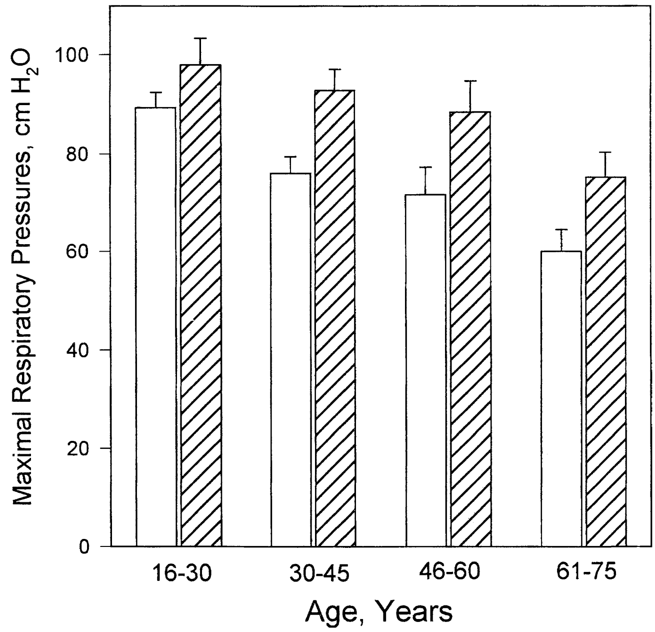
In summary, it appears that when populations of healthy individuals of widely differing ages are studied, moderate age-related decrements in respiratory muscle strength and endurance can be found. These studies usually define "healthy" only by the absence of disease and do not control for physical activity. They are complicated by marked interindividual variability, and longitudinal studies have not been reported. Respiratory muscle function may be better preserved with age than that of other skeletal muscles because of a straining effect of the continuous respiratory muscle activity. Finally, physical activity may have an additional straining effect that enhances inspiratory muscle endurance in all age groups.

Control of Breathing

Stanley and colleagues have found that elderly subjects (mean age 69 years) have a slower, more variable respiratory rate than a young control group [17, 18]. It is doubtful that this isolated observation has any functional significance, but it did suggest that ventilatory control changes with aging.

More important is that ventilation becomes much less responsive to stress in elderly individuals. It is well known that in young individuals sensitive ventilatory control mechanisms match minute ventilation closely to metabolic

Fig. 5 Representative variations in maximal respiratory pressure with age among women. Inspiratory and expiratory measurements were made at residual volume and total lung capacity, respectively. Open bars, maximal inspiratory pressure; hatched bars, maximal expiratory pressure. Error bars are standard errors of the mean. The variations with age were statistically significant but were small in magnitude. (From Chen and Kuo [16], with permission)



demands. As a result, arterial blood-gas values remain stable throughout a wide range of activities from rest to strenuous exertion, whereas oxygen consumption and carbon dioxide production vary widely. Similarly, when the efficiency of gas exchange is diminished by a variety of lung problems (e.g., atelectasis and pneumonia) or congestive heart failure, appropriate increases in minute ventilation minimize the potential for resulting hypercapnia or hypoxemia in healthy young individuals.

To compare old and young individuals, ventilatory control mechanisms have typically been tested by inducing either hypoxemia or hypercapnia while monitoring ventilatory parameters. Such tests have shown striking differences between young and elderly individuals in ventilatory and cardiac responses [19–22].

Diminished Ventilatory Response to Hypercapnia

Kronenberg and Drage [21] compared the ventilatory responses to hypercapnia while $PACO_2$ was allowed to rise to 65 mmHg. The elderly individuals had a significantly diminished ventilatory response to hypercapnia, measured as the slope of the relation between ventilation and $PACO_2$.

Diminished Ventilatory Response to Hypoxia

When these same authors [21] measured the ventilatory response to hypoxia, the contrasts between young and aged individuals were even more dramatic (Fig. 6). The ventilatory response to PAO_2 40 mmHg was uniformly smaller in the old subjects, and there was no overlap between the groups. The mean minute ventilation values at PAO_2 40 mmHg were 40.1 and 10.2 L/min in the young and old groups, respectively.

Diminished Occlusion Pressure Responses

Peterson and Fishman [23] showed that the differences in responses of elderly subjects to both hypercapnia and hypoxia are due to a lesser increase in tidal volume during stress, whereas the ventilatory rate increases normally. These authors also measured airway occlusion pressures, which are valuable indices of respiratory drive that are not affected by either respiratory muscle strength or respiratory mechanics. The measurements, called P_{100}, are the negative

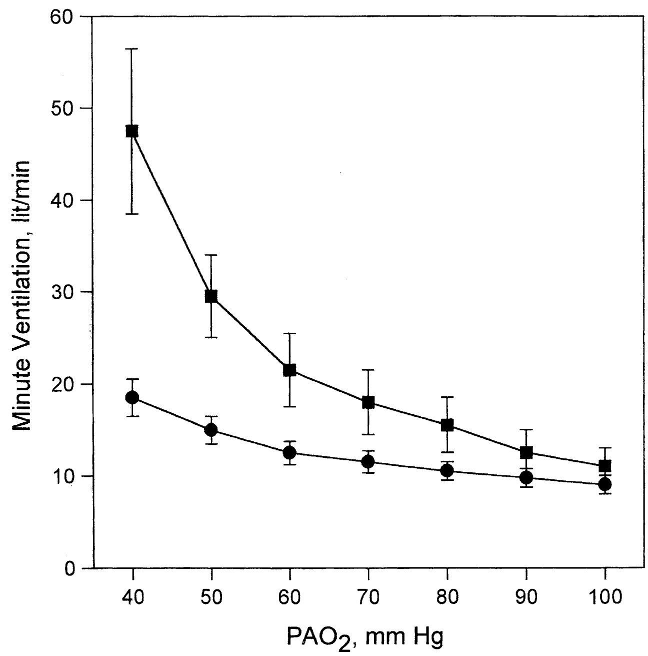


Fig. 6 Variations in ventilatory responses to hypoxia, with age. Eight normal men aged 64–73 years (mean 69.6 years) (circles) were compared to young controls aged 22–30 years (mean 25.6 years) (squares). Ventilation was measured while the subjects were exposed to isocapnic progressive hypoxia by a rebreathing method. Values are means ± SEM. Note that the ventilatory responses were strikingly attenuated in the older individuals. (From Kronenberg and Drage [21], with permission)

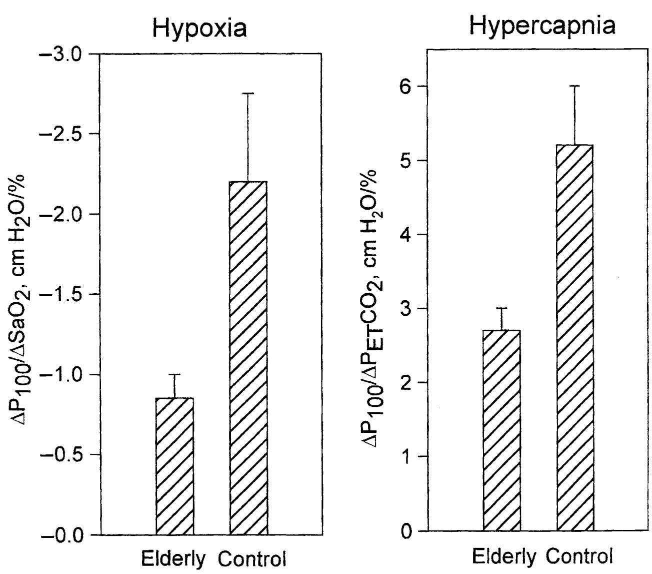

Fig. 7 Variations in occlusion pressure responses to hypoxia and hypercapnia, with age. Data are slopes of the relations between occlusion pressure responses and either SaO_2 or end-tidal PCO_2; error bars are the SEM. Occlusion pressure responses are an indicator of ventilatory drive independent of chest wall compliance and respiratory muscle strength. The elderly individuals showed significantly and strikingly diminished ventilatory drives in response to both hypoxia and hypercapnia. (From Peterson and Fishman [23], with permission)

pressures at the mouth when measured 100 ms after the start of inspiration against an occluded airway. The occlusion pressure responses to both hypoxia and hypercapnia (Fig. 7) were significantly reduced in ten elderly subjects (mean age 73.3 years) when compared to those of nine young control subjects (mean age 24.4 years) [22].

In summary, the compensatory change in tidal volume in response to either hypoxemia or hypercapnia is reduced (often strikingly) with age. The less-effective homeostasis is apparently due to reduced responsiveness of either the ventilatory drive or the neural output from the respiratory center. It has not been determined whether the diminished ventilatory drive results from altered chemoreceptor function or altered function of the respiratory center. Kronenberg and Drage favored altered receptor function based on their observation that elderly subjects responded to an alveolar oxygen tension of 40 mmHg with only an 11% increase in heart rate, whereas the young subjects responded with a 45% increase [21].

Respiratory Load Compensation and Dyspnea

Normally, when there is a change in the mechanical workload of the respiratory system (e.g., with lung disease, changes in posture, or mouth versus nose breathing), there is a reflex compensation that maintains the ventilation constant. To study the effects of aging, Akiyama and colleagues [24] measured responses to inspiratory flow-resistive loading in young and elderly individuals. In the young control group, inspiratory loading resulted in an increase in P_{100} at each level of induced hypercapnia, such that inspiratory loading did not change the ventilatory response to hypercapnia. In marked contrast, the P_{100} in the elderly group did not change when an inspiratory load was applied. Thus, ventilatory responses to hypercapnia were reduced during inspiratory loading in the elderly group.

At each level of PCO_2, the intensity of perceived dyspnea in response to inspiratory loading was higher in the elderly than in the control group. Thus, the sensation of dyspnea was intact or enhanced in the elderly subjects, while their compensatory responses were reduced.

Pulmonary Circulation

Pulmonary artery catheterization studies have typically been biased in that only subsets of patients have been reported. The reported studies were performed on individuals who had signs and symptoms that led to referral for heart catheterization. These individuals are probably not representative of "healthy" young and old cohorts. Furthermore, age-related changes in the pulmonary circulation are difficult or impossible to distinguish from changes due to heart disease or age-related changes in cardiac function. Even if they are real, the minor increases in pulmonary vascular resistance and age-related increases in pulmonary artery wedge pressure are probably not physiologically significant.

Pulmonary Function Tests

Several measurements of lung function and exercise capacity decline with age. However, descriptions of "normal" age-related changes are confounded by an increasing prevalence of disease, chronic illness, medication use, and an increasingly sedentary lifestyle. The influences of all of these factors are difficult to distinguish from each other. Superficially, it appears that longitudinal studies would provide the optimal design for distinguishing the effects of age from other influences. Longitudinal studies, however, have methodological problems and biases of their own, the most obvious being that the healthy elderly represent a healthy survival population. Regardless, it does seem that age alone has potentially important effects on lung function.

Lung Volumes

Figure 8 illustrates typical lung volume changes with aging based on cross-sectional studies. TLC, the volume of air in the lungs at the end of a maximal inspiration, is marked by the point at which the recoil pressure exerted by the respiratory system is exactly counterbalanced by the PI_{max} generated by the respiratory muscles. Cross-sectional studies of TLC summarized by the European Coal and Steel Community [25, 26], when combined, demonstrated no significant age coefficients for either men or women [25, 26].

Both slow and forced vital capacity (FVC) decline with age more rapidly in men than women. Average decrements in vital capacity per

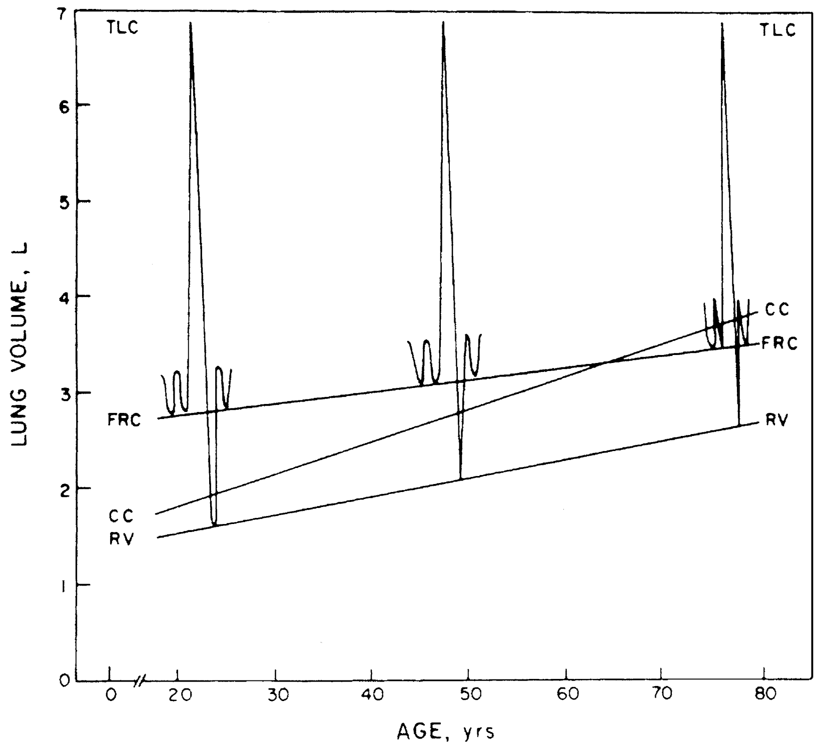

Fig. 8 Lung volume changes with age. *TLC* total lung capacity, *CC* closing capacity, *FRC* functional residual capacity, *RV* residual volume. Although not labeled, the vital capacity is TLC minus RV. The most consistent age-related changes are an increase in RV and a decrease in ventilatory capacity. (From Peterson and Fishman [23], with permission)

year vary considerably; in cross-sectional studies, declines range from 21 to 33 ml/year in men and 18 to 29 ml/year in women. Ware and colleagues [27], in a study containing both longitudinal and cross-sectional computations, found cross-sectional decreases in FVC for men and women to be −34 and −27.8 ml/year, respectively. Cross-sectional studies of residual volume (RV) and the RV/TLC ratio consistently show increases with age. In the young, RV (the volume of air in the lungs at the end of a maximal expiration) is the volume at which the outward static recoil pressure of the respiratory system is counterbalanced by the maximal pressure exerted by the expiratory muscles. In old subjects, the expiratory flow never completely reaches zero, and RV is determined in part by the length of time an individual can maintain the expiratory effort. Other factors leading to an increased RV with aging include loss of lung recoil, decreased chest wall compliance, decreased expiratory muscle force, and increased small airway closure (air trapping) in dependent lung zones [6].

FRC is also determined by the balance of the elastic recoil forces of the lung and chest wall, but in this instance, the equilibrium occurs at the end of a quiet (unforced) exhalation. Because lung recoil decreases and the chest wall stiffens with age, one would expect the FRC to increase. Cross-sectional studies, however, show inconsistent results, with most showing no change in FRC with aging. Studies that do find an increase in FRC with aging show a small positive age coefficient on the order of 7–16 ml/year. McClaran et al.'s longitudinal study found the FRC to increase 40 ml/year, but again the change was not significant [28]. Despite the conflicting data, it is generally believed that FRC increases somewhat with aging.

Loss of lung recoil also changes the volume at which airway closure occurs. When adults exhale fully, small airways close in the region of the terminal bronchioles in dependent lung zones. The lung volume at which this closure begins is measured as the closing volume or, if it is added to the residual volume, closing capacity. Closing volume increases linearly with age from about 5–10% of TLC at age 20 to about 30% of TLC at age 70. The loss of lung elastic recoil, a possible decrease in the recoil of the intrapulmonary airways, and decreases in small airway diameter probably explain most of the change in closing volume.

On average, closing volume encroaches on tidal volume by about age 44 when subjects are supine and at about age 65 when they are seated (Fig. 8). Airway closure during tidal breathing explains part of the decrease in arterial oxygen tension observed with aging.

Airflow

Although essentially all expiratory flows measured during a maximum expiratory maneuver decrease with age, the declines are most evident at low lung volumes (Fig. 9). Nunn and Dregg [29], in a study of 225 male and 228 healthy female nonsmokers, reported a modest decrease in peak expiratory flow (PEF) with aging. The rate of decline in FVC and forced expiratory volume at 1 s (FEV_1) with age tends to be more in (1) men, (2) tall individuals, (3) individuals with large baseline values, and (4) individuals with increased airway reactivity. Total airway resistance, measured at FRC, does not change with aging.

Gas Exchange

The carbon monoxide diffusing capacity (DL_{CO}) declines with age. Early cross-sectional studies reported a linear decline in DL_{CO} of about −0.1 ml CO/min/mmHg/year for men and −0.15 ml/min/mmHg/year for women [30, 31]. These declines are roughly 0.5% per year. In a large representative sample of US adult men, Neas and Schwartz [32] found an almost identical linear fall in DL_{CO}. In women, however, they found a nonlinear, quadratic decline in DL_{CO} with age. After age 47, the nonlinear component was not significant, and the decline in DL_{CO} was identical to that in the earlier studies. The decline in DL_{CO} with age did not vary with race.

The decline in DL_{CO} with age is not explained by increased nonhomogeneity of gas distribution. Measured DL_{CO} decreases as the alveolar PO_2 increases and the venous hemoglobin concentration falls. Neither alveolar PO_2 nor hemoglobin concentration varies enough with age to explain the aging-related decline in DL_{CO}. The magnitude of the decline in DL_{CO} corresponds fairly well to the magnitude of the known aging-related decrease in the internal surface area of the lung.

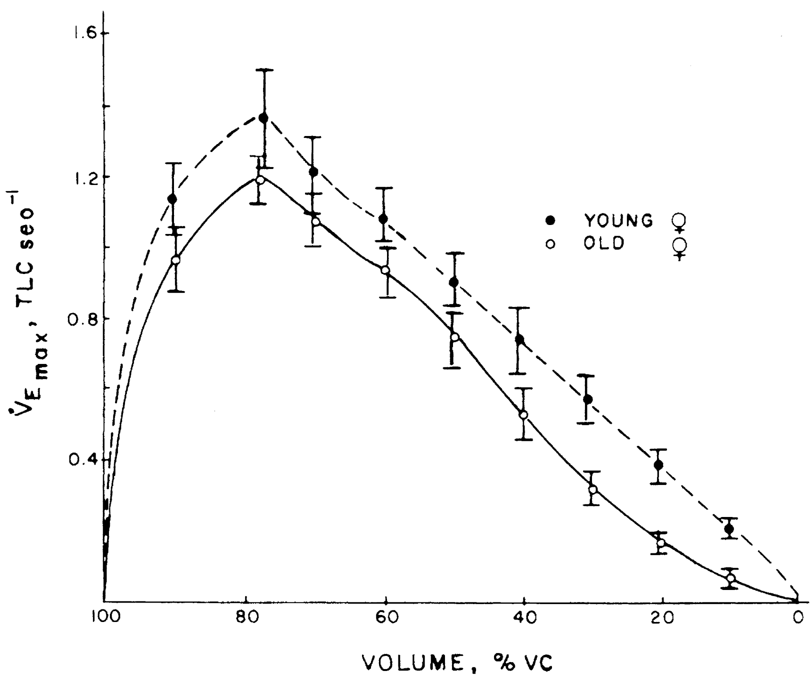

Fig. 9 Maximal flow-volume curves, showing the changes in expiratory flow rates with age. Data are for elderly women (mean age 63 years) and control young women (mean age 25 years). Although all flows tend to be reduced with aging, the reduction in flow is most evident at lower lung volumes, where the flow-volume curve is concave in regard to the volume axis. (From Peterson and Fishman [23], with permission)

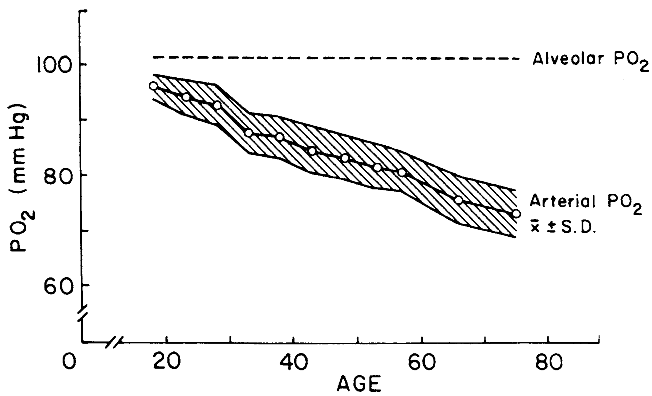

Fig. 10 Decreasing arterial oxygen tension (PO_2) with age. The lack of change in alveolar oxygen tension is also shown for comparison with PaO_2. The widening alveolar-arterial partial pressure difference for oxygen results from the development of basilar areas of low ventilation/perfusion ratios due to airway closure in the elderly. (Modified from Sorbini et al. [33], with permission)

Although alveolar oxygen pressure (PAO_2) remains constant with age, arterial PO_2 decreases, and the alveolar-arterial oxygen tension gradient ($PA\text{-}aO_2$) increases with aging (Fig. 10). The decline in PaO_2 with aging is more pronounced when subjects are studied in a recumbent as contrasted with an upright position. The most likely explanation for the decline in PaO_2 with aging is increased mismatching of ventilation to blood flow $\left(\dot{V}/\dot{Q}\right)$ as airway closure begins to occur during tidal breathing.

Summary and Implications for Geriatric Surgery

Aging is accompanied by readily measurable changes in respiratory system mechanics, gas exchange, ventilatory control, and respiratory muscle strength. Despite these changes, the activities of normal elderly individuals are not limited because they have substantial functional reserve of the respiratory system early in their lives. When anticipating operative morbidity and potential operative complications, however, the surgeon must be aware that elderly patients have lost much, or all, of their respiratory reserve. Operative stresses, pain, and bed rest are always less well tolerated by the respiratory system of elderly patients.

Changes in ventilatory control among geriatric patients deserve special attention. Because of changes in chemoreceptor function and respiratory center function, elderly individuals respond differently to hypoxemia and hypercapnia than their younger counterparts. Thus, an elderly patient who is developing respiratory failure may appear comfortable and may not be tachypneic or tachycardic. Vigilance and awareness on the part of the health-care team allow detection of respiratory complications early, through measurement of oxygen saturation and arterial blood gases. Such vigilance allows appropriate *nonemergent* interventions.

16 Renal Disease in Older Adults

Jeffrey M. Turner and Deep Sharma

Contents

Abstract

Renal disease is common in older adults, and it is an important factor to consider in the surgical patient. Of particular concern is the fact that the perioperative period creates significant vulnerabilities to a number of organ systems, and renal disease can often magnify these risks. In addition, de novo injury to the kidneys is a common event in the perioperative period, and it is important that preventive measures are in place to reduce or minimize these events. This chapter reviews the unique management challenges associated with surgery in older adults with renal disease, including the importance of identifying specific sequelae that can present as a result of renal dysfunction and methods to optimize risk during the perioperative period.

Assessing Renal Function in the Older Surgical Patient

The kidneys have several functions that are critical to maintaining health and survival. These include filtering plasma to regulate the body milieu, regulation of blood pressure via sodium handling, erythropoietin production to maintain red blood cell generation in the bone marrow, and vitamin D metabolism that promotes bone homeostasis. These functions are all interrelated, and kidney dysfunction typically includes abnormalities in all of these processes. However, it is the function of plasma filtration that has the most significant and immediate clinical implications and is most often of greatest concern to the clinician. The key anatomic structures involved in this process are the glomerulus, which is the filtering unit of the kidney that creates ultrafiltrate, and the tubule, which processes the ultrafiltrate by means of reabsorbing and secreting various electrolytes and organic substances to create the end product of urine.

The glomerular filtration rate (GFR) is an abstract parameter used to assess the kidney's filtering ability, and it is the key parameter by which global kidney function is assessed. The GFR in an individual with "normal" kidney function is greater than 100 ml/min/1.73 m^2. There are laboratory techniques to precisely measure GFR, and this includes the infusion of various exogenous biomarkers (inulin, ^{125}-iothalimate, and iohexol). However, these methods are not practical to perform in typical clinical settings. Measurement of endogenous biomarkers is therefore the standard method for calculating GFR in clinical laboratories. The most widely used biomarker is serum creatinine. Since the clearance of creatinine by the kidney closely associates with the GFR, quantification of the total creatinine in a 24 h urine sample can be used to calculate the creatinine clearance using the following formula: $C_{Cr} = (U_{Cr} \text{ x } V)/P_{Cr}$. Where C_{Cr} is the creatinine clearance over 24 h, U_{Cr} is the urine creatinine concentration, V is the urine volume over 24 h, and P_{Cr} is the plasma creatinine concentration. However, given the impracticality of having patients routinely submit a 24 h urine collection, various prediction equations have been developed to simply estimate the GFR based on the patient's measured serum creatinine value. These equations work under the assumption that both the production of creatinine from muscle cells and the removal of creatinine via the kidneys are occurring at a constant rate. For this reason, it is not appropriate to use these equations in the setting of acute kidney injury (AKI), as the GFR is not constant in this scenario. The Cockroft-Gault formula, the Modification of Diet in Renal Disease Study (MDRD) equation, and the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation are all commonly used. The equations are listed below:

Cockroft-Gault formula:

$$\text{Male } C_{Cr}\ (\text{ml/min}) = (140 - \text{age}) \times \text{weight}/72 \times S_{Cr}\ (\text{mg/dL})$$

$$\text{Female } C_{Cr}\ (\text{ml/min}) = (140 - \text{age}) \times \text{weight} \times 0.85/72 \times S_{Cr}\ (\text{mg/dL})$$

MDRD equation:

$$\text{GFR}\left(\text{ml/min/1.73 m}^2\right) = 175 \times \text{standardized } S_{Cr}\ (\text{mg/dL})^{-1.154} \times \text{age}^{-0.203} \times 0.742\ (\text{if female}) \times 1.210\ (\text{if black})$$

CKD-EPI equation:

$$\text{GFR}\left(\text{ml/min/1.73 m}^2\right) = 141 \times \min\left(S_{Cr}/\kappa, 1\right)^{\alpha} \times \max\left(S_{Cr}/\kappa, 1\right)^{1.209} \times 0.993^{\text{Age}} \times 1.018\ (\text{if female}) \times 1.157\ (\text{if black})$$

Where κ is 0.7 for females and 0.9 for males, α is −0.329 for females and −0.411 for males, min indicates the minimum of S_{Cr}/κ or 1, and max indicated the maximum of S_{Cr}/κ or 1.

Note that the Cockroft-Gault formula requires inputting the patient's age, sex, and weight, in addition to the serum creatinine, while the

MDRD and the CKD-EPI equations require inputting the age, sex, and race, in addition to the serum creatinine. The Cockroft-Gault was the first equation that was developed. It actually predicts the creatinine clearance (a surrogate for GFR) rather than the actual GFR itself. Creatinine is secreted by the tubule in small amounts under normal conditions, in addition to being filtered by the glomerulus, so the creatinine clearance overestimates the GFR slightly, and this is one of the limitations of the Cockroft-Gault equation. The MDRD equation was more recently developed, and it is widely used in many clinical laboratories currently. The MDRD equation estimates the GFR, as opposed to the creatinine clearance, so it is more accurate than the Cockroft-Gault formula. However, the MDRD equation is less accurate in individuals with a GFR above 60 ml/min. The CKD-EPI equation is the most recently developed equation and is equally as accurate as the MDRD equation in individuals with a GFR < 60 ml/min/1.73 m^2; however, it has the advantage over MDRD of also providing accurate estimates of GFR in those with mild reductions as well as those with normal filtering function (GFR > 60 ml/min/1.73 m^2).

In the aging kidney, GFR declines on average by about 1.0 ml/min/1.73 m^2 per year after the age of 40 years old [1]. Therefore, older individuals will often have a lower GFR than younger individuals, irrespective of any disease-related injury. In addition, in those with CKD from chronic illnesses, the additive effect of the renal injury from their disease and the age-related changes can result in a higher severity of renal impairment than what might be seen in younger individuals with similar chronic comorbidities. This in part explains why the prevalence of CKD (defined as a GFR < 60 ml/min/1.73 m^2) is 38% among individuals over the age of 70 years old, as compared to only 8% in the general population [2].

As previously discussed, serum creatinine is a function of creatinine production by skeletal muscle and creatinine clearance by the kidney. As individuals age, muscle mass declines, and therefore creatinine production will decline as well. This results in a lower serum creatinine at any given degree of creatinine clearance in an older individual as compared to a younger individual. One can be misled by looking at the serum creatinine alone to assess renal function in an older individual, and this often results in an underappreciation for the degree of renal dysfunction. For this reason, most clinical laboratories now automatically report the eGFR with serum creatinine measurements (using one of the abovementioned formulas), and this has led to improvements in diagnosing CKD and referrals to a nephrologist [3]. As stated above, the prediction equations cannot accurately estimate GFR when the serum creatinine is not in steady state, therefore, they should not be used in settings of AKI. Given these points, we recommend using the eGFR when the serum creatinine is stable to establish the baseline kidney function in the preoperative period. However, during the perioperative period, when patients are prone to AKI, it is the change in serum creatinine from baseline that is more important to monitor as opposed to the reported eGFR. A doubling in the serum creatinine will roughly correlate to a 50% reduction in the GFR.

Specific Concerns for the Older Patient with Kidney Disease Undergoing Surgery

Volume Management

Impairments in volume regulation and blood pressure control can pose particular challenges in the older surgical patient with renal dysfunction. Kidney disease impairs the ability to excrete sodium and water, therefore, the excessive administration of fluids or blood products can result in severe hypertension and critical volume overload. For this reason, volume administration needs to be done in a thoughtful manner and guided by the clinical assessment of the patient. The volume of intravenous fluid administration, including during the fasting preoperative period, should be based on the clinical exam. Patients with kidney dysfunction are prone to hypertension and volume overload, therefore, it is not appropriate to reflexively order preoperative intravenous fluids irrespective of the clinical picture. In patients with obvious signs of volume overload (hypertension, elevated jugular venous pressure, edema in the extremities and lungs), fluids should be withheld. Intravenous loop diuretics can be used to treat volume overload in patients during the perioperative period, including those with acute kidney injury. Clinicians should appreciate that impaired kidney function results in the need for higher doses of loop diuretics to achieve similar natriuresis efficacy as those with normal kidney function [4, 5]. As a reasonable guide, in those with a GFR of less than 30 ml/min/1.73 m^2, an intravenous bolus of furosemide of at least 80–160 mg is typically necessary to achieve meaningful diuresis. In addition to increasing the dose of loop diuretics, other strategies for overcoming diuretic resistance include increasing the frequency of dosing (twice or three times daily or switching to a continuous infusion), adding a thiazide diuretic for additional sodium reabsorption blockade in the nephron, intensifying salt restriction in the diet, or coadministration of albumin in patients with severe hypoalbuminemia (typically less than 2.0 mg/dL) [6].

Hypertension

Given the kidneys are a critical organ for blood pressure control in the body, hypertension is nearly universal in patients with significant renal dysfunction. The prevalence of hypertension in advanced CKD is about 90% [7, 8]. Several pathophysiologies contribute to increases in blood pressure in the setting of kidney dysfunction, but none are as critical as sodium and water retention [9]. For this reason, diuretics are central to treating hypertension in patients with CKD. Loop diuretics have traditionally been the preferred diuretic agents in patients with advanced CKD (GFR $<$ 30 ml/min/1.73 m^2), and this sentiment is reflected in many guidelines that suggest avoiding thiazide diuretics except when used in combination with loop diuretics. These recommendations have been based on the dogmatic belief that thiazide diuretics are ineffective when the GFR $<$ 30 ml/min/1.73 m^2. However, it is worth appreciating that robust data is lacking to support these claims.

Activation of the renin-angiotensin-aldosterone system (RAAS) is another important pathophysiology of hypertension in patients with kidney failure [10]. Ample data have shown that angiotensin-converting enzyme inhibitors (ACEi) and angiotensin receptors blockers (ARBs) reduce proteinuria and slow GFR decline in CKD [11]. While these data are most robust in the setting of diabetic kidney disease, ACEi and ARBs should be considered first-line agents for the management of hypertension in all forms of CKD in the absence of refractory hyperkalemia. With that said, clinicians should be aware that controversy exists regarding the role of RAAS antagonists in perioperative period. These agents have the potential to exacerbate intraoperative hypotension while at the same time inhibiting renal autoregulation, so concerns exist whether they increase the risk for perioperative AKI. Data have shown that ACEi and ARB administration in the morning prior to surgery is associated with more frequent intraoperative hypotension events; however, these studies have not consistently shown increased risks for AKI, myocardial infarction, or death [12, 13]. To the contrary, some studies have suggested a myocardial protective effect of these agents in patients undergoing cardiac surgery [14, 15]. Given the mixed findings, there is currently no consensus on whether ACEi or ARBs should be held prior to surgery. Therefore, it is important to closely consider the risks and benefits of continuing RAAS blocking agents in each individual case.

Beta blockers and calcium channel blockers are effective agents for blood pressure lowering in patients with CKD; however, unlike diuretics and RAAS blocking agents, they do not offer unique benefits to this population. Second-line agents for the treatment of hypertension in CKD include mineralocorticoid inhibitors such as spironolactone, afterload reducing agents such as hydralazine, and alpha antagonists such as doxazosin and clonidine.

Hyperkalemia

Given the reduction in the kidneys' ability to excrete potassium, hyperkalemia is a common concern in patients with CKD, especially in the presence of high levels of potassium intake. While elevated serum potassium can cause severe muscle weakness and even paralysis, the most acute concern in hyperkalemia is the high risk of fatal cardiac arrhythmias. Small changes in the extracellular potassium concentration can lead to ventricular tachycardia and ventricular fibrillation due to destabilization of the resting membrane potential in the cells involved with cardiac conduction.

It is critical to review all sources of potassium intake in patients with hyperkalemia. Patients should be counseled to avoid foods high in potassium (Table 1), and daily intake should be restricted to less than 1000 mg in those with advanced CKD. In addition, intravenous fluid choice needs to be carefully considered in the context of the serum potassium. Balanced electrolyte solutions such as Ringer's lactate/acetate or Hartmann's solution contain 4 mEq and 5.4 mEq of potassium per liter, respectively. Under normal conditions this is not an excessive potassium load; however, in patients with moderate to severe hyperkalemia ($K > 5.5$ meq/L), these solutions should be avoided. It is also important to review medications that can cause hyperkalemia (Table 2). Renin angiotensin aldosterone system blockers such as ACE-I and ARBs are some of the most commonly used drugs that are associated with hyperkalemia, and the risk is particularly high when these are used in combination with a mineralocorticoid receptor antagonist. Unfractionated and low molecular weight heparin, which is commonly given in the perioperative period for deep venous thrombosis prophylaxis, suppresses aldosterone production in the adrenal glands, which can result in hyperkalemia [16]. This can be seen irrespective of dose, and with both intravenous and subcutaneous routes. In addition, succinylcholine has been well described as causing a rapid efflux of potassium from the muscle cells into the extracellular space, and predisposing risk factors for this include necrotizing pancreatitis, burn injuries, severe infections, and upper or lower motor neuron defects [17].

When evaluating a patient with hyperkalemia, an electrocardiogram (ECG) is essential to screen for peaked T-waves or prolonged QRS complexes [18], as these are early abnormalities that predict a high risk for the development of fatal arrhythmias. With that said, many patients with moderate or even severe hyperkalemia may not manifest ECG

Table 1 High potassium foods that may need to be restricted

Food	Potassium concentration (mg)
Baked potato	925
Clams, canned	535
French fries	470
Potato chips	465
Sweet potato	450
Dried beans	450
Banana	425
Spinach	420
Lentils	365
Milk	365
Prune	305
Fish (salmon, perch, haddock)	300
Tomatoes	290
Orange	240
Orange juice	235

Table 2 Medications commonly associated with hyperkalemia

ACE inhibitors
ARBs
Nonselective beta blockers (labetalol, propranolol, carvedilol)
Succinylcholine
Aliskiren
Potassium sparing diuretics (amiloride, triamterene)
Mineralocorticoid receptor antagonists (spironolactone, eplerenone)
Heparin
Trimethoprim-sulfamethoxazole
Ketoconazole
NSAIDs
Pentamadine
Calcineurin inhibitors (tacrolimus, cyclosporine)

NSAIDs nonsteroidal anti-inflammatory drugs, *ACE* angiotensin-converting enzyme inhibitor, *ARB* angiotensin receptor blocker changes, and it is often difficult to predict the risk of developing ventricular tachycardia or ventricular fibrillation in a given individual. Urgent treatment should be given in all patients with ECG changes attributed to hyperkalemia. In patients with serum potassium levels >6.0–6.5 meq/L, urgent treatment should always be considered irrespective of the presence of ECG changes or not. Treatment includes intravenous calcium gluconate to rapidly stabilize the membranes of cardiac conduction cells, followed by insulin, sodium bicarbonate, and beta agonists to promote cellular uptake of potassium. Diuretics (if the patient is not anuric) or dialysis (if the patient is anuric or if hyperkalemia persists despite other therapies) should be employed to remove potassium from the body. Sodium polystyrene sulfonate (e.g., Kayexalate) is a potassium exchange resin often given to promote potassium excretion in the stool; however, given it takes many hours to result in a meaningful lowering of the serum potassium [19], it offers little to no immediate benefit for patients presenting with severe hyperkalemia. Patiromer is a newer potassium exchange resin that is indicated for therapy of chronic hyperkalemia, but efficacy data for using it to treat acute hyperkalemia is lacking, and therefore it should be avoided or used cautiously in this scenario.

Metabolic Acidosis

The kidneys are critical in maintaining acid base balance as they are responsible for bicarbonate generation and conservation. Under normal physiologic conditions, the kidneys generate about 80 mEq of bicarbonate daily, which is critical for neutralizing acid loads. In addition, the kidney tubules must reabsorb approximately 4500 mmol of the bicarbonate that is filtered by the glomerulus daily [20]. Renal injury impairs the kidney's ability to perform these functions and results in the development of metabolic acidosis. In patients with CKD, the severity of metabolic acidosis is typically inversely associated with the level of GFR. Many patients will have mild to moderate levels of metabolic acidosis at baseline, and therapy with oral sodium bicarbonate is indicated when the serum CO_2 is less than 22 mmol/L. In the perioperative period, patients with CKD are particularly vulnerable to the development of hyperchloremic metabolic acidosis from sodium chloride infusion in the form of 0.45% and 0.9% saline infusion. This can lead to clinically significant degrees of metabolic acidosis which can lead to end organ dysfunction in the perioperative period. For this reason, balanced electrolyte solutions or other non-chloride-based solutions, such as sodium bicarbonate, should be preferred in patients with CKD and metabolic acidosis.

Preventive Strategies for Acute Kidney Injury in the Perioperative Period

The population of older patients undergoing surgery consists of an extremely heterogeneous group of individuals, ranging from the very healthy to the critically ill. The risk for AKI will vary significantly across this group depending on the underlying illness of the patient, the type of surgery they are undergoing, and what medications they are exposed to. The overall incidence of postoperative AKI has been estimated to be 1.2% [21]; however, this risk is much higher in certain at risk groups, such as those undergoing cardiac surgery, where the incidence of AKI has been reported to be as high as 50% [22].

Significant research efforts have focused on the diagnosis and treatment of postoperative AKI in recent years. Consensus criteria have been developed to standardize the diagnosis of postoperative AKI. The Kidney Disease Improving Global Outcomes (KDIGO) criteria define AKI as a 0.3 mg/dl (>26.5 mol/l) rise in serum creatinine from baseline within 48 h of surgery, or a 50% rise in serum creatinine from baseline within 7 days of surgery, or a decrease in urine output below 0.5 ml/kg/h for 6 h following surgery. In addition, efforts are ongoing to identify non-creatinine biomarkers to detect AKI earlier in patients undergoing surgery. These biomarkers include neutrophil gelatinase-associated lipocalin (NGAL), kidney injury molecule-1 (KIM-1), interlukin-18 (IL-18), tissue inhibitor of metalloproteinases (TIMP-2), and insulin-like growth factor binding protein 7 (IGFBP-7). These agents have been most extensively studied in homogenous populations undergoing cardiac surgery, and data have demonstrated an association between elevated biomarker levels with AKI as well as nonrenal outcomes [23–26]. At this time these biomarkers are for the most part restricted to research use, and studies are ongoing to determine their role in routine clinical use to identify early onset of AKI before rises in serum creatinine occur, as well as differentiate functional causes of creatinine elevations from those that induce cellular injury.

Ischemic Kidney Injury

Acute tubular injury (ATI) secondary to ischemia is the most common cause of AKI in all hospitalized patients, and it accounts for 50% of cases of AKI in elderly hospitalized patients [27]. The aging process results in a reduction in renal plasma flow, a blunted ability to autoregulate blood flow within the kidneys, and poor renal reserve function in part due to reduced nephron number. These factors make older individuals more prone to developing ischemic ATI, especially in the perioperative period [28]. Data from animal models show that elevations in blood urea nitrogen and creatinine are more severe in older rats as compared to younger rats when exposed to similar degrees of ischemia, highlighting the increased vulnerability of aging kidneys [29]. In addition, there are impaired regenerative mechanisms in the aging kidney that result in a prolonged recovery period after ATI occurs [30].

Several strategies exist for preventing ischemic ATI in older patients undergoing surgery. It is critical to first identify those at high risk for perioperative AKI. Important variables for this include patient-related factors, operative characteristics, and pharmacologic exposures (Table 3). Since the kidneys receive about 20–25% of the blood flow from cardiac output, stable hemodynamics are a primary component to avoiding renal injury. Data have shown that the risk of AKI markedly rises with intraoperative mean arterial pressures (MAP) less than 60 mmHg [31]. To prevent renal ischemia, volume status should be closely monitored during the intraoperative period. Static parameters such as blood pressure, heart rate, pulse pressure, and peripheral arterial oxygenation are routinely used to guide fluid therapy. In high risk patients, the use of dynamic parameters of volume status, including transesophageal echocardiogram measured stroke volume, systolic pressure variation, and pulse pressure variation, may allow for earlier identification and correction of volume depletion, therefore reducing the risk of ATI. There is often a fine balance between volume resuscitating to achieve optimal cardiac output to prevent renal ischemia and giving too much fluid which puts the patient into overt volume overload. This is an important point, as overzealous fluid therapy resulting in volume overload can also contribute to AKI and impair renal recovery [32, 33]. Goal-directed volume therapies that aim to achieve a specific goal based on a hemodynamic parameter (e.g., giving 250 ml boluses of crystalloid solution when $>10\%$ declines in systolic blood pressure, stroke volume (as visualized by intraoperative transthoracic echocardiogram), or pule pressure occur during the intraoperative period) can lead to better renal outcomes by avoiding hypovolemia and hypervolemia in surgical patients [34]. These

Table 3 Factors associated with increased risk for perioperative acute kidney injury

Patient factors	Operative factors	Pharmacologic factors
Older age Male sex Underlying kidney disease Diabetes mellitus Infection Congestive heart failure	Emergency surgery Cardiac surgery Intra-abdominal surgery Prolonged duration of surgery Introperative bleeding Intraoperative hypotension	NSAIDs ACE inhibitors ARBs Antibiotics (aminoglycosides, penicillins, vancomycin) Calcineurin inhibitors Hydroxyethyl starch solutions Iodinated radiocontrast agents

NSAIDs nonsteroidal anti-inflammatory drugs, *ACE* angiotensin-converting enzyme inhibitor, *ARB* angiotensin receptor blocker strategies should therefore be favored over fixed volume therapies that are not guided by hemodynamic parameters.

Additional variables that may be important for renal protection against ischemic ATI in the older surgical patient include the choice of fluid composition used for volume management as well as the need for adjunctive vasopressor agents. Crystalloids, colloids, and blood products are all commonly used agents for replacing volume losses during surgery. Colloid solutions such as albumin are expensive and have not shown superiority over crystalloid solutions for volume resuscitation [35]; therefore, there is no renal benefit to routinely using albumin in the perioperative period. In general, blood transfusions should be used when significant intraoperative blood loss occurs. This will improve oxygen delivery to the kidneys and potentially improve renal outcomes in situations with significant hemorrhage. On the other hand, hydroxyethyl starch solutions should be avoided in surgical patients given its association with AKI and increased mortality [36, 37]. For individuals with hypotension refractory to volume resuscitation, vasopressors should be added to support blood pressure and renal hemodynamics. Although norepinephrine does result in renal vasoconstriction, this agent will have a net benefit of raising the MAP and favoring improved renal perfusion and oxygenation in patients with hypotension [38]. Therefore, this agent is an acceptable first-line vasoactive agent for addressing intraoperative vasodilatory shock. Overall, clinicians must remain diligent about optimizing hemodynamics before, during, and after surgery in older individuals. Close monitoring, thoughtful replacement strategies, and adjunctive vasopressor agents are important to reducing the risk for ischemic ATI in this population.

Avoiding Nephrotoxins

A number of medications can cause nephrotoxic ATI in the perioperative period. The most important culprits are nonsteroidal anti-inflammatory drugs (NSAIDS), antibiotics, and iodinated contrast exposure. Although NSAIDs are widely used in the general population and are readily available, these agents need to be thoughtfully considered when administered to older surgical patients. Renal prostaglandin production results in afferent arteriole dilatation that is essential for maintaining GFR in settings of reduced renal plasma flow. Use of NSAIDS (including cyclo-oxygenase-2 inhibitors) inhibits prostaglandin production and therefore impairs vasodilatory responses in the kidney. This results in ATI in high-risk subjects, especially those who develop hypotension or who are on RAAS blocking agents. This is especially problematic in the older surgical patient given the wide fluctuations in blood pressure that can occur during the perioperative period and the extensive use of RAAS blocking agents in this population. Thus pain management in the perioperative period needs to be approached thoughtfully. Tylenol or opiates can be used as alternatives to NSAIDs in those at risk for ATI.

Antimicrobial drugs are another class of medications that older surgical patients are commonly exposed to and that can cause AKI. These agents often reach high concentrations in the renal tubules as they pass down the nephron, and this magnifies their toxic potential to adjacent renal tubular epithelial cells and can result in ATI. Common culprits responsible for this include aminogylcosides, vancomycin, and pentamadine. Another mechanism of renal injury commonly seen with many antibacterial drugs is acute interstitial nephritis (AIN). AIN is a viscous inflammatory response in the renal parenchyma and tubular cells that is triggered by exposure to various agents. Penicillins, cephalosporins, and sulfa drugs are some of the most common medications that cause this. It is important that these agents are carefully administered to older surgical patients. Drug levels may need to be frequently monitored when gentamycin or vancomycin is being given, as their potential for injury is directly related to the plasma concentration level. In cases in which AKI is suspected from an antimicrobial medication, the offending agent should be discontinued immediately, and in some situations glucocorticoids are recommended.

Contrast-induced nephropathy (CIN) is another common cause of usually reversible AKI in the hospital setting. It typically manifests as a rise in serum creatinine within 1–3 days following iodinated contrast exposure. The incidence of CIN has decreased dramatically in recent years given the near ubiquitous use of low osmolar contrast agents as opposed to high osmolar contrast agents that were previously used [39]. The risk is highest in those with underlying kidney disease, diabetic nephropathy, high contrast volume exposures, and congestive heart failure [40–42]. In addition, older individuals, especially those over the age of 70, are at higher risk than younger individuals [43]. The exact pathophysiology is not completely understood, but evidence from animal studies suggests that ATI results from contrast-induced vasoconstriction and direct tubular cell injury [44, 45]. The best way to prevent CIN is to avoid contrast altogether. For this reason, careful consideration of the risks and benefits of contrast exposure should be made. Alternatives such as noncontrast computed tomography, ultrasound, and magnetic resonance imaging should be considered.

In those patients at high risk for CIN who must undergo contrast studies to obtain critical diagnostic information or to undergo important interventions, prophylactic measures should be employed. Pre- and post-contrast volume expansion with isotonic saline is one of the central measures to CIN prevention [46, 47]. A common protocol is to give 1 ml/kg/h for 12 h pre- and 12 h post-procedure. Diuretics typically should be held prior to the procedure as they negate the efforts for volume expansion. Newer studies have investigated novel methods to carefully guide fluid repletion. This includes using left ventricular end diastolic pressures to guide the rate of fluid administration post cardiac catheterization as well as the RenalGuard system in which volume replacement is closely matched to urine production from forced diuresis with furosemide [48, 49]. Older, small studies showed mixed benefits regarding the use of *N*-acetylcysteine for preventing CIN; however, a recent, large randomized control trial in which low osmolar contrast use was the standard of care has shown no overall benefit with this medication [50]. For this reason, many clinicians no longer routinely recommend *N*-acetylcysteine for preventing CIN.

Surgery in the Older Adult Patient with End-Stage Renal Disease on Dialysis

Timing of Dialysis Prior to Surgery

Patients with end-stage kidney disease on dialysis have a high burden of comorbidities; therefore, surgical procedures, both elective and nonelective, are common in this population. Not surprisingly, studies have shown that this group is at an increased risk for postoperative complications as compared to those not on dialysis [51, 52]. This includes a higher perioperative mortality. In a study of 1157 dialysis patients undergoing abdominal aortic aneurysm repair, the 30 day mortality for open repair was 16% and for endovascular repair it was 10% [53]. This compares to 30 day mortality rates of 1–5% for open repair and 1% for endovascular repair of abdominal aortic aneurysms in the nondialysis population [54]. The factors that contribute to higher perioperative morbidity and mortality in dialysis patients include increased risks for cardiovascular events, high rates of electrolyte abnormalities (namely hyperkalemia), frequent hemodynamic instability, and increased bleeding complications. There is sparse published data on how to best manage surgical risk in dialysis patients; however, most clinicians accept that a thoughtful approach is needed for presurgical dialysis treatments. For hemodialysis patients, it is common practice to perform dialysis the day prior to surgery. This means that Monday surgeries are not ideal, as it is standard practice for the vast majority of dialysis units to be closed on Sundays for routine treatments. Some situations may call for performing dialysis immediately before going to surgery (e.g., if moderate to severe hyperkalemia is present), but this is not necessary in most cases. For patients on peritoneal dialysis, there is variability in practice. Some nephrologists will increase the amount of dialysis by adding an extra exchange each day for 5–7 days prior to surgery, while other nephrologists will not make any changes to the peritoneal dialysis prescription prior to surgery. An important factor that may guide one strategy over the other for patients is the likelihood of not being able to perform peritoneal dialysis in the days following surgery. This situation arises in patients who are having intra-abdominal surgeries, such as catheter repositioning or hernia repairs, as the integrity of the peritoneum is disrupted and dialysis must be held until it heals. In such situations, increasing the number of daily exchanges prior to surgery will result in extra clearance and allow for the patient to better tolerate missing dialysis in the postoperative period for a limited time.

Protecting Vascular Access in Hemodialysis Patients

ESRD patients that undergo dialysis with a catheter have increased risk of mortality compared to patients that undergo dialysis with an arteriovenous access, either a fistula or graft [55, 56]. For this reason, it is critical that clinicians remain diligent about protecting the patency of vascular accesses in dialysis patients. There is particular concern in the older patient on dialysis as these patients are particularly prone to arteriovenous access failure [57]. Efforts to protect arteriovenous fistulas and grafts include performing needle sticks and blood pressure measurements only in the contralateral arm to the vascular access. In addition, the limb needs to be free of restraints to avoid occlusive pressure that may cause thrombosis of the access. Hypotension in the intra- or postoperative period can also cause thrombosis of the access, so this adds further emphasis for the need to carefully monitor hemodynamics and to promptly intervene if patients develop hypotension or hypovolemia. It is also important to examine the access frequently, in those patients who lack a thrill or bruit over the arteriovenous access, timely interventions for access declotting may need to be arranged.

Abstract

As the elderly population continues to grow, so does the number of injured older adults. The most common mechanisms of trauma in persons over the age of 65 include falls, motor vehicle collisions, and suicide. Physiologic changes associated with aging impair stress response to injury in the elderly. Regardless of mechanism or severity of injury, geriatric trauma patients consequently have increased morbidity and mortality. They also present unique challenges with respect to triage in the field, disposition postdischarge, and overall burden of healthcare costs. A full appreciation of the subtle differences surrounding geriatric trauma care is required in order to optimize treatment for these individuals and aim to return them to baseline functional status. Ethical considerations including patient wishes, goals of care, and end-of-life support are also highly relevant, even in the acute care setting.

Introduction: Epidemiology of Injury in the Elderly

Injury is currently the leading cause of death for those under the age of 44, and the seventh leading cause of death in persons over age 65 [1] (Table 1). However, while some consider trauma to be a disease of the young, deaths associated with fall-related injuries (largely comprised of older adults) exceeds deaths due to motor vehicle traffic collisions or firearm-related injuries (Table 2). This highlights the fact that trauma is every bit a disease of the elderly. In fact, in 2013, approximately 6 million adults 65 and older were seen in US emergency departments for injuries, comprising 17% of all visits and costing over 30$ billion in medical care [2]. Furthermore, older adults are more likely than younger adults to be admitted to hospital for their injuries (24% age 65 and older admitted vs. 11% of those age 45–64) [2]. This is due in part to comorbid diseases and existing disabilities. Most importantly, older adults are consistently at a higher risk for death after injury, regardless of injury severity or mechanism of injury [3]. Decreased physical reserve, preexisting comorbidities, and a lack of provider understanding of the healthcare needs of older patients may all contribute to this finding.

This change in trends for trauma-related mortality is associated with changing population demographics. The elderly constitute one of the fastest growing segments of the US population. In 2013, the number of people 65 and older was 44.7 million, representing an increase of 25% over the previous 10 years [4]. By the year 2050, the number of persons over age 65 is projected to nearly double (83.7 million) [4]. The increase in the number of older adults is due in part to improved life expectancy. In 2013, the number of people in

the USA over age 85 was 6 million but is projected to be 14.6 million by 2040 [4] (see Fig. 1).

The most common mechanism of injury for older adults is fall-related injuries. An elderly person's risk of falling at least once in a given year is estimated to be as high as 27% [5]. Motor vehicle traffic collisions are the second most common cause of injury-related elder mortality. While blunt trauma is far more common than penetrating injury in the elderly, suicide by firearm is now the third-leading cause of injury-related mortality in older adults. Knowledge of the injury patterns common in older adults can help guide physicians caring for these patients. For example, physicians should consider social isolation, depression, and elder abuse in addition to risk for falls and safety behind the wheel.

The Impact of Altered Physiology and Comorbid Disease

Senescence affects all organ systems but does so to varying degrees and at variable times during the aging process. Lifestyle changes and advances in the treatment of debilitating medical conditions have enabled elders to live longer, healthier, and more active lives.

Accompanying this more active lifestyle is an increased risk for injury, including falls and motor vehicle crashes [6].

Despite overall improvement in quality of life moving into older age, functional decline is inevitable in all organs. There are many consequences to this process as it relates to injury. For example, increasing age can make assessing injury more challenging given the difficulty of understanding how dysfunction may relate to injury vs. underlying comorbid diseases. By age 75, over two-thirds of injured patients have one or more chronic medical conditions [7]. In those who reach the age of 95 years, the percentage is 82%.

Preexisting medical conditions also limit the ability of older persons to tolerate the increased physiologic demands associated with injury. Resting organ function often is preserved, but the ability to augment performance in response to stress is greatly compromised. Once injured, the elderly may have an increased rate of complications from preexisting conditions such as cardiovascular or liver disease, diabetes, chronic obstructive pulmonary disease, and renal insufficiency.

Finally, comorbid conditions may also have played a role in the risk for and severity of injury. An example of this is a patient with a cardiac condition on anticoagulants and beta blockers who becomes orthostatic and falls from standing, sustaining significant traumatic brain injury due to the acquired coagulopathy. It is imperative for an accurate history to be sought regarding the etiology of injury at the time of initial patient evaluation in order to accurately guide management and for secondary prevention. Treatment of comorbid illness will often be necessary in addition to that of the injury.

Changes in Physiology by Organ System

Central Nervous System

As we age, even the nondiseased brain experiences a slow, selective loss of brain parenchyma. Age-related brain atrophy between the 5th and 10th decade causes a reduction of approximately 15–20% of the cortical brain volume [8]. These findings are accelerated in patients with cognitive impairment [9]. For instance, patients with Alzheimer's disease have an additional 14–20% greater reduction in total cortical and forebrain brain volumes than expected during normal aging [8]. Another change is remodeling in cerebral vasculature. By age 45, 50% of vessels in the brain show intimal thickening [9]. Arterial wall stiffening leads to a decline in cerebrovascular autoregulation with age, making the brain more susceptible to injury during periods of systemic hypotension seen in trauma [10]. As a result of all of these changes, difficulties in cognition and memory are common in the elderly.

These changes have other implications in the setting of trauma. For one, determining mental status using tool such as the Glasgow Coma Scale (GCS) can be difficult. So can be distinguishing new neurologic findings from a patient's baseline neurologic function. Hearing loss and visual difficulty further complicate matters. Family members will often be the best source of information to determine if an elderly patient is at baseline mental status. Once admitted to the hospital, the elderly patient may experience episodes of delirium, agitation, and confusion, even in the absence of injury. This can further confound clinical assessments of a patient's recovery after injury.

Another consequence of decreasing brain parenchyma is an increase in the risk for extra-axial traumatic brain hemorrhage. As brain volume decreases, the dura remains adhered to the skull, causing an increase in the distance between the inner table of the skull and the outer surface of the brain. This lengthening causes the bridging veins to be pulled taut, thus rendering them more likely to sustain a shear-type injury during rotational stress, such as deceleration force in a motor-vehicle crash. Subdural hematomas are three times more common in the elderly.

In addition to cerebral-related injuries, changes in the cervical spine pose additional risks to the central nervous system. Degenerative disease of the bony cervical spine narrows the central spinal canal. Kato and colleagues demonstrated that these degenerative changes and spinal stenosis represent important risk factors for cervical spine injuries [11]. In addition, degenerative changes can limit mobility and strength.

Cardiovascular

With increasing age, structural and functional changes in the cardiovascular system alter the elderly patient's response to physiologic stress. Severely injured and critically ill patients over the age of 65 have a 32% incidence of depressed cardiac index and ejection fraction [12]. Cardiac imaging including MRI pulsed tissue Doppler echocardiography in the elderly confirm a limited ability of the heart to compensate in the setting of stress [13]. A dropping cardiac output may not be readily apparent given the fact that increasingly sclerotic arteries result in high blood pressure. The high blood pressure also increases afterload, resulting in hypertrophic remodeling of the left ventricle [14]. Similar stiffening of the right heart may be seen through increases in pulmonary arterial systolic pressures and vascular resistance. Diastolic relaxation and filling volumes can also be affected, predisposing the coronary vessels to alterations in perfusion. Due to worsening diastolic function, the atria enlarge to augment ventricular diastolic filling (the atrial "kick"). Patients in atrial fibrillation lose this kick and are more susceptible to hemodynamic compromise.

The aged heart also fails to respond appropriately to heightened endogenous or exogenous catecholamines. There is alteration in sino-atrial node conduction and decrease in beta-adrenergic response, lowering both intrinsic and maximal heart rates [15]. Maximum heart rate is reduced by about 30% between the age of 20 and 85 [16].

This decrease in chronotropy is often compounded in older adults taking beta-blockers, further masking physiologic response to hypotension or shock in injured patients, and predisposing to syncope.

As a result of these changes, older adults may present with a "normal" blood pressure and/or heart rate despite the fact they are in shock. Scalea et al. have demonstrated that as many as 50% of those who had "normal" blood pressure in fact had evidence of occult cardiogenic shock and a subsequent poor outcome [17]. In light of this, some have proposed the definition of hypotension in trauma for older adults be 10 points higher in older adults compared to younger adults [18].

Arrhythmias are another cardiac abnormality experienced frequently in the elderly. Arrhythmias can be elicited or exacerbated in response to shock, fluid, and electrolyte shifts and the mechanical atrial stretch from resuscitation [19]. One study specific to trauma patients demonstrated a 6% incidence of new onset atrial fibrillation in patients over 55 years, which was also an independent risk factor for mortality [20].

Coronary artery disease [21] is common in the elderly and may complicate the care for these patients. Wilson described a 5.6% occurrence of symptomatic CAD in a series of trauma patients over the age of 65. For those over 75 years of age, the incidence of symptomatic CAD was 12.9% [22]. In addition, CAD (especially right-sided coronary lesions) causes loss of autoregulation of coronary blood flow. Thus, as myocardial activity increases, the elderly can experience either occult or obvious cardiac ischemia with resultant pump failure.

Pulmonary

Decreases in respiratory function and reserve in the elderly are the result of changes in the chest wall and the lungs. After the age of 30, a 4% per decade decrease in alveolar surface area results in a negative effect on gas exchange as well as forced expiratory flow. Alveolar ducts enlarge, and the alveoli become flatter and shallower, reducing the area for gas exchange and leading to ventilation perfusion mismatch.

Decreases in chest wall compliance from anatomical changes such as kyphosis and a decline in respiratory muscle strength from muscle fiber atrophy lead to as much as 50% loss in maximal inspiratory and expiratory force [23]. Accessory muscles help to compensate for the decline in respiratory muscle atrophy. Lung elastance also progressively declines, causing a collapse of small airways and uneven alveolar ventilation (Tables 3 and 4).

Additionally, responses to hypoxia and hypercapnia are decreased. The aging mucociliary function worsens, with fewer cilia per square centimeter. Secretion clearance is also impaired. This, in addition to poor dentition, increased oropharyngeal colonization, swallow dysfunction, and a decreased lower esophageal sphincter tone, predisposes the elderly to aspiration pneumonia and pulmonary infection. Gram-negative organisms predominate in the oral flora, increasing the risk of pulmonary infection from aspiration.

Osteopenia of the thoracic cage may increase the rate of pulmonary contusions, rib fractures, and pneumo- and hemopneumothoraces as the bony thorax cannot absorb transmitted kinetic energy. In those with a flail chest, age has been shown to be the strongest predictor of poor outcome and is directly proportional to mortality [24]. As the number of rib fractures increases, so does the incidence of pneumonia and death [25], [26]. Mortality increases by 19% and the risk of pneumonia by 27% for each additional rib fracture in patients over the age of 65 (Fig. 2) [25]. Pain control is critical to allow deep breathing and prevent pulmonary complications.

Table 3 Factors predisposing the elderly to injury

Reduced ability to react to environmental hazards	Reduced hearing Presbyopia Degenerative joint disease Vertigo
Elderly placed in potentially dangerous situations	Dementia Cardiovascular accident Coronary artery disease
Increased consequences of injury	Osteoporosis Cirrhosis Chronic obstructive pulmonary disease Coronary artery disease Disabling central nervous system disorders

Renal Disease

A number of structural changes occur in the kidney with age. Decrease in renal tubular length and thickening of basement membranes, as well as interstitial fibrosis and atherosclerosis of capillary beds, lead to ineffective secretion and reabsorption abilities of the aging kidney

Table 4 Physiologic changes associated with the elderly by organ system

Organ system	Changes associated with aging
Respiratory	Increased alveolar-arterial gradient, increased ventilation/perfusion mismatch, diminished ventilatory response to hypercapnea and hypoxemia, decreased lung and chest wall elasticity
Cardiovascular	Stiffened, calcified arterial vasculature, increased systolic pressure, increased afterload, widened pulse pressure, hypertension, atrial enlargement, lowered intrinsic and maximal heart rate, decreased coronary perfusion
Neurologic	Slow loss of brain parenchyma, intimal thickening of cerebral vasculature, susceptibility to cognitive disorders
Gastrointestinal and genitourinary	Decreased pharyngeal and lower esophageal tone, decreased glomerular filtration rate, decreased muscle mass, slower renal and hepatic clearance of drugs
Immunologic	Reduced T and B cell antibodies, impaired neutrophil function
Muscoloskeletal	Increased risk of osteopenia and osteoporosis, fractures secondary to falls

Original table

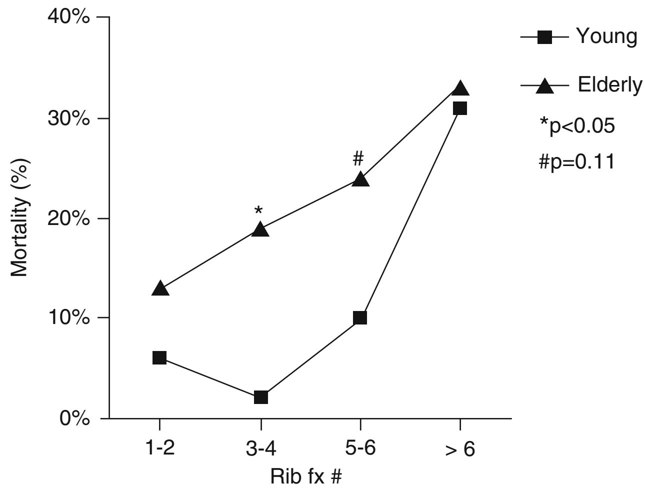

Fig. 2 Relationship between mortality and number of rib fractures (Reprinted with permission from Bulger et al. [24])

[27]. Between the age of 25 and 85, 40% of the nephrons become sclerotic and there is a decrease in renal mass, from renal cortical loss [28]. By age 80, the glomerular filtration rate (GFR) has decreased approximately 45%, but serum creatinine remains the same due to concomitant muscle mass loss [23]. Thus, serum creatinine for a given level of renal function is falsely low.

The lower GFR causes a diminished ability to concentrate urine in the aging kidney. A concomitant decrease in response to aldosterone and antidiuretic hormone further prevents the kidney from producing concentrated urine. Furthermore, diuretics prevent the aging kidney from concentrating the urine and make urine output a less reliable marker for renal perfusion in the elderly.

Once injured, the elderly who have renal insufficiency or failure may have additional problems. The platelet dysfunction commonly seen with renal failure may lead to prolonged bleeding even after minor trauma. Electrolyte disorders, most notably hyponatremia, hypo- or hyperkalemia, hypomagnesemia, and hypocalcemia, may cause dysfunctional neural transmission, cardiac dysrhythmias, seizures, mental confusion, muscular weakness, or syncope.

Drugs used to evaluate and treat the older trauma victim may further impair renal function. Extensive imaging with iodinated contrast may damage already impaired renal parenchymal and tubular system and lead to contrast-mediated nephropathy. Nonsteroidal anti-inflammatory drugs (NSAIDs) are frequently used to treat pain and avoid the sedative effects of narcotics, but use of these agents is associated with a significant risk of interstitial nephritis. Life-threatening infections with gram-negative organisms may require aminoglycosides, but such therapy may induce renal dysfunction despite seemingly acceptable drug levels. Despite renal replacement therapies, acute renal failure in trauma patients results in significantly increased mortality rate.

Musculoskeletal

Degenerative joint disease is common in the elderly and results in limited range of motion around major axial joints and puts the individual at high risk of injury. Lean body mass decreases by 4% every 10 years after the age of 25 and 10% every 10 years after the age of 50 [27]. Osteoporosis, with loss of up to 60% of trabecular bone and 35% of cortical bone, has been cited as a major factor contributing to the high incidence of fractures seen in elderly trauma patients [29].

Aging also influences the site of cervical spine fractures. In younger patients, the lower cervical spine region is more mobile and is the location of many cervical spine injuries. However, in the elderly, the lower cervical spine is less mobile due to degenerative changes, and the more mobile region of C1 and C2 is more often the site of injuries in the elderly [30].

Gastrointestinal

There is decreased hepatic function in the elderly due to a 40% hepatic mass loss by the age of 80 [23]. Preexisting liver dysfunction increases mortality after trauma [27]. Hepatic disease has the strongest effect on trauma mortality of all preexisting medical conditions and is associated with an increased mortality in elderly trauma patients with less severe injuries. Morris et al. demonstrated that cirrhosis, in trauma patients of any age, increased the risk of dying, with an odds ratio of 4.5 [31].

The elderly trauma patients are at an increased risk of intestinal infarction. Acute hemorrhage, neurogenic shock, or cardiac dysfunction from acute injury can all result in low flow states. In the elderly with underlying vascular calcification or mural thrombus, any decrease in flow can cause significant compromise to the bowel and result in intestinal ischemia.

Metabolic/Endocrine

By age 80, the elderly have lost almost 40% of their lean muscle mass [23]. During muscle breakdown for gluconeogenesis, critically ill patients lose a significant amount of muscle mass. As the elderly start with less muscle mass, the proportion of loss is greater. Thus after injury, the elderly quickly become severely malnourished, and nutritional support should begin early. Protein-energy malnutrition occurs in approximately 70% of the hospitalized elderly. A Cochrane review on nutritional supplementation in the elderly suggested that early nutrition reduced unfavorable outcomes, long-term complications, and days spent in rehabilitation [32].

The most notable endocrinopathy of aging is glucose intolerance. This hyperglycemia is a result of both decreased secretion of insulin and increased resistance to insulin. Increasing age is associated with an increase in serum glucose, but not an increase in insulin after mild or moderate trauma. There is also a decrease in thyroid function and responsiveness to metabolic stress in the elderly. Aging cause fibrosis of the thyroid gland with a decrease in the amount of T3 released, resulting in a lower basal metabolic rate. The elderly also lose their natural responses to cold and are at a higher risk of hypothermia. Warming, therefore, should be implemented as quickly as possible after injury.

Immunology

The aging adult experiences changes in both innate and adaptive immunity, thereby predisposing them to infections. These changes include impaired neutrophil function, a decline in T cells, as well as reduced B-cell antibody generation [33]. Conversely, there are elevations in levels of circulating inflammatory cytokines after relatively minor physiologic insult. A pertinent clinical example of this is seen in rib fractures in the elderly, where there is an increased risk of pneumonia and subsequent increase in mortality rate for hospitalized patients.

Common Injury Patterns in the Elderly

Falls

Falls are the most common injury in the elderly. The National Council on Aging states that one-third of Americans over age 65 fall each year [34]. In population-based analyses, fall-related injuries comprise over 50% of all injuries for individuals age 55 or older, and up to 80% of all injuries in the population over age 80. Most falls occur in or about the home, and most tend to be ground-level falls, while falls from great heights are uncommon. Between 30 and 40% of the population over 65 years of age who live in the community sustain a fall each year [35]. This is higher for persons living in long-term care facilities. Fractures occur in 4–6%, 25% being hip fractures, while other major injuries requiring hospitalization occur in an additional 2–10%. Elderly women are no more likely to fall, but sustain serious injury, usually fractures, more commonly than men. Men incur more CNS injuries and have higher mortality following falls. This may be from higher risk-taking and underreporting of less severe fall injuries in men. Inability to get up after a fall is common. Prolonged down time can cause decubitus ulcers, dehydration, and even rhabdomyolysis.

The elderly have numerous risk factors for falls. Debilitating chronic diseases such as Parkinson's, stroke, arthritis, dementia, and anemia are more prevalent in the population of elderly who sustain falls. Among the other factors are older age, Caucasian race, history of previous falls, polypharmacy (especially psychotropic agents, diltiazem, laxatives, and diuretics), dependence for activities of daily living, low body mass and impaired mobility, muscle strength, gait, balance, vision, hearing, and cognition. These factors have all been correlated with an increased risk of falls and fall-related injury. The role of exercise as a risk factor is not clear. Exercise may lead to increased coordination and strength. While some studies have shown significant decreases in the incidence of falls, exercise also increases the exposure of the elderly to possible fall scenarios.

Falls among the elderly result from complex interactions of structural and physiologic disabilities, as well as environmental factors. The consequences of a fall depend on such factors as the kinetic energy generated during the fall as well as the ability of the body structures to absorb and the fall surface to accept the energy. In addition, the protective responses, the garments of the faller, and the direction and body location of the impact will affect the outcome of the fall. Functional consequences of the aging process along with an alteration in cognition may lead to increased risk-taking. Lack of appreciation of their limitations also predisposes the elderly to falls. Loss of muscle mass and changes in body composition result in decreased strength. Combined with a limited range of motion due to degenerative joint diseases, the elderly are less able to absorb the kinetic energy during a fall. Thus, many falls that are categorized as accidents are truly interactions between identifiable environmental hazards and increased individual susceptibility to those hazards from accumulated effects of age and disease [35]. Therefore, management of the elderly fall victim must include an investigation into the cause of the fall, which can frequently be determined from a thorough history.

The extent of morbidity and mortality related to falls in the elderly is probably better captured when including discharge patterns from both hospitals and skilled nursing facilities (SNFs), as many elderly patients either have a prolonged recovery or progress to death in a SNF after ground level falls [36]. This reflects a "deferred mortality" associated with falls in older adults, as those who ultimately die do so after discharge but within 3 months.

The economic impact of falls in the elderly is huge. Direct medical costs totaled $616.5 million for fatal and $30.3 billion for nonfatal injuries in 2012 and rose to $637.5 million and $31.3 billion, respectively, in 2015. Fall incidence as well as total cost increased with age and were higher among women [37].

Motor Vehicle Collision

Motor vehicle collisions (MVC) are the second most common mechanism of injury in those 65 years of age and older. In 2012, there were 5,560 people age 65 and older killed and 214,000 injured in motor vehicle traffic crashes [38]. These older individuals comprise 17% of all traffic fatalities and 9% of all people injured in traffic crashes that year. Compared to the previous year, fatalities increased by 3% and injuries increased by 16%. Older drivers who are hospitalized after an MVC have significantly higher mortality rates, longer hospital stays, and are less likely to be discharged directly to their homes [39]. There is a greater frequency of intracranial hemorrhage and chest injury in the elder population, which also contributes to poor outcomes.

Elderly drivers appear to have lower crash rates compared with younger drivers, but they drive less often. When normalized for the number of miles driven, the >65 years group has the second highest crash rate after new drivers. The >85 years group has the highest per-mile-driven crash rate of all age groups. Reduced vision or hearing, impaired judgment, and reduced reaction times are well recognized as factors leading to

MVC in the elderly. Alcohol is less often involved in MVCs involving the elderly compared to younger drivers [40].

Pedestrian-Motor Vehicle Collision

The elderly are at risk to be involved in a pedestrian crash as a result of walking into oncoming vehicles, often due to confusion or impairment of visual or auditory acuity. Reduced gait speed of the elderly pedestrian may be inadequate to complete the crosswalk at time-controlled traffic intersections, leaving the elder in the street exposed to inattentive drivers. There is a demonstrated increased risk of pedestrian crashes and fatalities with increasing age [41].

Depression, Substance Abuse, and Suicide

Suicide is the third-leading cause of injury-related death for those 65 years of age and older [1]. Those over the age of 75 have the highest rate. The most common mechanisms of suicide in the elderly are by firearms, asphyxiation, or overdose. Only about 25% of the elderly who attempt suicide are actually successful. Risk factors for suicide in the elderly population include psychiatric disorders, especially depression; medical conditions, especially cancer or chronic lung disease; moderate to heavy alcohol use; and social isolation. Changes in behavior such as altering a will, new preoccupation with religion, or giving away life possessions may be warning signs of impending suicide.

There are approximately five million elderly suffering from depression, with higher rates in hospital settings [42]. In particular, up to 50% of nursing home residents may develop clinical depression within the first year of their stay [43]. Other risk factors for late-onset depression include social isolation, female sex, comorbid general medical conditions (in particular stroke, myocardial infarction and cancer), chronic pain, functional and cognitive impairment, and lower socioeconomic status.

Alterations in metabolism in the elderly require that particular attention be paid to the initiation and titration of antidepressant pharmacotherapy, which should be closely monitored in conjunction with a psychiatrist. SSRIs and mirtazipine are most commonly used for their safety profiles and efficacy. Electroconvulsive therapy ECT is a useful adjunct in patients refractory to medications or those with suicide risk, psychotic features, or Parkinson's disease. Psychotherapy is also effective in older patients.

Substance abuse, particularly alcoholism, is a rising problem in the elderly population. Nearly 15% of adults over age 65 consume more than the weekly recommended allowance of 7 drinks. Risk factors include loss of a spouse, depression, anxiety, disability or chronic pain, and prior history of alcohol use [44]. With age, the ability to metabolize alcohol is progressively impaired by a decrease in hepatic blood flow and enzymatic processing. Decreases in total body water and lean muscle mass also contribute to higher concentrations of blood alcohol per unit of alcohol consumed. Intoxication and withdrawal both carry an increased risk of delirium and impaired cognition in the elderly.

During the course of acute treatment of the elderly trauma patient, it is easy to overlook symptoms of depression or substance abuse. While stabilization of the patient takes priority, the clinician should also have a low threshold to screen for mood and substance disorders in patients presenting with repeated or suspicious falls or accidents. The surgical intensivist may use validated tools such as the Patient Health Questionnaire-2 and the Geriatric Depression Scale to screen surgical and trauma patients for signs of depression or dysthymia [45].

The American Geriatrics Society recommends routine questioning of elderly patients regarding the specifics of alcohol use, as well as incorporation of a modified version of the "CAGE" questionnaire to those with suspected trauma related to alcohol use [46]. In patients over 65, other forms of substance abuse involve polypharmacy, particularly with sedatives and hypnotics. These medication categories, as well as overuse of antidepressants and benzodiazepines, have been shown to significantly increase the risk of falls and traumatic injury in the elderly [47].

Burns

Deaths from burns are the eight most common cause of unintentional injury death in adults over age 65 [1]. In 2014, there were approximately 1151 fire/burn-related deaths in this age group. Diminished senses, impaired mentation, slower reaction time, reduced mobility, and bedridden states may decrease an elder's ability to identify fire and also to escape harm. Advances in burn care have improved mortality rates across all age groups including the elderly [48]. While long-term outlook for burn survivors is improving, the elderly still have a significantly higher morbidity and mortality rate for any size burn than their younger counterparts [49]. Overall mortality in those age 75 or older is between 45% and 60% [49, 50]. Risk factors are multifactorial, including premorbid conditions, decreased lean body mass, protein-energy malnutrition, decreased pulmonary reserve, and impaired response to infection. In addition to the standard management of burn victims, the burn victim may suffer hypoperfusion in the face of normal vital signs and adequate urine output. As older adults are more sensitive to large fluid shifts, a judicious approach to resuscitation is advised, titrating volume replacement calculations to physiologic parameters. Other pillars of modern burn care, including enteral nutrition, early wound closure, and aggressive rehabilitation, are also advised in the elderly, resulting in decreased length of hospitalization and decreased mortality. Early excision and grafting in the elderly yields fewer episodes of infection, resulting in a reduction in hospital stay and improved survival [48]. Long-term disability potential after discharge is greater in elderly burn patients, with fewer older adults returning home within a year of injury as compared to younger burn victims [51]. The management of burns in elderly patients remains a challenge from the clinical, rehabilitative, and psychosocial recovery process.

Elder Abuse

The US National Academy of Sciences defines elder abuse as: "(a) intentional actions that cause harm or create a serious risk of harm to a vulnerable elder by a caregiver or other person who stands in a trust relationship to the elder or (b) failure by a caregiver to satisfy the elder's basic needs or to protect the elder from harm" [52]. The abuse includes physical, psychological, sexual, and financial, as well as neglect. Such injuries can be subtle in their presentation compared with those from a physical assault.

Thomas estimated that the incidence of elder abuse ranges from 2% to 10% [53]. This number may underestimate the magnitude of the problem owing to the victim's reluctance to admit abuse for fear of loss of care, retribution from the abuser, or from being ashamed to be in an abusive relationship.

Risk factors should alert the healthcare provider to the diagnosis of abuse. Once suspicion is raised, the victim should be interviewed one-on-one to increase the likelihood of disclosure of the extent and details of the abuse. Victims may be embarrassed revealing such details to a group of health-care personnel. The details of the abuse should be documented completely in the medical record for the possibility of subsequent legal action. The physician who documents or suspects elder abuse is ethically obligated, and in most states legally bound, to report the case to an adult protective service agency.

The most important intervention is to protect the victim from danger. The victim may be reluctant to leave the care of their abuser because of ambivalence regardless of the perceived danger. Unless the victim lacks the cognitive skills to make informed decisions, individual liberty must not be compromised. The physician should interview the abuser in a nonconfrontational fashion to better understand the situation. The physician should acknowledge and empathize with the difficulty of shouldering the burden of elder care. Armed with this additional information, the physician is better prepared to intervene to break the abuse cycle.

Management of the Elderly Injured Patient

Triage

Triage for the geriatric patient should provide the appropriate intensity of medical care, taking into account factors including severity of injury, cost, availability, prognosis for functional recovery, and patient goals of care. This process begins in the prehospital setting when decisions must be made regarding the appropriate facility. The American College of Surgeons Committee on Trauma recommends that patients over the age of 55 years be considered for triage to a trauma center [54]. However, in reality, the elderly are the most undertriaged group [54]. A large multicenter study emphasized the importance of educating emergency medical services (EMS) personnel to recognize high-risk elderly trauma patients through an expanded set of triage guidelines [55].

Initial Management and Resuscitation

The first few minutes of resuscitation of the elderly trauma victims differs very little from that of younger patients. Early intubation in the multi-injured elderly trauma patient should be considered as it reduces the work of breathing and may avoid progressive respiratory failure and cardiovascular collapse. As the elderly have limited cardiovascular reserve, they are vulnerable to hypotension from induction agents, and reduced doses should be used. In addition, limited pulmonary reserve may make preoxygenation difficult, causing rapid desaturation during intubation.

A normal blood pressure for a younger patient may be a relative hypotension for an elderly patient with history of hypertension. Geriatric patients are more likely to present in shock than younger patients matched for trauma and ISS. Admission base deficit [56] levels correlate with mortality in the geriatric population, and the rate of serum lactate clearance after trauma correlates with survival [57].

Considerations for Specific Injuries in the Elderly

Head Injuries

In persons 55 years of age and older, more than 323,000 traumatic brain injuries (TBI) occur, the primary cause of which is falls [58]. Older age has been well recognized as an independent predictor of worse outcome after TBI, even with relatively minor head injuries. Older TBI patients also have been found to have longer length of stays, resulting in greater cost of care [59]. Large retrospective studies have shown that elderly patients with severe TBI (sustained Glasgow Coma Scale <9) have at least an 80% likelihood of death or major disability leading to placement in a long-term care facility [60].

As many as 73% of elderly TBI patients may have at least one comorbid condition as compared to only 29% of younger patients [61]. Treatment of some of these chronic conditions includes the use of aspirin and warfarin, which increases the risk of TBI in the elderly. Approximately 10% of the older patients with TBI are taking warfarin preinjury and this is associated with more severe TBI and a higher rate of mortality [62]. Urgent reversal of anticoagulation is advised, as the amount of bleeding is a major determinant of outcome. The Eastern Association for the Surgery of Trauma recommends that elderly patients taking warfarin presenting with intracranial hemorrhage should have their INR corrected (<1.6) within 2 h of admission [63]. Traditionally, fresh frozen plasma (FFP) has been used. However, large volumes of FFP are often required to fully reverse warfarin. This can cause pulmonary edema and volume overload in the elderly patient with compromised cardiac and/or renal function. Other alternatives include prothrombin complex concentrates [PCCs] as well as vitamin K and cryoprecipitate. A more complete and faster reversal time in patients on warfarin needing an emergent neurosurgical intervention using PCCs compared to FFP and vitamin K.

Hourly neurological exams, correction of coagulopathy, and repeat CT head every 6 h should be standard of care until clinical exam and radiologic findings stabilize. Even if the initial head CT scan shows no injury, the elderly patient on warfarin, with head trauma and a therapeutic INR, should be admitted and observed for a minimum of 12–24 h. A repeat CT scan should be done anytime for any change in the patient's neurologic exam.

There are several other management considerations in the elderly presenting with TBI. Well-validated practice guidelines regarding CT imaging in head trauma [NEXUS II, Canadian CT Head Rule] specifically excluded older populations from their studies. Brain atrophy allows for more space for intracranial blood to accumulate before causing symptoms, so clinicians should have a low threshold to image older patients. Intracranial pressure [ICP] monitoring and ensuring adequate cerebral perfusion pressure [CPP] are also altered because there is a decrease in the autoregulation mechanism in the elderly. Comorbidities may affect the responsiveness and perfusion needs of the cerebral vasculature in these patients, and guidelines for CPP management must be customized accordingly.

Spinal Injuries

Cervical fractures have a prevalence of 2–5% in patients older than 65 years, with low-energy falls being the most common mechanism [64]. Patients who are awake, alert, nonintoxicated, have no cervical tenderness, neurologic deficit, or distracting injury do not need further radiographic evaluation, regardless of age [65]. Although the three-view plain radiograph has been the traditional initial modality for cervical spine evaluation, many now use CT as the initial evaluation tool for cervical spine injury due to the high rate of missed injuries on plain films. If a neurological deficit is present, then magnetic resonance (MR) should be used to evaluate ligamentous and/or spinal cord injury. Clinicians should have a lower threshold to image the elderly with suspected cervical spine injury, given underlying risk factors such as cervical stenosis and degenerative osteoarthritis in this population. High cervical fractures, including odontoid fractures, are among the most common in the elderly. Cervical stabilization is the primary end point, be it with a cervical collar, halo, or operation.

Central cord syndrome (CCS), usually resulting from hyperextension, is more likely to occur in the elderly due to underlying cervical stenosis. Patients usually present with upper extremity motor weakness that is greater than lower extremity weakness, bladder dysfunction, and variable sensory loss below the level of injury. Younger patients with central cord syndrome typically regain independence in self-care of bladder and bowel function more frequently than elderly patients [66].

Thoracic Injuries

A number of studies have focused on rib fractures in the elderly and subsequent outcome. The elderly have a higher mortality from chest trauma as a result of the initial injury as well as secondary pulmonary insults. Major risk factors for mortality include age over 65 years, three or more rib fractures, or pre-existing cardiopulmonary disease. In 2000, Bulger et al. retrospectively evaluated patients over the age of 65 years with rib fractures compared to those younger than 65 [25]. Despite similar ISS and chest abbreviated injury score, the elderly fared significantly worse in all outcome measures. Morbidity and mortality increase as the number of rib fractures increased. With each additional fractured rib in patients over 65 years, mortality increases by 19% and the risk of pneumonia increases by 27% [25]. Close monitoring in a step-down or intensive care unit, appropriate pain control, aggressive pulmonary toilet, and early mobilization are all crucial in reducing complications in this patient population.

Traumatic blunt aortic injures (BAI) are often initially suspected by a widening of the mediastinum on a plain chest X-ray, and definitively diagnosed by CT angiography. Over the last 10 years, there has been a significant change in the management of BAI from the traditional, standard operative repair. Endovascular stent grafts were initially used for high-risk, multiply injured patients or those with comorbid disease, i.e., the elderly. However, many centers now use them as their initial treatment of choice for BAI. Nonoperative management, using aggressive blood pressure control (systolic <110), is successful in some high-risk elderly patients with small aortic tears [67].

Abdomen/Pelvis Injuries

Significant intra-abdominal injury occurs in approximately one-third of elderly patients with multisystem trauma. Although abdominal injury patterns are similar to the younger adult trauma population, abdominal wall laxity, alterations in pain fibers, and decrease in abdominal musculature may make the clinical abdominal exam more challenging in the elderly [27]. In addition, polypharmacy, dementia, or Alzheimer's disease can obscure the physical exam in the elderly, making the diagnosis of an intra-abdominal injury more difficult. As such, radiologic adjuncts may prove to be particularly helpful focused ultrasound is a reliable initial radiographic modality for evaluating for free fluid, but it cannot differentiate between a solid organ injury and a hollow viscous injury. CT scan can be used to evaluate a hemodynamically stable patient to identify the presence of intraabdominal injuries. IV contrast agent typically used to better identify vascular injuries, but can be problematic in the elderly for a number of reasons. Contrast-induced nephropathy can be as high as 25% in patients with preexisting renal dysfunction, diabetes, advanced age, and concurrent usage of nephrotoxic drugs. Patients at increased risk of contrast-induced nephropathy include those with a serum creatinine >1.5 mg/dL, or an estimated glomerular filtration rate [eGFR] <60 ml/1.73 m^2. Adequate volume expansion via isotonic intravenous fluids (isotonic bicarbonate or isotonic NaCl) pre- and post- procedure help minimize the risk of renal injury [68].

Nonoperative management of blunt splenic injuries has become standard of care, though there has been a change in thinking about how this applies to the elderly. Early studies showed a high failure rate for those over the age of 55 years. Recently, however, this has been challenged, and a number of studies have shown that age is not associated with increased failure rate [69] [70]. Thus, age over 55 years is no longer considered a relative contraindication to nonoperative management of splenic injuries.

Fractures

Overall, efforts to minimize fractures in the elderly should include fall-prevention programs and education around reducing osteoporosis risk. Fractures in the elderly can be due to force of impact from mechanical falls or other trauma, but the clinician must also consider the likelihood for the presence of a pathologic fracture from metastasis.

Hip fractures remain the most frequent cause of hospital admission after trauma in the elderly. Injuries can be intracapsular (femoral neck and head) or extracapsular (intertrochanteric and subtrochanteric). Unrevealing plain radiographs should be followed by a CT scan or MRI if clinical index of suspicion for fracture is high. In addition, factors associated with in-hospital death include sepsis, pneumonia, thromboembolism, and gastrointestinal disorders. The risk of dying after hip fracture is doubled in patients with cardiac disease, cancer, or cerebrovascular disease [71].

Complicated fracture-dislocation patterns in femoral neck fractures increase the risk of avascular necrosis due to the already tenuous blood supply to this area. While in younger patients, these injuries are usually secondary to a high-impact motor vehicle collision, similar patterns can be seen from a traumatic fall in the elderly.

Most hip fractures are treated surgically. Almost 40 years ago, Laskin et al. proposed a management scheme for intertrochanteric fractures in the elderly. This included early rigid fixation using compression hip screws to allow early mobilization and immediate weight bearing to assist with vigorous pulmonary toilet [72].The longer the elderly remain bedridden, the more likely they are to have complications, including atelectasis, pneumonia, need for mechanical ventilation, venous thrombosis, muscle atrophy, and skin breakdown, all leading to longer hospital stay and increase in mortality. Thus, early orthopedic consultation, fracture fixation, and physical therapy are warranted.

Pelvic fractures are also common in the elderly, including occult pelvic fractures of the pubic rami and sacral insufficiency fractures. A 2002 study by Henry et al. demonstrated that most elderly patients with pelvic fractures have lateral compression fractures, which are usually not associated with significant bleeding [73]. However, the authors found that the elderly are more likely than younger patients to have fracture-associated hemorrhage and require angiography. In addition, the outcome for older patients with pelvic fractures was significantly worse than for younger patients. Recognizing these differences in fracture and bleeding patterns in the elderly identifies those at high risk and helps guide resuscitation.

Rehabilitation and Disposition

The aim of rehabilitation is to restore an individual to his/her former functional environmental status or, alternatively, to maintain or maximize remaining function. Unlike younger patients in whom rehabilitative outcomes are more apt to be dramatic, the geriatric patient is likely to make subtle progress. The degree of independence the patient is able to attain can mean the difference between living at home and living in a long-term care facility. For many elders, maintaining functional independence is vitally important to having an acceptable quality of life. The physician caring for the injured elder must understand the importance of attaining or maintaining independence for their elderly patients and do whatever is necessary to achieve this. The elderly with chronic debilitating disease more frequently require rehabilitative services following trauma because of the limitations imposed by injury.

Multidisciplinary care of the trauma and critically ill geriatric patient is often required to facilitate the transition to home or a skilled nursing facility. Important considerations include whether the patient has the cognitive ability to execute his or her discharge instructions, and whether family and social supports are available.

There is an emerging body of evidence demonstrating that interventions addressing geriatric-specific conditions improve outcomes such as functional status, incidence of delirium, and hospital length of stay. Some hospitals incorporate care by geriatric trauma consultation teams (GTTs). Their involvement suggests improvements in pain management, medication counseling, advance care planning, and overall function prior to discharge. Similarly, the creation of geriatric trauma/ICU units shows reductions in length of stay and complication rates (urinary tract infections, respiratory failure, and pneumonia) [74]. As a quality improvement effort, the American College of Surgeons published a set of guidelines that can serve as checklist for surgeons [75]. By standardizing principles such as when to obtain geriatric consultation, medication management and delirium avoidance, the aim is to discharge geriatric trauma and ICU patients with better functional status, ADL performance, and lesser long-term morbidity.

Long-Term Outcome

It is generally accepted that both short-and long-term outcomes after injury are considerably worse in the elderly than in younger patients. Despite this, The Eastern Association for the Surgery of Trauma [EAST] practice guidelines recommend that age should not be used as a criterion for limiting care as with aggressive initial management because as many as 85% return to independent living [76]. Others have demonstrated somewhat less promising outcomes of the injured elderly. A study of 38,000 patients over the age of 65 demonstrated that 50% went home and that 25% were discharged to a skilled nursing facility [77]. Inaba et al. reported in a study of injured elderly that, at long-term follow-up, only 68% of patients were living independently as compared to before injury. Furthermore, an additional 20% required skilled home care [78].

Injury Prevention

The first step toward prevention of injury is to recognize the individuals who are most likely to suffer injuries, as well as the lifestyle factors contributing to injury. For active older adults, falls from a height or motor vehicle collisions are likely more common. In contrast, an inactive older adult may be at risk for falls from standing. As such, injury prevention efforts vary accordingly. Many of the factors that predispose the elderly to injury should be discovered on routine history taking in the elderly patient.

The most successful programs to date have been in fall prevention for frail elderly adults who experience a fall from their own height. These programs range from in-home safety inspections, exercise programs, gait training, and the use of devices such as hip protectors and other wearable technologies [79]. The American Geriatrics Society has published a clinical practice guideline that addresses the multifactorial nature of fall risk and prevention techniques including minimization of medications, exercise training, management of foot disorders, and modification of the home environment [80].

Similar prevention efforts directed toward identifying and reporting unfit drivers may help reduce rates of motor vehicle collisions. This includes persons with visual or hearing deficits, dementia, or disabling musculoskeletal disorders, and those using medications that decrease driving skills. In an effort to refresh skills and update traffic knowledge, the American Association of Retired Persons [AARP] and the National Retired Teachers Association have established driver education courses for adults over 55 years of age. Pedestrian accident-prevention programs can reduce fatal and serious injury occurrence through prolongation of traffic-light times to accommodate the decreased gait of the elderly, modifications of road and crosswalk signs, tighter speed-limit enforcement, and safety-education presentations at senior centers.

Decision-Making Capability

The process of informed consent and autonomous decision-making is often compromised in many trauma patients due to impaired cognition or life-threatening injuries. Older patients are particularly susceptible to alterations in mental status that would prevent them from making their own decisions regarding therapeutic interventions. The creation of advance directives or living will documents, as well as open communication with family members regarding goals-of-care wishes, are often helpful in guiding decisions when patients are not able to advocate for themselves.

In order for patients to make an informed decision, they must demonstrate an understanding of the diagnosis and proposed treatment plan, logically synthesize the information and be able to express a clear choice, with an understanding of how that choice will impact their lives. There are several validated assessment instruments at the clinician's disposal, including the MacArthur Competency Assessment Tool for Treatment [81] and the Assessment of Capacity for Everyday Decision-Making [82].

A patient who lacks capacity and does not advance directives in place requires a substitute decision-maker. Laws regarding the appointment of this individual vary by state; there are regions that seek out a next-of-kin, and others that select by ethics committee the person deemed most fit to act on behalf of the patient. Regardless of the differences in regulations, the role of the substitute decision-maker is to make decisions that would be most consistent with the patient's previously expressed wishes and best interest.

It is the physician's responsibility to provide realistic expectations regarding possible outcomes. If interventions such as CPR are clinically contraindicated by best professional judgment, the American Medical Association states that the physician may communicate the medical futility of certain interventions in the fatally ill and not deliver that intervention. The difficult nature of these conversations requires clear and ongoing communication, with a common ethical goal of acting in the patient's best interest.

End of Life/Withdrawal of Treatment

As injury is the fifth leading cause of death in adults over the age of 65, goals of care should be addressed early in the treatment of elderly trauma and surgical critically ill patients [6]. Documents such as advance directives or living wills are helpful in guiding the process, but not a substitute for clear and advance open communication between patients and their families, so as to guide care providers with respect to the patient's wishes. Despite every effort to avoid decision-making during acute decompensation or injury, trauma surgeons and surgical intensivists are frequently called upon to navigate these difficult conversations and must be adept at forming new, trustworthy therapeutic alliances with patients and their families.

Admission to a surgical intensive-care unit, and the aggressive interventions that accompany this, may not be consistent with the patient's best interest or their wishes. The discussion regarding end of life and withdrawal of care is often a multistep process. The decision not to perform cardiopulmonary resuscitation or to intubate is often the first decision that families or surrogates make. Often, it takes families some time to come to the reality that despite all medical advances, their loved will not survive. It is imperative to emphasize a clear and consistent message to all loved ones involved. Although there is a hierarchy of legal decision makers, having family members achieve cohesion on the direction of care can be invaluable in the coping process.

Early involvement of the palliative care team can help by providing resources and symptom management, as well as facilitate discussions between patients, families, and treating physicians without directing treatment to comfort only measures.

There are several models of palliative care available in most hospitals, and palliative care consultation may be appropriate for patients who: either has acute severe injury with poor prognosis or chronic and life-limiting critical illness, is greater than 80 years old, or for whom a specific medical intervention may be inconsistent with their desired goals of care.

If and when the decision is made by the family to withdraw treatment, the physician must ensure a smooth process. A patient-centered approach should be maintained at all times, whereby the patient and family's attitudes are respected. Some families may find closure from being present during the process of withdrawal of treatment. Adequate narcotics and sedatives help prevent any additional suffering. Turning off monitors and intravenous pumps and ensuring a quiet peaceful atmosphere for the patient and family enhances the family's experience.

Conclusion

With an increase in the number and lifespan of adults over the age of 65, care of the injured elderly has become an important component of the trauma surgeon's skill set. Resuscitation and specialized management of this patient population requires intimate knowledge of the numerous physiologic changes manifested in older adults. Furthermore, appropriate treatment decisions often call into balance consideration of goals of care and patient disposition. Early discussions with the patient, family, and decision-makers help to align expectations regarding expected treatment course and potential for recovery. With continuously expanding resources being made available, it is imperative to provide the best standard of care for geriatric trauma patients through a multidisciplinary approach.

Case Study

AB, a 78-year-old male, with past medical history of atrial fibrillation and hypertension, was a restrained driver involved in a motor-vehicle collision. The patient was t-boned on the driver side by a car traveling at approximately 50 miles/h. On arrival, he denies any loss of consciousness, complains of some left-sided hip pain, which is worse with movement. In addition, he complains of left-sided chest pain, which is worse with deep inspiration. He denies any abdominal pain or back pain.

Past medical history: atrial fibrillation, hypertension

Past surgical history: cholecystectomy

Medications: warfarin, aspirin, metoprolol, alendronate, and multivitamin

Allergies: none

Social history: denies alcohol, tobacco, or drug use

Physical Exam

Vital signs: Height – 75 inches, Weight – 85 kg, heart rate – 75 beats/min, blood pressure – 100/60 mmHg, respiratory rate – 30 breaths/min and shallow, oxygen saturation – 93% on 6 L by nasal cannula, EKG – rate-controlled atrial fibrillation.

On exam, there is a left-sided scalp hematoma and small laceration that is not currently bleeding. The patient has significant left-sided rib tenderness on palpation; no subcutaneous soft tissue air is appreciated. He also has notable hip and pelvis pain on palpation, though the pelvis does not appear to be unstable. Distal extremities are cool to the touch, but peripheral pulses are intact. All other aspects of the physical exam are normal.

Lab Work

Sodium – 139 mmol/L, Chloride – 109 mmol/L, Potassium – 4.0 mmol/L, Bicarbonate – 19 mmol/L, Glucose – 100 mg/dL, BUN – 35 mg/dL, Creatinine – 1.75 mg/dL, White blood cell count – 12,000, Hemoglobin – 10 g/dL, Hematocrit – 32.0%, Platelets – 175,000/mcl, INR – 2.2, PTT – 30s, PT – 19.5 s, Lactic acid – 4.5 mmol/L.

Serial cardiac enzymes are normal.

Arterial blood gas: pH 7.30, pCO_2 – 40 mmHg, pO_2 – 90 mmHg, O_2 saturation – 93%, base deficit – 6.5 mmol/L.

Radiographs

Chest x-ray: multiple left-sided rib fractures, no pneumothorax, no hemothorax.

CT head: scalp contusion, no intraparenchymal hemorrhage.

CT cervical spine: degenerative changes, no acute fractures or subluxations.

CT chest with IV contrast: left-sided rib fractures 5–10, no pneumothorax, small hemothorax, normal aorta.

CT abdomen/pelvis with IV contrast: left-sided inferior and superior rami fracture. Left-sided sacral fracture. Active extravasation in the pelvis. No solid or hollow viscous organ injury.

Things to Consider

1. Early intubation in an elderly person with multiple rib fractures and respiratory decompensation.
2. Optimize analgesia to assist with pulmonary toilet in the setting of multiple rib fractures, consider insertion of an epidural catheter.
3. Mild hypotension and normal heart rate in the setting of acute trauma may be related to medications the patient is taking (i.e., beta blockers)
4. Administration of IV contrast for CT scan in the elderly patient with a decreased GFR and creatinine clearance merits close observation of renal function and adequate IV hydration.
5. The need for warfarin reversal in lieu of active bleeding in the pelvis, and the method by which warfarin can be reversed.
6. The need for intensive care monitoring for this elderly patient with multiple rib fractures, unstable respiratory status, and pelvic fracture.

Hospital Course

AB received 2 units of fresh frozen plasma, which corrected his INR to 1.5. After consideration of his elevated INR and the fact that he has been on aspirin, he received a patient-controlled analgesia (PCA) pump to help with pain control, rather than an epidural catheter.

Due to AB's signs of hypoperfusion including cold extremities, acidosis, and base deficit, as well as the CT abdomen/pelvis imaging, it was clear that AB was developing signs of hemorrhagic shock. He was taken to interventional radiology for embolization. A bicarbonate infusion was started to protect his renal function in the setting of additional IV contrast load. Orthopedic surgery was consulted regarding the pelvic fracture.

After successful angioembolization of pelvic bleeding, AB returned to the intensive care unit with increased work of breathing. This was likely multifactorial in nature; including volume from the fresh frozen plasma and bicarbonate infusion, the supine position for the angiographic procedure, and the splinting due to multiple rib fractures. AB was intubated for airway protection and maintenance of adequate oxygenation and ventilation.

Five days into her hospital course, AB was hemodynamically stable and had weaned from the ventilator. He was subsequently extubated after an epidural catheter was placed for pain control. Unfortunately, 36 h later, he required reintubation for increased work of breath and dropping oxygen saturation. He became febrile and his white blood cell count was elevated, and chest x-ray revealed a right lower lobe consolidation consistent with pneumonia. He was started on broad-spectrum IV antibiotics and remained hemodynamically stable off vasopressors. On day 8 of hospitalization, after discussions with the family and AB, a tracheostomy was performed in order to improve pulmonary toilet and facilitate weaning from the ventilator. Five days later, he was off the ventilator and tolerating trach collar. Once transferred to the ward, he was able to pass a swallow study and eat. More than 2 weeks after admission, AB was transferred to a rehabilitation facility for further care.

Ethical Issues in Older Adults

Abstract

Normative ethics addresses the criteria or standards by which we judge whether an action is considered to be right or wrong. Medical ethics is built on a utilitarian ethical structure; it bases what we *ought* to do on competing principles that are applied in the context of the clinical setting and not on overarching deontological moral imperatives. The guiding principles of American medical ethics are those of respect for autonomy, nonmaleficence, beneficence, and justice (Table 1).

Table 1 Definitions in medical ethics

Respect for autonomy	Maximize the individual's ability for self-determination
Nonmaleficence	Do no harm by direct action or negligence
Beneficence	The weighing of benefits, risks, and burdens for the greatest good
Justice	The fair and equitable distribution of resources, greatest good for the greatest number of people

guiding principles of American medical ethics are those of respect for autonomy, nonmaleficence, beneficence, and justice (Table 1). Autonomy is defined as the right to self-determination, the right to make one's own choices. The principle of nonmaleficence, often equated with the phrase primum non nocere, first do no harm, is better described as the obligation not to knowingly do harm by either an action or the omission of an action. Beneficence is the act of doing the most possible good; to take the action which will result in the most beneficial outcome for the patient. Justice, in the context of health care, refers to equality of medical treatment and the access to care. For any given clinical situation, the application of each of these principles may give different answers to what is right or wrong [1].

Weighing these competing principles in cultural, societal, and the individual contexts may lead to different actions. Not all cultures approach ethics in the same manner. For example, some religion-based cultures may feel that there are specific rules or god-given imperatives that may never be compromised and therefore all competing interests are secondary. The relative value of the four stated principles may be different for someone in a family-centered culture where individual autonomy may be less important than it is for American culture [2]. In this chapter, we discuss how these principles are applied in modern, mainstream American medicine with a special focus on the geriatric population.

Appropriate treatment of the geriatric patient involves a shift in perspective and priorities. The physician must recognize the multifactorial nature of illnesses, the need to fully understand the goals of care prior to initiating workup, and the need to continually review these goals as events unfold. Most illness states in older patients do not follow the paradigm of a unifying pathologic event. There may be many factors that need to be identified and addressed; factors that have predisposed the individual to the event, changes that have precipitated the event, and consequences of the situation. With age, the patient's perspective on the relative values of quantity and quality of life may change. A patient might wish to live a full, vital life to the age of 100, but may not want to merely survive that long in an incapacitated state. What is seen as a benefit, what weighs heavier as a burden, or what risks that individual is willing to take may change with time and experience.

Truth-Telling

The principle of nonmaleficence has, for millennium, been cited to justify the withholding of "bad news" from patients. The edict to withhold bad news was little challenged until the 1950s when the validity of this assumption came under scrutiny. In surveys conducted during the late 1950s and early 1960s, less than one-third of responding physicians stated that they always tell the truth to their patients about the diagnosis of cancer [3]; and in one survey 69% stated that they usually do not or never tell the patient the diagnosis of cancer [4]. By 1979, a similar survey revealed that 97% of responding physicians thought that a patient should be told the diagnosis of cancer [5].

This profound shift in practice in less than 20 years reflects both advances in medical knowledge and shifts in the emphasis in medical ethics. The development of treatment options for cancer initially drove this shift in communication. Patients could not undergo chemotherapy or irradiation unless they consented to the treatment and in order for them to be able to consent they needed to be informed of their diagnosis. In this case, recognizing the patients' autonomous right to choose treatments, or to forego treatments, was felt to be stronger than what was perceived to be the avoidance of the catastrophic harm that would be done by telling them their diagnosis (nonmaleficence). Interestingly, disclosure of information has not been found, in and of itself, to do harm. It does, in fact, allow the patient to discuss their goals and preferences more fully, as well as their emotional reactions, and to plan how they wish to approach this phase of their life.

Even when treatment options are still limited or nonexistent, as is the case with patients diagnosed with Alzheimer's disease, the weight of the argument is in favor of autonomy and therefore for truth-telling [6]. As we place an increasing emphasis on advance health care planning, the obligation to inform patients while they are capable of making decisions about their own future has become paramount. This is especially true when there is a risk of the patient becoming incapable of participating in decision-making, whether the patient is in the early stages of cognitive decline or facing the possibility of complications during surgery which might render them incapable of decision-making.

Older patients may have their right to know their diagnosis subverted by family members who feel that the patient would be unable to handle by knowing the information. On occasion, because of cultural values or for other personal reasons, a patient may not wish to be told a diagnosis. Patients may waive their right to be informed, but this must be an explicit decision between the patient and the physician [7]. Surveys have shown that 90–95% of elderly patients would want to know their diagnosis if they have cancer, which is not different than the percentages for younger patients.

Table 2 Principles of informed consent

Assess the patient's ability to understand the consequences of the decision
If the patient is incapable, identify an appropriate surrogate
Document the goals/values of the patient (or surrogate) expressed as the most important for the decision
Explain how the goals would be affected by the benefits/burdens/risks of the intervention
Document the decision and those present for the discussion

Table 3 Proposed communication skills for discussing evidence with patients

Ability to communicate complex information using nontechnical language
Tailoring the amount and pace of information to the patient's needs and preferences
Drawing diagrams to aid comprehension
Considering the values of the patient while weighing choices
Explanation for the probability and the risk for each option
Facilitative skills to encourage patient involvement
Evaluation of internet information that patients might bring to them
Creating an environment in which patients feel comfortable to ask questions
Giving patients time to take in the information
Declaration of equipoise when present
Checking patient understanding
Negotiation

Informed Consent

Every adult patient who has decisional capacity has the right to accept or decline any treatment that is offered. Informing the patient of the benefits, side effects, and alternatives of even common and simple therapies (such as medications) is the first step toward the patient's consent as represented by their compliance with that therapy [8]. The process of informed consent when obtaining consent for invasive procedures is much more complex, but the same principles hold true (Table 2). The patient must understand the benefits of the procedure and the possible risks and burdens associated with it. The patient should also be informed of the benefits, risks, and burdens of all alternative therapies, including doing nothing. The quality of this discussion is as important as the content [9] (Table 3) [10]. Long lists of unlikely complications may not serve a useful purpose [11]. The discussion should be based on patients' values, fears, and goals and should inform them about the risks that either are common or, although rare, devastating. Documentation of the discussion should reflect the entire discussion, including the basis on which patients agreed or declined intervention and their ability to make the decision.

What information individual patients will want to know about their condition and possible treatments may differ with age. The 5-year prognosis may no longer be of as much significance as the quality of life to be had with different treatment options. The trade-offs between the burden of an intervention and its benefits will shift with different patient priorities [12]. An older person, or their surrogate, may wish to forego a diagnostic workup if they have already decided that they would not act on that information even if it was positive for disease. For example, a 90-year-old patient with multiple other medical conditions may decide to forego a biopsy of a lung lesion, having decided that she would not agree to surgery, radiation, or chemotherapy.

Many interventions other than those traditionally referred to as invasive are now requiring formal informed consent. The use of physical and chemical restraints in psychiatric and long-term care settings requires documentation of acceptance either by the patient or a surrogate. Appropriately informing patients of the meaning (i.e., positive and negative predictive value) of screening tests has been a recent focus, especially for cancer screening, in view of the patients' prognosis and preferences.

The corollary to a patient's right to informed consent is their right to decline treatment. In the 1991 case, *Cruzan v. the State of Missouri* the US Supreme Court ruled that patients have a right to refuse interventions and expanded this to include the right to refuse treatment for future care [13]. Chief Justice William H. Rehnquist wrote that a competent patient has a "constitutionally protected liberty interest in refusing unwanted treatment." The ethical conflict that the practitioners find themselves in is between the autonomous right of the patient to choose and practitioner's wish to do what they see as beneficent or nonmaleficent. This conflict often causes discomfort in the clinical setting. For example, a patient may choose to decline the repair of an abdominal aortic aneurysm despite what the physician knows is a very high risk of rupture and death.

The patient may decline a treatment before the intervention has been initiated or after it has been instituted. There is no legal or ethical distinction made between discontinuing and not initiating the same intervention [14], although frequently there is a stronger emotional component to the former. For example, if a patient has end-stage kidney disease and opts to forego dialysis, he or she will die from uremia. If patients who have been on dialysis for a period of time decide to stop dialysis, they too will die from their kidney disease.

Two areas often present a particular difficulty in the clinical setting: the discontinuation of ventilatory support and the discontinuing or non-initiation of artificial food or hydration. The discontinuation of ventilatory support parallels that of dialysis. The intervention has been instituted to maintain the patient through artificial means because of the failure of a vital organ to function. The patient will die from the effects of the underlying disease and resultant organ failure [15]. The conflicts cited in the case of discontinuation of ventilatory support are threefold: (1) that it is an active act (an act of commission) versus a passive act (act of omission) causing the demise of the patient; (2) that the proximity of the action to the death of the patient causes discomfort for the person stopping the ventilator; and (3) that the physician may not have a comfort level with palliation of the symptoms that may occur when ventilatory support is discontinued.

Much has been made of the arguments of "passive" versus "active" acts. Neither the legal nor the ethical literature supports it as a valid distinction [1], but it can make a major difference in the physician's level of comfort. Although the proximity of an action to the patient's death is uncomfortable for the physician, the need to discontinue invasive treatments for a patient who does not desire them is the more compelling duty. Being familiar with a routine of dignity and comfort care at the time of withdrawal of ventilatory support is crucial.

Discontinuing or foregoing artificial food or hydration in a dying patient also may cause discomfort on the part of physicians or patients' families, but not necessarily to the patients themselves [16]. Neither nutrition nor fluid support is necessary for comfort care, and there is evidence that fluids near the end of life cause discomfort by increasing secretions and suppressing the patient's endogenous endorphin responses. The duty to withhold artificial food and hydration if it is the patient's wish has been upheld in both state and federal courts and was confirmed in the *Cruzan* case. See the section below on "Decisions Near the End of Life" for more discussion of this topic.

Assessment of Decisional Capacity

Decisional capacity refers to the patients' ability to understand the consequences of the decision they are making, to make that decision, and to communicate the reasons for the decision. Understanding the consequences of the decision includes both the ability to understand the relevant information and to appreciate the situation and the impact of the decision [17, 18] (Table 4). Decisional capacity is decision specific, i.e., there are different standards of decisional ability needed to make different types of decisions (e.g., medical or financial) as well as different levels of complexity involved in the decision (e.g., simple procedure versus a complex procedure).

The ability to understand may be impaired because of temporary conditions such as delirium, transient coma, intoxication, or depression; or it may be permanently impaired by cognitive damage or psychiatric illness. Whatever the cause of the impairment, the key to the determination of capacity is the patient's ability to comprehend the advantages and disadvantages of treatment options and to make a decision. Whether we believe that the patient's decision is rational is not a determinant of capacity. Our society allows people to make what most would label as "irrational" decisions but, as part of our respect for autonomy, we cannot force what we would see as the right decision on others [19]. For example, we cannot prohibit alcoholics from drinking, even when it has been shown to impair their health or shorten their longevity. Patients' religious or ethnic beliefs may conflict strongly with our own beliefs, but they have the right to refuse any

Table 4 Legally relevant criteria for decision-making capacity and approaches to assessment of the patient

Criterion	Patient's task	Physician's assessment approach	Questions for clinical assessment[a]	Comments
Communicate a choice	Clearly indicate preferred treatment option	Ask patient to indicate a treatment choice	Have you decided whether to follow your doctor's (or my) recommendation for treatment? Can you tell me what that decision is? (If no decision) What is making it hard for you to decide?	Frequent reversals of choice because of psychiatric or neurologic conditions may indicate lack of capacity
Understand the relevant information	Grasp the fundamental meaning of information communicated by physician	Encourage patient to paraphrase disclosed information regarding medical condition and treatment	Please tell me in your own words what your doctor (or I) told you about: The problem with your health now The recommended treatment The possible benefits and risks (or discomforts) of the treatment Any alternative treatments and their risks and benefits The risks and benefits of no treatment	Information to be understood includes nature of patient's condition, nature and purpose of proposed treatment, possible benefits and risks of that treatment, and alternative approaches (including no treatment) and their benefits and risks

(continued)

Table 4 (continued)

Criterion	Patient's task	Physician's assessment approach	Questions for clinical assessment[a]	Comments
Appreciate the situation and its consequences	Acknowledge medical condition and likely consequences of treatment options	Ask patient to describe the views of medical condition, proposed treatment, and likely outcomes	What do you believe is wrong with your health now? Do you believe that you need some kind of treatment? What is the treatment likely to do for you? What makes you believe it will have that effect? What do you believe will happen if you are not treated? Why do you think your doctor has (or I have) recommended this treatment?	Courts have recognized that patients who do not acknowledge their illnesses (often referred to as "lack of insight") cannot make valid decisions about treatment Delusions or pathologic levels of distortion or denial are the most
Reason about treatment options	Engage in a rational process of manipulating the relevant information	Ask patient to compare treatment options and consequences and to offer reasons for selection of option	How did you decide to accept or reject the recommended treatment? What makes (chosen option) better than (alternative option)?	This criterion focuses on the process by which a decision is reached, not the outcome of the patient's choice, since patients have the right to make "unreasonable" choices

Source: Appelbaum [18]
[a]Patients' responses to these questions need not be verbal

treatment option they believe is in conflict with their beliefs.

On the other hand, understanding the patient's goals and preferences, their priorities as they age, is of fundamental importance to helping the physician to be comfortable and understand the decisions a patient may make as well as giving them the appropriate options from which to choose. Respect for each individual's unique point of view, needs, and desires is fundamental not just for respecting their autonomy, but for truly doing no harm with and maximizing the benefit of interventions.

Every physician obtaining informed consent should be able to do a basic assessment of decisional capacity. The physician should be able to diagnose delirium and, if needed, assess basic cognitive function. Tools focused on parietal lobe function, as do many of the commonly used cognitive mental status tests, are relatively poor predictors of the ability to make decisions, per se, but instruments that have a larger emphasis on frontal lobe or executive function, such as the clock drawing and other executive function examinations, may be more useful. What is most important is the physician's thoughtful discussion with the patient and the real-time assessment of the patients' understanding of the consequences of the decision they are making. Since the standard for decisional capacity is situation specific, it is important that one is able to assess their ability to understand the level of information needed for the decision at hand.

There are many other decisions that a patient may need to make other than informed consent where their capacity will need to be assessed and differing standards met. For example, a very high standard for decisional capacity must be met for a patient to agree to participate in a research study [20, 21], whereas a very low standard is applied to their ability to make a last will and testament. Of particular concern to the clinician is deciding whether patients retain the ability to decide on care options and whether they can return home

Table 5 Levels of decisional capacity

Medical decisions
Ability to understand relevant information
Ability to understand the consequences of the decision
Ability to communicate a decision
Research subject
Ability to understand the probability of a lack of benefit
Appreciation of risks and the uncertainty of the risks
Appreciate their right to withdraw from the study
Decisions of self-care
Ability to care for oneself *or*
Ability to accept the needed help to keep oneself safe
Finances
Ability to manage bill payment
Ability to appropriately calculate and monitor funds
Last will and testament
Ability to remember estate plans
Ability to express logic behind choices

Table 6 Hierarchy of decision-making

Patient's current wishes
If the patient has decisional capacity, this ALWAYS takes precedence
Substituted judgment
Done by the surrogate decision maker only when the patient is not fully capable of making the decision
Based on the patient's prior values and wishes
Advance directive is used as a guide
Patient input is used when possible even if the patient is not fully capable of making the decision
Beneficence
Done by the surrogate decision maker when the patient lacks decisional capacity and evidence does not exist for substituted judgment
Weighing of benefits and burdens as based on the patient's present indications of pleasures and burdens
Input from caregivers is very important

Source: Modified from [24]

or need a more intense environment in order to remain safe [22, 23] (Table 5) [24].

If the physician is unsure of a patient's capacity, a psychiatric consultation may be requested if the question arises from a psychiatric illness; or a neuropsychologist or geriatrician may be consulted about cognitive or functional problems. The patient's decisional capacity at the time of any decision, whether they decide to accept treatment or to decline treatment, should be recorded in the medical record.

Competence is a term that has legal implications beyond what a physician judges on examination. Physicians should avoid using this term unless a court has ruled on the patient's competence. The court recognizes two major categories of competence; competence for financial decisions and competence to make decisions of person. Only if the court has ruled the individual to be incompetent *of person* should the individual be assumed to lack decisional capacity for medical decisions.

Decision-Making for Incapacitated Patients (Table 6)

If a patient is found to lack the capacity to make an informed decision, a surrogate decision maker must be identified. The principle of autonomy guides us to seek a surrogate who is the person most capable of representing the patient's wishes. If the patient has completed an Advance Directive that names a proxy decision maker, this is the person to whom questions should be deferred if the patient has lost decisional capacity. This designee may be variously referred to as the Durable Power of Attorney for Health Affairs or the Health Care Proxy, Surrogate, or Agent. It needs to be emphasized that this person can only make decisions for the patient if the patient no longer has decisional capacity. A patient may also choose a person in a less formal manner, and documentation of such a choice should help to guide the decision. A person who holds Power of Attorney for Finances does not, simply by having this limited power of attorney, have the ability to make other decisions for the person.

If the patient's choice of surrogate is not known, usually the next-of-kin is utilized. The hierarchy of authority is spouse, adult children, parents, siblings, nieces, or nephews. Adult friends may sometimes be able to act as surrogate if the relationship with the patient is such that they can act on his or her behalf. If it is thought that the person identified by this procedure cannot, in fact, act as an appropriate surrogate, if there is conflict about identifying a decision maker, if there is a lack of consensus among individuals, or if there is no one to take on this role, the court may need to decide who will act for the patient. In emergent situations, where the decision-making process is unclear, physicians should apply the "best interest rule" and proceed with any interventions necessary to save the patient's life or preserve function until the situation is clarified. Each institution may have different procedures for obtaining such permission to act, such as an agreement to act by the Chief of Staff. If there is time, emergency conservatorship from a court can be sought. As the situation and the patient's wishes become clear, and an intervention that had been started as an emergency procedure is found to be against the patient's wishes, then the intervention must be discontinued.

The task of making the decision for the incapacitated patient should honor the patient's autonomy by maximizing the individual's continued influence on the ultimate decision. If a patient gave explicit directives that apply to the situation at hand at a time when he or she was capable of decision-making, they must be followed. For example, if a patient with a terminal illness requests that no further interventions be done, including artificial food and hydration, a family member cannot reverse this directive once the patient is in a coma.

If patients have not been explicit about their wishes, the surrogate decision maker and the physician are then obliged to apply substituted judgment. This term is defined as "the application of the patient's preferences and values . . . trying to choose as the patient would have wanted" [25]. In studies comparing hypothetical decisions made by would-be surrogates and patients with decisional capacity, there is a 66% correlation. Previous discussions between the patient and the surrogate help to make these decisions much more representative of the patient's wishes [26]. Helping a family to understand that their obligation is to do what their relative would have wanted often relieves them of some of the burden of decision-making and helps clarify their thinking. Living Wills may be useful in this context. Living Wills may be formal documents executed by a lawyer, but they may also be readily available forms completed by the patient with or without assistance or simply a written statement or narrative. If patients are still capable of making decisions, all treatments must still be discussed with them even if they have a Living Will.

The Living Will is a "what if" statement – a hypothetical situation. The patient is saying, "*If* one of these conditions occurs to me (e.g., permanent coma), *then* do not attempt resuscitation." It does not necessarily mean that the patient does not desire this intervention in their present state of health. For example, a patient who is fully capable of making decisions has a Living Will that states that he or she would decline resuscitation if in a vegetative state. If this patient was to have a cardiac arrest in their present state, resuscitation should be attempted. If after the resuscitation the patient is found to be vegetative, the Living Will would take effect and no further resuscitation attempts should be made were the patient to arrest again.

Frequently, the exact circumstances outlined in a Living Will are not met, but it can still give a good indication of the patient's preferences and values, which then can be applied to the current situation [27]. Living Wills cannot cover all circumstances that may arise, and most patients wish to have a proxy decision maker to interpret their intent. State laws vary as to whether the Living Will or the proxy decision maker takes precedence when there is a conflict with the decisions. Encouraging the family to remember other health care decisions or comments the patient made when other family members were ill is also helpful in trying to define what someone "would have said."

If there is no information that helps the surrogate decision maker to reconstruct what the patient would have said, the guiding principle becomes that of beneficence, defined as weighing the benefits, risks, and burdens of an intervention in the context of the individual. With beneficence, although a patient may no longer be fully capable of making a decision, their voice can still be an important one. Their stated preferences and fears can be used to guide the decision about relative benefits and burdens [28]. This can be true for even markedly demented patients.

For example, the relative burden of an intervention in two patients, equally cognitively impaired, can be quite different. One patient may not become agitated when an intravenous line is started, and intravenous treatment would not be a great burden. Another patient may fight such an intervention, repeatedly pulling out the intravenous catheter and needing restraints. Although the second patient is not making an informed decision to forego intravenous therapy, the relative burden of the intervention is greater in this patient and therefore the relative benefit would need to be greater than other less noxious alternatives for the burden/benefit ratio to be the same.

There can, at times, be conflicting interests in adhering to this hierarchy as circumstances change and the patient's condition alters what is a burden and what is a benefit. Surrogate decision-making often uses a combination of substituted judgment and beneficence to arrive at a treatment decision [29]. What is most important is that these discussions occur as they can have major impact both on patients' quality of life and on the bereavement adjustment of the relatives [30].

As previously stated, decisional capacity is decision specific and capacity is often not black or white. Utilizing an Assent/Consent modal is commonly being accepted. This allows for different levels of patient involvement in the decision-making process. If the patient seems to be capable of making the decision but, due to memory problems or waxing and waning mental status, there is some question as to their ability to retain information, the family may be asked for their "assent," i.e., they agree that it is what the patient wants. If the patient cannot make the decision, the family may give the formal consent but the patient may need to "assent" in order to carry out the procedure. For example, a family may consent to chemotherapy but the patient must be willing to cooperate. The consent/assent modal balances the prior statements of the patient (future-looking autonomy) with beneficence for the person they are at this moment in time [31].

DNR Orders in the Operating Room

A patient's previously stated wish to forego intubation or attempts to resuscitate may be suspended at the time a patient undergoes surgery. Elective intubation in order to perform surgery or a cardiac arrest that occurs under general anesthesia where an immediate response is possible and where the cause may be readily reversible is different from a cardiopulmonary arrest under other circumstances. It may therefore be perfectly compatible with a patient's goals to have these procedures done in the operating room but not want them initiated in other circumstances. Indeed, intubation may be necessary if a procedure which the person does desire is to occur.

If a decision is made to reverse a do-not-resuscitate or do-not-intubate order during surgery, there must be a clear understanding prior to surgery of how postoperative events should be handled in case the patient is not then capable of making decisions. How long should an intubation continue if the patient is not quickly able to be extubated? If the patient does arrest and is resuscitated but has lost decisional capacity, what other treatment modalities would be an unwanted burden? Discussions with the patient, surgeon, anesthesiologist, and primary care physician can help safeguard against confusing and distressful situations [32].

Confidentiality

The Health Insurance Portability and Accountability Act (HIPAA) of 1996 has greatly enhanced the confidentiality of written records and communications [33]. It has also impacted verbal communication, but not to the same extent.

Sharing information with patients' relatives or friends is appropriate in only two circumstances: when patients have specifically stated that the physician may discuss their condition with the individual or when the patient has lost decisional capacity and a surrogate decision must be made. It is advisable to ask patients well in advance who they wish to have informed and how much they wish to have told.

The sharing of information among colleagues should be done in private and with respect for the patient's right to confidentiality. Casual conversations in public places, rounds in the hallways, and discussions in lobbies or waiting rooms with multiple families present can be a breach of a patient's right to privacy. Our sensitivity to this issue must be heightened, and the policing of each other should become everyone's responsibility.

Sharing medical information among health care providers without the patient's explicit authorization, if the clinical circumstances so require, is permitted. The use of clinical material for teaching purposes can be done only with sufficient safeguards to anonymity so the individuals involved are not identifiable. Other information can be released only with the patient's or surrogate's authorization unless it is required by law, as in the case of public health reporting of communicable and sexually transmitted diseases.

Limits to Autonomy and Choice (Futility)

The previous sections have dealt heavily with the respect for and safeguards of the patient's right to exercise autonomy. There are circumstances where this autonomy is tempered by other forces. Autonomy may be limited if the patient is a danger to others, a danger to self, or for the good of society. Laws may govern what procedures or interventions may be available to an individual. For instance, physician-assisted suicide is explicitly illegal in most states in the USA.

Although the US Supreme Court has affirmed an individual's right to refuse treatment, there is no corollary right to demand treatment [34]. In addition to the healthcare professionals' responsibility to understand the patient's goals of treatment and respect patient's own assessment of their quality of life, they also have the responsibility of knowing if an intervention is futile and not offering such treatments to the patient.

There are two perspectives on the definition of futility; referred to as quantitative and qualitative. An intervention is said to be quantitatively futile if it cannot achieve its physiologic objective. Because it is difficult to know what level of evidence is needed for what cut-off to call something physiologically futile, this concept has limited utility. A therapy is said to be qualitatively futile if it is unlikely to help patients achieve their primary goal even if it has a physiologic effect [35, 36]. An example is the foregoing of antibiotic therapy in a patient who is in the terminal phase of an illness. Although the antibiotics might have the physiologic effect of treating the infection, it would have no effect on comfort and a negative effect if it prolongs the patient's suffering. This concept, of futility in the light of the treatment goals, is paramount to the appropriate treatment of the geriatric patient.

If a procedure is judged futile, the physician does not have to offer the intervention to the patient or the surrogate. The very act of offering conveys the sense that there must be some benefit, some chance of success. Why else would it be offered? Therapies the patient and family might expect to have performed but that have become futile, such as an attempt to resuscitate a patient when circumstances clearly demonstrate that it would be futile, should be discussed in the context of their futility. For example, the patient or family should be told that where the patient's heart to stop, attempts to restart it would be futile and therefore would not be initiated. Simply ignoring the subject may engender mistrust, as most individuals are aware of the spectrum of treatments available. One in 20 patients who die in the ICU do not have a surrogate decision maker. The majority of the time physicians decide to cease life-sustaining interventions on the basis of their futility [37].

Defining a therapy as futile is simple under some circumstances and more difficult under others. The decision that someone is "not a surgical candidate" is frequently made when the relative risks and benefits clearly demonstrate that the treatment is not indicated. The decision to stop a therapy may also be made on the grounds of professional judgment. For example, if a tumor is not responding to chemotherapy, it can be unilaterally stopped by the clinician. The difficulty lies more in defining which therapies near the end of life still hold enough of an advantage for the patient that they should be offered.

Prognostication

In order for patients to be able to set goals, they need to be able to understand their prognosis and how interventions may or may not change that prognosis. Unfortunately, we are not very accurate in being able to prognosticate. Being able to predict short-term mortality in the acute care and intensive care unit setting has been explored through the SUPPORT Study [38] and through the use of the APACHE III instrument [39]. These instruments use a combination of diagnosis, cause of illness, and a scale for physiologic parameters to predict mortality risk, but the ability to apply them clinically remains a challenge [40]. The patients' physical and cognitive function prior to their hospitalization is the strongest predictors of outcome after an intervention [41].

Such legislative acts as the Medicare Hospice Benefits, and the Oregon Death with Dignity Act define the terminal phases of disease as the last 6 months of life. Our ability to accurately prognosticate this length of time is relatively poor, with only one-third of predictions being within 50% confidence intervals (i.e., if prognosis is 3 months, "accurate" would be from 1.5 to 6 months). Most physician prognoses are too optimistic [42].

Individuals in their eighth and ninth decades may define their goals similarly to patients with terminal diagnoses. Quality of life and relief from the burdens of illness and interventions may be more important than longevity per se. On the other hand, it should not be assumed that this is true for all individuals of advanced age. Although some elderly patients may look forward to more years of life, they may not wish to do so under any or all circumstances. In surveys of patients with and without terminal illnesses about why they might be motivated to avail themselves of physician-assisted suicide, fear of disability and dependence are the two most common motivators for wishing to end one's life. Predicting the risk or progression of disability is even more difficult than predicting death [43].

Decisions Near the End of Life

As has been emphasized in previous sections of this chapter, goal-oriented care is of the utmost importance to all geriatric care, but it is the sine quo non of end of life care. When a patient has a terminal illness or is faced with chronic, disabling, and progressive disease, decision-making must become very goal-focused. We have already discussed foregoing and discontinuing interventions when they no longer meet the goals of care. Treatment of suffering, physical, mental emotional or spiritual may lead to actions where the physician is seen as hastening death, either inadvertently or deliberately.

The potential for hastening the death of a patient is highest where there is a narrow therapeutic window between the dose of medication needed to control a symptom and the dose that could cause suppression of respiratory drive. The underlying ethical principle of "double effect" rests on the physician's intention and an acknowledgement that treatment may have two effects: one on symptoms and one on longevity. This is an acceptable risk to take if the physician and patient or surrogate have agreed that comfort is more important than longevity and the medication or treatment is given with the *intention* of relieving symptoms.

At some point in the patient's clinical course, interventions that we normally think of as prolonging life may have shifted to prolonging death. An example of this may be antibiotics for pneumonia. The symptoms of pneumonia can be treated (e.g., with scopolamine to control secretions and morphine for dyspnea) without treating the underlying pathophysiology of the pneumonia. Since every patient will, eventually, die of something, there comes a time when it makes sense to allow the clinical course to determine the mode of death. Aggressively treating the symptoms is often preferable to a prolonged dying process with the occurrence of increasingly hard-to-control symptoms.

Physician-assisted suicide and euthanasia (physician-assisted death) are instances when a therapy is prescribed, provided, or administered with the *intention* of ending that patient's life. The acceptability of such actions from both a moral and a practical point of view is under wide debate within the profession and in society in general. Those who argue for the practice of physician-assisted death point out that there are some symptoms that cannot be alleviated short of death (e.g., the discomfort and indignity of destructive head and neck cancer), and individuals should have the right to determine the time and mode of their death. Arguments against physicians assisting in suicide point out that the medical profession's obligation is to "care and to cure" and not to end life [44]. The four principles of autonomy, non-maleficence, beneficence, and justice are active parts of this debate. Some argue that out of respect for autonomy, individuals should be allowed to determine the time and mode of their death, especially if it is within the last 6 months of their "natural" lives. Others argue that if there is unbearable suffering that cannot be relieved by other means, then the principle of beneficence tells us that they should be allowed to end their lives. Many feel that physicians prescribing or acting with the intent of ending a patient's life would be professionally wrong because it would mean intentionally doing harm to the patient (non-maleficence). Finally, many fear that the practice will be a "slippery slope" leading to the premature death of certain segments of society such as the elderly and the disabled. As of now, physician-assisted dying is legal in two states in the USA (Oregon and Washington) and many countries in Europe. Although the debate remains open, the fear of abuse has not proven to be a reality in any locale where it is legal, where it has remained a small minority of patients (less than 5% of deaths) who decide to actively end their lives.

Conclusion

As an individual ages and the accumulation of both life experience and illness burden increase, decisions need to be made on the basis of the individual's goals and preferences. Patients need to be informed of their situation, their prognosis and their options as best we can define them. They have a right to decide their course of action within choices that are not futile and they have a right to influence decisions made for them if they have become incapacitated. Weighing autonomy and beneficence is often hard for the patient who has lost the ability to make decisions. Finding appropriate surrogate decision makers and helping them to understand their role is paramount to this process.

Abstract

The practice of surgery involving older patients is extensively regulated in the United States in a variety of ways. Besides direct government command and control ("Thou shalt" and "Thou shalt not") regulation and indirect regulation through Medicare and Medicaid reimbursement rules, a number of private entities contribute to the oversight of surgery practice through their standard-setting and disciplinary activities. A further source of regulation is the American judicial system, under which the courts may be used by individual patients who bring private civil malpractice lawsuits to seek financial compensation from particular surgeons and other health care professionals and institutions for harms that the defendants have wrongfully caused. Particularly egregious behavior, such as patient abuse, may even subject a health care professional to the possibility of criminal law prosecution. This chapter examines three specific areas of legal regulation affecting the practice of surgery for older patients. These foci are medical malpractice litigation, informed decision-making requirements and exceptions, and confidentiality protections. Additionally, general risk management considerations for the surgeon treating geriatric patients are outlined.

Introduction

The practice of surgery involving older patients is extensively regulated in the United States in a variety of ways. (Although this chapter focuses exclusively on surgical practice within the United States, many of the legal considerations discussed here apply to other countries as well) [1]. Under the US federal system, governmental regulation of surgery practice occurs for the most part at the state level, mainly through the activities of state medical boards that enforce the licensure and disciplinary provisions of their respective state Medical Practice Acts. The states regulate medical practice under their inherent police power, reserved to the states by the 10th Amendment to the US Constitution, to protect and promote the health, safety, welfare, and morals of the general population and also under the states' parens patriae (or parental) authority to protect individuals (including older patients) who are unable to protect themselves from harm.

Besides direct government command and control ("Thou shalt" and "Thou shalt not") regulation and indirect regulation through Medicare and Medicaid reimbursement rules, a number of private entities contribute to the oversight of surgery practice through their standard-setting and disciplinary activities. These private bodies include hospital medical staffs, specialty certification boards, and medical specialty societies.

A further source of regulation is the American judicial system, under which the courts may be used by individual patients who bring private civil malpractice lawsuits to seek financial compensation from particular surgeons and other health care professionals for harms that the defendants have wrongfully caused. Particularly egregious behavior, such as patient abuse, may even subject a health care professional to the possibility of criminal law prosecution.

This chapter examines three specific areas of legal regulation affecting the practice of surgery for older patients. These foci are medical malpractice litigation, informed decision-making requirements, and confidentiality protections. Additionally, general risk management strategies for the surgeon treating geriatric patients are outlined.

Medical Malpractice

In a typical malpractice lawsuit based on the tort theory of negligence, the plaintiff/patient must prove to the fact-finder (usually a jury), by a preponderance of the evidence (more than 50% likelihood), each of four essential elements in order for professional liability to be imposed by the court. The four elements of a prima facie (valid on its face) negligence claim are: (a) a duty owed, (b) breach or violation of that duty (negligence/fault), (c) damage or injury suffered, and (d) both factual and legal (proximate) causation.

Duty/Standard of Care

The surgeon owes a professional duty only to one with whom that surgeon has established a physician/patient relationship within the relevant time frame. Within that relationship, the legally enforceable duty owed is one of "due care" or "reasonable care under the circumstances." In the medical context, a combination of common law (judge-made law) tort doctrine, which is developed incrementally on a case-by-case basis, and applicable state statutes (legislative enactments) traditionally have required the physician to have and use the degree of knowledge and skill that is usually possessed and used by peer physicians in the same or similar circumstances. However, there is a significant current trend in many states to alter the traditional customary, peer-based professional standard of care in favor of imposing more objective, external standards of "reasonableness" against which the professional's behavior is to be evaluated. An objective standard of reasonableness may exceed (i.e., require more knowledge and sophistication than) the prevailing customary practice within the professional community at the time in handling a specific clinical challenge presented by a patient. Thus, it is possible that the state of the art in a particular area of care, required under a reasonableness standard, may not be synonymous with and satisfied by the current customary practice within the practitioner community.

Fact-finders (ordinarily a jury, but sometimes the judge acting in a fact-deciding capacity as well as a decider of legal questions) have the job of determining the applicable standard of care in any particular case. Fact-finders look to a variety of sources for that standard of care. Even in jurisdictions following a reasonableness standard, customary practice prevailing at the time of treatment among a majority or at least a "respectable minority" of the defendant's peers still carries substantial, but not necessarily conclusive, weight. Relevant statutes and regulations, especially those relating to professional licensure and discipline, are also a part of the equation, as are professional codes of ethics. Voluntary (but nonetheless potentially admissible into evidence at trial) standards of care may be created by private accrediting or certifying bodies such as the Joint Commission or the Accreditation Association for Ambulatory Healthcare. Guidelines issued by medical specialty societies (such as guidelines for structured training for surgeons performing robotic surgery created by the Society of American Gastrointestinal and Endoscopic Surgeons [2]) may influence a hospital's internal policies and procedures, which in turn may be introduced into evidence to help prove the standard of care to which physicians and others practicing within that hospital should be held legally accountable. Medical journal literature, textbooks (learned treatises), and informational materials for medical devices and drugs approved for physician use on patients by the Food and Drug Administration and contained in the Physician's Desk Reference (PDR) and pharmaceutical package inserts (PPIs) also may be introduced into evidence for the fact-finder's consideration.

Another source of the standard of care stems from the acknowledgement by leaders in health care delivery and financing that a good deal of routine medical practice has long been predicated more on habit and inertia than on solid empirical evidence establishing clinical efficacy. Out of a concern about both wasteful resource usage and the insufficient quality of patient care, over the past several decades there has been a concerted movement to rationalize medical practice. A central strategy for rationalizing medical practice is to develop, collect, and disseminate to practicing clinicians a variety of evidence-based Clinical Practice Guidelines (CPGs) or parameters to educate practitioners about whether a particular diagnostic or therapeutic intervention actually has been demonstrated to produce desired health benefits for patients. This movement has been led by professional organizations and specialty societies including the American College of Surgeons (ACS) and American Geriatrics Society, governmental agencies led by the federal Agency for Healthcare Research and Quality (AHRQ) and the Patient-Centered Outcomes Research Institute (PCORI) established by the Affordable Care Act, and individual institutions and agencies in the USA and elsewhere.

In a related matter, the American Board of Internal Medicine Foundation and Consumer Reports have partnered in a Choosing Wisely initiative designed to encourage and enable patients and physicians to share in making decisions about medical care that is supported by available medical evidence, not duplicative of other tests or procedures already tried, and necessary for that particular patient. Numerous medical specialty organizations have joined in this initiative, identifying common practices in their respective specialties for which physicians and patients ought to ask questions about the value obtained from routine use.

Unfortunately, the push toward more rational care through CPGs, Choosing Wisely, and other evidence-based best practice initiatives is impeded by physician perceptions of the arbitrariness of the courts in applying legal standards of care. Physicians often are afraid to reduce their ordering of screening tests and treatment interventions for fear of litigation if they act responsibly, but a bad outcome occurs nevertheless. One prominent example of legally induced overtreatment is the case of prostate cancer where, despite the US Preventive Services Task Force recommendation against routine prostate-specific antigen (PSA) screening for asymptomatic individuals, PSA screening has lessened only minimally [3]. This deviation from evidence-based prudence is exacerbated by the many subsequent prostate biopsies and surgeries that follow unnecessary PSA tests revealing conditions that should have been left alone [4].

Physicians' legal anxieties, especially in the geriatrics context, are generally overblown. Older persons have been underrepresented statistically as plaintiffs in medical malpractice lawsuits. Moreover, the legal ramifications of CPGs or practice parameters continue to evolve in a positive direction. There is an increasing tendency for the courts to admit into evidence, on behalf of either side to a malpractice dispute (i.e., for either inculpatory or exculpatory purposes), properly validated, scientifically supported contemporary CPGs on the issue of the standard of care to be applied under any specific set of circumstances. This development already has beneficial consequences, in that anecdotal reports indicate that most plaintiffs' attorneys consider physicians' compliance with, or deviation from, relevant CPGs in making decisions about whether to initiate malpractice litigation at all and how to conduct settlement negotiations for claims that are pursued. Compliance thus creates a kind of functional safe harbor for physicians while, even when the physician has deviated from a pertinent CPG, adequate documentation in the patient's record of the physician's reasons for alternative treatment in light of the particular patient's situation will justify the physician's conduct and preclude the imposition of liability.

Circumstances influencing the applicable duty of care under a reasonableness standard include the patient's age and related needs and capacities. The surgeon must be thoroughly sensitive to and knowledgeable regarding the patient's particular age-based characteristics that may affect diagnostic or therapeutic decision making and action for an older patient. For example, a patient's age is likely to exert an impact on which drugs are prescribed, the risks they may pose to the patient (especially polypharmacy), and the proper dosages and routes of administration. Further, the ability to factor the patient's age into calculating the risks of mortality and morbidity of proposed surgical interventions is part of the physician's duty of due care in advising the patient. Thus, for instance, the ACS as one of its Choosing Wisely recommendations urges physicians and patients to "avoid colorectal cancer screening tests on asymptomatic patients with a life expectancy of less than 10 years and no family or personal history of colorectal neoplasia" [5].

In a medical malpractice trial, each party ordinarily attempts to educate the lay (i.e., not medically trained) fact-finder about its respective version of the applicable standard of care through the testimony of expert witnesses. First, the judge determines as a matter of law whether a particular proffered witness possesses sufficient credentials to be allowed to testify as an expert and present a professional opinion. Usually, this means that expert testimony about the standard of care applicable to the performance of a particular type of surgeon may only be provided by a witness with credentials of the same type as the defendant surgeon. Potential expert witnesses may be drawn by either party from a national pool, since the standard of care is a national rather than a local one. Once a legal decision has been made to allow the jury to hear the expert testimony of a witness on the standard of care to which the defendant should be held accountable, then it is up to the fact-finder to decide how much weight or credibility to attach to the witness' testimony. The testimony of expert witnesses (mainly those testifying for plaintiffs) in medical malpractice trials sometimes is scrutinized for accuracy and honesty [6] by professional organizations and state medical boards.

Breach of Duty

The second necessary element the plaintiff must prove in a negligence-based malpractice lawsuit is a breach or violation of the applicable standard of care, that is, the element of negligence. The physician does not guarantee particular results, let alone perfection. By the same token, however, it is not enough for physicians to simply "do their best" if their conduct does not rise to the applicable level of care, even when the errors or omissions are unintentional. The concept that a defendant may be held legally liable only when shown to be at fault is fundamental to the traditional American tort system. Although there are proposals periodically made by academics and political lobbyists to move the handling of medically caused patient injuries toward some form of no-fault system, fundamental alteration of the existing tort system is unlikely.

Negligence is defined as unintentional, but blameworthy, wrongdoing that may occur in one of three categories. Nonfeasance is fault happening through inaction or omission, i.e., failing to do something that should have been done. Misfeasance consists of performing an act that should have been performed, but doing it in a substandard manner. By contrast, malfeasance is the wrongful performance of an act that should not have been done in the first place.

In the surgical context, this means that the surgeon is legally obligated to properly assess the patient before surgery, both in terms of the need for surgery in light of viable alternatives and in terms of the likely risks for that patient. Misdiagnosis or poor judgment may result in unnecessary surgery or, alternatively, delayed or foregone surgery [7]. Additionally, the surgeon is expected to perform the surgery competently in technical terms. The duty of due care extends to engaging in reasonable preoperative actions to reduce risks, as well as to competent handling of postoperative care involving routine checks for and recognition of somatic problems, infection, pain control, confusion, and other complications [8]. After hospital discharge, the patient is entitled to adequate follow-up care by the surgeon for a reasonable period of time.

Delineating the legally enforceable standard of care may become a particularly difficult matter in the murky area of surgical innovation or newly emerging techniques. At present, how surgical innovation is treated for malpractice litigation purposes depends on the specific case: as a species either of generally accepted and practiced therapeutic care, on the one hand, or of biomedical research involving human subjects (with its own extensive, distinct web of regulations), on the other hand.

A surgeon may be held personally liable for the consequences of his or her own negligent acts or omissions. The surgeon also may be held vicariously liable, under the doctrine of respondeat superior, for negligent conduct engaged in by an employee of the surgeon (such as a nurse or physician's assistant employed to assist in caring for patients in the physician's office) while acting within the scope of the individual's employment. The longstanding "captain of the ship" doctrine in the past was used to hold the surgeon responsible for the negligence of anyone participating in an operation, on the theory that the surgeon as "captain of the ship" ought to be in charge of – and precluded from delegating away responsibility for – everything occurring during the surgery; thus, for example, under this doctrine, liability would be imposed on the surgeon for retained instruments, sponges, and needles forgotten in the patient, even though the nurses (not the surgeons) were the ones who personally erred in counting. Although automatic application of the "captain of the ship" doctrine has been widely discredited today as unrealistic in light of the complexity of the modern operating room, courts will look at the surgeon's right of control over staff members and impose vicarious liability when such a right of control (whether or not control actually is exercised) is present.

Vicarious liability may also come into play when the surgeon is acting as the mentor/supervisor of a person in a medical trainee status, including medical residents, fellows, and students. Because the negligence of the trainee resulting in patient injury may be attributable to the surgeon based on the existence of a trainee/supervisor relationship even if the supervising surgeon was not personally at fault, surgeons in a formal teaching role should take care in assigning specific tasks to trainees, overseeing their trainees' performance in patient care, and evaluating trainees. In addition to vicarious liability exposure in the teaching role, the supervising surgeon may be exposed to possible direct liability for personal negligence in meeting the standard of care expected to be exercised by a reasonable surgeon in supervising a trainee.

Surgery occurs within a hospital or other corporate (either for-profit or not-for-profit) entity such as an ambulatory surgery center (ACS). Many patient injuries (including many of those leading to malpractice litigation) are caused by multifaceted health care delivery system failures, rather than by isolated deficiencies in the knowledge, skills, or character of an individual surgeon or other single members of the health care team. The entity within which the surgery takes place may be sued not just derivatively under a vicarious liability rationale for the acts and omissions of its employees, but also directly under a corporate liability theory for systemic negligence that causes patient injury. Health care institutional providers owe independent duties to their patients, including the duty to properly evaluate and supervise the physicians they employ or to whom they grant clinical admitting and treating privileges.

Institutional protocols should delineate operational procedures of their health care teams and the supervisory responsibilities of individual physicians. When there are multiple consultants for an individual patient, medical staff bylaws must spell out the continuing coordination and monitoring obligations of the identified attending physician; failure to do so unambiguously increases the liability exposure of all involved clinicians and the hospital in the event of a bad clinical outcome. Consultants who are not hospital employees must be credentialed to practice within the hospital according to criteria contained in the medical staff bylaws.

Damage or Injury

For the third requisite element of proof in a malpractice action, the plaintiff must produce sufficient evidence and persuade the fact-finder that some damage or injury has taken place. In the surgery context, virtually all filed claims involve an allegation of physical injury, with severity of injury being the most important single factor influencing the decision to sue. Particularly in claims involving older patients, frequently the patient's death is the injury claimed. Often, claims for emotional injuries, pain, and suffering are raised in conjunction with complaints about physical injuries.

If a meritorious malpractice claim has been established to the fact-finder's satisfaction (i.e., by a preponderance of the evidence), a judgment is entered by the court and the defendant is ordered to pay a specific amount of money damages to the injured plaintiff. Ordinarily, this financial payment is made by the defendant's liability insurance carrier on the defendant's behalf and must be reported to the National Practitioner Data Bank (NPDB), established under the Health Care Quality Improvement Act (HCQIA) of 1986, as an adverse action relating to that physician. Even if a malpractice claim is voluntarily settled by the parties without proceeding to trial and verdict (the most common way that cases get resolved), any payment made by or on behalf of the physician to settle the claim must be reported to the NPDB.

The overwhelming majority of malpractice lawsuits in which liability is found involves the awarding of compensatory damages. These dollars are intended to compensate the victim for his or her injuries, to make the victim "whole" again to the extent that money can accomplish that objective. Pecuniary (also called economic or special) compensatory damages encompass precisely measurable out-of-pocket expenditures or lost opportunity costs, such as extra medical bills, special equipment needs, and foregone wages. By contrast, nonpecuniary (also called noneconomic or general) damages encompass real – but more subjective and difficult to measure – losses, such as pain and suffering.

Punitive or exemplary damages are awarded over and above compensatory amounts. Such damages are rarely awarded in malpractice cases, because they are intended to punish defendants for egregious, malicious wrongs (such as patient abuse) and to set an example to deter others from engaging in similar conduct. Negligence is the theoretical basis for most medical malpractice lawsuits and, by definition, consists of unintentional wrongdoing. Therefore, punitive or exemplary damages would not make much sense in the negligence context. However, sometimes as a strategic maneuver a plaintiff includes a request for punitive damages in the complaint solely to be able to introduce before the jury evidence that otherwise would be inadmissible concerning the robust financial status of the defendant.

Causation

Frequently, the most important element to prove in a malpractice action is that the injury suffered by the patient was caused by the defendant's negligence. This is an especially big hurdle for many older patients to surmount, because often it can be counter argued by the defendant that any adverse results sustained are the product not of physician (or other health care professional) negligence, but rather the natural and probable consequence of the older patient's underlying morbidities.

To satisfy the causation requirement, showing mere possibility is insufficient. First, the patient must establish that the physician's negligence was a "cause in fact" of the injury. Under this requirement, it must be shown that either "but for" (sine qua non) the physician's negligence the injury would not have occurred or, alternatively, the physician's negligence was at least a substantial factor in bringing about the injury.

Moreover, the plaintiff is required to show that the physician's negligence not only was the factual cause of the injury suffered, but also that it was the most direct or proximate cause of the injury sustained. Put differently, there can be no intervening, superceding (i.e., unforeseeable) factors that occur to break the causal link between physician negligence and patient injury, or else the plaintiff's claim fails.

Take, for example, the case of a surgeon who performs an operation improperly. As a result of the surgeon's mistake, it is necessary for the patient to undergo additional surgery the next day. On the way from the patient's hospital room to the operating room, the patient falls out of the wheelchair in which he or she was not securely tied by an orderly, hits the floor, and suffers additional injuries. The surgeon's error the previous day in operating would be the "cause in fact" of the patient's injuries because "but for" the physician's negligence the patient would not have been in the process of being transported to the operating room and the fall and resulting harm would not have happened. However, in this scenario, the physician would not be liable for the additional injuries because the orderly's failure to transport the patient properly was an intervening, superceding (i.e., unforeseeable) event that broke the necessary proximate cause linkage.

Informed Consent

Under the ethical principle of autonomy or self-determination, every adult patient (with no upper age limit) has the right to make personal decisions regarding medical care, including decisions about which diagnostic and treatment interventions to undergo or decline. This ethical principle has been translated into the legal doctrine of informed consent. The substantive parts of the informed consent doctrine have evolved over time in the courts, on a case-by-case basis, as a product of state common law. Moreover, individual states have enacted statutes and promulgated regulations codifying a jurisdiction's specific details regarding informed consent.

It is important to note that although the adult patient has a right to decline a particular suggested diagnostic or therapeutic intervention, there exists no corresponding right for the patient or surrogate to demand medical tests, treatments, or procedures that the physician believes will be nonbeneficial or even harmful to the patient; rather, in such circumstances, the physician has an obligation to refuse to accede to the patient's demand. According to the ACS Statements on Principles [9]: "When patients agree to an operation conditionally or make demands that are unacceptable to the surgeon, the surgeon may elect to withdraw from the case."

Elements

For a patient's choice about any specific medical intervention to be considered a legally valid exercise of informed consent, three distinct but interconnected elements must be present. These elements are voluntariness, knowledge or information, and decisional capacity. Assurance that a patient's choice regarding medical alternatives is legally valid based upon these three elements is an imperative of the fiduciary or trust relationship between physician and patient.

Voluntariness

First, the patient's participation in the decision-making process and the final decision must be voluntary. This means it must take place free of force, fraud, duress, intimidation, or any other form of undue constraint or coercion. One aspect of voluntariness is that the patient is entitled to seek out independent opinions from physicians other than the original surgeon, although responsibility for payment for second and subsequent opinions may vary depending on the third-party payer involved.

Knowledge or Information

Second, the patient's medical choice or choices must be based on adequate knowledge or information. The physician has the responsibility to communicate in understandable, nontechnical terms material information about the patient's medical situation (material information being defined as information that might make a difference in the decision-making calculus of a reasonable patient in similar circumstances). Moreover, the physician additionally must be concerned with the flip-side of giving information to the patient, namely being certain that the patient understands the information conveyed [10]. Physicians should take care to assess whether the information they share is actually comprehended by the patient, since physicians often either overestimate patient comprehension or fail to consider it altogether [11]. A high prevalence of both health illiteracy and functional innumeracy within the general population poses serious obstacles to achieving meaningful patient comprehension [12].

In terms of specific data items that need to be shared with the patient, the ACS takes the position that the informed consent discussion conducted by the surgeon should include:

1. "The nature of the illness and the natural consequences of no treatment.
2. The nature of the proposed operation, including the estimated risks of mortality and morbidity.
3. The more common known complications, which should be described and discussed. The patient should understand the risks as well as the benefits of the proposed operation. The discussion should include a description of what to expect during the hospitalization and post hospital convalescence.
4. Alternative forms of treatment, including non-operative techniques.
5. A discussion of the different types of qualified medical providers who will participate in their operation and their respective roles."

The ACS further warns, "The surgeon should not exaggerate the potential benefits of the proposed operation nor make promises or guarantees" [9]. Managing patient expectations to keep them reasonable is an important part of the communication process from the surgeon's legal risk management perspective [7].

The AHRQ advises the consumer public to ask their physicians the following questions [13, 14]:

1. "What operation are you recommending?
2. Why do I need the operation?
3. Are there alternatives to surgery?
4. What are the benefits of having the operation?
5. What are the risks of having the operation?
6. What will happen if I don't have this operation?
7. Where can I get a second opinion?
8. What has been your experience in doing the operation? How many have you performed?
9. Where will the operation be done?
10. What kind of anesthesia will I need?
11. How long will it take me to recover?
12. How much will the operation cost?"

The ACS offers a similar set of queries for patients to pose before consenting to surgery [15]:

> "What are the indications that have led your doctor to the opinion that an operation is necessary?
>
> What, if any, alternative treatments are available for your condition?
>
> What will be the likely result if you don't have the operation?
>
> What are the basic procedures involved in the operation?
>
> What are the risks?
>
> How is the operation expected to improve your health or quality of life?
>
> Is hospitalization necessary and, if so, how long can you expect to be hospitalized?
>
> What can you expect during your recovery period?
>
> When can you expect to resume normal activities?
>
> Are there likely to be residual effects from the operation?"

The ACS Informed Consent statement for consumers [15] adds, at the conclusion of this list:

> "Of course, your surgeon may volunteer much of this information. However, if you still have questions, don't hesitate to ask. Remember, the operation is being performed on you, and you should seek any information that you need to improve your understanding. Your doctor should be willing to take whatever time is necessary to make sure that you are fully informed. No doctor can, or should, guarantee outcomes, because each operation is different, depending upon the individual condition and response of each patient. Nonetheless, your surgeon will be able to give you a good idea of what to expect."

For the older patient with multiple, serious comorbidities, the need for information about the whole health context is especially important. So, too, is accurate, honest discussion about what surgery can and cannot realistically be expected to accomplish and the possible outcomes of different approaches besides life versus death [16]. A surgeon should be sensitive to the fact that individual patients differ in terms of the amount and type of information they desire and that some older individuals want less information because they tend to defer to the physician's opinion [17]. However, the surgeon's presentation of, or at least offer to present, must be forceful enough to fulfill the surgeon's ultimate responsibility to assure the patient sufficiently understands the material considerations concerning the reasonable medical options presented.

Besides the essential informational items listed above, there are other potential items whose mandatory inclusion in the informed consent disclosure process is still being debated as we continue to figure out the best way to usefully inform and empower patients without overwhelming them with unhelpful data. Additional pieces of information in this evolving category include: complementary and alternative medicine options, which are increasingly popular with older individuals; the particular physician's success rate with the particular intervention being recommended [18]; other physician-specific information, such as a drug or alcohol dependency problem or the physician's age-related deterioration in physical and/or cognitive performance that might act as enhanced risk factors; the physician's financial or personal conflict of interests (e.g., consulting relationships with medical device makers [19]) or other incentives arguably impacting the patient's care [20]; the level of uncertainty in the medical community regarding the particular recommended intervention for someone in this specific patient's situation; and the role, if any, that defensive medicine considerations are playing in the health care professional's treatment proposal.

Further, one set of authors recommends the surgeon inform the patient when the surgeon has scheduled other surgeries to be done concurrently with that patient's surgery. The fact of concurrent surgeries, a detailing of who will do what parts of the patient's surgery, and an explanation of why concurrent surgeries have been scheduled should be shared with the patient as early as possible so the patient can use this consideration in making a decision about whether to have the surgery performed and by whom [21].

Live, in-person interaction directly between patient and physician is the most important modality of preoperative communication. However, this interpersonal interaction is increasingly being supplemented (but should never be supplanted) by the use of written literature and video modalities explaining proposed medical procedures, and such informational supplements have been shown to improve both patient knowledge and satisfaction [22]. The Internet and the easily accessible information it can convey to computer-savvy healthcare consumers and their families also has valuable potential as an effective decision aid for patients, as long as the medical profession helps patients to sort out authoritative, reliable from unreliable material available online [23].

Another increasingly important source of information, and not infrequently misinformation, is direct-to-consumer advertising in the popular media for specific medications, medical devices, and types of surgery. Patients no longer arrive in the surgeon's office as a blank slate in terms of knowledge and presuppositions, so it is incumbent on the surgeon to initially determine what accurate information or erroneous misinformation the patient already has at the outset of the informed consent conversation [24].

Meaningful communication with patients is especially challenging in the case of individuals with diminished proficiency in the physician's language. One study found that impaired language facility was associated with reduced patient comprehension even when written forms and other modes of information were translated for the patient, but the unanticipated result in that study may be explained more by the participants' educational level than their native language [25]. Federal law requires that health care institutions offer to make interpreters available for US patients with diminished proficiency in spoken English, but actual surgeon practice frequently entails deference to the wishes of the patient and family when they decline the presence of an interpreter, as well as differing thresholds before surgeons turn to professional or ad hoc (e.g., family) interpreters or attempt to rely upon themselves for the interpreter role. In terms of compliance with federal law, it is preferable that surgeons follow the hospital's adopted policy regarding the use of interpreters rather than try to handle the issue on a largely subjective, case-by-case basis [26].

Studies of the informed consent process point to substantial opportunity for improvement in the information communication part of that process, which ideally should serve an educational and bonding role. Physicians with all levels of educational background too commonly have a deficient understanding of their legal obligations in this arena and patients often very inadequately understand the information provided to them. There is some evidence that formal training improves surgery residents' ability to discuss treatment options with patients [11].

Among the strategies suggested by one Task Force for promoting shared decision making to achieve more goal-concordant care in seriously ill older patients with surgical emergencies has been a proposal for a structured approach to guide surgeons in communicating with patients [27]. The nine key elements in that proposed structured approach are: formulating prognosis, creating a personal connection, disclosing information regarding the acute problem in the context of the underlying illness, establishing a shared understanding of the patient's condition; allowing silence and dealing with emotion, describing surgical and palliative treatment options, eliciting patient goals and priorities, making a treatment recommendation, and affirming ongoing support for the patient and family.

Another set of authors has proposed a similar structured physician-older patient communication approach consisting of clarifying the patient's prognostic understanding and expectations for recovery, identifying the patient's priorities and goals for treatment, determining health states that the patient would find unacceptable, recommending palliative treatment alongside life-prolonging intervention as best aligned with the individual's personal goals and wishes, and affirming the clinician's commitment to the patient's well-being [28].

Decisional Capacity

Legally valid medical decisions require that there be a capable decision maker. A patient must be cognitively and emotionally able to weigh alternatives rationally; autonomous choices cannot be made by a nonautonomous person. The US legal system begins with a rebuttable presumption that every adult (with no upper age limit) is capable enough to make his or her own medical decisions if provided with sufficient information.

However, for some geriatric patients, this aspect of medical decision making may be factually problematic. It is "estimated that nearly half of U.S. adults near the end of life [are] unable to make decisions for themselves about whether to accept life-prolonging technologies" [29]. In particular, a substantial portion of the geriatric surgical population lacks adequate decisional capacity to make legally valid decisions about undergoing surgery [30].

There are a number of clinical factors that may interfere with an older patient's decisional capacity. There is a significant and increasing incidence of dementia, depression and other affective disorders, delirium, and other mental health problems such as psychoses among older individuals. However, the severity of mental illness, in terms of cognitive and behavioral impairment, and therefore the illness' impact on functional ability, varies for different patients at different times along a continuum. For that reason, there is not an automatic, precise correlation between an older person's clinical diagnosis and a simple, dichotomous determination that the individual definitely does or does not possess sufficient present capacity to personally make important decisions about medical care. Older individuals also are more likely to suffer sensory deprivations (such as hearing or sight deficits) that may interfere with the ability to understand and utilize information necessary for making medical decisions.

In each case, the attending physician needs to assess, either formally or informally, the particular patient's decisional capacity [31]. The literature suggests that physicians today often do an inadequate job of recognizing and properly investigating possible incapacity in patients [32]. One explanation for physicians frequently giving short shrift to the capacity issue is their tendency to avoid questioning the capacity of any patient who agrees with the physician's treatment recommendation, regardless of the patient's actual mental status.

Sometimes collaboration or consultation with a psychologist or psychiatrist in the capacity assessment endeavor can be very helpful. The conduct and documentation of such consultation can be a useful risk management practice for the surgeon, as the legal system affords mental health specialists a great deal (arguably an excessive amount) of deference as assessors of patients' decisional capacity.

A large amount of well-funded psychological and psychiatric research has been undertaken aimed at developing and disseminating new standardized instruments useful for the specific purpose of reliably measuring decision-specific capacity among older individuals. Despite this endeavor and the widespread incorporation of the Mini-Mental State Exam (MMSE) and the Cognitive Performance Test (CPT) into clinical practice for various diagnostic and treatment planning purposes, there exists no single, uniform, scientifically agreed upon standard of legal competence/decisional capacity for making medical decisions. Any capacity evaluation instrument should be relied upon only in conjunction with direct observation of the patient's ability to understand and manipulate information.

Assessment of decisional capacity should focus on function, rather than the patient's diagnosis or categorical label, since illnesses vary in severity and different people with the same clinical diagnosis may function at very different levels. Similarly, capacity assessment should not depend upon whether or not the assessor agrees with the particular choice made by the patient. Questions that should be included in the physician's tacit or explicit functional inquiry about a patient's decisional capacity are:

1. Can the patient make and communicate (in any manner) choices regarding medical interventions?
2. Can the patient articulate any reasons for the choices made (to indicate that some sort of reasoning process is taking place)?
3. Are the stated reasons given to explain the patient's choices rational in the sense that the patient starts with a factually accurate understanding of the medical circumstances and can reason logically from those circumstances to a conclusion?
4. Does the patient understand or appreciate the implications, including the foreseeable personal risks and benefits, of the alternatives presented and choices made?

Several considerations should guide the physician's assessment of a patient's decisional capacity. Most importantly, capacity is a matter of whether the patient has at least a minimally sufficient (not necessarily a perfect) degree of functional ability, regardless of the clinical diagnosis or whether the physician personally agrees or disagrees with the patient's decision. Second, capacity needs to be determined on a decision-specific, not a global or all-or-nothing, basis. A patient may be capable of rationally making certain kinds of decisions but not necessarily others; partial or limited capacity may be possible even when total capacity is not. A decision about undergoing surgery ordinarily involves an array of complex facets concerning significant potential risks, benefits, and alternatives and thus requires a relatively high level of cognitive/intellectual and emotional capacity on the patient's part.

Decisional capacity is variable, rather than static, over time in many older patients. It may wax and wane in particular cases depending on the environmental factors, such as time of day (for instance, the sundowning phenomenon in the elderly), day of the week, physical setting, presence of acute or transient treatable medical problems, other persons involved in supporting or interfering with the patient's decision, or the patient's reactions to medications. Physicians often can affect their patients' capacity, for better or worse, through the way they deliver care (e.g., through the choice and timing of medication administration). Physicians should endeavor to communicate with patients and, when possible, time the decision-making process around a patient's windows of lucidity.

Additionally, the presence of cognitive or emotional impairment, even if substantial, does not necessarily rule out the possibility of some level of involvement in decision making. Many older persons may be capable of engaging in shared or assisted consent with extra time and effort on the physician's part when the person has a supportive network of family and friends available. For instance, an older patient who cannot process information as swiftly or easily as a younger person still may be able to sufficiently understand the complexities of a proposed treatment plan and share in the decision making if afforded enough emotional support [31].

After surgery has taken place, there likely will be a series of postoperative treatment decisions that need to be made. The patient's decisional capacity may be an even larger issue at the postoperative stage. It has been reported that postoperative cognitive dysfunction (POCD), representing "a decline in a variety of neuropsychological domains including memory, executive functioning, and speed of processing," is a common clinical condition following major surgery in older patients, particularly in cardiac, vascular, urologic, and orthopedic surgery [33].

Exceptions to the Consent Requirement

The law recognizes certain exceptions to the usual informed consent requirement. The most relevant exception for surgeons concerns emergency situations. In the case of life-threatening emergencies, the law excuses noncompliance with the otherwise-applicable informed consent requirement on the rationale that we generally presume that a patient confronted with such an emergency would consent – if presently able to do so – to medical interventions necessary to preserve the person's life. Reliance on the emergency exception to dispense with obtaining the voluntary, informed, and capable consent of the patient prior to initiating an intrusive and risky medical intervention such as surgery should be strictly limited to situations containing all of the following characteristics: a true life-threatening emergency; time is of the essence and delay will greatly diminish the likelihood of success; the patient is unable at the time to make an autonomous decision about medical care; there is not enough time to identify, locate, and consult with a legally authorized surrogate decision maker; there is insufficient time to apply for a court order; and surgery is the least intrusive and risky alternative for accomplishing the goal of preserving the patient's life.

A more controversial exception to compliance with informed consent requirements is the doctrine of therapeutic exception or therapeutic privilege. The defense of therapeutic privilege to a claim of nondisclosure of material information about a patient's diagnosis, prognosis, or treatment is applicable when, in the physician's good faith professional judgment, disclosure would be likely to complicate or hinder necessary treatment, cause severe psychological harm, and be so upsetting as to render a rational decision by the patient impossible. The physician's desire to maintain a decent level of hope in a seriously ill older patient is understandable [34], but the courts have recognized the therapeutic privilege defense only very rarely and in extreme circumstances, lest this defense too readily become the exception that totally swallows the general rule.

Documentation of Consent

Although implied consent (implied by the patient's nonobjecting, seemingly acquiescing conduct) is sufficient for medical interventions that are not very intrusive or risky, surgery ought to be done only when the patient (or the patient's authorized surrogate) has indicated consent for the intervention expressly, and more specifically in writing. A signed, separate consent form does not by itself constitute compliance with legal requirements; the doctrine of informed consent ideally refers to a dynamic, authentic, shared decision-making process revolving around information provision and interactive communication between the physician and patient (or surrogate) [35]. A signed consent form does not by itself take the place of the requisite process of communication, but it does facilitate proving that the process took place, in the event that the sufficiency of informed consent is challenged after the fact. In addition, voluntary accreditation standards with which the physician's affiliated institution complies, such as those of the Joint Commission, may require the use of separate written consent forms for particular categories of medical interventions, certainly including surgery.

Research reveals that surgeon/patient conversations often deviate from the information on written consent forms the patient is asked to sign, with the conversations sometimes omitting information found on the forms and sometimes including information not found on the forms [36]. The information the patient receives should be consistent and coherent; hence, there is significant room for improvement both in the content of surgeon/patient discussions and in the drafting of consent forms.

Advance Medical Planning

Timely preoperative surgeon/patient conversations about the patient's goals for medical care are essential [37]. "The most important aspect of providing good end-of-life care to geriatric patients is having a discussion about the goals of care. Ideally, this conversation should include patients when they are at their normal functional status, as this allows them to express their desires as well as establish which family members they wish to be involved in the dialogue" [38]. These conversations happen [39], but not often enough [40]. Nonetheless, in anticipation of future circumstances in which decisions about surgery might need to be made but the patient would lack sufficient decisional capacity to give or withhold informed consent, there are several legal mechanisms available to maximize the patient's prospective medical autonomy. Best Practice Guidelines issued by the American College of Surgeons' National Surgical Quality Improvement Project and the American Geriatrics Society for "Preoperative Assessment of the Geriatric Surgical Patient" recommend that clinicians "determine the patient's treatment outcomes" and place advance directives in the patient's medical record [41].

Any adult may, while still capable, execute certain legal instruments that voluntarily delegate or direct the exercise of future medical decision-making power. While oral advance medical directives, theoretically, are completely legally valid, patients should be encouraged to execute written versions to maximize the likelihood that the directive ultimately will be respected by family members and health care professionals. Organizational providers are required by the federal Patient Self-Determination Act to initiate discussions with capable patients about the availability of advance medical directives opportunities.

The durable power of attorney (DPOA) consists of a written document in which an individual (the principal) appoints an agent, or attorney-in-fact, to make various kinds of decisions for the principal. Each state has enacted one or more statutes that explicitly authorize the use of a DPOA for health care to empower an agent (including a nonfamily member) to make medical choices on a patient's behalf, should the patient later lose decision-making capacity. A DPOA may be immediate in nature, meaning that it comes into effect as soon as the agent is named. In a springing DPOA, on the other hand, the legal authority transfers (springs) from the patient to the agent only upon the occurrence of some specified future event, like a declaration of the principal's incapacity by a designated number of examining physicians. The patient should be notified by attending health care professionals when they have decided to act as though decision-making authority has sprung to the designated agent, so the patient can utter a protest, if desired, to the agent's exercise of power.

The DPOA is a proxy directive, and thus distinguishable from a living will, which is an instruction-type directive. In an instruction directive, a presently capable patient documents his or her wishes regarding future medical treatment (e.g., "no extraordinary measures" or "keep me alive forever no matter what pain or expense") rather than naming an agent to make future treatment decisions in the case of eventual incapacity. The two kinds of legal devices are not mutually exclusive; indeed, patients may be encouraged to execute them in tandem because the living will can help an agent named under a DPOA to exercise the patient's autonomy rights more accurately.

The latest innovation in advance health care planning is the Physician Orders for Life-Sustaining Treatment (POLST) Paradigm. (The precise title for this concept may vary among different jurisdictions.) A POLST is a mechanism that converts a patient's treatment wishes into the tangible form of a physician's order. Because physicians and other health care professionals (including emergency responders) are accustomed to carrying out medical orders, there is evidence that when treatment instructions are expressed in the form of a POLST they are substantially more likely to be honored and implemented in practice than are wishes expressed only in the form of a patient's prior expression or a surrogate's current representation of the patient's inferred preferences. Unlike an advance directive that is advisable for any adult, a POLST is appropriate only for a patient who is so seriously ill that a physician exercising sound judgment would not be surprised if that patient died within the next year. Individual states are at different points concerning the degree of POLST penetration in medical practice. Some states have enacted statutes and/or regulations specifically authorizing POLST, while other states are in earlier stages of legal recognition, although in no state are there any laws that prohibit either physicians from writing a POLST for an appropriate patient or emergency medical personnel or other health care professionals from following a POLST.

The POLST Paradigm builds on the Do Not Resuscitate (DNR) mechanism that has been utilized for appropriate patients for several decades. The DNR – also known as Do Not Attempt Resuscitation (DNAR) or No Code – order instructs health care professionals to refrain from initiating cardiopulmonary resuscitation (CPR) for a particular patient who suffers a foreseeable, even anticipated, cardiac arrest. The prevailing law is that a physician may write a DNR order if the decisionally capable patient decides that the likely burdens of CPR (a Code) would seriously outweigh any expected benefits (e.g., mere continued existence until the next, probably fatal, cardiac arrest).

DNR orders may be relevant to the surgery context in at least a couple of important respects. First, several studies have found that the preexisting presence of a DNR order is independently associated with a higher mortality rate among geriatric patients undergoing emergency surgery. This DNR versus non-DNR mortality discrepancy is due mainly to the greater incidence of renal insufficiency, heart attacks, organ/space surgical site infections, and pneumonia among postsurgical patients with preexisting DNR orders.

The authors of these studies uniformly conclude that the informed consent process should include patient and family counseling on surgical expectations because the risk of perioperative events are significantly elevated when a DRN order exists and that prognostic data may be material to patient/surrogate decisions about undergoing the surgery [42, 43]. Potential explanations for this risk elevation are that: patients for whom DNR orders have been written are likely to be sicker in the first place; physicians may be less aggressive in treating DNR patients postoperatively (although there is no evidence to confirm this theory); and/or that patients with DNR orders and their surrogates may be less willing to accept aggressive postoperative treatment [42]. It has been speculated that some patients with DNR orders might consent to emergency life-sustaining surgery but then resist aggressive postoperative interventions for complications, on the theory that after surgery when serious complications occur, patients adopt a different, more realistic perspective on the balance of potential benefits and burdens of various medical treatments [43].

Second, the American College of Surgeons, American Society of Anesthesiologists, and Association of Operating Room Nurses have published guidance to their members relating to the status of DNR orders as a part of operative and anesthesia care. According to this policy statement, "The best approach for these patients [who are considering surgery but have a DNR order already in place] is a policy of 'required reconsideration' of the existing DNR orders. Required reconsideration means that the patient or designated surrogate and the physicians who will be responsible for the patient's care should, when possible, discuss the new intraoperative and perioperative risks associated with the surgical procedure, the patient's treatment goals, and an approach for potentially life-threatening problems consistent with the patient's values and preferences" [44].

In recommending required reconsideration, the ACS policy statement rejects an automatic rule either requiring DNR enforcement during surgery or always revoking it as a precondition of surgery, leaving the resolution of the resuscitation issue ultimately up to the informed choice of the patient or surrogate. Nevertheless, because surgeons ordinarily anticipate and insist upon the need for aggressive postoperative care of patients undergoing high risk operations, many of them decline to operate altogether on patients who have advance directives that limit aggressive postoperative treatment [40]. This may occur because "surgeons seem to rely on assuming that patients understand surgery is high risk and assent that they require difficult postoperative care after a major procedure. This may account for the perception that surgeons are overly aggressive in prolonging life in postoperative care, because a surgeon has had a discussion with a patient and told the patient what to expect intraoperatively and postoperatively, and the patient agreed to pursue the intervention." [45]. Another way of interpreting surgeons' avoidance of patients with treatment-limiting advance directives is that many surgeons experience difficulty in moving from a curative medical treatment model to a more palliative mode of care, and we need to ask how physicians generally, and surgeons, particularly, can learn to negotiate acceptable accommodations with their patients centered around the patient's goals of care [37].

Surrogate/Proxy Decision Making

Even when a patient is determined by the medical team to lack sufficient present capacity to autonomously make specific necessary decisions about recommended interventions, informed consent principles still apply. What is different in the case of patient incapacity is that decisions must be made for that patient by a surrogate or proxy (terminology sometimes varying by jurisdiction).

The modern trend pertaining to all of the various mechanisms of surrogate decision making has been toward the substituted judgment standard. Under this approach, the surrogate is expected to make the same decisions that the patient would make, according to the patient's own priorities and values to the extent they can be ascertained, if the patient were presently able to make and express his or her own authentic decisions. The subjective substituted judgment standard is most consistent with respect for autonomy. When it cannot realistically be ascertained what the now-incapacitated patient would have decided if imbued with adequate present capacity, the surrogate is expected to act in a fiduciary or trust agent role and rely on the traditional best interests standard. The best interests test mandates that decisions be made in a manner that, in the surrogate's considered judgment, would confer the most benefit and the least burden on the incapacitated individual.

Formal designation of a person with legal authority to act as the patient's surrogate for medical decision-making purposes may be accomplished through several different channels. These surrogate designation mechanisms are described below.

Advance Planning

As was discussed earlier, a person may take steps, while still decisionally capable, to anticipate and prepare for his or her eventual incapacity. Advance directives may be executed by a presently able individual and the resulting DPOA may be used to designate a decision-making agent. Under a DPOA as described earlier, the principal may give the agent general or specific instructions to direct future medical decision making or may make an unrestricted grant of authority and in either case may make the delegation of authority effective immediately or on a future, springing basis.

The DPOA is distinguishable from the regular or ordinary power of attorney. The latter device ordinarily is used to delegate authority to make arrangements and take actions regarding the principal's financial or property affairs, and the agent's authority expires automatically when the principal becomes decisionally incapacitated. In the medical decision-making sphere, therefore, an ordinary POA usually is inapplicable.

Guardianship

Creation of a guardianship or conservatorship (precise terminology varying among different jurisdictions) is the most legally definitive means of transferring decision-making power to a surrogate without the patient's permission. It entails appointment by a state court of a surrogate (the guardian/conservator) who is empowered to make certain decisions on behalf of an incapacitated person (the ward). This legal process is initiated in response to a petition filed by the family, a health care facility, a financial institution, the local Adult Protective Services (APS) agency, or any other interested party. The legal proceeding involves review by the court of a sworn affidavit or live testimony of a physician who has examined the alleged incapacitated person and offers a professional opinion about the individual's present capacity. Most courts strongly prefer to appoint a family member who is willing and able to act as a guardian/conservator; in the absence of a willing and able family member, however, the court may appoint someone else (such as a close friend) or a public (governmental) or private guardianship program if those options are locally available. There are also professional guardians who are available for court appointment if the ward has money the court can order be used to pay for the guardian's services.

Creating total or plenary guardianship entails an extensive deprivation of an individual's fundamental personal rights. When a deprivation of rights (such as the right to make one's own medical decisions) is involved, the legal policy is that society should intervene only in the least restrictive or least intrusive manner possible consistent with accomplishing the legitimate purpose of the intervention. On the basis of the least restrictive alternative doctrine, limited or partial guardianship/conservatorship is preferred whenever feasible over the plenary variety. In every American jurisdiction, courts have been given the statutory authority to limit a surrogate's power in terms of duration and the types of decisions (e.g., surgery) covered.

Because the official legal process of guardianship/conservatorship ordinarily entails significant financial, time consumption, and emotional costs, it should not be initiated unless and until less formal approaches, like consultation with an Institutional Ethics Committee (IEC) or ethics consultation service, have been exhausted in an effort to reach an accommodation that all the involved parties (including the patient's physicians) can tolerate.

Default Authority Statutes

In the absence of judicial appointment of a guardian/conservator or the patient's prior formal designation of an agent, the longstanding medical custom has been for physicians to turn to family members (when available) to function as surrogates for their incapacitated relatives. This next-of-kin practice has been codified in the large majority of states by legislative enactment of "family consent' statutes that expressly authorize specific relatives, listed in a priority order, to make particular kinds of decisions (including medical decisions) for their incapacitated family members. This statutory codification of common practice is based on the presumption that family members generally know best the basic values and preferences of their relatives (thus making substituted judgment realistic) or, at the least, will act as trustworthy advocates for their relatives' best interests. However, physicians and other health care professionals must be alert to possible troublesome conflicts of interest – financial, emotional, or otherwise – that can render a family member inappropriate to act as a surrogate decision maker for the patient.

In the absence of any family member willing and able to act as surrogate decision maker for an incapacitated patient, state default authority statutes name certain others (e.g., friends) who are empowered to make decisions for the patient. Physicians should carefully avoid stepping into the surrogate decision maker role themselves, in order to avoid creating the appearance, let alone the reality, of a conflict of interest.

"Unbefriended" Patients

A challenging set of issues concerns the burgeoning number of incapacitated *unbefriended* older individuals who lack willing, available family or friends to advocate or engage in substitute decision making for them. This population group arises because of a combination of demographic and family structure changes in American society, namely older individuals today outliving their own decisional capacity and either never marrying or having children or, alternatively, outliving their spouse, children, and other relatives.

A few program models exist as a starting point to develop efficient processes to deal with situations involving treatment decisions for the unbefriended group. For example, programs have experimented with such options as internal institutional committees, public guardianship offices, professional guardians (when the ward has sufficient assets to pay for this arrangement), and volunteer guardianship projects. The health care system and the law need to continue clarifying theoretical matters and operational details pertaining to decision making for this population group. The surgeon should consult hospital legal counsel to determine acceptable local sources of surrogate decision making for the incapacitated patient without relatives or friends. In 2016, the American Thoracic Society and the American Geriatrics Society jointly established a Task Force charged with developing a relevant policy statement.

Nonbeneficial Surgery

There are times when a patient, or more usually the patient's family, may insist on initiating or continuing medical treatments ("doing everything possible"), including treatments relating to surgery [45], that the clinician believes are clinically and ethically inappropriate in terms of patient benefit. Neither patients nor families possess a legal right to demand, nor does a physician owe a duty to provide, nonbeneficial medical treatment. On the rare occasions when courts have become involved prospectively with this issue because families have asked a judge to order health care professionals to provide specific medical treatments, the judicial opinions generally have been confusing, inconsistent, and poorly reasoned. However, no court has ever held a health care professional or institution liable after the fact for failure to begin or perpetuate futile interventions for a critically ill patient, even when the family was insisting on doing everything technologically possible.

In practice, clinicians usually seem to take the path of least resistance in such circumstances and "treat the family," often out of misapprehension about potential liability exposure. Other factors that may contribute to the provision of nonbeneficial emergency surgery for older patients are the difficulty of making and communicating an accurate prognosis in light of insufficient data, problems in assessing whether and how much the patient is suffering, the patient's and family's image of surgery as an effort to "do something" to give the patient at least a chance to live and recover, and the surgeon's belief that offering nonbeneficial surgery gives the family time to cope with an overwhelming, emotional situation [46, 47]. In the vast majority of cases, better physician–family communication, perhaps supplemented with formal or informal dispute resolution mechanisms such as IECs, in which the realistic (i.e., negative) implications of "doing everything possible" are clearly delineated, can avoid or resolve serious disagreement over how to proceed [48].

Research Context

The requirements relating to informed consent in the diagnostic and therapeutic contexts all apply with full force in the context of biomedical research, including surgical research, involving the use of human participants as research subjects [49]. Besides common law doctrine, particular aspects of informed consent for human subjects research are governed by federal regulations (the Common Rule in all cases, 42 Code of Federal Regulations Part 46, and regulations of the Food and Drug Administration when investigational drugs or medical devices are involved) and state statutes. Under the federal regulations, research protocols enrolling human subjects as data points must be approved by an Institutional Review Board (IRB) before subject enrollment may commence. One of the primary responsibilities of the IRB is to assure that enrollment occurs only when subject or surrogate consent is given voluntarily, knowledgeably, and by a decisionally capable person, and separate written consent forms usually are required. The other main IRB tasks are assuring that risks to the subjects are minimized, the ratio of risks to potential benefits is ethically tolerable, and that subject selection is equitable.

Confidentiality

Because of the physician/patient relationship, surgeons constantly come into the possession of information about patients and their families. Health care professionals owe patients a fiduciary responsibility to hold in confidence all personal patient information entrusted to them as a consequence of the professional/patient relationship. This ethical obligation, founded on the patient's important interest in maintaining personal privacy and avoiding the social stigma and potential discrimination that breach of one's medical privacy might implicate, is enforceable under both state and federal law.

Every state, both within its respective professional Practice Acts and in separate statutes pertaining to particular health care delivery settings, has enacted statutory provisions delineating the confidentiality duties of health care professionals and institutions. Often, state agencies publish accompanying regulations to implement these statutes. Moreover, a strong common law health care confidentiality doctrine has been enunciated over time by state court decisions. Violation of state common law or statutory or regulatory requirements regarding the confidentiality of patient information may subject erring health care professionals to civil damage suits brought by or on behalf of the patient whose privacy was improperly infringed; additionally, violation of state Practice Act provisions may subject the violator to administrative sanctions by the state, including license suspension or even revocation.

However, numerous exceptions to the general confidentiality rule have been recognized, either by the courts as part of the common law or embedded in state legislation or regulation. The most prominent exception occurs when a patient, expressly or impliedly, voluntarily, and knowingly waives, or gives up, the right to assert that particular information be kept confidential. These waivers take place daily to make information available to third-party payers (for instance, Medicare claims processors and private health insurers), quality of care auditors (such as Joint Commission surveyors), and other public and private entities like health care surrogates authorized to make medical decisions on behalf of a decisionally incapacitated patient. Also, because the modern delivery of health care most often is a team endeavor, each patient implicitly gives permission for the sharing of certain otherwise private pieces of information among the members of the treatment team. Internal information sharing of this nature is essential to optimal care, especially for accomplishing coordination and continuity of surgical care for older patients. Indeed, failures in communication among the multiple professionals involved in the care of a patient needing such coordination and continuity may form the basis for negligence liability claims when harm results.

Second, the patient's reasonable expectation of privacy must give way when the health care professional is mandated by state statute or regulation to report to enumerated public health or law enforcement authorities such as APS the professional's reasonable suspicion that certain conditions or activities have occurred or are occurring. Such reportable conditions or activities may include elder mistreatment or neglect (in many states including cases of self-neglect within that definition), domestic violence, infectious diseases, births, and deaths. Some states that have declined to mandate the reporting of particular situations to public authorities nonetheless encourage voluntary reporting; a few states have pursued this approach regarding cases of suspected elder abuse or neglect. Those states supply an incentive for voluntary reporting by expressly providing legal immunity against any form of civil, criminal, or administrative liability for covered persons making good faith reports to public authorities. Mandatory and voluntary reporting statutes embody the state's exercise of either its inherent police power to protect and promote the general health, safety, welfare, and morals of the community or its *parens patriae* power to step up and safeguard individuals (such as persons with serious cognitive or emotional disabilities) who are not capable of protecting themselves.

Further, a health care professional may be compelled to reveal otherwise confidential information about particular patients by the force of legal process, namely, by a judge's issuance of a court order requiring such release. This is a possibility in any civil or criminal lawsuit involving a factual dispute about a patient's physical or mental condition. A court order (as opposed to a subpoena or subpoena *duces tecum*, which is issued simply as an administrative, nondiscretionary matter by the court clerk rather than by a judge) requiring one to produce personally identifiable patient information may overrule the state's professional/patient testimonial privilege statute that ordinarily would prohibit the professional from testifying in a legal proceeding regarding private patient information. Every state testimonial privilege statute provides for judicially compelled testimony on the part of the health care professional when, for example, the patient has placed his or her own health condition and medical treatment in issue in a lawsuit.

Besides state statutes, regulations, and common law provisions, there are a variety of federal statutes and regulations imposing on health care professionals and institutions particular confidentiality obligations when care is provided within specific types of health care settings, including federal penal institutions, veterans affairs facilities, military institutions, federal community health centers, and facilities specializing in the treatment of persons having drug and alcohol addiction. Violation of these laws may result in substantial civil fines. Statutes and regulations setting the conditions for receipt of Medicare and Medicaid payments contain confidentiality provisions, situated within general patients' rights standards. Noncompliance with those provisions could trigger a range of regulatory sanctions, at the extreme including decertification of the institutional provider from participation in federal health care financing programs.

Federal regulations codified at Title 45, US Code of Federal Regulations Parts 160 and 164 implement the Health Insurance Portability and Accountability Act (HIPAA) of 1996 (Public Law No. 104–191, title XI, Part C). These regulations, published in the form of a Privacy Rule and a Security Rule, impose on covered health care entities (defined in part as any health providers who transmit any patient-related information electronically) an extensive set of requirements regarding the handling of personally identifiable medical information contained in patient records. These regulations impose severe criminal and civil sanctions for unauthorized disclosures of protected health information (PHI). Substantively, HIPAA and its implementing regulations in essence codify preexisting state statutory and common law protections for patients, with the addition of provisions making it clear that patients now have the right to access the information contained in their own medical records. (Previously, state law had varied or was unclear regarding the issue of patient access to records.) HIPAA contains provisions authorizing covered entities to transmit PHI to certain others for purposes of "treatment, payment, and health care operations" such as quality assurance or marketing. These and other exceptions explicitly contained in HIPAA basically track the preexisting state statutory and common law exceptions.

The physician must guard against the unauthorized disclosure of protected PHI. The person who has the authority to give or refuse consent for medical treatment (the patient or a surrogate) usually controls the release of identifiable medical information to third parties, unless there is a court order or government regulation demanding something different. All questions about the release of medical information to third parties in specific cases should be directed to the institution's medical records department or legal counsel.

Patient Safety and Risk Management

A number of strategies are available to individual surgeons and the institutions within which they practice to reduce the risks of negative legal entanglements to which they are exposed. Effective risk management is integrally tied to the cultivation of a preventive safety culture within the health care institution [50]. The institution's risk management program (designed to identify, mitigate, and avoid potential injuries and other types of problems that could result in legal, and therefore financial, loss to the institution) should incorporate specific activities designed to address patient safety and associated legal risks prevalent in the surgery context. For instance, prior to surgery, an effective prevention strategy for POCD would identify risk factors in patients in terms of age-related physiological changes, comorbidities, and lifestyle, history, alcohol consumption, smoking, and the use of various medications [33].

This chapter section briefly outlines a few of the most salient patient safety/risk management strategies relevant to surgical care of geriatric patients. The surgeon should become knowledgeable about his or her own institution's risk management program and cooperate with institutional risk managers to ensure appropriate sensitivity to surgical practices and potential problems and their avoidance or mitigation. The surgeon should view the risk manager as a partner in pursuit of the common goal of providing, and if necessary proving after the fact that the surgeon provided, quality patient care.

Safety Checklists

Surgical complications represent a significant cause of mortality and morbidity in geriatric patients. Some of these complications are associated with human errors by individuals or teams, such as wrong patient/procedure/site surgery, equipment malfunctioning or availability problems, unanticipated blood loss, nonsterile equipment, and surgical items such as sponges or instruments left inside patients. It has been credibly estimated that medical error is the third leading cause of death in the USA [51]. Surgical checklists can potentially prevent errors and complications that may occur during surgery or perioperatively [52]. Checklists may reduce errors by, among other things, increasing the probability that all critical tasks have been done, facilitating a respectful team approach, encouraging communication, identifying and preventing near misses, and pushing the care team to prepare systematically for both anticipated and unanticipated complications. Checklists are useful in both hospital settings and in ambulatory surgical centers (ASCs) [53]. Ideally, checklists should be tools that support clinical practice without substituting a rigid formula in place of professional judgment [53].

A number of specific surgical checklists have been developed and disseminated. These include the: World Health Organization (WHO) Surgical Safety Checklist; Joint Commission Universal Protocol (UP) for Preventing Wrong Site, Wrong Procedure, Wrong Person Surgery; and Surgical Patient Safety System (SURPASS) checklist [52], as well as those incorporated in the Safe Surgery Saves Lives program [53]. Additionally, many individual institutions have developed their own surgical checklist versions.

Hospital Credentialing

In order to admit a patient to a hospital or ASC and/or treat them in that facility, a surgeon must be credentialed by the facility. Health care facilities grant admitting and treating privileges to physicians and other health care professionals based on a review of the applicant's training and experience by the facility's organized medical staff, with the facility governing board ultimately granting the credentials in response to the medical staff recommendation. In the past, privileges were often granted on a very broad, even unlimited basis. Today, by contrast, privileges are granted on a limited basis, restricted based on the medical staff's evaluation of an applicant's personal experience and qualifications regarding particular medical services. For example, a facility has the discretion to grant a surgeon privileges to perform surgery using traditional methods, but not extend those privileges to innovative new techniques such as the da Vinci Surgical System unless the surgeon can demonstrate particular expertise and experience in using the innovative technique.

Health care facilities owe their patients a legal duty to credential their physicians and other health care professionals in a nonnegligent manner, by using due or reasonable care in the credentialing process. Exercised judiciously, the legal authority and responsibility of health care facilities to credential practitioners can act as a powerful patient safety and quality assurance tool [2].

Documentation

Creating and maintaining accurate records of patient care is an integral part of the duty that a physician owes a patient. Good documentation is imperative to providing competent patient care and avoiding unexpected bad outcomes and thus is wise risk management practice. Moreover, in the event the surgeon is accused of providing substandard care, the surgeon's best (and sometimes only) defense will lie in the quality of documentation created to explain and justify decisions made and actions taken. In addition, institutional accreditation and third-party payment turn heavily on information drawn from medical records.

The quality of medical records is especially important in surgery, where patient conditions are subject to rapid change and many different professionals may be involved as members of the surgical team. The watchwords of documentation from both medical and legal perspectives are completeness, legibility, accuracy or truthfulness, timeliness, corrections made in a clear and unambiguous fashion, and objectivity. Dedicated training can make a positive, albeit fairly modest, impact on surgeons' documentation performance [11].

The ongoing evolution toward adoption of electronic health record (EHR) systems in health care institutions holds the strong potential for improving the quality and efficiency of patient care documentation. One of many problems that need to be solved, though, is the lack of interoperability among different EHR systems among different health care facilities and even within the same facility. The advent of EHR also implicates a number of HIPAA compliance and other information confidentiality concerns of the sort discussed previously.

Special attention should be directed to proper documentation of informed consent in the surgery arena. The role of informed consent documents has been discussed previously.

Error Disclosure and Apology

The disclosure of adverse events to patients, including adversities related to medical errors, is a vital component of a complete patient safety and quality improvement program [54]. The magnitude of medical errors committed in the USA is substantial [51], with many of those errors taking place before, during, or after surgery on older patients. The surgeon may be faced with the dilemma of whether to explicitly admit to a patient or surrogate that a problem being experienced by that patient may be related to the occurrence of a medical error. The immediate temptation may be to cover up the fact that an error has taken place.

Disclosure of errors to patients or surrogates is difficult for surgeons for several reasons [54, 55]. For one thing, often there is a relational distance between the surgeon and the patient, whom the surgeon may have met only once prior to the surgery. There rarely is a longstanding, mature relationship. For another thing, interactions between surgeons and patients or surrogates frequently take place in information-poor environments. Third, since surgical error may cause direct physical injury to the patient, the patient's or family's reaction to the error may be quite emotionally intense; anticipation by the surgeon of an intense, negative encounter may increase the surgeon's anxiety and potentially make the surgeon more averse to facing these disclosures. In addition, empathy does not come naturally to most surgeons, and many need to learn how to do better at engaging in empathic behaviors.

Of course, a major impediment to a vigorous assault on the medical errors problem is the fact that many physicians and other health care professionals persist in equating the admission of error with legal suicide. As explained below, physician anxieties about adverse legal consequences, while sincere, are mainly exaggerated or erroneous.

Another obstacle is the traditional shame-and-blame culture of medicine. Individual actors have been singled out for making mistakes, rather than an environment in which errors are recognized as a complex systematic phenomenon requiring broader solutions. In the shame/blame environment, where errors are seen as a form of personal moral failure that shatters the pervasive aura of infallibility, the physician's fear of losing face in front of one's peers seriously impedes efforts to encourage a more forthright response to medical errors.

Indulging the temptation to cover up errors in medical care, besides violating basic ethical principles, probably constitutes ineffective or even counterproductive legal risk management [1]. For one thing, modern medical care has become such a complex enterprise involving so many different professionals potentially interacting with the patient, the medical record, and external evaluators (including attorneys) that, pragmatically speaking, it is unlikely that a cover up of essential facts about a medical error relating to serious patient harm could be sustained for very long. Moreover, the majority of patients and surrogates expect and respect honesty on the physician's part; patients who feel they have been communicated with candidly are more likely to trust than sue the physician. Patients tend to approach plaintiff attorneys with an eye toward filing a malpractice lawsuit when they are angry at the physician [56], and nothing makes most patients angrier that believing that the physician has not been truthful with them, particularly when serious harm for which the patient was not prepared occurs.

When a patient has been injured by a medical error, placing the focus on patient welfare (i.e., working to remedy or mitigate the patient's medical problem, even though that might entail admitting the error), rather than on concealing the error from the patient, is the most constructive defensive practice. Error disclosure has not opened up a floodgate of new litigation that otherwise would not have happened [57]. Even when litigation occurs, the disclosure of an error by the physician ordinarily is not harmful to the physician's defense. Many states have enacted *I'm Sorry* statutes that prohibit or greatly limit the admissibility into evidence at trial of an apology by the physician made to the patient. In addition, the federal Patient Safety and Quality Improvement Act affords protections to those who report errors to certified data collection organizations by shielding the content of reported patient safety information from legal discovery and disclosure. Unfortunately, many physicians are not aware of these statutory protections and hence remain reluctant to participate in the kinds of patient safety initiatives that the Patient Safety and Quality Improvement Act intends to encourage [58].

Transparency and apology regarding medical errors is likely to be positive in another respect as well, even if litigation were to occur despite the disclosure and apology. In medical malpractice litigation alleging negligence, technically the focus is on whether the physician deviated from the standard of reasonable care under the circumstances in that specific case. In reality, however, the jury usually must be convinced (i.e., angered) that the defendant physician was a bad person who treated the patient not just improperly but cavalierly and uncaringly. It assists the plaintiff to satisfy that unwritten but real burden of proof when the physician has tried to conceal a medical error to protect the physician's own legal and financial interests even though concealment of the error may have interfered with the patient's recovery. At the same time, a defendant physician can favorably impress the jury with his or her positive character by demonstrating that the error was quickly acknowledged so that full attention could be devoted to improving the patient's medical condition (and the care of future patients) in light of the error.

Expectations for disclosure of errors are now codified into regulatory requirements and guidelines published by medical professional organizations. Joint Commission standards mandate that patients be informed about all outcomes of care, including unanticipated outcomes.

In examining the issue of admitting medical errors, one must distinguish between admitting the fact that something has gone askew, on one hand, and volunteering the opinion that one or more members of the healthcare team were negligent, on the other. Not all mistakes fall to the level of a deviation from professionally acceptable standards of care; deciding whether negligence has taken place, let alone whether that negligence proximately or directly caused a financially compensable injury, requires legal determinations by a jury or judge and is a set of questions beyond the competence of a physician to make unilaterally. Hence, the physician's obligation to be truthful extends only to acknowledgment that a mistake has happened and a show of empathy for the patient's situation ("I am sorry that you have to go through all this hassle"), not to personally concede or accuse others of being at legal fault.

Physicians should make themselves aware of the disclosure support resources of their institution or malpractice insurer and take advantage of these supports. Institutions can support physicians and other health care professionals through methods such as just-in-time disclosure coaching, role modeling by senior physicians, skills training, simulation, and offering clinical coverage and support [54]. The federal AHRQ has created and made available, http://www.ahrq.gov/professionals/quality-patient-safety/patient-safety-resources/resources/candor/index.html, a Communication and Optimal Resolution kit as a process designed to open lines of communication between clinicians, patients, and their families after harm occurs.

Conclusion

Surgeons and other health care professionals, plus the institutions and organizations within which they serve older patients, continuously and inevitably interact with law and the legal system. These interactions may concern a wide slew of pertinent subjects. This chapter has surveyed a few broad areas within which such interaction is likely to occur and directly affect every physician who cares for older patients. For personalized attention and advice in particular situations, especially for questions pertaining to the detailed law of a specific jurisdiction, specialized legal consultation should be secured from knowledgeable attorneys in private practice, risk managers employed or retained by the institutional health care provider, the physician's professional liability insurance carrier, or an IEC.

Abstract

Older adults undergo age-related physiologic changes that are important to consider in anesthetic management. Key cardiovascular

R. A. Rosenthal et al. (eds.), *Principles and Practice of Geriatric Surgery*,
https://doi.org/10.1007/978-3-319-47771-8_70

changes include left ventricular hypertrophy and changes in autonomic responses. Key pulmonary changes include changes in lung structure, blunted responses to hypoxia and hypercapnia, and increased risk of aspiration. Older adults are also more susceptible to postoperative cognitive changes. The interaction of anesthetic drugs with changes in cardiac, pulmonary, and neurological systems must be anticipated. Pharmacokinetic and pharmacodynamics properties of individual anesthetic drugs will also be altered in older adults. The anesthetic plan should be tailored to the needs and physiology of older adults, keeping in mind important principles of geriatric care.

Anesthesia · Physiology · Geriatric

Introduction

This chapter focuses on the *interaction* of anesthesia and age-related physiologic changes that are likely to increase perioperative complications. The reader is encouraged to consult relevant chapters contained in this textbook on preoperative assessment and specific organ systems for a comprehensive discussion of general physiologic changes with aging.

A Patient

An 85 y/o man presents for emergency exploratory laparotomy. He recently underwent ankle surgery subsequent to a fall, and in the setting of postoperative opioid administration, developed ileus with concern for bowel ischemia. He has a high level of education, but his wife has noticed some cognitive decline recently. He is independent with his acts of daily living at baseline and can climb one flight of stairs. He has moderate aortic stenosis, a history of paroxysmal atrial fibrillation, and was a former smoker. In talking to the patient, he does appear mildly confused. His heart rate is 98 and his blood pressure is 160/74. He is afebrile.

In this patient, as with all older adults, anesthetic drug choice and dosing need to be considered carefully. Physiologic changes in older adults and the interaction of these changes with both co-morbidity and anesthetic agents are also critically important. Specifically for this patient, key anesthetic goals include: safe induction in light of aortic stenosis and volume fluctuations, optimizing hemodynamics in a patient with both aortic stenosis and paroxysmal atrial fibrillation, avoiding pulmonary complications, and minimizing the risk of postoperative delirium. Although fundamental principles of anesthetic care clearly apply, there are unique aspects to consider in the geriatric population. This chapter will provide an overview of these important anesthetic considerations for safely taking care of older adults, generally organized by organ system and anesthetic drug. Table 1 summarizes important organ-specific considerations in anesthetizing older adults.

Cardiovascular Implications of Anesthesia in the Elderly

Cardiovascular Changes with Aging that Affect Anesthetic Physiology

Characteristic changes in the cardiovascular system occur with age and affect the response to anesthesia and to perioperative stress. These changes include systolic and diastolic dysfunction, left ventricle hypertrophy, increased arterial stiffness, altered conduction systems, altered autonomic responses, and cardiovascular disease. Each of these changes will be discussed in more detail.

Left Ventricle Structure and Function

Structural changes occur in the aging heart, including decreases in myocyte number and size

Table 1 Organ-specific considerations in anesthetizing older adults

	Key physiologic effects of aging	Clinical anesthetic implications
Cardiac	Left ventricle hypertrophy and diastolic dysfunction Conduction abnormalities and autonomic dysfunction High prevalence of coronary and valve disease	Preload dependent, but susceptible to volume overload. Labile hemodynamics with blunted compensatory mechanisms. Evaluate for coronary artery disease and aortic stenosis
Pulmonary	Increased V/Q mismatch Decreased response to hypoxia and hypercarbia Loss of lung elasticity and decreased chest wall compliance Decreased cough reflex	Increased A-a gradient Risk of respiratory failure, especially in the setting of anesthetic agents Increased work of breathing Increased aspiration risk
Neurologic	Increased brain sensitivity to anesthetic agents	Increased postoperative delirium and cognitive dysfunction
Renal	Decreased renal mass	Decreased drug clearance; Susceptible to acute renal failure
Hepatic	Decreased blood flow during anesthesia	Decreased clearance of drugs with high hepatic extraction ratios
Endocrine	Impaired glucose tolerance	Hyperglycemia: Infection
Thermoregulation	Decreased muscle mass and blunted thermoregulatory mechanisms	Hypothermia, which can lead to increased infection, coagulopathy, risk of arrhythmia, and postoperative myocardial infarction

and an increase in the amount of connective tissue [1]. These changes result in decreased systolic function of the heart. Decreased intrinsic contractile function may be partially compensated for with increasing muscle mass and subsequent left ventricular cardiac hypertrophy.

Left ventricle hypertrophy may also result from vascular changes that are common in older adults. Arterial stiffening is highly related to age and occurs through a variety of mechanisms, including loss of elastic lamina, increase in collagen, inflammation, and calcification [2]. As shown in Fig. 1, the consequences of vascular stiffening are profound, with increased pulse wave velocity resulting in aortic pressure waves that are reflected back towards the heart during systole. This in turn causes an increased afterload during late systole, which can lead to compensatory left ventricular hypertrophy.

Left ventricle hypertrophy is associated with important physiologic changes, including diastolic dysfunction. Diastolic dysfunction is thought to occur when low cardiac output results from a ventricle with thick walls but a small cavity

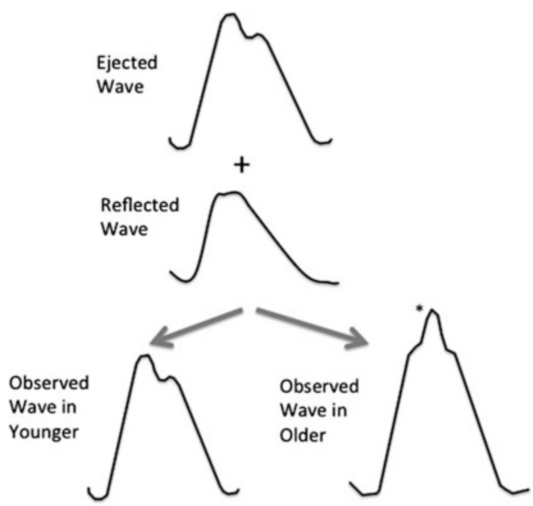

Fig. 1 The observed wave is composed of the *ejected* wave (due to ventricular contraction) and a *reflected* wave, which propagates backwards after reflection at points of vascular branching. Due to increased vascular stiffness, the reflected wave returns earlier and faster in older adults compared to younger counterparts. This results in characteristic changes in the observed wave in older adults, including systolic hypertension (*)

[3]. In this physiologic state, delayed relaxation impairs early diastolic filling [4] and enhances the importance of late diastolic filling in maintaining cardiac output [5]. Late diastolic filling, however, must now overcome ventricular stiffness and that requires higher atrial pressures. To boost cardiac output in the setting of increased ventricular stiffness, elderly patients depend on higher diastolic filling pressures and are often preload-dependent. Additionally, the atrial contribution to ventricular filling becomes critical and creates greater susceptibility to hypotension should atrial fibrillation occur. Adequate preload and normal rhythm are critical given the reduced ability of older adults to augment cardiac contractility during periods of increased demand.

Another factor that affects diastolic filling of the ventricle is the relative time the heart spends in systole versus diastole. In the aging heart, length of diastole is shortened and systole is lengthened as a compensatory mechanism to maintain ejection fraction [6, 7]. Increased left ventricular filling does increase inotropy by means of the Starling forces, but the compensation for the systolic function is at the expense of higher diastolic pressures and greater time in systole [8, 9]. Shortened diastolic time also affects coronary perfusion [10, 11].

Stiffening of the vessel walls occurs in the venous system with aging, with the implication that rigid veins fail to function as a preload buffer. The venous system normally contains 80% of blood volume, so low venous capacitance means that the aging venous system cannot accommodate excess volume or adapt to low volume states without a comparatively large change in filling pressure [12].

Conduction Abnormalities

Conduction abnormalities are common in the elderly. Dilation and fibrotic change in the atria predispose the elderly to atrial fibrillation. Bradycardia is the second most common initiating rhythm after premature atrial contractions [13] and may increase the incidence of new onset atrial fibrillation. The high incidence of sinus bradycardia may be related to drop-out of sinus node pacemaker cells to as little as 10% of levels seen in young adults [7]. New onset atrial fibrillation during the perioperative period in the elderly frequently results in significant blood pressure changes. The cell populations in the aging AV node are maintained. AV conduction slows with aging, however, resulting in lengthened P-R interval [14, 15].

Autonomic Responses

The aging of the autonomic nervous system is characterized by progressively limited capacity to adapt to stress. In particular, cardiovascular responsiveness in the elderly is impaired. For instance, maximal heart rate decreases with aging and can be estimated by the formula: maximum predicted heart rate = 220 – age [16]. As a consequence, the ability of older adults to increase cardiac output by means of an increase in heart rate is limited. There is also reduced adrenergic responsiveness [17], affecting both the β-adrenergic absolute heart rate response [18, 19] and inotropy [20] and alpha-adrenergic mediated arteriolar tone [21].

Rapid response to hypotension is mediated by baroreceptor function. The stiffening of arterial walls in the elderly may contribute to the well-documented decrease in baroreceptor response. There is a decrease in baseline vagal tone [22] and consequently diminished carotid sinus baroreceptor response to hypotension in the elderly [23, 24].

Cardiac Disease

In addition to physiologic changes associated with "normal" aging, older adults are at high risk for cardiovascular disease. The prevalence of coronary heart disease, myocardial infarction, congestive heart failure, and valvular calcification increases markedly with age [25]. Optimal perioperative evaluation of a patient's cardiac status according to established guidelines [26] is crucial, and a high index of suspicion for cardiovascular disease is required in older adults. In contrast to pulmonary complications, in which age is the primary risk factor, the degree of cardiovascular disease appears to be more predictive of cardiac complications than age alone.

The Interplay of the Aging Cardiovascular System and the Effects of Anesthesia

Individual Anesthetic Drugs

Although anesthetic drugs have different mechanisms of action and effects on the cardiovascular system, an important point is that most anesthetic drugs can be used safely without hemodynamic compromise in the elderly population if several principles are kept in mind. Anesthetic dose requirements of both intravenous induction agents and inhalational agents decrease with age. In addition, slower titration of medication as opposed to bolus administration may be warranted because changes in body composition alter the pharmacokinetics of intravenous agents. The so-called greater "sensitivity" of aged patients to the bolus administration of certain drugs has been related to a reduction in either the initial volume of distribution or the initial distribution clearance. In elderly patients compared to younger ones, the same bolus dose will generate a markedly higher plasma concentration and thus a greater pharmacologic effect.

As far as individual anesthetic agents, there is no one "best" agent to optimize cardiac physiology in older adults. Rather, the individual physiology of the patient must be considered with respect to cardiovascular effects of anesthetic agents. It is useful to consider effects on heart rate, rhythm, preload, contractility, and afterload. Indeed, the cardiovascular effects of anesthetic agents are pleiotropic and affect most of these variables to varying degrees.

Specifically, it is clear that decreased ventricular contractility occurs with intravenous anesthetic agents. Propofol is the most common induction agent used today and is generally thought to be a direct myocardial depressant. The negative inotropic effect of propofol is mediated by a decrease in intracellular calcium [27]. In fact, propofol is a greater myocardial depressant than the inhalational anesthetics [28]. Even ketamine, which produces a sympathetically mediated increased heart rate and blood pressure, causes some direct myocardial depressant effect [29, 30]. It appears that opioids have minimal effects on contractility [29]. It has been suggested that etomidate is the induction agent of choice in elderly patients with limited cardiovascular reserve. However, hemodynamic instability after induction with this agent in severely compromised patients can be remarkable. In comparison to the intravenous agents, inhaled anesthetic agents are associated with less myocardial depression. Volatile anesthetics decrease inotropy by means of their effects on the L-type calcium channels, the sarcoplasmic reticulum, and the contractile apparatus [31]. Cardiac output is generally maintained under the modern agents because the myocardial depression is accompanied by afterload reduction [32].

Most anesthetic agents also reduce afterload by decreasing arteriolar tone. Propofol is a potent vasodilator [33]. Opioids are also vasodilators, though this effect is small when compared to propofol or the inhalational agents [34]. Reduced afterload is a common effect of anesthetic agents and is often treated with small doses of alpha-agonist drugs. However, it is important to consider that alterations in preload and contractility may also be important factors and need to be addressed.

Anesthetic agents blunt baroreceptor function. The degree of inhibition depends on the anesthetic agents administered. As a result, tachycardia may not be observed in response to hypotension. Inhalational agents blunt baroreceptor function in a dose-dependent manner [35]. Although both opioids and propofol alter baroreceptor function, the effect is much less than observed with the inhalational agents [28]. Significant bradycardia can occur, however, because of the direct vagotonic effect of the opioids, especially fentanyl.

General Interactions of Cardiovascular Aging with Anesthetic Management

The most frequent cardiovascular problem that occurs with anesthesia in the elderly is hemodynamic instability, which manifests itself primarily as hypotension. The broad differential diagnosis of hypotension in the perioperative setting includes changes in cardiac rate, rhythm, preload, contractility, and afterload. In terms of heart rate, elderly patients may tolerate tachycardia poorly due to decreased time for filling during diastole, as well as imbalances in oxygen supply and demand. Thus, the anesthetic depth and sympathetic stimulation must be carefully titrated. Preload may be reduced due to anesthetic-induced vasodilation as well as decreased intravascular volume from fasting, blood loss, and insensible losses. Older adults with diastolic dysfunction may be highly dependent on adequate preload [7]. However, older adults are also at increased risk of fluid overload. Indeed, the balance of euvolemia is more delicate in the elderly than in the younger patient, as the clinical range between hypovolemia and fluid overload is narrowed. Anesthetic agents also decrease contractility and inhibit baroreceptor responses. Furthermore, older adults have diminished inotropic stimulation to β-receptor stimulation. This makes the aging heart with diastolic dysfunction more dependent on adequate preload to maintain cardiac output. Finally, anesthetic-induced sympatholysis may result in decreased systemic vascular resistance.

Perioperative congestive heart failure in the elderly occurs in a bimodal type of time frame. It may first appear in the immediate recovery phase after anesthetic emergence. It is most likely to occur when sympathetic tone reappears and may be the result of pain or fluid shifts from the peripheral vasculature to the heart. It may next appear on postoperative days two to three and likely occurs with mobilization of extravascular fluid. Late postoperative congestive heart failure is exacerbated by underlying renal dysfunction, and its prevention requires physician attentiveness and diuresis.

Mode of ventilation during anesthesia can have significant cardiovascular effects in the elderly. Positive pressure ventilation decreases venous return via an increase in intrathoracic pressure. Similarly, hyperventilation can cause hypotension via impairment of venous return. An additional mechanism of hypotension is the decrease in sympathetic tone associated with hypocapnea [36, 37]. Spontaneous ventilation is associated with less hypotension in the elderly patient with diminished cardiovascular reserve, because venous return is augmented during inspiration.

The prone position can be associated with a significant reduction in the cardiac index secondary to vena cava compression [38]. Both the sitting position and reverse Trendelenburg position decrease venous return and can worsen hypotension in severely preload-dependent elderly patients. Trendelenburg augments venous return. Lateral position is generally not associated with significant hemodynamic effects. Although right lateral decubitus has improved venous return over the supine and left lateral decubitus positions, the effect is probably minimal except in patients with congestive heart failure [39].

Laparoscopic insufflation causes decreased venous return. This, coupled with the depressant effect of anesthetic drugs, can result in hypotension. It is typical for $PaCO_2$ to slowly rise after 30 min of laparoscopy. This results from the increased CO_2 load and the decreased ability to eliminate CO_2 secondary to pneumoperitoneum. The hypercapnea and its associated increase in sympathetic tone [40] may cause hypertension and ectopy. Correction of hypercapnea requires ventilatory changes such as increased respiratory rate, tidal volume, and peak airway pressures, which may further impair venous return.

Elderly patients frequently take cardiovascular medications, which interact with anesthetics. For instance, bradycardias are apt to occur in anesthetized patients being treated with β-blockers and calcium channel blockers. Bradycardia may also be associated with anesthesia-specific medications such as high-dose narcotics, acetylcholinesterase inhibitors for reversal of neuromuscular junction blockade, and with a rare acetylcholine-like effect of succinylcholine (a short-acting neuromuscular relaxant). Under rare instances, heart block can occur; the risk increases with preexisting bundle branch block. Preoperative use of ACE inhibitors [41] and angiotensin receptor blockers [42] has been closely associated with increased risk of hypotension in anesthetized patients. It is controversial, however, whether discontinuing these medications preoperatively will decrease the incidence of perioperative hypotension.

Regional Anesthesia: Spinal and Epidural

Spinal and epidural anesthesia cause significant afterload reduction due to blockade of sympathetic fibers. Because the sympathetic fibers are small in diameter, they are highly susceptible to local anesthetic blockade. The sympathectomy associated with regional anesthesia has greater effects in the elderly because of limited ability to mount a compensatory response and possibly greater propensity to obtain a higher spinal anesthetic level [43]. With epidural anesthetics, the decreased compliance of the epidural space in the elderly is associated with achievement of a higher dermatome level of anesthesia with the same dose of local anesthetic in comparison to younger patients. A decrease in blood pressure with neuraxial blockade is nearly universal and often heralds the onset of motor and sensory blockade (Fig. 3). Preload reduction contributes to hypotension as well as afterload reduction. Tachycardia is the normal compensatory response but may be impaired in the elderly. With a very high sensory level (T1 to T4), the cardioaccelerator fibers may be blocked, thus precluding the tachycardia response and predisposing the patient to severe hypotension and reduction in cardiac output. When hypotension occurs after administration of spinal anesthesia in the elderly, volume loading is generally insufficient to correct the hypotension, and vasopressors are generally required [44]. Furthermore, excessive volume loading can be associated with ventricular dysfunction [45].

It should be noted that the careless use of spinal anesthesia in a hypovolemic patient with limited cardiac reserve will likely result in cardiovascular collapse. These events are associated with profound bradycardia, resulting from activation of the Bezold-Jarisch reflex. When patients are hypovolemic and spinal anesthesia is to be used, it may be best to use a continuous catheter technique. This allows slow titration of drug so that hemodynamic changes have a slower onset and can be treated in a timely manner. Epidural anesthesia also can be administered slowly via a catheter so that the hemodynamic response can be gradual and controlled. Even with gradual administration, there is a risk of rapid hemodynamic changes if the patient is not closely monitored.

Spinal and epidural anesthesia can be desirable modes of anesthesia in the elderly in order to attenuate the stress response to surgery, avoid central nervous system depressants, avoid airway manipulation and its associated pulmonary complications, and assist in postoperative pain management.

Pulmonary Implications of Anesthesia in the Elderly

Pulmonary complications are a major cause of postoperative morbidity in the elderly. Postoperative respiratory complications are associated with 40% of the perioperative deaths in patients older than 65 years of age [46]. The aging of the pulmonary system and anesthesia interact to increase the likelihood of these events.

Pulmonary Changes with Aging that Affect Anesthetic Physiology

Normal structural changes account for some of the increased risk of respiratory compromise in the elderly. There is a loss of elasticity of the lung tissue, and the chest wall becomes less compliant. The result is increased residual volume of the lung. Total lung capacity remains unchanged or slightly decreases, but the increase in residual volume causes a decrease in vital capacity [47]. The effect is increased work of breathing for given level of gas exchange and increased shunt and dead space.

The geriatric patient is more susceptible to hypoxia stemming from increased closing capacity of the small airways. As the aging lung loses elasticity, the smallest airways are no longer stented open by elastic tissue but instead rely on some minimal amount of lung inflation, or closing capacity, to maintain small airway patency. As lung volumes decrease with active expiration, there comes a point when the summation of intra-airway pressure and elastic forces stenting open distal air passages become insufficient to overcome the tendency of these distal airways to collapse. There is a general trend toward increased closing capacity with aging. By age 66, closing capacity exceeds functional residual capacity (FRC) in the sitting position [48]. When closing capacity exceeds FRC, some portion of the lung will be ineffective in gas exchange during at least part of the respiratory cycle. This mechanism leads to increasing V/Q mismatch in the elderly and a gradual decrease in blood oxygenation. On average the PaO_2 decreases 0.31 mmHg per year of age [47].

The loss of muscle mass with aging does not spare the muscles of respiration. Decreased muscle strength in the intercostals and accessory muscles of respiration impairs the ability to perform maximal ventilatory maneuvers and impairs the ability to mount a strong cough. Clearance of secretions is in part dependent on the patient having sufficient strength to perform the maneuver. Elderly patients are less able to maintain adequate tidal volume and generate sufficient inspiratory or expiratory force. If the weakness is severe enough, it may interfere with extubation and weaning efforts.

Other changes in the elderly that are of importance to anesthetic physiology include a blunting of the response to hypoxia and hypercarbia [49, 50]. In addition, aging leads to dysphagia, decreased esophageal motility, and decreased cough reflex.

The Interplay of the Aging Pulmonary System and the Effects of Anesthesia

During spontaneous ventilation, the inhalational agents decrease tidal volume and minute ventilation [51, 52]. This is associated with an increase in $PaCO_2$ and respiratory rate. In the absence of opioids or other respiratory depressants, profound tachypnea can occur. Despite the increase in respiratory rate, however, the net effect on the alveoli is a decrease in ventilation. In the anesthetized state, spontaneous ventilation in the supine position results in decreased functional residual capacity due to cephalad displacement of the diaphragm and inward displacement of the ribcage [53]. The work of breathing [54] is increased because the weight of the abdominal contents must be displaced with inspiration. Decreased functional residual capacity means less oxygen reserve prior to any apneic interval.

Ventilation-perfusion (V/Q) mismatching occurs during anesthesia and is caused largely by atelectasis [55] and impaired hypoxic pulmonary vasoconstriction. Atelectasis commonly forms in dependent regions of the lung shortly after induction of anesthesia and progresses as gas is absorbed from poorly ventilated regions [56]. Positive end-expiratory pressure can reduce atelectasis formation, but large tidal volume recruitment maneuvers are generally necessary to reverse shunt [57]. Hypoxic pulmonary vasoconstriction reduces blood flow to underventilated regions, but this mechanism is partially inhibited by anesthetic agents [58].

These physiologic changes mean that an A-a gradient is likely to occur in older adults under anesthesia. Impaired oxygenation is secondary to the anesthetic effects of decreased minute ventilation, increased atelectasis, and the aging effect of increased closing capacity. In addition, hypoxic pulmonary vasoconstriction is impeded by the aging effect on pulmonary vascular rigidity and by anesthetic inhibition.

Normal ventilatory drive depends on central and peripheral chemoreceptor response to hypercapnea, hydrogen ion concentration, and pH. The response to hypercapnea is independent and synergistic with the response to hypoxia. The carbon dioxide response curve is shifted to the right under anesthesia requiring higher CO_2 [59] for a given minute ventilation. Likewise, there is impaired response to hypoxia with even minimal residual inhalational anesthetic levels [60]. Ventilatory failure may occur secondary to the combined effects of anesthesia and aging to decrease minute ventilation, depress hypoxic and hypercarbic respiratory drive, and increase the work of breathing in the face of decreased muscle mass. This is particularly important in older adults.

Other anesthetic effects on the pulmonary system include impairment of bronchial mucociliary clearance in intubated patients [61] and impairment of swallowing reflex from pharyngeal dysfunction and risk of aspiration at subhypnotic concentrations of anesthetic [62]. Decreased pharyngeal tone results in upper airway obstruction. The incidence of apnea due to upper airway obstruction is increased in obese individuals.

The pulmonary implications of residual anesthetic effects after emergence are a serious issue in the elderly. Of primary importance are the effects of muscle relaxants. Age-related pharmacokinetic and pharmacodynamic changes interact with the decrease in muscle mass to potentiate the effects of these drugs, thus increasing the risk of respiratory compromise in the early postoperative period [63, 64]. The respiratory depressant effects of sedative agents, narcotics, and inhalational anesthetics are prolonged. As a special case, the inhaled anesthetics are eliminated primarily by the lung. Decreases in minute ventilation and cardiac output, as well as V/Q mismatch, will prolong the elimination of inhaled anesthetic agents [65, 66].

Laparoscopic surgery deserves special mention. The insufflation pressure during laparoscopy displaces the diaphragm cephalad; this reduces tidal volumes toward that of the dead space volume. In this case, adequate ventilation is maintained either by increasing the airway pressure to maintain adequate tidal volume or by decreasing insufflation pressures. Under these conditions, atelectasis develops at an accelerated rate. Low levels of PEEP may be used in this setting as long as intrathoracic pressures do not impair venous return so as to cause hemodynamic compromise.

Regional Anesthesia and Pulmonary Implications

With spinal or epidural blockade of sufficient dermatomal height for abdominal procedures, the musculature of the thoracic cage will be anesthetized, eliminating the contribution of the intercostal muscles to respiration. Spontaneous ventilation is still possible, however, because the diaphragm is the major muscle of respiration. In these circumstances, loss of accessory muscle function may be an issue in patients with limited pulmonary reserve. Protective airway reflexes are maintained although cough may be impaired.

Spinal and epidural anesthesia have been advocated as a means of decreasing postoperative pulmonary complications. Epidural anesthesia continued into the postoperative period may help in promoting early mobilization, cough, and deep breathing by relieving postoperative pain. In theory, spinal or epidural anesthesia helps to minimize the administration of central nervous system depressants during the perioperative period, thereby maintaining protective airway reflexes. It is common practice, however, for sedation to be administered during spinal and epidural anesthetics. Therefore, it is important to identify at-risk patients and verify recovery of protective reflexes in the elderly after an anesthetic, including sedation for spinal.

Physiologic Response to Anesthesia in the Aging Nervous System

Age-related decreases in central nervous system functional reserve lead to alterations in pharmacodynamics and increased susceptibility to postoperative cognitive dysfunction and delirium.

Altered Pharmacodynamics

Brain sensitivity to most anesthetic agents increases with age, as shown in Fig. 2.

This necessitates decreasing the drug dose in the elderly. The minimum alveolar anesthetic concentration (MAC) decreases by 5–6% per decade of age [67]. There is also a significant sensitivity to the common induction agent propofol [68]. Many opioids, including fentanyl, are more potent in older adults due to increases in brain sensitivity [69]. However, the pharmacodynamics of muscle relaxants do not appear to be altered with age. The underlying mechanism to explain altered brain pharmacodynamics is unclear at present. Altered brain pharmacodynamics may result from age-related changes in the receptors, signal transduction, or homeostatic mechanisms. Within

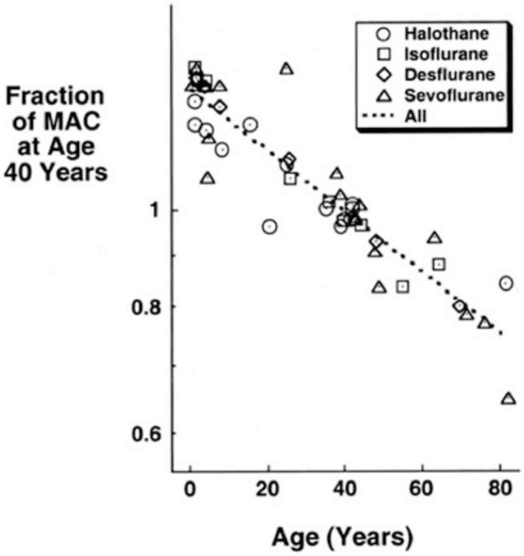

Fig. 2 Aging influences MAC in humans for desflurane, isoflurane, halothane, and sevoflurane. One MAC equals the minimum alveolar concentration at which 50% of subjects age 40 would not move in response to a surgical stimulus. MAC is at its peak in humans less than 1 year of age and decreases by approximately 40% in older adults.

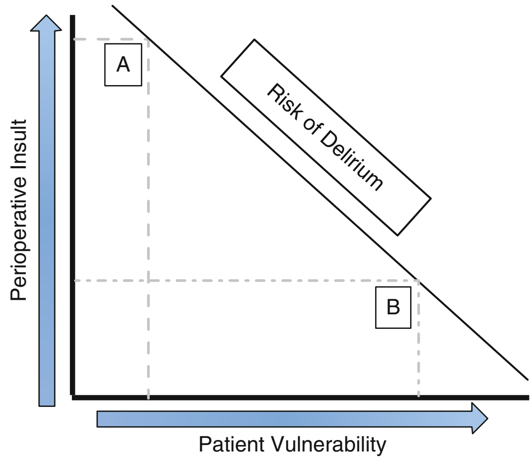

Fig. 3 Conceptual model of risk of delirium based on patient vulnerability and perioperative insult. Patient "A" has low vulnerability, so the perioperative insult leading to delirium is likely high. Patient "B" has high vulnerability, so the perioperative insult leading to delirium may be much lower

the central nervous system, aging is associated with decreases in dopaminergic and cholinergic neurons and receptors as well as a decrease in the number of synapses [70]. There are also alterations in brain phospholipid chemistry associated with changes in second messengers such as diacylglycerol [71]. A definitive association between these changes and age-related brain pharmacodynamics has yet to be established. Some components of the elderly drug response can also be explained by pharmacokinetic changes associated with aging [71]. These responses are specific to each drug and are highly related to drug distribution and clearance.

Increased Susceptibility to Postoperative Delirium and Cognitive Dysfunction

Sensitivity to anesthetic agents may manifest as neurologic dysfunction after surgery. The incidence of postoperative delirium and postoperative cognitive dysfunction has been reported to exceed 50% in certain surgical populations [72] and seems to be highest after cardiac surgery and hip fracture repair [73, 74]. Thus, postoperative delirium and postoperative cognitive dysfunction are two of the most common postoperative complications in the elderly, with an incidence that is higher than that of myocardial infarction or respiratory failure [75].

Postoperative delirium is thought of as an acute confusional state, characterized by changes in cognition, attention, and consciousness [76]. The pathophysiology of delirium is not well defined, but it generally results after an acute insult in a vulnerable patient. The degree of surgical or physiological insult required to precipitate postoperative delirium or postoperative cognitive dysfunction varies from patient to patient. As shown in Fig. 3, in patients with a high degree of preoperative cognitive reserve, a substantial insult is required for postoperative delirium and/or postoperative cognitive dysfunction to occur. Conversely, in patients with a lower degree of cognitive reserve, a relatively minor stress is all that is necessary for postoperative delirium and/or postoperative cognitive dysfunction to develop [72]. Several validated risk models for postoperative delirium have been developed in both cardiac

[74] and noncardiac [77] surgery. Important risk factors include patient age, education, baseline cognitive status, history of cerebrovascular disease, and other comorbidities.

The anesthetic contribution to delirium is unclear, but certain key anesthetic decisions may be important. A wide variety of drugs are associated with delirium, many of which are used frequently in the perioperative period. These include benzodiazepines, anticholinergics, opioids, corticosteroids, anticonvulsants, antidopaminergic, antiemetics, and H_2 antagonists [78]. In particular, the use of benzodiazepines has been strongly linked with delirium in the intensive care unit [79], although the evidence during surgery is less rigorous. Recent large trials have suggested a potential benefit for dexmedetomidine for perioperative sedation [80], even in extubated patients [81].

The benefit of regional compared with general anesthesia to reduce delirium has been investigated, with the hypothesis that sparing of general anesthesia would reduce the incidence of postoperative delirium. However, studies to date have not consistently supported that hypothesis [82]. One potentially confounding factor is the depth of anesthesia, since patients receiving a regional anesthetic may in fact have a level of consciousness consistent with general anesthesia [83]. Indeed, several trials have suggested that avoidance of excessively deep levels of anesthesia may result in less postoperative delirium [84–86]. An observational study further suggested an association between burst suppression and postoperative delirium [87].

Variation in intraoperative blood pressure has been proposed as a modifiable risk factor for delirium, with the hypothesis that inadequate cerebral perfusion may contribute to postoperative delirium [88]. Importantly, both low blood pressure and high blood pressure have been associated with delirium [89, 90]. However, the results have been inconsistent and there is no clear consensus on optimal blood pressure goals for older adults during surgery [91].

Pain may be an important risk factor for postoperative delirium [92, 93]. As a class, opiates are not associated with postoperative delirium, except for meperidine [94]. This may be because of its atropine-like structure and influence on brain cholinergic activity.

In the postoperative period, it is important to recognize that postoperative delirium may be the presenting symptom of a number of complications, including sepsis, urinary tract infections, myocardial infarction, stroke, and pneumonia [95]. Thus, the first step in managing postoperative delirium is to identify and treat underlying medical and/or surgical causes.

Changes in cognition that continue well beyond the perioperative period are commonly labeled as postoperative cognitive dysfunction (POCD). However, the definition of POCD is not clear, and the incidence of POCD varies dramatically according to the methodology used [96, 97]. Nevertheless, well-done studies have suggested an incidence of 6–33% in the early weeks after surgery, with declining incidence between 1 and 12% in the 3–12 months after surgery [96, 98].

Similar to delirium, the etiology of POCD is likely to be multifactorial, and the mechanism is unclear. POCD may even be independent of surgery and anesthetic, with a similar reported incidence of POCD among patients undergoing angiography with sedation, total hip replacement, and cardiac surgery [99]. However, in vitro and animal studies do suggest that inhalational and intravenous anesthetic agents alter neuronal function after exposure [100, 101]. Neurons exposed to anesthetics in vitro have increased oligomerization and cytotoxicity of β-amyloid, the protein associated with Alzheimer disease [102, 103]. In aged rats, exposure to anesthetic agents causes long-term declines in cognitive function [104, 105]. POCD is also highly related to underlying patient comorbidities, cognitive status, and cerebrovascular disease.

There is currently no standard of care for POCD prevention. However, an intriguing association has been reported between postoperative delirium and subsequent cognitive decline [106, 107], suggesting that prevention of delirium may be one strategy to prevent longer-term cognitive change.

Renal Implications of Anesthesia in the Elderly

Anesthesia decreases renal perfusion and glomerular filtration rate. When a patient receives an anesthetic, glomerular filtration rate may be acutely decreased by hypotension, redistribution of blood flow away from body core, or a specific pressure effect of laparoscopy. The potential for postoperative acute renal injury is greater with preexisting renal disease.

Drug excretion and metabolism by the kidney is proportionately decreased with aging. Many anesthetic drugs depend on renal elimination. Dose adjustment of most medications should be anticipated in the elderly. Of special note, many of the commonly used opioids and muscle relaxants have some component of renal elimination, and their effects are prolonged in the elderly. Fortunately, there are alternate drugs, with little or no dependence on renal elimination. Inhaled anesthetics are eliminated primarily by the respiratory route. Serum enzymes degrade certain drugs such as cisatracurium, remifentanil, and chloroprocaine. Due to the blood stream degradation of cisatracurium, this agent may be of special value in the elderly patient with renal impairment who requires muscle relaxation.

Hepatic Implications of Anesthesia in the Elderly

Hepatic functional reserve is fairly well maintained with healthy aging. As a result, anesthetic drug binding to serum proteins produced by the liver is not significantly affected. One potential effect of anesthesia is decreased hepatic blood flow. Hepatic blood flow parallels cardiac output and correlates with the rate of elimination of drugs with high hepatic extraction ratio [108, 109]. Commonly administered anesthetic agents with high hepatic extraction ratios include fentanyl, sufentanyl, lidocaine, meperidine, ketamine, and propofol. Drugs with lower hepatic extraction ratios are less impacted by hepatic blood flow.

Endocrine Implications of Anesthesia in the Elderly

Hyperglycemia is a frequent issue during surgery in the elderly patient. Inhalational anesthetics impair glucose tolerance. The mechanism is unclear but may be secondary to direct inhibition of insulin secretion [110]. Thus, hyperglycemia occurs in the anesthetized state with or without surgery. Insulin resistance and prevalence of diabetes is increased in the elderly. This effect is compounded in the face of obesity.

Thermoregulation

Normal human thermoregulation allows only small fluctuations in core temperature within the narrow interthreshold range of 0.2 °C; this range can be extended to 2–4 °C under the effects of anesthesia [111]. Multiple inputs from the core and periphery contribute to the detection of temperature variation. Peripheral sensation tends to contribute largely to behavioral aversion to unpleasant environments, while core sensing mechanisms have a relatively larger impact on autonomic responses [111]. The response to decreased temperature begins when the threshold of vasoconstriction is reached. Beyond the vasoconstriction threshold lies the threshold for the energy intensive shivering mechanism. Non-shivering thermogenesis, although important in neonates, is negligible in adults. The response to elevation in core temperature begins when the threshold for sweating is reached. With extremes of temperature elevation, active vasodilation can also occur [111].

During anesthesia, hypothermia is a common challenge as a consequence of several colluding factors. Preparations for surgery entail exposing large surfaces of the patient's skin. Operating rooms are traditionally kept very cool. Under anesthesia, vasodilation occurs as a direct anesthetic effect. This results in an immediate decrease in core body temperature from a redistribution of body heat from the core to the periphery and eventually results in greater dissipation of heat to the environment. By central mechanisms, anesthesia decreases the threshold temperature for vasoconstriction and shivering, allowing drift of the core temperature.

The elderly are predisposed to hypothermia [112] as a result of decreased muscle mass and neural and hormonal mechanisms. Thyroid function and overall metabolic rate decrease with aging. Decreased muscle mass leads to greater heat loss and less heat generation. The neural thermoregulatory mechanisms [112] are altered with a lowered threshold for vasoconstriction, decreased maximum vasoconstriction response, decreased α-adrenergic response [113], and decreased thermal perception.

These changes with aging compound the tendency, present among all patients, to develop hypothermia during both general and spinal anesthesia. The effects occur across a wide spectrum of anesthetic techniques and agents [114].

Complications of hypothermia include possible coagulopathy [115], increased risk of surgical wound infection [116], and increased cardiac risk [117] secondary to hypermetabolism if shivering occurs after emergence from anesthesia.

Anesthetic Drugs in Older Adults

As a general rule, using the shortest acting, most reliably cleared drugs in the geriatric patient population is an important strategy to overcome the increased sensitivity and potentially prolonged clearance of drugs used in anesthesia [118]. Further, it is important to recognize that delayed time to peak effect and increased sensitivity associated with aging can lead to "dose stacking" – a dangerous overshooting beyond the desired effect. To avoid dose stacking, slow, gentle titration of intravenous anesthetics such as propofol, with a dose that may be 50% of the weight-based dose in younger adults, is necessary. Hypotension should be anticipated and treated [119]. Further, polypharmacy and drug interactions must be considered, particularly when multiple drugs cleared by a common pathway are used, potentially leading to increased drug half-life.

Pharmacokinetic Considerations

Most intravenous anesthetic and analgesic drugs are cleared by Phase I and II metabolism in the liver [120]. Phase I reactions are mediated by the cytochrome p450 reductase family of enzymes and are a source of drug-drug interactions in daily life and in the perioperative period. Phase II reactions are rarely rate limiting steps and do not appear to be significantly affected by aging. The data are mixed as to whether cytochrome p450 (CYP) activity decreases with age [121, 122]. However, decreased hepatic blood flow, loss of hepatic mass, and changes in expression of CYP are likely contributors to delayed clearance of drugs used for anesthesia [120]. Further, pharmacogenetic variation in CYP isoenzymes may further influence individual variability in metabolism elderly patients [123].

Specific Anesthetic Drugs

Anxiolytics

Benzodiazepines are commonly used for anxiolysis and amnesia. In general, midazolam is the shortest acting benzodiazepine available and is the primary drug in the class considered for anesthetic purposes in the elderly patient. It is metabolized via hepatic hydroxylation by cytochrome p450 3A4 and 3A5 to its major metabolite l-hydroxymidazolam and is subsequently conjugated and excreted. Pharmacodynamic changes with aging result in increased sensitivity to midazolam and the starting dose should be reduced to 0.25–1 mg and titrated gently if needed [124]. When used alone, hemodynamic effects of midazolam are usually minimal. However, hypotension has been observed when midazolam is combined with fentanyl, propofol, or other anesthetic agents. The use of midazolam is controversial in older patients primarily because benzodiazepines have been associated with delirium in the ICU [125]. However, midazolam in small doses can be a useful adjunct during monitored anesthesia care with procedural sedation, especially when remifentanil, ketamine, or dexmedetomidine are the primary agents. Of note, benzodiazepines are reversible with flumazenil, a unique feature of this class of sedative/anxiolytic drugs.

Overall, the elimination half-life of midazolam appears to be moderately increased in elderly patients. Further, midazolam clearance has been shown to be prolonged by the simultaneous administration of propofol, as well as calcium channel blockers such as diltiazem, likely through interactions with CYP3A [126, 127].

Diazepam and lorazepam are longer acting benzodiazepines that have also been associated with delirium. Further, diazepam has active metabolites that can result in unpredictable clearance. In general, these longer acting benzodiazepines should be avoided in frail geriatric patients, except perhaps when treating seizures or withdrawal syndromes.

Remimazolam is an ultra-short acting benzodiazepine that is under Phase III investigation. It is rapidly cleared by tissue esterases with a half-life of approximately 8 min and remains reversible with flumazenil [128]. While the pharmacokinetics may be very attractive in the aged population, if it is approved further studies in the elderly will be needed.

Induction Agents

Propofol is the most commonly used intravenous anesthetic agent, providing excellent hypnosis, relatively rapid recovery after bolus dosing, and some protection against nausea. As discussed previously, propofol also causes significant vasodilation and potential hypotension that is exaggerated in older patients, especially in the presence of hypovolemia. In general, older patients require less drug (20–60% reduction) to achieve the same level of anesthesia. The initial propofol dose in the older patient is distributed in a smaller central volume of distribution, and the peak concentration may be more pronounced and prolonged compared with a younger patient in whom the redistribution occurs rapidly after the bolus dose. This translates to an increased sensitivity of older patients to smaller bolus doses and a delay to peak effect, including delayed peripheral vasodilation. Thus in the elderly patients, it is important to reduce the bolus and increase the interval between repeated doses to avoid dose-stacking. When continuous infusions of propofol are used, the context sensitive half-life can be prolonged and unpredictable, particularly in elderly patients, and this variability must be accounted for.

Etomidate is frequently used to induce anesthesia, especially in elderly patients, trauma victims, and emergency situations. Etomidate has less significant hemodynamic effects at typical induction doses compared with propofol because it tends to increase the SVR; thus, it requires less rescue with vasopressors [129]. However, in the elderly patient, it may still cause a reduction in cardiac output and hemodynamics may still need additional support. In general, the induction dose should be reduced by 25–50% in the elderly patient. Etomidate is associated with adrenal suppression. In retrospective studies, etomidate has been associated with increased mortality in hospitalized patients, but it is unclear if this is due to selection bias or causation [130].

Ketamine is an NMDA blocker that produces dissociative anesthesia. Ketamine causes the least respiratory depression of any sedative agent, has significant analgesic effect, and is synergistic with other anesthetic agents, including propofol, midazolam, and opioids. In the elderly patient, small doses of ketamine can reduce opioid requirements and offset the hypotensive effects of higher doses of propofol. While its use has been associated with psychomimetic effects and agitation in younger patients, this appears to be less of a problem in elderly patients, especially when administered with benzodiazepines or propofol. Preemptive low-dose ketamine infusions in the postoperative period have been used to treat significant pain that is resistant to traditional medications [131]. The opioid sparing effects of ketamine can be very useful in the older compromised patient. At these lower doses, there has been no evidence of any increased cognitive problems. Further, ketamine has been shown to have anti-inflammatory effects and may have cerebroprotective effects [132].

Opioids

Elderly patients exhibit increased sensitivity to central respiratory effects of opioid medications, and this may lead to an increase in the risk of unrecognized postoperative hypoventilation and apnea. In general, all initial opioid doses should be reduced in older patients and careful monitoring of both oxygenation and ventilation is required.

Fentanyl is a synthetic opioid, about 50–100 times more potent than morphine. It is lipid soluble and has a rapid onset of approximately 5 min, relatively short duration of effect and relative hemodynamic stability. Fentanyl does not cause histamine release. During induction of anesthesia, fentanyl has been shown to block the adverse hemodynamic effects of intubation [133, 134].

Remifentanil is another highly potent synthetic opioid that is becoming increasingly popular for short, stimulating procedures, especially in elderly patients in whom significant perturbations of the cardiovascular system can be deleterious. Remifentanil is metabolized by nonspecific esterases in the blood and tissue and is suitable for infusion. In older patients, the initial dose and infusion should be reduced by about 33%. When larger doses are administered bradycardia (that can be profound) and respiratory depression may occur, limiting use [69].

Hydromorphone is a semi-synthetic morphine derivative that causes less histamine release than morphine with similar duration of effect and half-life to morphine, but without significant active metabolites. In elderly patients, the volume of distribution and clearance are decreased and the half-life is increased. Thus, reduced dosing in elderly patients is important [135].

Morphine is the prototypical opioid for postoperative pain [136, 137]. Older patients show an increased sensitivity and decreased clearance. In the elderly patient, especially in the presence of renal failure, active metabolites can complicate the pharmacological profile and make the activity and duration of effect unpredictable. Several studies have suggested that the initial postoperative requirements of morphine are similar in old and young patients, but the maintenance doses should be reduced [138]. Further, morphine can cause significant histamine release.

Meperidine is no longer recommended as an analgesic, as its metabolite normeperidine can accumulate and cause seizures, and it has been implicated as a cause of delirium in elderly patients.

Neuromuscular Blocking Agents

Muscle relaxation during surgery is critical for exposure and to prevent patient movement and is generally achieved through the administration of nondepolarizing drugs such as vecuronium, rocuronium, and cisatracurium. These drugs are competitive antagonists of acetylcholine at the motor end plate. The most important anesthetic concern for the elderly patients is the complete reversal of these agents at the end of the surgery. Any residual drug effect could result in significant respiratory impairment in the recovery room, especially when combined with residual anesthetics and analgesic medications. For this reason, the longer acting muscle relaxant pancuronium should be avoided altogether in the elderly.

Sugammadex is a noncompetitive reversal agent that binds rocuronium and vecuronium, leading to reversal of neuromuscular blockade. While it has been used worldwide for several years, it was approved in the United States in December, 2015. Sugammadex appears to take longer to reverse neuromuscular blockade in elderly patients, but appears to be quite effective. Sugammadex is not currently indicated for patients with renal failure and has been associated with bradycardia and anaphylaxis. While it is promising, further studies in elderly patients are needed [139].

Inhalational Agents

General anesthesia usually includes the addition of a volatile anesthetic agent: the agents currently in use in the United States are sevoflurane, desflurane, and isoflurane. It is well documented that older patients require less volatile anesthetic to attain a suitable depth of anesthesia. The amount of inhalational agent decreases linearly with aging so by age of 80 years a patient requires 2/3 of that needed in a 20-year-old patient.

Other

Dexmedetomidine is an alpha 2 agonist that is more selective than clonidine. It is approved for sedation and has gained popularity as a sedative and anesthetic adjunct. Dexmedetomidine has analgesic properties and can be used in small bolus doses or continuous infusion. In addition to providing sedation and analgesia, dexmedetomidine is also a hemodynamic depressant and can cause hypotension and bradycardia and can be used in withdrawal syndromes. In general, the cardiovascular side effects must be considered and mitigated by patient selection, adequate volume resuscitation, and inotropic or vasopressor support. Recent studies have shown promise that dexmedetomidine may be beneficial in reducing the rate of postoperative delirium in elderly patients in both cardiac surgery and non-cardiac surgery [81, 140].

Acetaminophen is frequently overlooked as a useful opioid sparing analgesic in the immediate postrecovery phase. For the older patient without liver impairment, scheduled dosing is recommended and frequently combined with multimodal approach that includes low doses of NSAIDs or opioids [141].

Ketorolac is a NSAID available for intravenous administration. It can be a useful adjunct for pain relief and results in significant opioid sparing. Ketorolac, like all NSAIDS, must be used cautiously in elderly patients, especially in patients with dehydration or renal failure, a history of gastrointestinal bleeding, or anticoagulant or antiplatelet therapy. Postoperatively ketorolac should be administered for short duration, and in older patients the dose should be reduced by 50% starting at 15 mg and not exceeding total 60 mg/24 h.

Gabapentin is an anticonvulsant that has analgesic properties [142]. The mechanism of action of gabapentin is not fully understood, but involves binding to voltage-gated calcium channels. Single preoperative doses of gabapentin have been found to reduce pain intensity and opioid use in the first 24 h postoperatively. In addition, gabapentin administration is associated with a reduced incidence of postoperative nausea and vomiting, constipation, and urinary retention, although an increase in sedation has been noted, especially at higher doses.

Conclusion

Aging affects every body system, so the interplay between anesthesia and aging is necessarily complex. It is crucial to specifically consider age-related changes in the cardiac, pulmonary, and neurologic systems. Labile hemodynamics and potential for diastolic heart failure are important cardiovascular issues in older adults. The risks of postoperative ventilatory failure and pneumonia are increased in the elderly. Postoperative cognitive dysfunction is a common entity after all types of major surgery. Because of decreases in hepatic and renal reserve, pharmacodynamics and pharmacokinetic changes must also be taken into account. At this time, it is difficult to define the optimal anesthetic for the elderly. Rather, the anesthesiologist must understand age-related changes, important comorbidities, and the planned surgery to design an anesthetic that accounts for all of these factors and is based on fundamental principles of geriatric anesthesia.

Abstract
Arguably more than any other community, the care of the geriatric surgical patient draws on the full breadth of a physician's skills, interweaving a sophisticated understanding of age-related physiology, advanced therapeutics, and vigilant humanitarian concern for an at-risk and often neglected patient population. Seldom is this more evident than in the geriatric surgical patient in acute post-operative pain. In their review, Brennan, Carr, and Cousins note that "because pain management is the subject of many initiatives within the disciplines of medicine, ethics, and law, we are at an 'inflection point' in which unreasonable failure to treat pain is viewed worldwide as poor medicine, unethical practice, and an abrogation of a fundamental human right" (Brennan et al. Anesth Analg 105:205–221, 2007).

Introduction

In their review, Brennan, Carr, and Cousins note that "because pain management is the subject of many initiatives within the disciplines of medicine, ethics, and law, we are at an 'inflection point' in which unreasonable failure to treat pain is viewed worldwide as poor medicine, unethical practice, and an abrogation of a fundamental human right" [1].

Clearly this right to receive adequate pain management extends to the postoperative surgical patient of any age, and yet fear of uncontrolled postsurgical pain continues to be among the primary concerns of patients about to undergo surgery [2]. This fear is not unfounded since, despite increasing research and clinical attention, many adult surgical patients continue to experience moderate to severe pain, while less than half who undergo surgery report adequate postoperative pain relief [3, 4]. These findings are even more concerning when extrapolated to the elderly, who enter the surgical arena with higher levels of uncontrolled pain, particularly those who are cognitively impaired [5, 6].

The elderly are also more likely to have multiple comorbidities with less physiologic reserve, which compounds their risk for postoperative complications. For instance, uncontrolled acute pain in the postoperative setting leads to increased sympathetic activity which in turn leads to tachycardia, hypertension, and increased myocardial oxygen demand [7]. In elderly patients with coronary artery disease, the risk of myocardial infarction increases. Inadequate postoperative analgesia in the elderly has been linked to longer hospitalizations, lengthier rehabilitation, frequent readmissions, and the aforementioned cardiopulmonary morbidity. Less well recognized is the fact that inadequate acute postsurgical pain management can lead to chronic pain syndromes [8–10]. Chronic neuropathic pain states are difficult to treat once established and can affect the future quality of the patient's life through a constellation of maladaptive physical, psychological, family, and social consequences [11] (Fig. 1).

In addition to the objective physiologic implications, pain exists simultaneously as a subjective psychological phenomenon. Many factors combine to form a patient's concept of pain, including previous pain experiences, cultural background, coping styles, social supports, the degree of control felt over the pain/disease, fear, anxiety, and depression [12]. This subjectivity extends to those

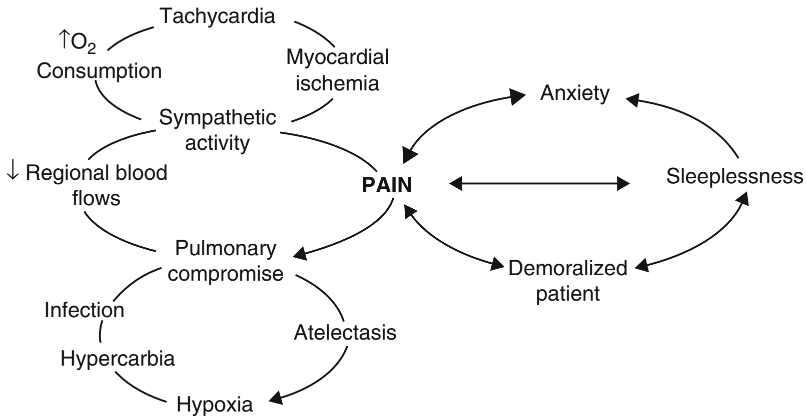

Fig. 1 Harmful effects of unrelieved acute pain (reprinted from Sinatra [7], with permission from Elsevier)

caring for the elderly patient as well, subtly influencing behavior and care patterns.

The global population is aging due to parallel declines in mortality and fertility rates [13]. By the year 2050, there will be a fourfold increase in the elderly population compared with only a 50% global population increase, and at that time 25% of the elderly will be over the age of 80 [14]. The US geriatric population is quickly growing, with 10,000 individuals reaching the age of 65 every day. In 2007, adults 65 and older comprised only 13% of the US population but represented 43% of all inpatient hospital days [15]. Elderly patients have surgery four times more frequently than the younger population, and these tend to be more painful, including elective joint replacements, emergent reductions of fall-related fractures, and complex surgeries for cancer [16].

However, there is little merit in considering the treatment of acute pain in the elderly population unless it differs from that provided to younger patients [14]. This begs the questions of whether elderly patients perceive pain differently from younger patients; are there changes in nociception that occur with aging, and do elderly patients process and respond to nociception differently?

Nociception Is Not Pain

Activity induced in the nociceptor and nociceptive pathways by a noxious stimulus is not "pain," which is always a psychological state. Although we appreciate that pain most often has a proximate physical cause, especially acute pain, activity in nociceptor systems is not equivalent to the "experience of pain" [17]. The recognition that pain serves an important biologic function related to survival raises the important question: to what extent do age-related changes in nociception impact on the capacity of the pain experience to fulfill an "enteroceptive" function such as thirst, hunger, and thermoception that constitute sensory indexes of the health of the body? [18].

Assessment and intervention for pain in the elderly should therefore begin with the assumption that all neurophysiologic processes subserving nociception are intact [19]. In fact Gagliese and Melzack demonstrated that age did not affect the rating of pain by postsurgical patients [20]. That is to say, tissue injury produces the same experience of pain in an elderly person as in a young person.

There are data to suggest, however, that some impairment of Aδ fibers occurs with aging and therefore impedes the early warning of tissue injury [18]. There are also data that suggest that widespread and substantial changes in structure, neurochemistry, and function occur in the dorsal horn of the spinal cord and CNS with aging [18].

Multiple studies report reductions in the descending inhibitory modulating systems for nociception in the elderly [18, 21]. Gibson and Ferrell conclude that the reduced efficacy of endogenous analgesic systems might be expected to result in a more severe pain experience following prolonged noxious stimulation [18]. It is also possible that the documented decline in afferent transmission pathways could be offset by a commensurate reduction in the endogenous inhibitory mechanisms of older persons, with a net result of little or no change in the perceptual pain experience [18]. They further conclude that any deficit in endogenous analgesic response (which is stimulus intensity dependent) will become critical, thereby making it more difficult for persons of advanced age to cope with severe or persistent clinical pain conditions [18].

Evidence suggests that as age advances, pain threshold increases, but pain tolerance decreases [22]. The net effect may be that elderly patients experience acute surgical pain in the same way as younger patients. It is clear that if a surgeon was to make a skin incision with a scalpel in an elderly unanesthetized patient, then the patient would most certainly scream with pain. Yet silent myocardial infarctions are more common in the elderly, and the bowel must be more distended before the elderly sense pain, often delaying the diagnosis of such conditions as a bowel obstruction [22, 23].

With respect to the heart, the complete absence of "the perception of pain" that can occur in the presence of myocardial ischemia, arteriolar occlusion, myocarditis, early acute endocarditis, valvular ulceration, etc. makes it difficult and yet extremely important to assess for pain in elderly patients recovering from surgery [24].

But while there is controversy over whether the number and integrity of nociceptors decreases with age, the clinical position that age dulls the "sense of pain" is untenable [18]. It is the processing and transmission of the nociceptive information that may be altered in the elderly, and the elderly may be more sensitive to the side effects of medications that are used to treat pain. These observations thereby give the impression that the elderly are less sensitive to pain. But no physiologic changes in pain perception in the elderly have been demonstrated according to a five-state study by Cleeland [23]. This is supported by the observation that age does not affect the success of traditional interventions for the treatment of pain [19].

Again one would not assume that a surgical incision in an elderly patient will "hurt" less and therefore does not need to be treated. Likewise, anyone who has observed an elderly patient with acute herpes zoster certainly can attest to the excruciating pain that these unfortunate patients report. If given adequate preoperative teaching, assessed preoperatively for any impediments to the use of patient-controlled analgesia (PCA), e.g., dementia, elderly patients were successfully started on PCA in the postanesthesia care unit after general anesthesia once they were awake and responsive enough to receive a loading dose of opioids titrated to comfort [19].

Pharmacodynamics/Pharmacokinetics, Organ Function, and Aging

The aging process is characterized by a progressive functional decline in all organ systems as well as compromised organ reserves, which can negatively affect the ability to deal with perioperative stress. Even the fit elderly patient's ability to compensate for perioperative stress is compromised. These physiologic changes impact the pharmacodynamics and pharmacokinetics of anesthetic and analgesic medications [25]. Because baseline cardiac, hepatorenal, and neurologic functions are typically adequate in the absence of acute challenges, it can be very difficult to predict the effect of perioperative stress on the older patient [26].

In general, the pharmacodynamic actions of drugs (what the drug does to the patient) are unaffected in the normal aging process, although dose requirements to produce the same effect may change with age, and the therapeutic window between intended effect and side or adverse effects may be narrowed in the elderly [27–29].

The pharmacokinetic actions of drugs (what the patient does to the drug), on the other hand, are more greatly affected by the reduced cardiac output and organ blood flow of aging. These pharmacokinetic changes may complicate medication management [30], as demonstrated by Woodhouse and Mathur who studied the 24-h cumulative PCA opioid administration as a function of age. Morphine and fentanyl both showed an expected reduction in dose by 50% in the elderly, while meperidine was more variable due to a more complex pharmacology [31].

A general slowing of the CNS and alterations in drug metabolism and excretion account for much of the increased sensitivity to analgesics in the elderly [32]. There is decreased cerebral blood flow, decreased cortical mass, and as noted above altered perception and affective expression of pain. Similarly decreased blood flow to peripheral nerves can combine with common comorbid conditions such as diabetes to cause peripheral nervous system dysfunction manifesting as decreased sensitivity to pain, temperature, and pressure.

The liver exhibits decreased hepatocyte mass and blood flow, decreased cytochrome p450 function, and prolonged drug metabolism [33]. There is an age-related decrease in basal metabolic rate of the liver and a decline in albumin production of about 10% [34]. Although most tissues have some enzymatic metabolism, the majority occurs in the liver. Patients with impaired liver function will therefore have altered metabolic capacity for drug elimination, particularly demethylation. Drugs that are administered simultaneously and that are metabolized by the p450 system of enzymes will compete for binding sites leading to altered blood levels [35].

With aging there is a decreased lean body mass and total body water and an increased proportion of body fat; these alter the volume of distribution and redistribution of drugs and alter their rates of clearance and elimination [26]. Renal blood flow is compromised, approximately 10% per decade of life after the age of 50 with a concomitant loss of renal parenchyma, demonstrated best by decreasing glomerular filtration rate (GFR) rather than blood urea nitrogen/creatinine ratios [36]. Anesthetics, surgical stress, pain, sympathetic stimulation, and renal vasoconstrictive drugs may all compound subclinical renal insufficiency [26]. Impaired renal clearance may lead to accumulation of metabolites, increasing the half-lives of renally cleared drugs. Similarly, decreased plasma binding increases blood levels of active drugs such as opioids and NSAIDs [even the specific cyclooxygenase 2 (COX-2) inhibitors, such as celecoxib (Celebrex®)] [37]. Taken together these factors account for the increased incidence of medication side effects, iatrogenic overdosing, and drug-drug interactions in the elderly.

Perioperative Cognitive Impairment and Pain

Pathologic perioperative CNS dysfunction, as distinguished from physiologic CNS changes of aging, is a common phenomenon in elderly surgical patients and can complicate pain management [38]. Postoperative cognitive dysfunction (POCD) is a postoperative memory or thinking impairment that has been corroborated by neuropsychological testing [39], while postoperative delirium (POD) is defined as an acute change in mental status, with inattention and altered level of consciousness throughout the course of the day [40].

POD is typically transient and acute, while POCD is a more persistent problem of a change in cognitive performance, often noticeable to the patient and/or family. Preoperative confusion is a predictor for POD, which can occur in 5–15% of elderly patients undergoing noncardiac surgery, and up to 60% of cardiac and orthopedic procedures. POCD has been found to occur in 10–13% at 3 months and can have significant socioeconomic and medical implications including increased risk of death in the first year after surgery [18, 41, 42].

Little is known of the neurophysiological relationships between pain- and age-related degenerative brain diseases. The elderly patient with cognitive impairment is at a greater risk than cognitively intact patients for undertreatment of pain [43]. Studies indicate that individuals with cognitive impairment maintain normal pain perception thresholds [44]; however, altered central processing of pain stimuli at the cortical level where neurodegeneration is present can alter the patient's expression of pain. This is above and in addition to the physiologic CNS changes of aging but similarly impacts the affective component of pain primarily. Significant pain may therefore go unrecognized in the cognitively impaired, as clinicians and nurses assess pain in large part based on affect and pain behavior. It has been shown as well that the type of pain with which a patient presents may harbor bias toward undertreatment [45].

Various interventions have been studied to attempt to decrease the occurrence of POCD, including multimodal analgesia techniques and perioperative vitamin supplementation, though no clear effective strategy has been proven [46, 47]. As uncontrolled postoperative pain is a primary contributor to POD/POCD, the best course of action appears to be adequate analgesia along with anticipatory perioperative support should the inevitable CNS dysfunction occur.

Perioperative Pain Management Planning

As with any surgery, a complete history and physical exam prior to admission is paramount in obtaining a good postsurgical outcome. Acute pain in the perioperative setting can be compounded by preexisting chronic pain, which has been documented to exist in 25–73% of older people in the community and skilled-nursing facilities of Western nations [48]. Assessment and documentation of preexisting pain should be thorough with reference to location, intensity, aggravating/relieving factors, quality, and radiation. Comorbid psychological, emotional, and cognitive factors are predictors of postoperative side effects including pain, nausea, and fatigue and should be well documented as well [49].

Approximately 40% of elderly patients take at least 5 drugs per week, and 12–19% use at least 10 [50]. Thorough documentation of medications including the preoperative analgesic regimen will help anticipate post-op pain requirements as well as medication interactions. Consideration should be given to continuing adjuncts and anxiolytics throughout the perioperative period albeit at a reduced dose, particularly if the patient is physically dependent on them despite being generally contraindicated in the elderly. This may include centrally active muscle relaxants such as carisoprodol and common benzodiazepines. Antidepressants should be continued with consideration for any interactions with anesthetic and analgesic medications.

Education, Counseling, and Forming a Plan

The American Pain Society recommends preoperatively providing individually tailored programs of education and support for patients and families with more intensive needs such as the elderly and cognitively impaired. Such a strategy may provide for reduced postoperative opioid consumption, less preoperative anxiety, fewer requests for sedative medications, and reduced length of stay after surgery [51].

Meeting with patients and their families preoperatively is an important opportunity to educate them about their care while simultaneously dispelling commonly held notions which may hinder pain control. For example, older patients may endure pain longer, waiting until it is severe before reporting to the nursing staff [52]. Men in particular may fear being viewed as weak if they report their pain [53]. Older generations often acquiesce to the opinions and beliefs of family members which may in turn prevent them from being honest about their own pain [54]. It has been suggested that older people fear a loss of independence and may play down their pain in an attempt to maintain autonomy [55].

These sociological biases extend to medical practitioners as well. Common misconceptions include pain being a normal part of the aging process, perception of pain decreasing with age, older people using pain as a means of seeking attention, and opiates as dangerous or addictive to the elderly [56–59]. Patients, families, and practitioners alike may benefit from pertinent information and education relating to analgesia in the pre- and postoperative period [60].

During the perioperative planning, every attempt should be made to minimize or negate the elderly patient’s hospital stay entirely. Bed rest can induce functional decline in elderly patients after only 2 days of hospitalization. The worse the patient's functional status is preoperatively, the greater the expected benefit of avoiding hospitalization [61]. Elderly patients are less able to adapt to unfamiliar environments and routines and recover faster in their familiar home environment. Avoiding hospitalization in the elderly undergoing minor surgery has been shown to result in less POCD at 1 week, as well as reduced respiratory events, nosocomial infections, and early postoperative complications [62].

Along these lines, Launay-Savary et al. [63] recently reviewed the evidence as to the feasibility and efficacy of enhanced recovery after surgery (ERAS) programs in the elderly, finding them overall beneficial for patients over 70 undergoing colorectal surgery. These multidisciplinary care protocols target specific perioperative goals such as analgesia, re-feeding, drains, surgical approach, and postoperative care in an attempt to minimize perioperative morbidity and mortality. While no longer questioned in younger patients, the increased frailty and age-related morbidity of the elderly warrants special adaptation of the endpoints to this population. Examples include returning to the same domicile, maintaining a certain quality of life the patient is accustomed to, and avoiding loss of autonomy. While morbidity remained increased and compliance to such protocols decreased when compared to younger patients, the reduced duration of hospital stay and overall morbidity when compared to age-matched non-ERAS patients attest to the efficacy of ERAS versus traditional management.

Methods of Post-Op Pain Assessment

Adequate pain management would be impossible without accurate and reliable methods of measuring pain. Established methodology breaks down into self-reported and behavioral/physiologic methods, each offering different efficacies depending on the cognitive state of the patient. Common self-report scales used to measure pain intensity include the visual analogue scale (VAS), verbal rating scale (VRS; using familiar words such as none, slight, mild, moderate, and severe), numeric rating scale (NRS; 0 = no pain; 10 = worst imaginable pain), and facial pain scale (FPS) [64, 65]. In the postoperative setting, the VRS and the NRS are most validated as well as preferred by elderly populations [66, 67]; however, they require the patient to have minimal to no cognitive dysfunction.

In those with mild to moderate cognitive dysfunction, the VRS stands out as the preferred tool though patience and persistence may be required to obtain answers [68]. For those with severe cognitive dysfunction as in dementia or POD, behavioral methods are necessary and assessment of the patient's pain by family or caretakers may be helpful. The Doloplus and Doloplus-2 are batteries of assessments taking into account somatic, psychomotor, and psychosocial elements to render a pain level. They have been validated for elderly postoperative populations, but can be time-consuming to obtain [69]. The Algoplus is a more recent behavioral acute pain scale validated in elderly patients unable to communicate [70], and may be obtained by briefly observing the patient with regard to face, gaze, body, behavior, and auditory indices. Two or more positive signs out of the five categories indicate pain.

Whichever method is ultimately chosen, it is important to consistently reassess not only for pain but for efficacy of interventions and side effects, with adjustments to the pain management plan following accordingly. In the postoperative period "dynamic pain relief" or the patient's ability to ventilate deeply, cough, and ambulate without pain are important indices of adequate analgesia as well.

Multimodal Therapy

As we have seen the elderly present a heterogeneous mix of physiological changes, comorbid conditions and medication regimens for which broad generalized pain management strategies are difficult. Each case presents a unique challenge.

With that in mind, we will now start developing our toolbox with which to treat acute postoperative pain. The analogy is appropriate, for the role of pharmacologic adjuvants and nonpharmacologic techniques in postsurgical analgesia has been greatly expanded over the past years in part because of increasing awareness of the morbidity attributed to opioids [71]. The concept of balanced or multimodal analgesia was developed to both improve analgesic efficacy and reduce side effects [72]. Targeting different receptors and pain mechanisms with smaller individual amounts of medications creates an opioid-sparing synergy which may work to decrease postsurgical morbidity and mortality in geriatric populations. Appropriate selection is critical; however, a contraindicated tool will potentially cause more harm than good.

Systemic Pharmacologic Therapy

Opioids

Despite the cautionary rhetoric, opioids remain the closest drugs we currently have to an ideal analgesic. They exhibit no ceiling effect and can produce profound analgesia by progressive dose escalation. They are the most effective agents for the relief of any type of acute pain because of their predictable dose-dependent response, which is only altered in the elderly by their increased dose sensitivity. Their versatility is unmatched. They are effective when given orally, parenterally via provider bolus or patient-controlled analgesic (PCA) formulations, or neuraxially via epidural (infusion or patient controlled epidural analgesia [PCEA]) or intrathecal routes.

Opioids have been shown to produce a greater incidence of respiratory depression, cognitive depression/delirium, constipation, and sedation in the elderly; but the elderly seem to be less sensitive with respect to nausea and vomiting [73]. Opioids have no significant long-term organ toxicity and can be used for years [74]. Addiction is negligible when opioids are used appropriately in the context of medical care [75].

Morley introduced a concept of "Broad Spectrum Opioids" versus "Narrow Spectrum Opioids" [76]. The narrow spectrum opioids have analgesic actions limited to the Mu, Kappa, and Delta opioid receptors. For purposes of acute postoperative pain management, we are primarily dealing with Mu opioid agonists. The broad spectrum opioids find more usefulness in chronic pain and neuropathic pain with their Mu opioid action enhanced by actions also as *N*-methyl d-aspartate (NMDA) receptor antagonists. In addition, some have central neuromodulating effects through inhibition of reuptake of serotonin and norepinephrine similar to many antidepressants. Some broad spectrum opioids have all three properties (e.g., methadone).

When opioids are used in a fixed oral dose mixed with a nonopioid analgesic, their efficacy is limited by the maximal safe dose for the adjuvant (acetaminophen, aspirin, or NSAID typically). A list of the common combination oral opioids is shown in Table 1.

The concept of "start low and go slow" is paramount with opioid use in the elderly. Many oral formulations are scored for use as half-doses. Patients experiencing moderate pain should be started on a weak opioid. Strong opioids are used for more severe pain such as postsurgical. They have a wide therapeutic window and no ceiling effect, with higher doses producing an increasing level of analgesia. They are the agents of choice for parenteral administration [77].

Weak Opioids

Codeine, an alkaloid of opium, is the prototype "weak" analgesic. Although a parenteral preparation is available, it is nearly always given orally and often in a fixed mixture with a nonopioid analgesic. It is 10–20% less efficient than morphine; a 200 mg dose is equipotent to 30 mg of morphine. The half-life of codeine is 2.5–3.0 h [77]. Codeine is often combined with acetaminophen with or without caffeine in doses of 300 mg acetaminophen, 30 mg codeine, and 15 mg caffeine (e.g., Tylenol 3™). Codeine is converted to Codeine-6-glucuronide, a renally excreted metabolite with activity equal to the parent compound. This will prolong activity and toxicity in patients with renal insufficiency; doses should be halved and spaced out accordingly [69].

Table 1 Combination opioids available for oral administration. The dose is limited by the adjuvant and not the opioid component. The maximum doses should be reduced in the elderly or in the presence of liver and renal insufficiency

Trade name®	Opioid component	Dose of opioid (mg)	Adjuvant drug	Dose of adjuvant (mg)	Tabs/caps per day
Advil			Ibuprofen	200	12
E.S. Tylenol			Acetaminophen	500	8
Tylenol-3	Codeine	30	Acetaminophen	300	13
Tylenol-4	Codeine	60	Acetaminophen	300	13
Darvon	Propoxyphene	65			NL
Darvocet	Propoxyphene	65	Acetaminophen	325	13
Darvocet N-100	Propoxyphene	100	Acetaminophen	325	13
Vicodin	Hydrocodone	5	Acetaminophen	500	8
Vicodin ES	Hydrocodone	7.5	Acetaminophen	750	5
Lortab Elix	Hydrocodone	7.5	Acetaminophen	500	8
Lorcet 10/650	Hydrocodone	10	Acetaminophen	650	6
Norco	Hydrocodone	10	Acetaminophen	325	13
Vicoprofen	Hydrocodone	7.5	Ibuprofen	200	12
Percodan	Oxycodone	5	Aspirin	325	6
Percocet	Oxycodone	5 10	Acetaminophen	325	13
Tylox	Oxycodone	5	Acetaminophen	500	8
Oxycodone	Oxycodone	5			NL

Hydrocodone is a codeine derivative, available in the USA in combination with acetaminophen, aspirin, or ibuprofen. It is more potent than codeine, although good data are lacking [77].

Codeine (Tylenol™ 3 or 4), dihydrocodeine (Synalgos™ DC), and hydrocodone (Vicodin™, Lortab™, Norco™, etc.) do not have opioid action until they undergo metabolic conversion to morphine or hydromorphone respectively by the action of the enzyme CYP2D6, one of the P450 group of enzymes [78]. Eight to thirty percent of the population is reported to be deficient in this enzyme and therefore will have a poor to absent response to these medications [79]. In addition, there are a number of drugs common in elderly populations which will depress the action of CYP2D6 leading to decreased analgesic efficacy, such as amiodarone (Cordarone®), fluoxetine (Prozac®), haloperidol (Haldol®), paroxetine (Paxil®), propafenone (Rythmol®), quinidine, ritonavir (Norvir®), terbinafine (Lamisil®), and thioridazine (Mellaril®) [78].

Oxycodone is a semisynthetic derivative of the baine, an opium alkaloid. Because of its high bioavailability (>50%), it is suitable for oral administration and is 1.5 times more potent than morphine by this route and 10 times more potent than codeine [80, 81]. When administered parenterally, its intensity and duration of analgesia are 25% less than those of morphine [81]. However, in the USA, oxycodone is exclusively an oral medication. Oxycodone given orally has a half-life of 2–3 h and duration of action of 4–5 h. It is metabolized like codeine: demethylated and conjugated in the liver and excreted in the urine [81]. Oxycodone has been considered a "weak" analgesic because of its use in a fixed combination with acetaminophen and aspirin, e.g., Percocet® (oxycodone 2.5, 5, or 10 mg with acetaminophen 325 mg) or Percodan® (oxycodone 5 mg with aspirin™ 325 mg) which limits its dose. When oxycodone is used alone, it has no ceiling effect for analgesia. It is more potent than morphine, and there are reports suggesting that it might have fewer side effects [82, 83]. Its availability in 5 mg tablets permits careful titration in patients with a narrow therapeutic margin. It is also available in extended-release preparations with doses of 10, 20, 40, and 80 mg without acetaminophen, which can be used for q12h dosing or occasionally q8h dosing.

Oxycodone is therefore a versatile and flexible oral medication that can be used to treat pain of any intensity requiring an opioid analgesic [77]. It is also interesting that patients who report poor analgesic effect from codeine- and hydrocodone-based opioids will report excellent analgesia from oxycodone-based analgesics. This is a result of enzymatic metabolism of oxycodone by CYP2D6. Therefore, the patients who are deficient in this enzyme cannot convert codeine or hydrocodone to morphine, but also will not metabolize oxycodone quickly and therefore have a prolonged effect from oxycodone [78]. The reverse would also be true in that those patients who genetically have high levels of CYP2D6 will get excellent analgesia from codeine or hydrocodone, but oxycodone although effective will have a shortened duration and require more frequent dosing.

Tramadol (Ultram®) is weak opioid analgesic that also inhibits the reuptake of serotonin and norepinephrine while providing some NMDA-antagonistic properties. It has about one-tenth the potency of morphine and is effective for mild to moderate pain. Unlike other opioids, tramadol exhibits an analgesic ceiling, which limits its use for severe pain syndromes. Tramadol appears not to be associated with physical dependence but does have a relatively high incidence of associated nausea compared with that of other opioids [84]. Similar to codeine, it depends on CYP2D6 for production of its main active metabolite, O-desmethyl-tramadol, which is renally excreted and may accumulate in patients with renal insufficiency. Those without CYP2D6 activity will be resistant to the analgesic effects of Tramadol. It can be given IV with less respiratory depression and constipation than morphine [68]. Tramadol is also available as a combination drug with acetaminophen (Ultracet® 37.5 mg tramadol/325 mg acetaminophen) or as a sustained-release tramadol of 100 or 200 mg (Ultram® ER).

Tramadol should be used with caution in patients with epilepsy or taking seizure-lowering medications. Additionally, it is contraindicated with monoamine oxidase inhibitors (MAOI) for fear of serotonin syndrome. Use with serotonin-reuptake inhibitors (SRI) should be monitored [85]. A maximum daily dose of 300 mg is suggested for healthy individuals, with a reduction to 200 mg in patients with other risk factors [86].

Tapendatol (Nucynta®) is an oral, centrally acting synthetic mu-agonist with norepinephrine reuptake inhibiting properties. In the USA, it is approved for moderate-severe pain. In orthopedic postsurgical musculoskeletal pain, 50–100 mg every 4–6 h was equivalent to oxycodone 10–15 mg every 4–6 h with decreased incidences of nausea, vomiting, and constipation [87].

Strong Opioids

As described by Morrison et al., *morphine* is the prototype strong opioid agonist [77, 88]. Like other “strong” opioids, there is no ceiling to the analgesic effect, although side effects, particularly sedation and confusion, may intervene before optimal analgesia. Morphine is metabolized in the liver, where it undergoes glucuronidation at the 3- and 6-positions. Morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G) accumulate with chronic morphine administration [89]. M6G binds to Mu receptors with affinity similar to morphine but also binds to delta receptors, which may account for its higher analgesic potency [75, 90].

M6G appears to be 20 times more analgesic than morphine when administered directly in the periaqueductal gray, but only 0.077% of this metabolite crosses the intact blood–brain barrier following oral or parenteral administration [90, 91]. With single-dose morphine studies, the relative parenteral/oral potency ratio is 1:6 [92]. After chronic use, the ratio changes to 1:3 as a result of the accumulation of active metabolites [93]. There is experimental [94] and clinical [95] evidence that M3G, which has negligible affinity for opioid receptors and does not produce analgesia, has excitatory effects on neurons and can cause myoclonus and rarely a hyperalgesic state [90]. It is thought that the myoclonus and hyperalgesia precipitated by M3G are mediated by different receptor mechanisms [96].

The half-life of morphine is about 2 h but the onset time for analgesia from a bolus dose can be as long as 90 min [97]. Shafer and Flood comment that this slow onset of analgesia should make it difficult to titrate morphine [30] even though Auburn showed that titration of small morphine doses every 5 min was safe and effective in the elderly [28, 97].

Extended-release oral preparations of morphine have been available for many years in many different doses permitting q8h, q12h (MS Contin™), and once daily dosing (Kadian™ and Avinza™). Slow-release preparations should be used only after dose titration with morphine sulfate and only if the pain is expected to continue [77]. Morphine metabolites are eliminated by glomerular filtration and can accumulate in patients with renal insufficiency, leading to an increased incidence of side effects [98]. Opioids with fewer or no active metabolites are preferable in frail patients and those with renal disease [x].

Hydromorphone (Dilaudid®) is a potent semisynthetic phenanthrene-derivative opioid agonist [24]. When single doses are administered parenterally, 2 mg of hydromorphone is equipotent to 10 mg of morphine. Hydromorphone is somewhat shorter acting than morphine but has a higher peak effect. Its bioavailability is 30–40% with an oral to parenteral ratio of 5:1 [99]. It has a half-life of 1.5–2.0 h, and active metabolites may accumulate during renal failure [100]. Because hydromorphone is highly water soluble, continuous subcutaneous infusion and intravenous infusions of hydromorphone result in similar analgesia and side effects [101].

Fentanyl is a synthetic phenylpiperidine-derivative opioid agonist that interacts primarily with Mu receptors [102]. It is 80–100 times more potent than morphine and highly lipophilic [30]. The onset time for analgesia when administered intravenously is 2–3 min making it an ideal agent for analgesic titration, intra-op, and in the post-anesthesia care unit (PACU).

Fentanyl is also available in both a transdermal (Duragesic™) form and oral transmucosal (Actiq™) form. The transdermal form is not recommended, however, for the treatment of postoperative pain because the titration is lengthy and it lacks the flexibility, which is the cornerstone of treatment for acute and evolving pain. Oral transmucosal fentanyl is being used for severe breakthrough pain requiring rapid onset without intravenous access (e.g., at home). Its inherent safety is that the patient can discontinue administration with the onset of analgesia without having to use the entire dose; however, Actiq™ is only FDA approved for cancer pain.

Methadone is a synthetic diphenylheptane-derivative opiate mu agonist with serotonin/norepinephrine reputake inhibition at the level of the spinal cord, as well as NMDA antagonistic properties [103]. It is an inexpensive and effective analgesic, but its use is limited by the need for a carefully individualized dose and interval titration. When administered to opioid naive patients, especially the elderly, the risk of overdose is high. It should therefore be used only for selected patients and only by individuals experienced with its use [104]. The oral bioavailability is high, ranging up to 100%, and it is rapidly absorbed from the gastrointestinal tract with measurable plasma concentrations within 30 min after oral administration [104, 105]. It has no active metabolites and its clearance is not affected by hepatic or renal disease [105].

When administered in single parenteral doses to opioid naïve patients, methadone is equipotent to morphine, with duration of analgesia of 4–6 h [106]. Its plasma level declines in a biexponential manner with a half-life of 2–3 h during the initial phase and 15–60 h during the terminal phase [107]. This biexponential decline accounts for the relatively short analgesic action and the tendency for drug accumulation with repeated dosing. A reduction in dose and interval frequency is often needed during the first few days of treatment to prevent side effects from overdosage [108]. The rare patient allergic to morphine and intolerant to fentanyl might benefit from methadone because of its different chemical structure. Furthermore, since methadone is cleared almost exclusively by the liver, it can be a useful medication in patients with renal failure [109].

Given its NMDA antagonism, patients with neuropathic pain or opioid tolerance can often obtain relief when changed to methadone.

However, methadone must be started at a much lower dose and increased slowly, with a frequency of not less than every 3 days. Breakthrough doses of the present opioid must be maintained during this transition period [103]. Another interesting recent finding concerning methadone is the report that it is a potent inducer of cell death in leukemia cells and inhibited proliferation of these cancer cells [110].

Principles of Dosing and Delivery Methods

After most major surgical procedures opioids are first-line treatment for post-op pain. While tenet of "start low go slow" still applies, immediately after surgery is a time to be more aggressive as uncontrolled pain may drive delirium, particularly in the cognitively impaired [111]. The addition of nonopioid adjuvants will provide a synergistic effect and decrease overall opioid requirement.

Shafer and Flood describe several concepts that must be considered when treating the elderly with opioids by bolus intravenous administration or by continuous infusions as is commonplace in the postoperative period [30]. They state that "the calculation of the equianalgesic dose is complicated by the relative intrinsic potency of the opioids, the different pharmacokinetic profiles, and the large differences in the rate of blood–brain equilibration." Further, because of these stated differences in the properties of the opioids, the equianalgesic dose also becomes a function of the time after the injection was made, and they give an example of fentanyl (50 μg), which has a rapid onset and will have the same effect at 10 min as 5 mg of morphine which has a slow onset time. However, at 60 min postinjection, 50 μg of fentanyl will have the same effect as 1 mg of morphine [30]. Thus, one must be careful in titrating morphine with frequent bolus doses since it may result in stacking the effect which may not become evident until 60 min later. It may be better to load a patient to comfort with fentanyl while starting a PCA with morphine or hydromorphone, in order to allow enough time for the longer acting and slower onset opioids to reach peak effect and steady state.

For patients with severe acute postoperative pain, parenteral morphine has classically been the opioid of choice [77]. Today, at least in the well-monitored site of the postanesthesia recovery room, hydromorphone and fentanyl have become more common. Whichever the initial choice of opioid is, a good rule of thumb is to reduce the starting dose by half compared with that in a younger patient and maintain the same dosing interval [112]. After the initial dose determination, drugs are titrated based on the analgesic effect. Opioids should be titrated until one of the two endpoints is reached: adequate analgesia or the development of intolerable side effects [113].

PCA is a safe, effective modality for the delivery of opioids for pain that is expected to resolve (e.g., postoperative pain). The patient self-delivers fixed doses of an opioid by pressing a button. Post-op bolus opioid titration to comfort must be accomplished before beginning PCA. In the experience of the authors, one can utilize the total dose required to obtain comfort as a measure of the 3-h patient requirement in setting up a PCA. Estimated morphine consumption by age in the first 24 h after major surgery is: 100 – patient's age ≈ mg of IV morphine [12]. Basal infusion rates are not recommended for the elderly as accumulation of dose can occur during periods of sleep. But the lockout period must also be adjusted so that the patient has adequate time to experience the effect of the analgesic but short enough that the patient can "catch up" with his/her pain.

With PCA an overdose is infrequent because the patient must be alert to press the button, and there is a lockout time between delivered doses during which pressing the button does not result in the delivery of medication. Family members must be cautioned not to press the button for their loved ones while the patient is sleeping in response to a groan or grimace. The usual PCA starting dose for morphine is 1 mg and for hydromorphone is 0.2 mg. The usual lockout time is 8, 10, or 15 min, although this should be adjusted for the individual patient depending on the severity of pain, the age of the patient, and whether there is a basal rate. Some advocate a low-dose basal infusion of opioid at night (e.g., morphine 0.5 mg/h or hydromorphone 0.1 mg/h) to avoid frequent awakenings because of pain, especially for the first 2–3 nights after surgery, although this may increase the daily morphine consumption [114]. Others feel that in the elderly it is better that the patients be allowed to awaken and press the PCA button on their own [115]. However, when PCA was compared with the more traditional "as-needed" administration of intramuscular opioids in a randomized trial involving postoperative pain control in elderly men, PCA using morphine without a basal rate was clearly found to result in better analgesia, fewer complications, less sedation, and higher patient satisfaction than intramuscular opioids [116].

For patients unable to operate PCA or in situations where PCA is not available, a continuous opioid infusion (e.g., morphine 0.5–1.0 mg/h or hydromorphone 0.10–0.25 mg/h) could be started and the patient observed for excessive sedation (reduce dose) or behavioral cues of pain (increase dose). This may be necessary for intubated patients or patients treated in end-of-life care. Frequent behavioral assessments focusing on face and body language that may indicate pain are essential, particularly during the first 24 h following surgery [77]. However, most hospitals might require an intensive care setting in order to provide a continuous infusion of opioid analgesia which the patient's condition may not warrant. It has also been shown that round the clock bolus dosing of intravenous opioids can provide good pain control if the patient is unable to use the PCA machine. This could be in the mode of "nurse-controlled analgesia" and would probably be safer than the continuous infusion.

For patients in whom pain is difficult to control, it has been shown that optimum pain control with minimal side effects could be obtained using PCA with a combination solution of 1 mg/ml morphine and 1 mg/ml ketamine, with a lockout period of 8 min [117]. This takes advantage of the ability of ketamine to block NMDA receptors and enhance the opioid analgesic effect of morphine.

When venous access is problematic, the subcutaneous route can be used. The infraclavicular area is generally the best site when a continuous infusion, PCA, or both are used. A 27-gage butterfly needle is well tolerated and can be maintained for 3–5 days, after which the site must be rotated. When intermittent dosing is required, an insulin syringe is used to minimize trauma. Doses for subcutaneous administration are equal to intravenous doses, and hydromorphone is the agent of choice because of its high potency and lipid insolubility. It is best to avoid the intramuscular route because of erratic absorption and pain from the injection [77]. One must remember, however, that the subcutaneous tissue site can only accommodate <2 ml volume per hour and so solutions must be concentrated. Hydromorphone being more soluble and more potent than morphine is suitable for concentrating.

With all opioid modalities, anticipation of side effects and treating them accordingly is preferable to stopping treatment altogether. Coadministration of stool softeners and antiemetics helps to prevent the common side effects of constipation and nausea [10].

Systemic Nonopioid Adjuvants

Acetaminophen

A nonspecific centrally acting cyclooxygenase inhibitor with few peripheral effects, acetaminophen has been a useful analgesic for mild to moderate pain for some time. Despite fears of dose-dependent hepatic necrosis, in recommended doses (1000 mg every 4–6 h; max 4000 mg/24 h) it is well tolerated in the elderly [118]. In the absence of significant renal impairment, there is evidence that no dose reduction is required for the elderly at all [68]. Hypovolemic surgical patients, as well as those with compromised liver function (malnourished, alcohol abusers, hepatitis), should have reduced doses of 2000 mg/24 h.

Acetaminophen is very effective when given intravenously where it exhibits higher CNS concentrations than oral or rectal routes [119] and may be used as such for the first 24–48 h post-op before switching to oral formulations. Given its opioid-sparing effects, scheduled dosing of acetaminophen should be the core component of a multimodal analgesic regimen [120, 121].

NSAIDs

To understand the cascade of renal effects of NSAIDs, it is necessary to look at the beneficial effects of the enzyme cyclooxygenase 1 (COX-1) on converting arachidonic acid to various prostaglandins. These prostaglandins are necessary for maintaining good renal blood flow, adequate glomerular filtration rate, and homeostasis of potassium and sodium retention through appropriate secretions of renin, aldosterone, and antidiuretic hormone (ADH). When the conversion of arachidonic acid to prostaglandins is inhibited by NSAID inhibition of COX-1, then the kidney comes under risk and loses its ability to regulate salt and water balance. This detrimental effect of NSAIDs on the kidney is potentiated by renal hypoperfusion states [122]. All NSAIDs can result in renal insufficiency; and with the exception of salicylsalicylic acid and choline magnesium trisalicylate, for which the risk is less, they can inhibit platelet aggregation and cause dyspepsia and gastric ulceration [77].

NASIDs have peripheral and central effects [123]. The "Constitutive" effects of the prostaglandins resulting from the actions of COX-1 also include protection of the stomach and intestinal lining and preservation of platelet function [124]. The "Inducible" effects of COX-2 on conversion of arachidonic acid to prostaglandin E-2 leads to inflammation and pain. Blockade of the action of COX-2 reduces inflammation and pain without affecting the good effects of the prostaglandins that are COX-1 dependent [124, 125]. In the presence of inflammation, COX-2 can be found elevated in the CNS. The common NSAIDs are nonspecific because they have variable effects on blockade of COX-1 and COX-2. The most common oral NSAIDs used in clinical practice are shown in Table 2.

There is a ceiling dose effect to all of the NSAIDs, above which no further analgesia is obtained; and although the dose may vary, it usually falls below the maximal recommended dose of the manufacturer [126]. In general, for elderly patients, agents with short half-lives (e.g., ibuprofen) are most appropriate; for patients with a history of dyspepsia, ulcer disease, or bleeding diatheses, either salicylsalicylic acid or choline magnesium trisalicylate should be used if a traditional NSAID is indicated [77]. NSAIDs, when combined with opioids in the PCA setting, both decrease overall opioid consumption and decrease pain intensity [127].

Parenteral NSAIDs are being used increasingly for postoperative pain as sole analgesic agents and in conjunction with opioids as opioid-sparing agents [128]. The efficacy of ketorolac has been well established with 30 mg being equianalgesic with 10 mg of parenteral morphine [128]. Intravenous ketorolac has been shown to reduce opioid requirements for knee and hip replacement surgery by 35–44% and by 50–75% for thoracotomy and upper abdominal surgery [129, 130]. While

Table 2 Common oral NSAIDs by chemical class [222]

Propionic acids	Salicylates	Fenamates	Oxicams	Acidic acids	Benzine-acidic acid
Ibuprofen (Motrin®)	Aspirin	Meclofenamate sodium (Meclomen®)	Piroxicam (Feldene®)	Tolmetin sodium (Tolectin®/DS)	Diclofenac sodium (Voltaren®) (Voltaren® XR)
Naproxen (Naprosyn®)	Diflunisal (Dolobid®)			Indomethacin (Indocin®) (Indocin® SR)	
Fenoprofen calcium (Nalfon®)	Salicylsalicylic acid Disalcid®			Sulindac (Clinoril®)	
Ketoprofen (Orudis®)	Choline magnesium trisalicylate Trilisate®				

ketorolac can reduce opioid requirements, it is not potent enough to be used as a sole analgesic after major surgery such as intraabdominal surgery [131].

Peak analgesia from ketorolac is typically seen 1–2 h after administration, and the half-life is approximately 6 h, although it may be prolonged in patients with reduced renal function or in the elderly. The manufacturer's recommended dose for elderly individuals or those with renal insufficiency is 15 mg every 6 h following a 30 mg loading dose, and doses as low as 7.5 mg q6h have been found to significantly reduce opioid requirements in such painful surgeries as spinal fusion [132].

Ketorolac has a side-effect profile similar to those of other NSAIDs. There appears to be a significantly increased risk of gastrointestinal bleeding in the elderly, particularly with high doses and with the duration of use of more than 5 days [133–135]. But when used in doses of 15 mg or less q6h for less than 3 days, toxicity seems to be minimal. A recent meta-analysis of randomized controlled trials found no increased risk of postoperative bleeding related to ketorolac use, despite fears of platelet inhibition [136].

Recent development of intravenous ibuprofen (Caldolor®) has given practitioners another parenteral tool for multimodal analgesia. Perioperative administration of 800 mg every 6 h in abdominal surgery decreases morphine requirements and pain scores, while being generally well tolerated [137].

Parecoxib is a specific COX-2 inhibitor that is available in Europe for intravenous administration. In a study of parecoxib 40 mg IV administered on induction of general anesthesia, and then q12h for 24 h, improved postoperative analgesia without increased bleeding for total hip arthroplasty was observed. It is well known that COX-2 is responsible for the synthesis of prostaglandins, which sensitizes the nociceptor and acts as excitatory neuromediators in the CNS and in the periphery [125, 138].

In another study, parecoxib was found to be an effective analgesic in acute postoperative pain at 20 or 40 mg over placebo given either intravenously or intramuscularly. The number needed to treat (NNT) for parecoxib 20 mg IV for at least 50% pain relief over 6 h was 3.0 and for 40 mg was 2.2 [139]. This compares favorably with other analgesics, e.g., morphine 10 mg where the NNT was 3, ibuprofen 400 mg where the NNT was 2.7, and acetaminophen 1,000 mg where the NNT was 4.6 [140]. Ibuprofen was actually more effective than morphine at these doses. In direct comparison of 4 mg of intravenous morphine with 30 mg of intravenous ketorolac or 20 mg of intravenous paracoxib, the times to remedication were 3 h for morphine versus 5.5 h for both the ketorolac and paracoxib at the specified doses [141].

Impairment of wound healing has been attributed to the use of NSAIDs in the postoperative period. Studies have shown that there was no effect on epidermal wound healing with selective COX-2 and nonselective COX inhibitors in a mouse model. The authors propose that this was probably due to redundant mechanisms for wound repair, most of which are not influenced by the COX-2 inhibitors [142].

Power indicates in his review article that the data is conflicting with respect to bone healing and nonunion when these agents are used in orthopedic procedures [143]; but much of the adverse data come from animal studies which may not have clinical significance in humans [144, 145]. Short-term use of COX-2-specific inhibitors may play an important role in preventive analgesia for postoperative pain management [138, 146].

It is important to remember that COX-2-specific inhibitors do not affect platelet aggregation [125, 138] and therefore may pose a risk for myocardial infarction (MI) if the patient is taken off aspirin therapy. Since low-dose aspirin is increasingly being used for cardioprotection, it is important to note that coadministration of selective COX-2 inhibitors does not alter this protective effect [147]. It has recently been shown that celecoxib (Celebrex™) does not appear to be associated with an increased risk of serious cardiovascular thromboembolic events and it is the only remaining oral COX-2 inhibitor available in the USA [148]. It could therefore be used as a preoperative medication and continued postoperatively through healing (e.g., $<$10 days) as part of a multimodal preventive analgesic regimen, if the patient is able to take oral medications and does not have an allergy to sulfa-containing medications.

Gabapentinoids

A relatively new nonopioid adjuvant in the treatment of postsurgical pain, gabapentin and pregabalin bind to the alpha-2-delta subunit of neuronal calcium channels and decrease neuronal pain transmission. They have been extensively studied and shown to have opioid-sparing effects in a wide variety of surgical procedures including spine surgery, orthopedics, and hysterectomy [149–151].

Opioid-sparing effects of gabapentin occur after a single preoperative oral dose, and this is thought to be protective against postoperative delirium [152]. 300–400 mg doses are reasonable in the elderly. Larger doses may be used but could cause dose-dependent sedation. Gabapentin exhibits no metabolism and is completely renally excreted. Other side effects include dizziness, visual disturbances, and swelling of lower extremities. The uptake of gabapentin is less predictable than that of pregabalin, which is more potent and bioavailable. Pregabalin causes less sedation.

Ketamine

Ketamine is an N-methyl-D-aspartate (NMDA) receptor blocking agent which exhibits dose-dependent analgesia, amnesia, unconsciousness, and akinesia, while avoiding respiratory depression [203]. Lower concentrations and doses predominately block the closed form of the NMDA channel leading to analgesia rather than anesthesia [204]. Due to the potential for hallucinations, patients with psychiatric or substance abuse (alcohol, amphetamines) comorbidities should not receive ketamine [153]. Despite fears of ketamine's undesired dissociative and dysphoric side effects, more recent research points to the many advantages of perioperative use including effective opioid-sparing postoperative analgesia, attenuation of the acute analgesic tolerance to opioids, and prevention of rebound pain that occurs following opioid usage [203, 204].

Bell et al. retrospectively studied the efficacy and tolerability of ketamine for perioperative control of acute pain in adults and found reduced pain intensity, reduced rescue pain medication requirement, or both perioperatively. Ketamine in the first 24 h after surgery reduced morphine requirements and decreased incidences of postoperative nausea and vomiting [154]. Though many forms exist, the most common perioperative analgesic dosing ranges from 0.2 to 0.5 mg/kg IV and 0.5 to 1.0 mg/kg IM in adults, with continuous IV infusions usually starting at 0.1–0.2 mg/kg/h [155, 156]. As with most analgesics in elderly populations, it is recommended to decrease this by 10–30% with careful consideration given to administering in the cognitively impaired. An antisialogogue may be required with infusions.

Glucocorticoids

Glucocorticoids given both preoperatively or postoperatively have been shown to reduce postoperative nausea and vomiting and to decrease pain [157, 158]. A single dose of glucocorticoid steroid can reduce pain following ambulatory surgery without increasing postoperative bleeding risk in the elderly [159]. Less than 8 mg of dexamethasone or 150 mg of methyprenisolone intravenously seems to be adequate.

α2-Agonists

Preoperative oral administration of clonidine, an α2-agonist, reduces pain and postoperative analgesic requirement, provides sedation, and facilitates emergence from anesthesia [160]. Analgesia from intrathecally administered morphine was enhanced by oral clonidine premedication after total abdominal hysterectomy [161].

Antidepressants

Antidepressants that have been used in pain management are listed below (Table 3) along with starting doses and tolerability [162]. In summary,

Table 3 Antidepressants in clinical practice. Tricyclic antidepressants: The dosages are low (adjusted for the elderly patient). The antidepressants that are effective in pain management are those that have both serotonin and norepinephrine reuptake inhibition effects. The tricyclic antidepressants all have these effects but their side effect profiles determine the tolerability of these drugs particularly by elderly patients, e.g., anticholinergic effects, sedation. The non-tricyclic antidepressants that are effective in pain management tend to be less sedating and have a faster onset of effect with respect to decreasing neuropathic pain after initiation of therapy than the tricyclic antidepressants that can require several weeks of treatment to become effective

Tricyclics	Anticholinergic effects (sedation)	Dose range	Tolerability
Amitriptyline (Elavil®)	Least effect	10–25 mg qhs	
Desipramine (Norpramin®)	Least effect	10–25 mg qhs	Best
Doxipin (Sinequan®)	Most effect		Most sedating
Imipramine (Tofranil®)	Intermediate	10–25 mg/day	Best
Nortriptyline (Pamelor®)	Intermediate	10–25 mg/day	Best
Non-tricyclics			
Venlafaxine (Effexor®)		≥150 mg/day	
Duloxetine (Cymbalta®)		30–120 mg/day	Best
Bupropion (Wellbutrin®SR)		150–300 mg/day	
Trazadone (Deseryl®)	Sleep aid in women	50–300 mg/day	Risk of priapism in men

amitriptyline is probably the most studied in pain management and its efficacy is well established. Of the newest antidepressants that have been studied in pain management, duloxetine (a non-Tricyclic) is well tolerated with a fast onset of effect after the initiation of treatment [162].

Regional Analgesic Techniques

Many regional techniques exist to provide perioperative anesthesia and analgesia ranging from neuraxial administration (epidural, intrathecal) of medications to peripheral perineural deposition and combinations of both. Indwelling catheters may additionally be placed to prolong analgesic effect with sustained administration of medications perineurally or into the epidural space. When studied versus conventional parenteral administration of analgesics, regional techniques are clearly superior for postoperative pain relief, particularly dynamic pain relief [163]. However, lack of consistency within regional anesthesia studies and protocols remains an important factor that has limited the ability to portray firm indications, guidelines, and recommendations about any advantageous or optimal technique in the geriatric population [164]. When compared to general anesthesia regional techniques have failed to show significant long-term variation in morbidity and mortality, except reduced incidence of deep vein thrombosis and reduced blood loss when regional is utilized [165].

As part of a multimodal anesthetic/analgesic however, regional techniques provide excellent pain relief as well as opioid-sparing capacity which shortens care stays, allows for earlier ambulation and return of bowel function, and improves mental status post-op [86]. Compared to parenteral analgesia, better outcomes have been consistently shown using epidural and peripheral nerve blockade in rehabilitation after major surgery in the elderly, though these same studies often note increased complication rates as well with use of epidurals [68].

While regional is no panacea, when instituted as part of a multimodal technique in appropriate patients, the reduced postoperative neurological, pulmonary, cardiac, and endocrine complications may outweigh the potential downsides.

Neuraxial Analgesia

The epidural route of administration for opioid, local anesthetic, or a combination provides superior analgesia for dynamic or rest pain in comparison with systemic opioids [166] and may be used for continuous infusion with or without patient-controlled epidural analgesia (PCEA). Most of the benefits of epidural analgesia stem from the opioid-sparing effects of the local anesthetic and the abolition of the surgical stress response in the spinal cord. Benefits to bowel motility are limited to epidurals placed at the thoracic level, and local anesthetics alone alter bowel motility and stress responses; epidural opioids do not [167].

Carli et al. in a study of 64 patients for elective colon surgery randomized to an IV PCA group or epidural group found that epidural analgesia enhanced functional exercise capacity and health-related quality of life indicators after colonic surgery [168]. The results indicated that the epidural group had improved outcomes for pain control, mobilization, gastrointestinal motility, and intake of protein and calories. This may be a function more of the local anesthetic, facilitating bowel function, thereby causing less nausea, and more willingness to eat. Decreased pain can also result in the same benefits, not just at rest but also with mobility, and less pain may ameliorate insulin sensitivity and hypercatabolism and maintain muscle protein better. These benefits seemed to carry out to 6 weeks in the study of health-related quality of life indicators, leaving little doubt that epidural analgesia is even better than systemic opioids in the elderly [168].

Neuraxial opioid injections can play a role in multimodal pain management, particularly in abdominal, pelvic, and thoracic surgery. Intrathecal morphine ensures good postoperative analgesia for several hours and reduces the rescue dose of intravenous opioids [169]. A smaller dose of intrathecal morphine may minimize the incidence of adverse events in the elderly, though dose-related urinary retention, hypotension, and respiratory depression still occur [69]. Doses of 100 micrograms were reported to provide optimal balance between analgesia and adverse effects [170], while 50 μg still afforded good results in the extremely elderly [171].

Due to the stenotic spine with smaller intervertebral foramina for medication to escape through, the elderly are at increased risk for respiratory depression with neuraxial opioids. A single intrathecal dose of hydrophilic opioid (morphine) remains in the CSF longer, is absorbed systemically slower, and travels more rostrally to brainstem respiratory centers [172]. Hydrophobic opioids (fentanyl, hydromorphone) may be more preferable as they will exhibit less rostral spread. Fentanyl tends to be sequestered in the fat tissue of the epidural space and absorbed rapidly by epidural vascular structures, reaching systemic plasma levels within 2 h of commencing an epidural infusion that would equal the same infusion rate given intravenously [173, 174]. Care must therefore be taken with fentanyl during the initial phases of the infusion, whereas the respiratory depressive effects of morphine or hydromorphone tend to be more delayed if they are to occur. As with IV dosing, a reduction of 25–50% of any neuraxial opioid in the elderly is wise.

Pruritis is a common side effect of morphine administered either parenterally (intravenous or intramuscular) or spinally (intrathecal or epidural) [175]. However, the mechanisms and therefore effective treatments are different. Parenteral morphine results in histamine release in a dose-dependent manner and can be treated with antihistamines such as promethazine or dyhenhydramine. Epidural or intrathecal morphine also produces pruritis through a central stimulating effect mediated through the mu opioid receptor. It is treated most effectively not with antihistamines but with a naloxone infusion at a low enough dose to ameliorate the pruritis without reversing the analgesic effect [175].

Combination of low-dose opioid and local anesthetic limits the toxic effects of each drug. Various combinations of opioid and local anesthetic can be used to meet the needs of individual patients. Today ropivacaine/hydromorphone 0.2%/0.02 mg/ml has become very popular as an epidural infusion. Local anesthetic side effects include orthostatic hypotension, numbness/weakness, and urinary retention. Opioid side effects include sedation, urinary retention, and pruritis [176].

The local anesthetic/opioid ratio is adjusted based on the type and severity of side effects that develop. Complications of epidural infusions include accidental subarachnoid puncture with postdural puncture headache (generally benign and self-limiting), epidural hematoma, and epidural abscess. Side effects and complications are minimal if the catheters are inserted and monitored by those experienced with the technique [77].

When compared to continuous epidural infusions, self-adjustment provided by PCEA allows for a reduction in analgesic consumption and a decrease in adverse events [177]. PCEA reduces analgesic requirements compared with continuous epidural infusion after major abdominal surgery [178]. No standard protocol has been validated specifically in the elderly. Several studies advocate a combination of local anesthetic with an opioid as background infusion from 3 to 6 ml/h, a bolus of 2–3 ml, and a lockout period from 15 to 20 min [179, 180].

Concomitant use of the epidural and parenteral routes is not recommended because (1) it makes titration of drugs overly complicated and (2) it becomes difficult to determine the origin of side effects if they develop. Generally, it is not advisable to maintain an epidural catheter for more than 8 days even if the site of insertion is without evidence of inflammation or infection. The source of epidural infection from continuous catheters is not well known, but skin flora is considered the primary source [181]. If the epidural route is still needed, the catheter can be replaced with a new one at the segmental level above or below the insertion of the old catheter.

An additional benefit of spinal anesthesia has been suggested, although not yet proven. The perioperative period is characterized by a state of immunosuppression, which was shown in animal studies to underlie the promotion of tumor metastasis by surgery [182]. Bar-Yosef and his associates demonstrated that spinal anesthesia when added to general anesthesia reduced tumor recurrence in an animal model. They propone that as the immunosuppression of surgery is partly ascribed to the neuroendocrine stress response, it is hypothesized that spinal blockade, known to attenuate this response, may reduce the tumor-promoting effect of surgery. They therefore conclude that the addition of spinal block in their model had an advantage over the use of general anesthesia alone, and they suggest that it acts by reducing the neuroendocrine response to surgery [182].

These authors further state that since in clinical practice, an epidural block can be carried over into the postoperative period, it is reasonable to assume, but certainly proof is needed, that the favorable effect of prolonged epidural block on immune function and tumor metastasis will exceed the effect they found using short-term spinal block. This study provides the first experimental evidence that neuraxial anesthesia may reduce postoperative metastatic development [182]. Controlled clinical studies are necessary to confirm this result in humans. We believe it is important to note that regional anesthetic and analgesic techniques have benefits that go beyond just pain control in order to encourage surgeons and primary care physicians to request such techniques where appropriate from the anesthesiologists.

Peripheral Perineural Analgesia

While epidural analgesia has been the gold standard for postsurgical analgesia for many years, the disadvantages as noted have spurred interest and utilization of peripheral nerve blocks, both single-shot and continuous (CPNBs) peripheral catheter techniques. Infiltration of local anesthetic around a peripheral nerve or plexus, proximal to the desired site of action allows for several hours of analgesia with the option of threading a catheter for continued blockade utilizing electronic infusion or disposable elastomeric devices. These blocks allow for unilateral analgesia, facilitating movement, and rehabilitation without the necessity of a Foley catheter, which can be a cause of delirium post-op. In addition, patients can safely be sent home with continuous elastomeric catheters, pulling the catheters out themselves when the disposable pumps are empty [183].

With the interscalene technique, blockade of the shoulder is possible. The upper extremities below the shoulder are easily blocked with supraclavicular or infraclavicular techniques. And the lower extremities including the hips can be blocked with a combination of sciatic with lumbar plexus or the so-called 3-in-1 femoral block. The transversus abdominis plane (TAP) block procedure is increasingly used after major abdominal surgery in the abdomen. It is easy to provide and has few complications and greater acceptability [184]. The rectus sheath block can be used for abdominal surgery with mid-line incisions above the umbilicus [185]. Thoracic surgery is amenable to paravertebral blockade. The use of ultrasound needle guidance in addition to nerve stimulation techniques has made these procedures more accurate and less risky [186]. The aim will always be to provide good analgesia without significant motor blockade.

Of significance is that in a recent report woman undergoing mastectomy for tumor removal had one-fourth the risk of metastatic recurrence when surgery was performed with a continuous paravertebral catheter [187]. The catheter was placed at T2-3 through which a bolus of local anesthetic was given followed by a continuous infusion of local anesthetic. These patients also received general anesthesia with intravenous propofol. This group of patients was compared with a group that received general anesthesia alone [188]. The paravertebral catheters were removed after 2 days.

Compared to general anesthesia-neuraxial anesthesia, peripheral nerve blocks reduce pain, opioid consumption, PONV incidence, and PACU stay and provide "fast-track" recovery with increased patient satisfaction, particularly after CPNBs [189]. After a peripheral plexus block, the elderly exhibit increased sensory and motor blockade which is significantly correlated with age [69]. Peripheral blocks are associated with minimal hemodynamic effects compared to neuraxial local anesthetic administration. CPNBs are utilized extensively in orthopedic surgery, allowing for prolonged analgesia, quicker mobilization, and rehabilitation in relative comfort [69, 190]. They reduce economic impact by decreasing parenteral analgesic need and the associated postoperative morbidity therein [191].

CPNBs are not without fault however. In a national survey, the incidence of catheter dislocation was 4.7% [192], which was an even greater problem if the patient was given no parenteral analgesics as backup. In a large prospective study, 4% of patients receiving CPNBs could not move their arm or hand for 16 h after surgery [193], and a 0.7% chance of falling following total knee arthroplastly with a femoral CPNB was reported by Feibel et al. [194].

Perineural blockade techniques are generally low risk in older patients, though may be more technically challenging in some situations. The elderly lose muscle mass and have poor tissue echogenicity under ultrasound, and obesity in older adults is prevalent causing difficulty in utilizing surface landmarks and nerve stimulator techniques. Patients with acute trauma such as hip fractures may be difficult to position for blocks, and the risk-benefit ratio of giving parenteral sedation/analgesia to facilitate positioning must be assessed. In these situations, utilizing ultrasound to obtain a femoral nerve block with fast-acting mepivacaine or lidocaine+bicarbonate while the patient is supine and relatively comfortable may facilitate positioning for lateral neuraxial administration of a spinal anesthetic.

Older adults with cognitive dysfunction require special consideration if they are to be discharged home with blocks and indwelling catheters. Caregiver and familiar education is important. They must be ready to supervise the patient so that the catheter does not get pulled out prematurely. Leaking catheters may agitate or cause skin breakdown at the catheter site, while motor blockade of the lower extremity can lead to falls. Should the catheter migrate or be removed unexpectedly, oral analgesics and emergency contact numbers should be provided.

Special mention is required for local anesthetic toxicity in the elderly, who have lower serum protein levels leading to higher local anesthetic concentrations in the plasma. Cardiac, hepatic, and renal end-organ disease should be documented and considered as these will decrease the ability to metabolize the medication and decrease the toxic threshold. When multiple catheters and blocks are utilized, the total volumes of anesthetic should be noted and subsequent infusion doses reduced accordingly. Ropivacaine seems most appropriate for long-term infusion, as it causes less cardiac and CNS toxicity than bupivacaine.

Unfortunately, unlike epidural analgesia which can in fact provide complete analgesia without the need for supplemental intravenous or oral opioid analgesia (since opioids are administered spinally), peripheral nerve blockade cannot be used to completely eliminate the need for supplement opioid analgesics. Patients should be discharged home with some form of oral analgesic should complications with the catheter arise.

Nonpharmacologic Therapies

It is advantageous to utilize all nonpharmacologic therapies as they have little to no side-effect profile and are often cost-saving. Transcutaneous electrical stimulation (TENS) and transcutaneous acupoint electrical stimulation (TAES) produce opioid-sparing effects [195]. Psychological techniques include guided imagery, cognitive-behavioral techniques, and mindfulness training. Reynolds [196] found that patients who believed such nonpharmacological treatments could be effective benefited from their use for managing pain.

Cold application decreases skin and joint temperature, decreases blood flow, and has a direct analgesic effect. Distraction (music, television, reading) is beneficial in the cognitively dysfunctional and intact alike. Deep breathing exercises can be discussed and utilized perioperatively. These techniques require no formal training to implement.

Transitioning to Outpatient Care

Once pain is controlled and bowel function restored, analgesics should be changed to the oral route. This conversion should be made prior to discharge, and it is recommended that at least 24 h of observation be allowed so that an adequate oral regimen can be established and tested prior to discharge. Depending on individual variability and the type of surgery, this transition should occur 3–8 days after the surgery. Standardized equianalgesic dose tables are available to aid conversion, but they present average data based on single-dose studies of the drugs in opioid naive patients. There may be individual differences in patient absorption, metabolism and response, and as such tables should be used for guidance only [197]. A good rule of thumb is starting at a lower than equianalgesic dose in the first instance and titrated upwards as required [198].

Occasionally patients require parenteral or epidural opioids for a more prolonged period, usually because of intervening complications. Typically, patients require oral opioids for 5–10 days after parenteral or epidural opioids are discontinued. A certain percentage of patients, especially after more painful surgeries, require oral opioids for 2 weeks or longer [77].

For example, for conversion from intravenous or oral morphine to a fentanyl transdermal patch, one only needs to remember that 60 mg/day of intravenous morphine or 180 mg/day of oral morphine will equal a 100 mg/h transdermal fentanyl patch. As with all sustained-release opioids, this is for continuous pain that is opioid responsive. One still needs to consider breakthrough pain medications, fast onset, and short duration, for activity-based pain. Since hydromorphone is about 4–5 times as potent as morphine, a similar conversion can be made from intravenous hydromorphone of 15 mg/day to a 100 mg/h transdermal fentanyl patch. Once patients have been receiving intravenous opioid medication for several days, the equianalgesic relationship between intravenous and oral doses changes from 1–6 (IV to oral) to closer to 1–3.

Oral analgesics such as oxycodone or codeine are appropriate choices for a patient with mild-to-moderate pain [199]. Fixed combinations with nonopioid analgesics can be useful, but they sometimes limit the careful individualized titration that is the basis of therapeutic success. The oral transmucosal route may prove effective for rescue doses, but absorption is probably inadequate for more sustained relief. This latter statement also holds for the rectal route, which, additionally, is often uncomfortable for the patient and the caregiver.

One example of the difficulty with combination medications is conversion from intravenous PCA to oral. As seen in Table 4, the oral

Table 4 Equianalgesic doses of common intravenous and oral opioids. Notice that the oral equivalent for 10 mg of intravenous morphine is 30 mg of oral hydrocodone. But when hydrocodone is combined with acetaminophen, the ratio is such that a toxic dose of acetaminophen would be taken with the hydrocodone. It is better to convert to a pure opioid agonist until such time that a reasonable dose of a combination medication can be given safely as shown in Table 2

Drug	IV (mg)	Oral (mg)
Morphine	10 mg	30 mg
Hydromorphone (Dilaudid®)	1.5 mg	7.5 mg
Methadone[a]	10 mg	12 mg
Fentanyl	0.1 mg (100 ug)	N/A[b]
Meperidine (Demerol®)	100 mg	300 mg
Codeine	N/A	200 mg
Oxycodone (Percodan®) (Percocet®)	N/A	20 mg
Hydrocodone (Vicodin®) (Lorcet®)	N/A	30 mg (5 mg/tab Vicodin® with 500 mg acetaminophen)

[a]Not recommended for acute titration; ratio depends on presence of prior opioid tolerance
[b]Oral transmucosal fentanyl is available in 200 μg, 400 μg, 800 μg, 1600 μg doses, and the transmucosal absorption depends on the duration of contact with the mucosa but will maximize at about 25% of the total dose with the remainder being swallowed and subject to a small degree of gastric absorption. An effervescent lozenge is also available in similar doses with a reported absorption of about 50%

equivalent of hydrocodone to 10 mg of intravenous morphine is 30 mg. The usual combination of hydrocodone with acetaminophen is 5 and 325 mg, respectively. Therefore, six tablets of this combination drug would be necessary to equal 10 mg of intravenous morphine.

Special Considerations

Some surgical procedures are associated with a higher risk of postoperative pain syndromes such as phantom limb pain syndrome after amputation. Regional anesthetic techniques offer the greatest protection; however, some patients either decline to have a regional blockade or the blocks are contraindicated for various reasons, and general anesthesia must be administered. General anesthetics alone do not protect the spinal cord from undergoing central sensitization leading to chronic neuropathic pain [200, 201]. But a polypharmaceutical approach, although not proven yet, seems to offer an advantage over traditional anesthetic and postoperative management techniques.

The following recommendations for the example of phantom limb pain prevention with amputation surgery are based on the author's experience, supported by the available evidenced-based medicine, which although limited in this regard, aims to target polypharmacy in such a way to help the brain modulate neuropathic pain [202]. The recommendations given below for this presented scenario of an amputation without the benefit of regional anesthesia is similar to the multimodal polypharmaceutical therapeutic recommendations of power, in which he reviews the uses of both opioid and nonopioid analgesics, anticonvulsants, and antidepressants in postoperative pain management [143].

As indicated above, in these authors' experience, agents that have NMDA receptor blocking action like ketamine [203, 204], drugs with Mu opioid agonist action, tetrodotoxin resistance (TTXr) sodium channel blockers such as the local anesthetics, serotonin and norepinephrine reuptake inhibitors such as antidepressants [205–207], neuronal calcium channel blockers such as the anticonvulsants gabapentin or pregabalin [208–213], and anti-inflammatory drugs if not contraindicated (see above) can all contribute to CNS protection. In such a case, preoperative oral gabapentin (Neurontin®) 300–1,200 mg [72, 79, 208–215] or pregabalin (Lyrica®) 75–150 mg, and if available a COX-2 inhibitor celecoxib (Celebrex®) 200 mg, can also be given orally which would alleviate the need for intraoperative ketorolac. It is true that COX-2 inhibitors are controversial with respect to patients at risk for stroke or myocardial infarction which makes up a large percentage of the elderly population. But there does not seem to be evidence that a single preoperative dose of 200 mg of celecoxib would pose a significant risk versus the benefit of preemptive analgesia [216].

Low subanesthetic doses of ketamine (0.10–0.2 mg/kg IV intraoperative preincision) can be used for as part of the intravenous induction, and repeat doses q2h intraoperative can provide additional inhibition of activation of spinal cord NMDA receptors. As previously stated, if the patient is unable to take a COX-2 inhibitor (celecoxib), then ketorolac 7.5–15 mg should be given prior to amputation intraoperatively and continued q6h intravenously for 48 h. Lidocaine 1.5 mg/kg IV at the time of skin incision and repeated during the amputation as a general sodium channel blocker can all be helpful.

Intraoperatively, the anesthesiologist (again in these authors' experience) can administer several adjuvants that will also assist in protecting the spinal cord from excessive nociceptive input. Methadone would be a good choice for an opioid because of its NMDA receptor antagonist effect, but it is often unavailable and its slow onset of action is not suitable for intraoperative administration. Fentanyl would therefore be a logical choice since it is potent and more easily titrated due to its rapid onset of action when administered intravenously.

Although the data are not conclusive, there is data to show that magnesium amplifies the analgesic effects of low-dose morphine in conditions of sustained pain [217]. Lysakowski et al., in a meta-analysis study of magnesium, concluded that the trials reviewed did not provide "convincing" evidence that perioperative magnesium has a favorable effect on postoperative pain intensity and analgesic requirements. Nevertheless, it may be worthwhile to further study the role of magnesium as a supplement to postoperative analgesia, since this molecule is inexpensive, relatively harmless, and the biological basis for its potential antinociceptive effect is promising [218]. There is a possibility that magnesium might have an additive or even synergistic effect with other NMDA antagonists, specifically ketamine although the optimum dose is not established [219, 220].

Considering the good tolerability of magnesium, these findings may have clinical application in neuropathic and persistent pain. Again the appropriate dose of magnesium is not known, but 30 mg/kg IV intraoperative administered prior to skin incision seems to be safe even in the elderly population. In combination with low-dose gabapentin, significant improvement in the effectiveness of morphine is observed in a rat model of nerve ligation neuropathic pain [214]. Referring to the above-stated preoperative dosing of gabapentin, the two should enhance the protective analgesic effect of the opioid used.

Postoperatively, the antineuropathic regimen should be continued until the wound (stump) has healed in terms of continued gabapentin or pregabalin (100–300 mg tid or 50 mg tid, respectively) along with an appropriate opioid, anti-inflammatory, and antidepressant (for serotonin and norepinephrine reuptake inhibition action).

The Elderly Chronic Pain Patient

Initial opioid doses are much higher for patients on chronic opioid therapy. For these patients, the presurgical opioid dose must be converted to a continuous infusion, and the as-needed PCA dose should be set equal to the hourly infusion dose. When converting oral opioids to parenteral opioids refer to an opioid conversion chart (Table 3). A patient receiving 180 mg of oral morphine every 24 h prior to surgery, for example, should be started postoperatively on 60 mg of morphine intravenously in 24 h (2.5 mg/h) and a PCA dose of 2.5 mg every 15 min. If the pain is severe, the continuous infusion rate should be increased. Patients on chronic opioid therapy have almost always developed tolerance to the respiratory suppressant and cognitive side effects of opioids, and so it is rare for these patients to develop these symptoms, even after receiving doses substantially higher than their baseline [77].

Oxycodone is not available for intravenous administration and so the oral dose must be converted to a morphine or hydromorphone equivalent to convert to an intravenous dose. Since oxycodone is about 1.5 times more potent than morphine, 120 mg/day of oxycodone (extended-release oxycodone) would be equivalent to 180 mg/day of oral morphine or 60 mg/day of intravenous morphine [77]. This equivalency can then be used to set up a PCA of morphine or hydromorphone (15 mg/day hydromorphone = 60 mg/day morphine).

Addiction, Dependence, Tolerance, Pseudoaddiction

The fear of addiction or psychological dependence is one of the major barriers to the appropriate management of pain in the USA. Psychological dependence is the development of drug-seeking behavior that persists despite harm to the patient or others. Such drug-seeking behavior includes the hoarding of medication, use of medication for purposes other than control of pain, and obtaining opioids from multiple sources. It is important to distinguish true psychological dependence from "pseudoaddiction" [221], which can develop in patients who are undermedicated for their level of pain. Pseudoaddiction is drug-seeking behavior motivated by a need to obtain enough analgesia to control pain. When pain is appropriately managed and adequate analgesia provided, the behavior disappears. Although further research is needed, it appears that the incidence of psychological addiction in patients without a history of substance abuse and treated with opioids for control of pain is rare [75]. Fear of addiction should never limit the use of opioids for pain control in the elderly patient who has no history of substance abuse [77].

Conclusion

As aptly stated by Morrison, Carney, and Manfredi, in the first edition of this book, "good pain management in the elderly surgical patient is a complex, challenging undertaking of critical importance. Ensuring adequate analgesia requires an understanding of age-related changes in pharmacokinetics and pharmacodynamics, pain physiology, the appropriate use of analgesic agents, and knowledge of these agents' limitations and side effects. Unfortunately, few studies have focused on the assessment and treatment of pain in elderly individuals, and guidelines for analgesic therapy are often based on the experiences of young and middle-aged adults. Further research involving pain in the elderly is critically needed given the evolving changes in population demographics (persons over 65 represent the most rapidly growing segment of the US population) and the increasing rates of surgery in this population. Until such research is completed, clinicians must continue to interpret the available data in the

Table 5 Choosing the best option for postoperative pain control in the elderly. Continuous epidural or peripheral nerve block techniques offer the best control of postoperative pain in the elderly patient; however, if not appropriate or contraindicated, then intravenous administration must be utilized. Transition to oral medications must be adequate to control pain prior to discharge. When intravenous access is not available and the oral route cannot be used, the subcutaneous route is better than the intramuscular route. When the subcutaneous route is used, the absorption is less erratic with hydromorphone (more lipid-soluble) than with morphine. For intermittent dosing, it is best to use an insulin syringe. For continuous infusion, a 27-gauge butterfly needle can be used. Postoperative orders for pain medication should be standing rather than PRN. The remarks "hold for excessive sedation" and "patient may refuse" add a safety valve to the order. PCA, patient-controlled analgesia. Modified from Morrison et al. [77]

Cognitively intact	Cognitively impaired
More painful procedures (e.g., thoracotomy, complex abdominal/pelvic surgery)	
Epidural: lipophilic opioid (e.g., fentanyl) plus local anesthetic as a continuous infusion with or without epidural PCA *or*	*Epidural:* opioid plus local anesthetic as a continuous infusion without PCA *or*
Intravenous: strong opioid as an intravenous infusion with intravenous PCA	*Intravenous:* strong opioid as a continuous infusion without PCA, or nurse administered "PCA" without a basal rate based on patient assessment
Less painful procedures (e.g., lower abdominal surgery, hip/knee replacement)	
Intravenous: strong opioid via PCA or given intravenously every 4–6 h	*Epidural:* opioid plus local Anesthetic as a continuous infusion without PCA *or*
	Intravenous: strong opioid as a continuous infusion without PCA
If appropriate for the surgery, continuous peripheral nerve blocks with supplemental oral medications	If appropriate for the surgery, continuous peripheral nerve blocks with supplemental oral medications

context of their knowledge of age-related physiologic changes, medication effects, side effect profiles, and clinical experience. This approach is summarized in Table 5 and results in appropriate pain management for most elderly surgical patients" [41]. The increased use of regional and peripheral nerve block techniques holds much promise for acute postsurgical pain management in the elderly population, as does our increasing knowledge of the pathophysiological mechanisms of pain translating into advances in the polypharmaceutical multimodal approach to pain management.

Postoperative Delirium

22

Michelle Humeidan and Stacie G. Deiner

Contents

Abstract

Postoperative delirium (PD) is one of the most common complications in geriatric patients after surgery and is linked to significantly increased morbidity and mortality in affected patients. An acute change in consciousness along with inattention and disorganized thinking are key characteristics of PD, which typically occurs in the first 24 to 72 h after surgery. This chapter provides a detailed discussion of modifiable and non-modifiable risk factors for PD in the preoperative, intraoperative, and postoperative phases of care. Being able to risk stratify geriatric surgical patients and quickly recognize symptoms of PD is important for prevention and timely intervention. A brief discussion of PD pathophysiology is presented; however, much more research is needed to better understand the mechanisms

Postoperative delirium · Postoperative complications · Geriatric · Confusion assessment method

Introduction

A significant increase in health-care consumers over the age of 65 years and the associated rise in demand for surgical procedures [1] highlight the importance of understanding postoperative complications in elderly patients. Postoperative delirium (PD) is common after major surgery in the elderly and presents in the first 1–3 recovery days. PD manifests with a dynamic change in consciousness with key features of attention deficit and disorganized thoughts. As many as 65% of patients undergoing high-risk procedures such as hip fracture repair and cardiothoracic surgeries experience PD. Even low-risk surgeries such as elective outpatient procedures have an incidence of PD of 4–7% [2, 3]. PD can have serious consequences, including increased mortality. Billions of healthcare dollars are spent annually on the costs of PD, including increased postoperative morbidity and loss of function and independence [4–7]. This chapter will provide a fundamental overview of patient and procedural risk factors for PD, only some of which are modifiable, and will discuss the most widely utilized and accessible diagnostic tool, the Confusion Assessment Method (CAM). In addition, pathophysiology and important considerations for differential diagnosis of PD are discussed. The American Geriatrics Society (AGS) has published specific guidelines on the management of patients at high risk for PD, which form the basis of the current best practices for perioperative optimization and treatment strategies presented in this chapter [8].

Risk Factors for Postoperative Delirium

Risk factors associated with the development of PD can be categorized as preoperative, intraoperative, or postoperative. Pre-existing factors are inherent to the patient or situation, in contrast to risk factors that develop during the perioperative period (i.e., triggering risk factors). Additionally, risk factors may be considered amenable to optimization or nonmodifiable.

Preoperative Factors

Aging patients with neurobiological dysfunction at baseline are at increased risk for PD. Patients with systemic illness, reflected by higher American Society of Anesthesiologists (ASA) physical status scores and poor functional status, are also high risk for development of PD. Preoperative risk factors for PD can be recognized broadly as decreased cognitive reserve, burden of physiological and cognitive-behavioral comorbidities, and substance exposure and abuse (Table 1).

As older patients undergo a wide variety of surgeries, the risk of PD appears to go up starting at approximately 60 years [9–17]. Insult to the physiology and function of the central nervous system is associated with PD. Cerebrovascular disease [17–19], history of dementia [20] or delirium [21], subjective reporting of memory complaints [22] or objective performance below a standard reference score on cognitive tests [13, 20, 21, 23–26] are all surrogates for decreased

cognitive reserve. Low baseline regional oxygen saturation level in the brain is also a risk factor for PD [27, 28]. Amount and severity of systemic disease likewise correlates with development of PD. Diabetes [17, 18], peripheral artery disease (PAD) [18, 29], cardiovascular disease (atrial fibrillation [16, 30], heart failure [9, 19]), obstructive sleep apnea [31], and renal failure [32] have all been linked to risk for PD. Similar to the ASA physical status score used preoperatively, the Charlson Comorbidity Index (CCI) is more broadly utilized to quantify the comorbidity load a patient carries. Higher CCI scores are strong predictor of PD risk [33–37]. Additionally, decreased functional capacity and preoperative frailty are risk factors for PD [23, 36, 38, 39]. High level of dependence on care givers as measured by Activities of Daily Living (ADLs) [40] and lower overall quality of life [41] are associated with PD. More robust patients are at decreased risk for PD compared to those with poor preoperative nutritional status [42, 43], dehydration [44] and fluid fasting [45], and low BMI [23, 37].

Psychosocial factors should be elicited as part of the patient's history as they may modify the patient's risk for PD. An optimistic attitude and positive expectations have been shown to be protective against PD [46], while patients with depressive symptomatology [13, 18, 47] or a history of depression [48] are at increased risk for PD. PD is seen more commonly in patients dissatisfied with their degree of preoperative social support [49], and patients with a history of substance abuse are more likely to develop PD including alcohol [20, 21, 50], drugs [14], and tobacco [16, 51]. The experience of pain can increase risk for PD as higher baseline pain scores reported before surgery predict increased likelihood of developing PD [17, 35, 52].

Drugs can greatly impact physiology and cognition in geriatric patients. The American Geriatrics Society has published the Beers Criteria List, a comprehensive assessment of medications best avoided in elderly patients [53] [54], and Beers Criteria medications like benzodiazepines, nonsteroidal anti-inflammatories (NSAIDS), antihypertensives, and sliding scale insulin are routinely given to surgical patients. Used perioperatively for their antihistamine, antispasmodic, and anti-emetic properties [55, 56], anticholinergic compounds found on the Beers Criteria List should be avoided in geriatric patients. Administration of corticosteroids and meperidine has been linked to development of PD and should be avoided as well [8, 54]. Avoidance of specific medications and decreasing polypharmacy are good strategies for lowering risk of PD [57, 58].

Intraoperative Factors

Risk for PD has been associated with a number of intraoperative variables. Hemodynamic instability is linked to increased risk of PD, and medication-specific risks are seen intraoperatively as well as preoperatively (Table 2).

After invasive surgery [14, 59–62] and emergency surgery [10, 60, 63], patients have increased likelihood of developing PD. Surgical time has been positively correlated with incidence of PD [20, 37, 64]. Intraoperative hypotension and hypothermia are risk factors for PD [50, 65, 66], as well as blood loss [67], blood transfusion [12, 68], and increased fluid administration [17]. Increased embolic load to the cerebral vasculature during cardiopulmonary bypass (CPB) is hypothesized to be a mechanism of PD [69, 70].

Contributions of anesthetic medications to the risk of PD have been investigated in several studies, but overall the two major approaches to surgical anesthesia, general and regional techniques, have not been shown to differ in risk for PD [71–73]. Identified as a potentially modifiable factor, depth of anesthesia is being studied for impact on PD risk. Exposure to episodes of deep anesthesia was shown in one study to increase PD [74], and deep sedation with propofol infusion (Bispectral Index Score (BIS) of 50) has been associated with significantly higher prevalence of PD compared to light sedation (BIS of 80) [75]. Midazolam can be desirable for its amnestic properties and for its hemodynamic stability, but its use (at least as an infusion) is associated with PD [49]. Likewise, administration of long-acting [45] and short-acting opiates during surgery increases risk of PD [45–77].

Postoperative Factors

Several characteristics of postoperative management, in addition to various postsurgical complications, are associated with onset of PD (Table 3).

Paradoxically, both poorly controlled pain and use of opioids [78–80], such as meperidine [81–83] and tramadol [84], have all been associated with increased PD risk. Intravenous administration of opiates with patient-controlled analgesia (PCA) is associated with more risk of PD than oral opioids [40, 78]. Lumbar plexus block plus PCA has been shown to significantly reduce the risk of PD compared to PCA alone in hip arthroplasty patients [85]. Ideally, a plan for analgesia is developed by the surgeon and anesthesiologist for any major surgery in a geriatric patient. Incorporation of opioid-sparing techniques like adjunctive medications (e.g., acetaminophen, gabapentin) and regional analgesia (e.g., peripheral nerve blocks and epidurals) should be part of the analgesia plan. A prophylactic pharmacologic bowel regimen should be started if opiates are necessary to decrease problems associated with decreased bowel motility [86].

Postoperative complications have a significant impact on the risk for PD. Critical illness requiring postsurgical admittance to the ICU [36] and longer duration of mechanical ventilation [64, 77] have been associated with PD, along with pneumonia [19, 87] and low cardiac output syndrome [11, 64]. Anemia [67] and blood transfusion increases risk for PD [67], as does low postoperative oxygen saturations [88]. PD is more frequent in the setting of markedly abnormal postoperative levels of sodium, potassium, or glucose [89]. Systemic inflammatory response syndrome (SIRS) [34], elevated levels of CRP [77, 90], and increased

Table 3 Postoperative risk factors for postoperative delirium

Risk factor	Study	Population

postoperative body temperature have been associated with increased risk of PD.

Features, Etiology, and Diagnosis of PD

Features

The Diagnostic and Statistical Manual of Mental Disorders Fifth Edition (DSM V) diagnosis of delirium requires that symptoms must have an acute onset and be fluctuating in their course. Decreased orientation to the environment, cognitive disturbances like altered memory, language, perception, and visuospatial abilities, along with inattention are necessary to diagnose delirium. A comprehensive evaluation for conditions in the differential diagnosis of PD should commence quickly in geriatric patients, initiating with prompt intervention for life-threatening conditions like hypoglycemia, hypoxia, and ischemia (Table 4).

Table 4 Differential diagnosis for postoperative delirium

Emergence from anesthesia drugs (polypharmacy, withdraw, anticholinergics, antihistamines, barbiturates, and benzodiazepines)
Endocrine and metabolic disturbances (hypoglycemia, hypothyroidism, hyponatremia, Hyperammonemia, etc.)
Mental disorders (dementia, depression, and anxiety)
Hypoxia and ventilation disturbances
Infection
Sensory deprivation or overload
Ischemia (TIA, CVA)
Intracranial neoplasm
Seizure disorder (postictal state)

Courtesy Michelle Humeidan, Stacie G. Deiner, and Nicholas Koenig

The duration of dysfunction and the activity level of the patient are used to identify subtypes of PD. Acute PD (hours to days) and persistent PD (weeks to months) can manifest with hyperactivity, hypoactivity, or mixed activity. Mood lability, agitation, and/or refusal to cooperate with medical care are often seen in hyperactive delirium. Sluggishness and decreased psychomotor activity are features of hypoactive delirium. Delirium tends to wax and wane over a patient's clinical course, and individuals may display mixed characteristics of both extremes of activity in PD [91]; however, the majority of patients will be one or the other. The hypoactive subtype has the worst overall prognosis [92].

Etiology

Significant preclinical and translational research efforts are focused on elucidating potential mechanisms of PD, though clear targets for the prevention and modification of PD outside of clinical risk factors are currently lacking.

Immune activation can lead to CNS dysfunction and is a promising field of study [93] . Markers of immune activation can be measured in a variety of tissues including plasma, urine, and CSF, and investigations in delirious patients have reported elevated levels of C-reactive protein (CRP), interleukins (IL), tumor necrosis factor-α (TNF-α), and cortisol to name a few [93, 94]. Pro-inflammatory cascades are initiated by important perioperative events like surgical trauma and/or infection, but just the process of aging can prime the immune system and CNS of geriatric patients for exaggerated and pathologic inflammatory response to stress [93–95]. Oxidative stress is important to immune function, but can also be detrimental if the burden of reactive oxygen species overwhelms metabolism. Energy imbalances and local ischemia associated with oxidative stress can have significant downstream effects on CNS function.

Sleep hygiene is an important part of optimizing care for geriatric patients as sleep-deprivation impairs cognitive function. Both major and minor surgery can disrupt circadian rhythms resulting in diminished postoperative sleep quality, slowed recovery, and possibly a predisposition for PD [96]. Although endogenous melatonin dysregulation is seen after major surgery [97] and patients with PD have been reported to have low melatonin levels [98], postoperative melatonin supplementation for prevention of PD in ICU patients after major elective surgery has not shown benefit [99].

A variety of disruptions in neurotransmitter regulation have been implicated in PD, including altered acetylcholine, dopamine, norepinephrine, glutamate, serotonin, histamine, and g-aminobutyric acid (GABA) [93, 94]. A cholinergic mechanism is central to the pathophysiology of Alzheimer's disease and may be an important mechanism contributing to increased risk of PD in patients with pre-existing dementia [100, 101].

Diagnosis

Once various metabolic, physiologic, and pharmacologic reasons for delirium have been excluded, PD can be screened for using a variety of validated assessment tools like the Delirium

Symptom Interview (DSI), NEECHAM Confusion Scale, Intensive Care Delirium Screening Checklist (ICDSC), and Nu-DESC (Nursing Delirium Screening Scale). As per the AGS Guidelines, health professionals caring for post-surgical patients should be recognizing, evaluating, and documenting signs and symptoms associated with delirium [8]. Likely the most utilized delirium assessment tool – the CAM – was developed as a bedside assessment for delirium that could be administered quickly by non-psychiatrists. The CAM is validated as a sensitive, specific, reliable, and easy to use tool for delirium identification [8, 102]. The CAM has been modified for use in different patient populations. Recognizing the communication difficulties inherent to ICU patients secondary to mechanical ventilation, presence of orogastric tubes and exposure to psychoactive medication, the brief 4-question CAM-ICU was created [103].

Treatment of PD

Prevention efforts targeting PD should involve awareness of factors important for identification of high-risk patients, followed by attempts to impact any modifiable characteristics of the patient, surgery, and anesthetic plan. Despite best practices for prevention, PD will develop in some geriatric patients, and environmental adjustments, appropriate diagnostic testing, and addition of consultants to the care team are recommended by the AGS Guidelines as part of a comprehensive treatment plan for PD (Table 5).

Both nonpharmacologic and pharmacologic approaches can be used for treatment of PD. Based upon the Yale Delirium Prevention Program, the Hospital Elder Life Program (HELP) has been the most studied treatment strategy for delirium in hospitalized medicine patients. Pre-existing cognitive impairment, sleep deprivation, immobility, visual impairment, hearing impairment, and dehydration are targeted by a standardized protocol, which has been associated with a 14.4% decrease in delirium and an estimated cost savings of >$1.2 million per year in a 500-bed community teaching hospital [104]. Additional focus on early mobilization, nutrition optimization, and cognitive activities in abdominal surgery patients has shown promising ability to decrease PD [105]. In general, non-pharmacologic interventions for the effective treatment of PD include increased physical activity and cognitive stimulation, constant access to hearing and visual aids, good sleep hygiene, and adequate nutrition and hydration. Engaging a full range of team members from nursing to geriatric medicine consultants for the optimal care of the delirious postoperative geriatric patient is important.

According to the AGS Guidelines, only patients that are severely distressed or agitated and pose a threat to themselves or others warrant pharmacological treatment with antipsychotics. Antipsychotics are not indicated for prophylaxis against delirium. Daily face-to-face evaluation of patients with PD should be completed, ensuring that the lowest effective dose and shortest possible duration guides administration of psychoactive medications to geriatric patients.

Conclusion

PD is one of the most common complications after surgery in geriatric patients. The impact of PD on postoperative recovery is significant, putting patients at risk for loss of function and mortality, while adding tremendous costs to healthcare. Knowledge of key risk factors is important to give perioperative providers an awareness of patients at risk for PD. Screening patients for risks can identify modifiable factors and bring attention to those patients that may require enhanced services as part of their care. The most encouraging approach to preventing and treating PD employs a multidisciplinary team of providers to optimize perioperative care of geriatric surgical

Table 5 Summary of best practices in the prevention and treatment of postoperative delirium [8]

Perioperative phase of care	Best practice	Strength of recommendation	Quality of evidence
Preoperative (prevention)	Educational programs to improve understanding of epidemiology, assessment, prevention, and treatment	Strong	Low
Preoperative (prevention)	Multicomponent nonpharmacologic intervention program (e.g., cognitive reorientation, sleep enhancement, early mobility, adaptations for sensory impairment, nutrition, fluid repletion, pain management, adequate oxygenation, prevention of constipation)	Strong	Moderate
Postoperative (management/ treatment)	Multicomponent intervention program (cognitive reorientation, mobility/exercise/physical therapy, therapeutic activities/cognitive stimulation, sensory adaptation, nursing education, and geriatric consultation)	Weak	Low
Postoperative (management/ treatment)	Perform medical evaluation, make medication and/or environmental adjustments, order appropriate diagnostic tests, and obtain appropriate clinical consultations to identify and manage underlying PD contributors	Strong	Low
Preoperative/ postoperative (prevention)	Provide regional anesthetic at the time of surgery and postoperatively to improve pain control	Weak	Low
Postoperative (prevention)	Optimize postoperative pain control with nonopioid medications if possible	Strong	Low
Postoperative (prevention)	Avoid medications that induce delirium (e.g., benzodiazepines, anticholinergics, sedative-hypnotics, meperidine)	Strong	Low
All (prevention and management)	Avoid newly prescribing cholinesterase inhibitors to prevent or treat PD	Strong	Low
Postoperative (management/ treatment)	Use antipsychotics at lowest effective dose for the shortest possible duration to treat severely agitated or distressed patients (only if behavioral interventions have failed) – evaluate ongoing use daily	Weak	Low
Postoperative (management/ treatment)	Avoid benzodiazepines as first-line treatment of agitated patient except when specifically indicated (i.e., treatment of withdrawal)	Strong	Low
Postoperative (management/ treatment)	Avoid antipsychotics and benzodiazepines in older adults with PD who are not agitated (e.g., hypoactive PD)	Strong	Low

Table excludes practices for which the American Geriatrics Society Expert Panel did not issue a recommendation for or against and/or practices lacking sufficient evidence of efficacy

patients with both pharmacologic and nonpharmacologic approaches. Early recognition of PD is of paramount importance, and all care providers for geriatric surgical patients should be able to recognize PD symptomatology. Protecting the cognitive function of geriatric patients should be a primary goal of geriatricians, surgeons, anesthesiologists, and nursing working through collaborative strategies to provide optimal care to the aging surgical population.

Abstract

The science of health care targeting the unique needs of older adults has evolved tremendously during the last 30 years including the development of several geriatric models of care across all health care settings. This chapter describes the most prominent geriatric hospital models of care, including their objectives, unique strategies, and outcomes. All geriatric care models aim to prevent complications and address hospital factors that can contribute to complications. Although each may differ in their approach, all incorporate the principles of comprehensive geriatric assessment: physical health, functional status, psychological health, and socio-environmental parameters. The overall objectives of the models are similar: educate health care providers in core geriatric principles, target risk factors for complications, incorporate patient or family choices and treatment goals, employ evidence-based interventions, promote interdisciplinary communication, and emphasize proactive discharge planning (or transitional care). Geriatric models of care usually include institutional approaches that address workforce issues as well as how the evidence-based geriatric care processes are embedded within the organizational structure of the hospital or health system. Specific models of care described include the consultative service or mobile ACE unit, NICHE, and HELP as well as evolving surgical specialty models of care.

Introduction

Models of care addressing the unique needs of older hospitalized patients can be traced to the comprehensive geriatric assessment (CGA) programs first developed in the 1970s [1]. CGA programs screen older patients at high risk for geriatric specific problems, assess for modifiable risk factors, and implement evidence-based strategies consistent with the patient's treatment goals. Over the last 35 years, changes in the health care system, coupled with the increasing older adult population, has led to development of several geriatric models of care across all health care settings. In general, the goals of these geriatric models of care in the hospital focus on (1) prevention of complications that occur more commonly in older adults and (2) address hospital factors that contribute to complications. This chapter provides an overview of complications that are more frequently found in older patients, care delivery issues that are addressed by geriatric models of care, and a description of the most commonly employed hospital models.

Complications of Older Hospitalized Patients

Although patients aged 65 and over represent about 14.5% of the US population, they account for 55% of those undergoing surgical procedures in American hospitals [2]. In addition to the high proportion of older patients, the most troublesome finding is that older patients also represent a higher complication rate for certain conditions which subsequently lead to higher health care costs and account for three-quarters of postoperative mortality [2]. Older adults are more likely to experience additional types of complications that, in addition to reducing survival, can result in loss of independence and lead to hospital readmission, increased usage of rehabilitation services, and new placement in a nursing home. The physiologic changes with aging coupled with the higher likelihood of physical frailty and cognitive impairment (either chronic dementia and/or delirium) all contribute to the older person's vulnerability to complications during hospitalization [2–4]. The complex challenges of those adult patients with cognitive impairment are often not adequately addressed. Table 1 provides examples of common behaviors of cognitively impaired persons that can lead to complications. The resulting increased length of stay, increased risk of posthospital complications, and higher costs are well documented [6, 7].

Although geriatric models of care can improve the overall outcomes and experiences of hospitalization, [8] in general, these programs are designed to target those adverse events that occur more commonly in older patients. Table 2 provides a summary of these complications and the clinical and related cost outcomes associated with these complications. These complications are often referred to as "geriatric syndromes" that are further described in ► Chap. 5, "Geriatric Syndromes."

The Inpatient Prospective Payment System that the Centers for Medicare & Medicaid Services (CMS) uses to reimburse hospitals instituted provisions in October 2008 for eight preventable hospital-acquired conditions that would not receive payment [9, 10]. Three of these eight are complications are known to occur most frequently in older inpatients and have been found to be reduced when geriatric models of care are employed [8, 11]. These three complications (fall-related injury, pressure ulcer, and catheter-associated urinary tract infection) are among the six adverse events or complications specifically associated with hospitalization of older adults.

Table 1 Behaviors of cognitively impaired patients contributing to high complication rate (Silverstein and Maslow [5])

Behaviors	Example	Potential complication
Inability to follow directions	Does not use call bell to ask for assistance and gets out of bed without needed assistance	Fall-related injury
Removal of treatments	Pulls out central lines	Hemorrhage
		Infection
		Physical restraints and associated complications
Not able to communicate needs	In pain but not able to verbally communicate this to nurse	Functional decline
Wandering	Leaves unit and exits hospital in gown	Hypothermia
		Other injuries
		Use of physical and chemical restraints that increase likelihood of delirium, falls, fall-related injury, and nutritional problems
Misinterprets visual and auditory cues	Resists staff attempts to assist the patient to get out of bed which is perceived as an assault and then hits staff	Agitation-related injury
		Overuse of psychoactive medication that increase likelihood of delirium, falls, and fall-related injury
Decreases inhibition of inappropriate behaviors	Removes clothing and walks down the hallway nude	Agitation-related injury
		Overuse of psychoactive medication that increases likelihood of delirium, falls, and fall-related injury

Table 2 Complications in the older surgical patient[a]

Complication	Hospital factors[b]	Clinical outcome	Cost implications
Functional decline	Immobility Bed rest without medical/surgical indication Physical restraint Inappropriate medication prescribing New psychoactive drug use Obstacles in the hospital physical environment	Reduced/loss of independence in function (activities of daily living) Reduced/loss of ambulation Pain Increased rate of pressure ulcers, falls, fall-related injuries, and development of contractures	Longer length of stay (LOS) Increased rate of institutional or home-based rehabilitation Nursing home placement
Fall-related injury	Immobility Physical restraint Inappropriate medication prescribing New psychoactive drug use Obstacles in the hospital physical environment	Pain Fracture requiring surgical intervention Reduced/loss of independence in function (activities of daily living) Reduced/loss of ambulation	Medicare will not pay for treatment[c] Surgery Longer LOS Institutional or home-based rehabilitation Nursing home placement
Under/malnutrition	Immobility Inattention to oral care Lack of feeding assistance for those with physical or cognitive impairments	Reduced wound healing Discomfort due nasogastric tube placement Percutaneous enteral access procedures (gastrostomy) Delirium Physical restraint to prevent tube removal Aspiration Functional decline	Longer LOS Surgery Institutional or home-based enteral nutrition therapy
Pressure ulcer	Immobility Physical restraint Under/malnutrition Dehydration	Immobility Sleep deprivation Pain Sepsis Septicemia Surgical debridement Surgical techniques (direct closure, flaps, and skin grafting)	Medicare will not pay for treatment[b] Longer LOS Institutional or home-based skilled nursing treatment

Urinary tract infection (UTI: secondary to catheter use or CAUTI)	Emergency room placement without indication Incontinence treatment No postsurgical monitoring of catheter use	Immobility Pain Delirium Acute pyelonephritis Bacteremia Sepsis Prosthetic joint infection Higher risk for death	Medicare will not pay for treatment[b] Longer LOS Rehospitalization
Delirium	Physical restraint Inappropriate medication prescribing New psychoactive drugs Urinary catheterization CAUTI Immobility Under/malnutrition Dehydration	Functional decline Persistent cognitive impairment Falls, injuries Undetected infection Sleep deprivation	Longer LOS Rehospitalization Nursing home placement Death

[a]Geriatric syndromes refer to conditions highly associated with aging such as frailty, sleep disorders, self-neglect. For the purpose of this review, these syndromes and potential complications are more narrowly defined
[b]Hospital factors. There is a myriad of patient and hospital factors that contribute to each complication; however, this list provides examples of those specific hospital practices that place the older adults at high risk and which are the focus of geriatric care model interventions
[c]As of October 2008, hospitals no longer receive payment for eight hospital-acquired conditions; three of these eight indicated in the table are complications known to occur most frequently in older inpatients and are reduced when geriatric models of care are employed (fall-related injury, pressure ulcer, and catheter-associated urinary tract infection)

Although there are other geriatric syndromes (e.g., incontinence) and other potential complications associated with older inpatients (e.g., sleep deprivation, inadequate pain management, dehydration, adverse drug effects), many of these syndromes and complications are either risk factors or outcomes of these three and/or functional decline, under/malnutrition, or delirium. More details about each of these can be found in other ▶ Chaps. 7, "Frailty," ▶ 8, "Function and Prehabilitation," ▶ 22, "Postoperative Delirium," and ▶ 24, "Nursing Issues in Older Adult Surgery Patients."

The occurrence of each of these complications leads to interventions that can often prolong the hospital stay. Following hospital discharge, they frequently contribute to death, institutionalization as well as disproportionately high pre-hospitalization rates, high emergency department usage, and increased need for rehabilitation therapy services. As illustrated in Table 2, the *inter-relationships* among these various complications during hospitalization are obvious. The data supporting the importance of prevention, early detection and treatment of these complications in older surgical patients is well documented [8, 11, 12]. This led, in 2012, to the American College of Surgeons (ACS) partnering with the American Geriatrics Society (AGS) and the John A. Hartford Foundation to develop the American College of Surgeons National Surgical Quality Improvement Program (NSQIP)/American Geriatrics Society (AGS) Best Practices Guidelines: Optimal Preoperative Assessment of the Geriatric Surgical Patient. This guideline was updated rereleased in 2016 [4].

Although patient characteristics, especially multiple comorbidities, frailty, and cognitive impairment, may increase vulnerability of older inpatient to negative consequences, the hospital environment plays an independent and significant role in determining staff practice and subsequent patient outcomes such as iatrogenic complications [13]. Thus, geriatric models of care are meant to address these hospital-based or institutional factors that are likely to contribute to complications among older patients. Effective resolution of these negative consequences is dependent on geriatric models that target both patient and environmental (institutional) risk factors.

Geriatric Care Model Objectives

Although geriatric models of care differ in their approach to prevent complications and address care delivery problems that can contribute to complications, all share a common set of general objectives [14, 15]. Although these objectives could be applied to any patient regardless of age, it is how geriatric care models apply these that are age-specific. Table 3 provides examples of processes and interventions to meet these six general objectives.

The six general objectives of geriatric care models are:

Educate Health Care Providers in Core Geriatric Principles

The complications most frequently encountered among *o*lder patients are often due to system-level problems. These include inadequate educational preparation of health care providers to recognize age-specific factors that increase risk of complications [16, 17]. All geriatric care models require a coordinator or clinician with advanced geriatric education, however, the implementation of any model depends on direct care staff with the knowledge and competencies to deliver safe and evidence-based care to older patients. Thus, the coordinator or other geriatric clinician role includes teaching of other staff through rounds, journal clubs, conferences, and other internal institutional educational venues [18].

Target Risk Factors for Complications

Given the disproportion of certain complications or geriatric syndromes among hospitalized older adults, the clinical focus of all geriatric models is prevention via risk factor reduction and early detection of these problems. Some models may focus on

Table 3 Geriatric care models: objectives, processes, and interventions

Objective	Examples of processes	Examples of interventions
Educate health care providers in core geriatric principles	Resident training includes required geriatric rotation *or* mandatory geriatric rotation for residents Institutional continuing education includes geriatric-specific training *or* geriatric-specific interdisciplinary continuing education programs Geriatric specialist responsible for geriatric training initiatives	Hospital intranet includes geriatric programming Journal club includes geriatric journals and/or articles focusing on geriatric outcomes Medical, surgical, nursing, and interdisciplinary rounds include geriatric case studies
Target risk factors for complications	Policies, protocols, and documentation system includes assessment tools and practices that identify older adults at risk for complications Assessment tools prompt providers to consult geriatric specialists for evaluation of high risk problems Geriatric specialist provides individual evaluation of risk factors	Electronic medical record (EMR) provides alerts for medications prescribed that are known to increase fall risk EMR prompts providers to document daily cognitive testing results Hospital policy for daily cognitive assessment of at-risk patients Cognitive assessment indicates delirium that leads to geriatric specialist consultation
Incorporate patient (family) choices and treatment goals	Policies and protocols support and documentation system includes forms that elicit patient choices as well as family involvement in care Geriatric nurses are prepared to coordinate an interdisciplinary evaluation and promote development of *informed* patient/family treatment goals and plan of care Palliative care is consulted and provides informed choices to patients/families in situations of life-threatening illness	Admission history includes evaluation of patient's preferences for postdischarge rehabilitation Unlimited visiting hours and bedside recliners encourage family participation in recovery Patient and family preferences for type and degree of family involvement is documented Patient with Alzheimer's disease who is unable to verbally indicate needs is evaluated by palliative care specialist for pain evaluation/treatment
Employ evidence-based interventions	Policies and protocols integrate geriatric specific implications Education and training for all clinicians include core geriatric content	Hospital protocol for urinary catheter removal within 2 days postsurgery Unit-based mobility program Physical environment reduces injury risk for nonambulatory patients with dementia such as low-height beds and bedside mats
Promote interdisciplinary communication	Medical record facilitates patient information across disciplines Processes in place to encourage face-to-face interaction among disciplines Unit-based and hospital-wide committee includes geriatric specialist representation	Interdisciplinary team rounds held biweekly Programmatic initiatives include all applicable disciplines, for example, physical and occupational therapy in unit-based mobility program Comanage patients across specialties such as geriatric oncology Collaborate with other programs such as palliative care in providing symptom management
Emphasize discharge planning or transitional care	Documentation system provides comprehensive hospital course information to primary care provider and other postdischarge providers (home care, nursing home, etc.) as well as elicits pertinent information *from* other providers	Patient and caregiver receive comprehensive documentation of hospital treatment, changes in treatment plan, and postdischarge instructions Understanding of instructions is evaluated before discharge Phone follow-up postdischarge to evaluate patient condition and needs

a particular syndrome; however, the interrelationship of these complications and their shared risk factors often result in a reduction of the other geriatric syndromes. Targeting risk factors requires standardized assessment tools known to be valid and reliable for older adults. See the 2015 Best Practices Guideline from ACS NSQIP/American Geriatrics Society [4], and the Portal of Geriatrics Online Education (http://www.pogoe.org/) for examples of assessment instruments. Implementation of geriatric care models often includes institutionalizing these practices such as incorporating these tools in the medical record as well as hospital policies, procedures, and protocols.

Incorporate Patient (Family) Choices and Treatment Goals

All health care decision should be guided by the patient's choices. Choices range from decisions about activity level and medication use to more complex issues including advance directives. Decisions regarding life-sustaining treatment are often influenced by quality of life considerations balanced by the potential length of life. For family members acting in the best interests of patients who can no longer participate in decision-making, this can be a complicated dilemma. Life-sustaining treatments are often employed with very old patients who die in the course of hospitalization although most prefer comfort care. Geriatric models are meant to address this lack of congruence by supporting efforts to provide care that is more consistent with patients' preferences [19]. For this reason, many geriatric models work collaboratively or in conjunction with palliative care programs [20]. See also the ▶ Chap. 18, "Ethical Issues in Older Adults."

Employ Evidence-Based Interventions

Given that most physicians, nurses, and other health providers have received minimal content in their training regarding geriatrics, it is not surprising that there is a higher complication rate for older hospitalized patients. Advances in geriatric science, similar to other research-based approaches, are not readily employed in hospital care. Problems with polypharmacy, inappropriate medications (e.g., overuse of psychoactive), overuse of restraints, inadequate detection of delirium, depression, and undermanagement of pain are some of the many hospital factors that can contribute to poor outcomes. Thus, geriatric models promote the use of standardized evidence-based guidelines [4].

Promote Interdisciplinary Communication

Since geriatric syndromes are not just medical problems but represent a complex interaction of medical, functional, psychological, and social issues, other disciplines such as nursing, pharmacy, social work, physical and occupational therapy are needed. Geriatric care models all include interdisciplinary teams, i.e., an approach that facilitates communication among disciplines, which is known to improve patient outcomes [21]. Examples of successful strategies include interdisciplinary rounds and standardized communication (e.g., SBAR) [22].

Emphasize Discharge Planning (or Transitional Care)

Many older patients will require rehabilitation or skilled nursing services following surgery. Older adults are more likely to experience problems associated with discharge planning that can lead to delays in discharge and greater use of emergency service use and hospital readmission. Hospital readmission for older patients is most likely associated with medical errors in medication continuity, diagnostic workup, or test follow-up. These poor outcomes are attributed to a lack of coordination among health care providers that can result in unresolved medical issues and deficient preparation of patients and their caregivers to carry out discharge instructions [23]. Geriatric models not only focus on the inpatient experience but also the post-hospital care environment and the care transition following hospital discharge.

Two of the six models consider the care transition a primary focus of their programs.

Geriatric Models

There are several types of geriatric models that are currently employed in hospitals throughout the United States. In addition to incorporating the original tenets central to comprehensive geriatric assessment (screen for those at high risk for geriatric specific problems, assess for modifiable risk factors, and implement strategies consistent with the patient' treatment goals) all also strive to deliver quality care for older adults in a cost-effective manner. Comprehensive geriatric assessment assumes that the systematic evaluation of a frail older person by a multidisciplinary health care team will uncover actual or potential health problems. The considerable advances in geriatric health care science over the last 35 years can then be applied in treating or preventing these conditions and thus result in better health outcomes.

Although the specific mode of intervening may differ among the models, they all address both common health problems and care delivery issues. The geriatric model may consider all geriatric syndromes or target specific ones such as delirium or functional decline. Similarly, a geriatric model may be employed as a hospital-wide approach, unit-based intervention, or focus on specific processes of hospitalization such as admission screening or discharge planning. Geriatric care may also be integrated within surgical specialty services. Regardless of the structure of the geriatric model, all facilitate the general objectives listed in Table 3. Table 4 provides a summary of the clinical foci, unique features, coordination, and interventions for each of the six most commonly employed geriatric models of care.

Geriatric Consultation Service

Older hospitalized patients are vulnerable to adverse events and certain medical conditions in the acute care setting or following hospitalization. Their multiple comorbidities and reduced physiological reserves place these individuals at risk to develop certain hospital-acquired geriatric syndromes such as hospital-associated deconditioning, delirium, pressure ulcers, falls, hospital-acquired infections among other geriatric syndromes. These geriatric syndromes in hospitalized older adults can increase morbidity, mortality, and resource utilization. Further, these adverse events can change the trajectory of recovery for a person and decrease the quality of life for the patient and family caregiver.

The geriatric consultation service focuses on early identification and treatment of vulnerable hospitalized older adults who develop geriatric syndromes. Nursing leaders and the interdisciplinary team are essential to providing the best care for this vulnerable population. Increasing awareness and timely recognition of common geriatric syndromes in older adults can significantly impact the outcomes in this particular population.

The geriatric consultation service and the multidisciplinary team provide input to other specialties that focus on preserving functional mobility, minimizing iatrogenic events, preventing the use of potentially inappropriate medications in hospitalized patients. The geriatric medicine consultation service works with other medical and surgical specialties to comanage complex cases. Often geriatricians will take the lead when addressing common conditions such as delirium, malnutrition, depressed mood, behavioral and psychological symptoms of dementia, frailty, pain, sensory impairment, and sleep disorders. The geriatric consult service can impact length of stay, readmission rates, complications, hospital costs, and mortality rates. The consultation service integrates other disciplines such as social services, physical therapy, occupational therapy, pharmacist, speech therapy, and dietitian services. The geriatrician's role on this team is to coordinate this comprehensive evaluation of the patient's medical and geriatric functional needs. Geriatric medicine also pays particular attention in delineating the patient's goals of care and determining post-acute care needs. The key approach to this model is to assess the patient's cognitive

Table 4 Core components of six geriatric care models

Model type	*Clinical outcome focus*[a]	*Unique features*	*Program/team coordination*	*Interventions*[b]
Geriatric consultation	Primary focus can vary depending on composition of consult team and may be specific to a surgical specialty or procedure	Employed by primary provider request	Individual consultant (geriatrician, geropsychiatrist or geriatric nurse specialist) *or* Interdisciplinary team that is coordinated by geriatric medicine or psychiatry fellow, geriatric nurse specialist or an administrative director	Comprehensive geriatric assessment: medical, psychiatric, functional, and social Recommends interventions based on consultant discipline (medicine, psychiatry or team that includes nurses, social workers, and others) Primary provider chooses which recommendation to employ
Acute Care for the Elderly (ACE)	Functional decline	Dedicated unit with explicit admission criteria Requires interdisciplinary team and Redesign of physical environment to accommodate physical and cognitive needs	Unit directed and/or team coordinated by geriatrician, geriatric nurse specialist, administrator or comanaged by clinician-manager	Physical environment to promote patient mobility, orientation, and staff observation Interdisciplinary rounds facilitate care coordination and thus: Identify modifiable risk factors for geriatric syndromes and complications Prevent avoidable discharge delay Promote timely referrals to disciplines or specialists
NICHE: GRN/ACE	Nursing processes related to all geriatric syndromes and potential complications such as avoiding restraint use, initiating urinary catheter removal	Focus on improving nursing care of all geriatric syndromes Prepares staff nurses to take active part in geriatric care management including coordinating or facilitating other geriatric models of care	Program implementation by NICHE Coordinator (usually a geriatric nurse specialist) Geriatric Resources Nurses (staff nurses with additional training) implement protocols Depending on availability, other clinicians (geriatrician, hospitalist, social worker, etc.) work as interdisciplinary team	Nurse-initiated protocols: Restraint and psychoactive drug reduction Functional mobility Fall/injury prevention Pressure ulcer assessment/treatment Prevention of UTI – early catheter removal Delirium assessment/treatment Organizational strategies including measurement schema, performance improvement techniques, and management tools to promote

(continued)

Table 4 (continued)

Model type	*Clinical outcome focus*[a]	*Unique features*	*Program/team coordination*	*Interventions*[b]
				implementation of above protocols
HELP	Delirium prevention and early management	Requires use of volunteers	Elder Life Nurse Specialist or Elder Life Specialists coordinates interdisciplinary team (geriatrician, recreation therapy, physical therapy, etc.) and trained volunteers	Delirium risk factor protocols: Mental orientation Therapeutic activities Early mobilization Vision and hearing adaptations Hydration and feeding assistance Sleep enhancement
APN transitional care model	Reducing complications specific during the transition from hospital to home	Requires advanced practice nurse coordinator to follow patient in hospital and following discharge	Advanced practice nurse (nurse practitioner or clinical nurse specialist)	Protocols to assess/ intervene with: Medication discrepancies and inappropriate medication usage Case management and APN surveillance across settings
The care transitions intervention	Reducing complications specific during the transition from hospital to home, such as prevent post hospital medication discrepancies, increase likelihood of patient/ caregiver detection of worsening condition	Requires nurse transitions coach to follow patient in hospital and following discharge	Transition coach (nurse or advanced practice nurse) empowers patient and caregiver	Personal health record includes data elements essential to promote productive patient-provider encounters across settings Discharge preparation checklist to facilitate patient's knowledge of discharge instructions Medication discrepancy tool used by transition coach to identify medication issues

[a]All programs are meant to address geriatric syndromes and potential complications; however, for the purpose of this review, these syndromes and potential complications are more narrowly defined to six of the most common complications for older surgical patients
[b]Interventions are guided by the use of standardized assessment tools [4]

function and their ability to participate in complex medical decisions. This is particularly important when evaluating patients with cognitive impairment or dementia.

Please refer to the paper of Deschodt et al. that addresses the impact of geriatric consultation teams on clinical outcomes in acute hospitals and the work of Sennour et al., which describes the development and implementation of a proactive geriatric consultation model in collaboration with hospitalists [24, 25].

The following clinical vignette demonstrates the approach of the geriatric consult service in the acute care setting.

A 75 year old man had a coronary artery bypass graft (CABG) at a large community teaching hospital. His postoperative course was complicated by acute kidney injury, severe anemia, respiratory failure and delirium. His nurse described the patient as delusional, intermittently impulsive and restless. The patient was pulling his arterial line, chest tubes and catheters. He required pharmacologic intervention and physical restraints to address difficult behaviors. The geriatric consult service was formally consulted four days after his surgery. His geriatric syndromes were identified as hyperactive delirium, cognitive impairment in the setting of delirium, functional impairment, malnutrition, dysphagia, pain and sleep disorder. His multidisciplinary care team engaged a pharmacist, who reviewed the details of how the patient had taken medications prior to coming to the hospital. The patient's family reported that he was prescribed alprazolam. The patient was taking up to 3 to 4 pills of this medication a day for "anxiety." It was determined that the patient's delirium was multifactorial and the patient started on scheduled Lorazepam for benzodiazepine withdrawal. Restlessness and anxiety improved. The patient was more cooperative with nursing cares and medical treatments. He was slowly weaned off of his benzodiazepines and transitioned to a selective serotonin reuptake inhibitor. The geriatric consult service worked with the team to provide a detailed initial assessment and a daily monitoring of the plan of care.

Key elements to remember in this particular case include: the early identification of the patient's geriatric syndromes, the multidisciplinary team approach, and the timely communication with other medical/surgical disciplines to create a personalized and comprehensive plan of care.

The Community Aging in Place: Advancing Better Living for Elders (CAPABLE)

Another innovative model of care that addresses the unique needs of vulnerable community-dwelling older adults is the CAPABLE project. This model of care is based in the home-setting but demonstrates important concepts relevant to the care of vulnerable older adults. When older adults are discharged from the acute care setting, often, functional limitations and home environment are not taken into consideration when addressing transitions of care. Ignoring functional impairment and home environment in vulnerable older adults can have important repercussions in patient's quality of life and health care costs.

CAPABLE is a patient-directed, team-based intervention compromising of an occupational therapist, a registered nurse, and *a handyman*. The occupational therapist identifies problematic functional deficits and evaluates difficulties, safety concerns, and environmental barriers. The registered nurse, further, addresses pain issues, depression, and medication management. She/he communicates with the primary care provider, and helps to define functional goals. The handyman determines what equipment or home modifications are necessary to support patient's functional goals. The therapist and the nurse collaborate with other clinicians to discuss their challenging cases. The main goal of this model of care is to decrease hospitalization and nursing home admissions. The program focuses on community dwelling older adults with functional limitations who are eligible to Medicare and Medicaid. Older patients enrolled in this intervention have improved ability to perform their self-cares [26]. The novel aspect of this model is engaging a handy man with the health professionals to address the patient's needs in their home. Putting it all together, the hospital-based geriatric consult service could integrate the CAPABLE intervention to improve care for vulnerable community-dwelling older adults.

Acute Care for the Elders (ACE) Units

An ACE unit is an evidence model of care that focuses on improving the care of hospitalized older adults. The core components of the ACE Unit model of care are: (1) patient centered, (2) nurse-driven geriatric care process, (3) medical care review with an emphasis on preventing iatrogenic events, (4) early care transition planning, and (5) a prepared environment promoting safe mobility and cognitive stimulation. The main goal of the ACE unit is to prevent hospital-associated disability. The interdisciplinary team is an essential component of the ACE units**.** The members of the team include a geriatrician medical director, clinical nurse specialist, nurse manager, bedside nurses, social worker as well as other disciplines such as pharmacy, occupational and physical therapy, nutrition, dietitian, and chaplain. The interdisciplinary team emphasize on maintaining functional mobility, preventing and managing geriatric syndromes, and coordinating early care transitions. The interdisciplinary team led by geriatricians facilitates care coordination and thus identifies modifiable risk factors for geriatric syndromes to promote timely referrals to other disciplines or specialists.

Palmer and colleagues (1994) designed the first ACE unit at the University Hospitals of Cleveland [27]. A randomized controlled trial of Acute Care for Elders in an academic medical center reported improved functional status (ADL or activities of daily living, instrumental ADLs and ambulation) at the discharge of patients hospitalized in the ACE unit compared to those on other units. Fewer patients from the ACE group were discharged to nursing homes. These beneficial effects were achieved without increasing in-hospital or postdischarge costs. There were no significant differences in mortality, length of stay, readmission, or hospital costs between the two groups [28]. In another randomized trial conducted in a community hospital, patients were randomly assigned to either ACE care or a regular care unit. Positive outcomes of the ACE intervention were demonstrated in several processes of care including a reduction in restraint use, days to discharge planning, and use of high risk medications. They also found benefit in a composite outcome of ADL improvement and nursing home placement but not in discharge ADL levels alone. There was no significant reduction in length of stay, hospital costs, or mortality in the ACE unit subjects compared to the regular unit subjects [29].

In a 2012 published systemic review and meta-analysis for over 6800 hospitalized older adults, Fox et al. demonstrated that acute geriatric unit care based on all or part of the ACE Model improves patient and system level outcomes, including fewer fall risks, less delirium, less functional decline at discharge from baseline 2 weeks prehospital admission status, shorter LOS, fewer discharges to nursing home [30]. Data collection and following unit outcome measures is crucial to sustain the ACE unit and to maintain leadership and stakeholder support. Ongoing education of the interdisciplinary team will help to disseminate the ACE program to the rest of the hospital or across the health care system.

Nurses Improving the Care of Health System Elders (NICHE)

The NICHE program (www.nicheprogram.org) is a national program aimed at system improvement to achieve positive outcomes for hospitalized older adults. NICHE has two main goals: improving the quality of care to patients and improving nurse competence. This is accomplished by modifying the nurse practice environment with the infusion of geriatric-specific: (a) core values into the mission statement of the institution; (b) special equipment, supplies, and other resources; and (c) protocols and techniques that promote interdisciplinary collaboration [31]. NICHE includes several approaches, each of which facilitates transfusion of evidence-based geriatric best practices into hospital care. A geriatric nurse specialist as the NICHE Coordinator functions in both a primary care role (evaluating and managing patients directly) and in a leadership role (teaching and mentoring others and changing systems of care). Foundational to NICHE is the Geriatric Resource Nurse Model (GRN), which is an educational intervention model that prepares staff nurses as the clinical resource person on geriatric issues to other nurses on their unit. The GRN model provides staff nurses, via education and modeling by a NICHE coordinator, with specific content for improved knowledge of care management for geriatric syndromes. Clinical protocols and organizational strategies provide necessary tools to apply evidence-based practice. For example, in one NICHE orthopedic unit, GRNs received intensive education on the prevention and detection of delirium in a unit where the primary diagnoses were joint replacement and hip fracture repair. Utilizing a combination of standardized assessment of cognition and focused interventions to prevent post-op delirium, the unit realized a significant reduction in the incidence of delirium. Other NICHE hospitals have GRNs employ delirium-specific order sets.

In single site studies, NICHE hospitals demonstrate improved clinical outcomes, rate of compliance with geriatric institutional protocols; cost-related outcomes; and nurse knowledge [30]. A few studies using aggregate data from the NICHE Benchmarking Service have found that nurses who perceive that their hospital provides adequate geriatric-specific resources (continuing education, specialty services), promotes interdisciplinary collaboration, and fosters patient, family, and nurse involvement in treatment-related decision-making is associated with positive perception of quality geriatric care received by older patients [32–34].

NICHE also promotes a unit-based ACE model. The ACE model within NICHE emphasizes: (1) implementation of nurse-driven protocols, (2) geriatric training of all nursing staff, and (3) utilization of geriatric-specific units within a health system's overall geriatric care programming. Similar to other ACE studies, a NICHE-ACE unit in which the majority of the staff nurses were nationally certified in geriatric nursing reported lower fall and pressure ulcer rates, and lower length of stay when compared to overall hospital [35].

Since NICHE is a system-level approach it provides a structure for nurses to collaborate with other disciplines and to actively participate or coordinate other geriatric care models. For example, in hospitals with a geriatric department or consultation service, GRNs screen for appropriate referrals to these services and can effectively implement geriatric service recommendations with support from the NICHE coordinator. The models enhance NICHE program effectiveness by expanding the scope of geriatric programming within a health system.

The Hospital Elder Life Program (HELP)

The HELP program (http://www.hospitalelderlifeprogram.org/http://elderlife.med.yale.edu/public/public-main.php) targets the prevention and management of delirium, a common postoperative complication in older adults which increases the risk for prolonged length of stay, functional decline, institutional discharge, and 30-day readmission [6]. This multicomponent strategy includes the use of protocols that target delirium risk factors, addressing: mental orientation, therapeutic activities, early mobilization, vision and hearing adaptations, hydration and feeding assistance, and sleep enhancement. These protocols were tested in several well-designed clinical trials and demonstrated significant reduction in the incidence of new delirium. Further, among those who did develop delirium, these protocols are associated with a significant reduction of total number of episodes and days with delirium, functional decline, costs of hospital services, and reduction in use of long-term nursing home services [36, 37]. Moreover, HELP is useful for prevention of falls, one of the Medicare no-pay conditions [38] and has been shown to improve patient and family satisfaction, as well as nursing satisfaction [37, 39].

HELP employs geriatric specialists of various disciplines (geriatrician, geriatric nurse specialist, recreation therapy, and physical therapy) working together as an interdisciplinary team with trained volunteers. The program is coordinated by Elder Life Specialists, typically a nurse who has advanced geriatric nursing education and is responsible for implementing nursing-related assessments and tracking of delirium risk- factor protocol adherence. The latter depends on the involvement of well-trained and supervised volunteers in patient care interventions. The volunteers provide daily visits which focus on orienting communication, therapeutic activities, and assistance with mobilization, feeding and hydration, correction of vision and hearing deficits, and sleep hygiene [36].

Implementation in many hospitals has been adapted based on hospital resources. This has led to wide variations in adherence to the intervention protocol. Although higher levels of adherence have been associated with lower rates of delirium, these adapted protocols continue to provide positive results [40]. Recently, the HELP protocol set was expanded to include constipation and dehydration. Additionally, the National Institute for Health and Clinical Excellence (NICE) in the United Kingdom enhanced the scope of the HELP program with three new protocols (hypoxia, infection, and pain) [41].

Transitional Care Models

Older adult patients with complex medical and social needs and their caregivers require assistance to effectively navigate the health care system, including recovery from surgery and return to premorbid health and living arrangements. There are numerous transitional care programs and the strength of the evidence to reduce post-discharge negative outcomes varies considerably. Two models that have demonstrated improved outcomes for older adults hospitalized for both medical and surgical interventions are the APN transitional care model and the Care Transitions model. More details can be found in ▶ Chap. 27, "Transitioning Care at Discharge."

The transitional care model (see http://www.transitionalcare.info/home) utilizes advanced practice nurses (APNs) whose primary responsibility is to optimize the health of high-risk, cognitively intact older adults with a variety of medical and surgical conditions during hospitalization and for designing and overseeing the plan for follow-up care following discharge. The APNs work collaboratively with the older adult, family caregiver, physician, and other health team members and are guided by evidence-based protocols. The same nurse implements this plan after discharge by providing traditional home care services and by phone availability 7 days a week.

The Care transitions coaching or Care Transitions Intervention (see http://www.caretransitions.org/index.asp) employs a nurse or "transitions coach" to encourage older patients and their family caregivers to assume more active roles during care transitions by facilitating self-management and direct communication between the patient/caregiver and primary care provider.

Surgical Specialty Models

Since recognition of comprehensive geriatric assessment enhances the recognition of older adults most likely to experience adverse events, independent of surgical prognostic indices [8], there has been proliferation of surgical programs consulting or integrating geriatrics. In some cases, a core geriatric interdisciplinary team screens patients for other related services such as palliative care, rehabilitative services, or pain management programs. Others have developed programs that integrate geriatrics within surgical specialties. Examples include orthopedics, cardiac surgery, oncology, and urology.

Orthogeriatric Models

The American College of Surgeons TQIP (Trauma Quality Improvement Program) Geriatric Trauma Management Guidelines (https://www.facs.org/quality-programs/trauma/tqip/best-practice) recommends specialized geriatric inpatient care including criteria for early geriatric consultation and geriatric expertise on the multidisciplinary trauma care team. During the last 25 years, orthopedic programs have emerged incorporating geriatrician input into hip surgery care. The expectation is that involvement of geriatricians in care management will avoid iatrogenic complications and streamline flow though in hospital care including early discharge that will improve survival, clinical, and cost outcomes [42].

There is, however, considerable variance in the way such orthogeriatrics programs are organized. These general models of practice include: (1) Routine geriatric consultation in which the geriatrician and/or geriatric interdisciplinary team consistently consults older patients admitted to an orthopedic hospital unit; (2) Geriatric unit, similar to an ACE unit, with the orthopedic surgeon providing consultation; and (3) Shared care or comanagement in which the responsibility for care of the older patient on an orthopedic unit is shared between the surgeon and the geriatrician [43]. In the last 10 years, comanagement has become the more utilized approach.

In addition to these different model types, the actual components of care that these orthogeriatric programs target also vary considerably [43]. For example, one program focuses on minimizing time to surgery and employment of standardized orders and protocols [44]. These programs have been shown to reduce delirium by over one-third, reduce severe delirium by over one-half, as well as decrease predicted length of stay, readmission rates, complication rates, and mortality [45]. Others have developed a geriatric trauma team that include a geriatrician and geriatric advanced practice nurse who evaluate older trauma patients and shared recommendations in weekly multidisciplinary rounds and performance improvement meetings of the trauma service. Most (91%) geriatric recommendations were followed and included: advanced care planning, disposition decisions to promote function, decreased inappropriate medications, and pain management [46].

The heterogeneity of the orthogeriatric programs (both the overall organization, personnel and the various assessments and interventions employed) makes it difficult to compare outcomes among these programs. A systematic review and meta-analysis of studies reporting outcomes associated with 18 orthogeriatric programs published between 1993 and 2012 [43]. Ten programs employed the routine geriatric consultation model of care and found significant decreases in long-term mortality, in-hospital mortality and time to surgery, compared to controls receiving traditional orthopedic oversight. It was not possible to report conclusions concerning the three geriatric unit studies due to low quality methodology and sample size. The five comanagement studies demonstrated shortened length of stay, compared to controls. Among the 18 studies, several varied clinical interventions were reported such as reduced post-op complications including decreased incidence of delirium and functional decline.

Since 2012, two other reviews of comanaged care have reported similar findings: reduction of short- and long-term mortality and in-hospital complication [42, 47]. Also two randomized control trials of orthogeriatric care have shown improved mobility at 4 months postsurgery compared to controls [48, 49].

The growing trend of orthogeriatric comanagement is consistent with US health care systems moving toward more integrated, multidisciplinary care. The studies to date demonstrate that consistent geriatric input embedded into the orthopedic service is ideal since “as needed” geriatric consultation is often too late to prevent common complications of older patients [42]. Reporting of a consistent set of outcomes is needed; the AO trauma network of Europe recommends that the following parameters should be collected at discharge: mortality, length of stay, time to surgery, complications (medical and surgical), and costs. At admission, quality of life, pain, satisfaction, function, falls, medication use, and place of residence should be collected [50]. Then, depending on the type of parameter, they as well as readmission rates should also be collected 30 days, 90 days, and 1-year post surgery.

Surgical Onco-Geriatrics

Cancer is considered mainly a disease of older adults, given that those over 65 years of age represent approximately 60% of cancer patients and account for 70% of annual cancer deaths. Additionally, the high complication rate, such as delirium, [51] with treatment has led to considerable attention of integrating geriatric assessment into standard oncology practice. A systematic review of nine systematic reviews reported that evaluations of functional status, comorbidity, and frailty are the most predictive of post-oncology surgery complications [52].

In response, oncology programs have either developed onco-geriatric consultation teams or have developed geriatric – oncology units, some of which are part of an existing ACE unit to address prevention or reduction of these complications [53–56]. These programs report that older oncology patients have more complex medical and social needs than adult oncology patients and thus require input from both perspectives.

Other Surgical Specialties

Both general surgery and other surgical specialties (urology, vascular surgery, cardiothoracic surgery, and neurosurgery) are developing geriatric comanagement programs. A VA hospital with these multiple comanagement surgical units reported higher rates of discharge back to the community [57]. A urology comanagement program utilizing a geriatrician-led unit rounds resulted in reduced inpatient stay by and total postoperative complications [58].

Conclusion

Although these models use different strategies, all share common goals of treatment. Each hospital or health system chooses a model based on the unique needs of that hospital's patient population, the resources available (geriatric specialists, bed capacity to support separate unit, volunteers, etc.) and especially senior administrator's commitment to geriatric programming. Since there is no direct reimbursement for many components of these models (interdisciplinary rounds, geriatric nurse specialist, volunteers, etc.), administrators seek external (grants, donor gifts) and internal funding (hospital foundation grants). Administrators are motivated by the model's alignment to the hospitals strategic plan (e.g., excellence in senior care), the institution's mission, patient/family satisfaction, relationship with the community, and costs savings by cost avoidance (i.e., reduction of complications). All of the models have demonstrated positive outcomes and each have been implemented in at least 50 hospitals; however, this still only represents a small proportion of American hospitals.

Each model was originally developed with government and/or foundation support. Future survival of these models may depend on advancing the unique contributions of each within an integrated model that will enhance the hospital experience of the older patient and/or integrating geriatrics within surgical subspecialties. Fulmer and Berman (2016) [59] of the John A. Hartford Foundation posit, "How do we move from a model at a time to a set of strategies that transform systems, drive improved health and cost outcomes, efficiently utilize available resources, deploy them strategically to those at greatest risk, and create the least amount of stress on the care delivery system?" The John A. Hartford Foundation has launched a new Age-Friendly Health Systems Initiative is launching with. Along with the Institute for Healthcare Improvement and the American Hospital Association, a \$3.19 million grant over 42 months will focus on initiating and evaluating a health systems-wide prototype model of care for older adults. The overall goal is that 20% of hospitals and health systems in the United States will be "age friendly" by 2020.

Another problem influencing geriatric model implementation is availability of geriatric clinicians. Since significant geriatric medicine input is needed for many of these models, they generally are limited to academic medical centers, which only represent a small proportion of US hospitals. All of these models require providers with knowledge of core concepts in geriatrics; however, there is a significant shortage of fellowship-trained geriatricians, geriatric psychiatrists, master's prepared geriatric nurse specialists, as well as other disciplines [60]. In addition to efforts to increase the training of geriatric specialists, several initiatives are underway that involve specialty organizations, medical schools, and resident training programs to integrate principles of geriatric care into curriculums and practice [61].

As more geriatrics is being integrated into undergraduate medical training and surgical resident training, knowledge of geriatric care principles, and collaboration with geriatric models will enhance outcomes of the older surgical patients. The Council of the Section for Surgical and Related Medical Specialties in the American Geriatrics Society program provides the Geriatrics Syllabus for Specialists; a useful guide (lectures, PowerPoint presentations, etc.) geared toward providing vital information for surgeons caring for older patients as well as faculty leadership training to promote geriatric training and research within their disciplines. The Special Resident toolkits are available for anesthesiology, general surgery, gynecology-urology, ophthalmology, and orthopedic surgery. The initiative also enables surgical professional certifying bodies and societies to build the capacity of their members to provide better care of older adults [62].

Financial and administrative barriers deter the implementation of geriatric models. Medicare payment system focuses on provider-specific reimbursement and thus limits payment for organizational redesign, multidisciplinary teams or nurse-coordinators. The new CMS financial incentives that will not reimburse for nosocomial "never" events such as pressure ulcers, catheter-associated infections, and fall-related injury, may eventually encourage the use of these models [9]. An IOM report recommended that "payers should promote and reward the dissemination of those models of care for older adults that have been shown to be effective and efficient" [60]. It is expected that these types of programs will increase in the next decade. In 2015, the John A. Harford Foundation awarded a $400,000 grant to the American Geriatric Society to develop a business strategy for implementing orthogeriatrics comanagement programs. This is expected to result in a business plan including marketing, training, outcome goals, and budget to facilitate sustainable programs.

Finally, most of the research documenting complications of the older patient are based on studies combining both medical and surgical patients, thus future research should address the risk factors of these complications specific to surgical patients. Further, with the exception of hip fracture and cardiac surgery, additional studies should also identify complications within specific types of surgical procedures. This may provide important data to tailor models to specific surgical populations.

Abstract
Models of care addressing the unique needs of older hospitalized patients can be traced to the comprehensive geriatric assessment (CGA) programs first developed in the 1970s [1]. CGA programs screen older patients at high risk for geriatric-specific problems, assess for modifiable risk factors, and implement evidence-based strategies consistent with the patient's treatment goals. Over the last 30 years changes in the health-care system, coupled with the increasing older adult population, has led to development of several geriatric models of care across all health-care settings. In general, the goals of these geriatric models of care in the hospital focus on (1) prevention of complications that occur more commonly in older adults and (2) address hospital factors that contribute to complications. This chapter provides a brief overview of complications that are more frequently found in older patients, care delivery issues that are addressed by geriatric models of care and a description of the most commonly employed hospital models.

Complications of Older Hospitalized Patients

Although patients aged 65 and over represent about 13% of the US population, they account for 40% of those undergoing surgical procedures in American hospitals [2]. In addition to the high proportion of older patients, the most troublesome finding is that older patients also represent a higher complication rate for certain conditions which subsequently lead to higher health-care costs. Age may be viewed as a proxy for multiple chronic diseases. Postoperative complications that are known determinants of short and long-term survival following major surgery such as myocardial infarction and sepsis are associated with age due to the increased likelihood of co-morbidities such as cardiac disease [3].

Older adults are more likely to experience additional types of complications that, in addition to reducing survival, can result in loss of independence and lead to hospital readmission, increased usage of rehabilitation services, and new placement in a nursing home. Physical frailty and cognitive impairment [4–6] (either chronic dementia and/or delirium) can further compound an older person's vulnerability to complications during hospitalization [7, 8]. Frailty refers to "decreased reserves in multiple organ systems" [9] that is highly associated (after controlling for age, race, sex, and comorbid illness) with an increased risk for falls, cardiovascular disease, hypertension as well as reduced mobility, decreased functional status, institutionalization, and death (see Chap. 10, "Invited Commentary") [10, 11].

Persons with dementia are more prone to negative outcomes related to disease management and hospitalization. Older patients with dementia hospitalized for exacerbation of a chronic disease have significantly longer lengths of hospital stays (LOS) as compared to older patients without dementia. For example, the LOS of older patient with COPD is 121 days/1,000 persons as compared to older patients with both COPD and dementia, who have a LOS of 361 days/1,000 persons [12]. For those who develop delirium (for both those with and without an underlying chronic dementia) during hospitalization, increased LOS and higher hospital costs is well documented [13]. The complex challenges of those adult patients with cognitive impairment are often not adequately addressed. Table 1 provides examples of common behaviors of cognitively impaired persons that can lead to complications.

Although geriatric models of care can improve the overall outcomes and experiences of hospitalization, in general, these programs are designed to

Table 1 Behaviors of cognitively impaired patients contributing to high complication rate

Behaviors	Example	Potential complication
Inability to follow directions	Does not use call bell to ask for assistance and gets out of bed without needed assistance	Fall-related injury
Removal of treatments	Pulls out central lines	Hemorrhage Infection Physical restraints and associated complications
Not able to communicate needs	In pain but not able to verbally communicate this to nurse	Functional decline
Wandering	Leaves unit and exits hospital in gown	Hypothermia Other injuries Use of physical and chemical restraints that increase likelihood of delirium, falls, fall-related injury, nutritional problems
Misinterprets visual and auditory cues	Resists staff attempts to assist the patient to get out of bed which is perceived as an assault and then hits staff	Agitation-related injury Overuse of psychoactive medication that increase likelihood of delirium, falls, and fall-related injury
Decreases inhibition of inappropriate behaviors	Removes clothing and walk down hallway nude	Agitation-related injury Overuse of psychoactive medication that increases likelihood of delirium, falls, and fall-related injury

target those adverse events that occur more commonly in older patients. Table 2 provides a summary of these complications and the clinical and cost outcomes associated with these complications. These complications are often referred to as "geriatric syndromes" which refer to "clinical conditions in older persons that do not fit into discrete disease categories" [14].

A US congressional mandate instituted on August 1, 2007 significantly changed the Inpatient Prospective Payment System that the Centers for Medicare & Medicaid Services (CMS) use to reimburse hospitals [15–17]. As of October 2008, hospitals will no longer receive payment for eight hospital-acquired conditions; three of these eight are complications that are known to occur most frequently in older inpatients and have been found to be reduced when geriatric models of care are employed [18]. These three complications (fall-related injury, pressure ulcer, and catheter-associated urinary tract infection) are among the six adverse events or complications specifically associated with hospitalization of older adults. Although there are other geriatric syndromes (e.g., incontinence) and other potential complications associated with older inpatients (e.g., sleep deprivation, inadequate pain management, dehydration, adverse drug effects), many of these syndromes and complications are either risk factors or outcomes of the following.

Functional Decline

Functional decline refers to the loss of the ability to perform basic activities of daily living (ADL). A systematic review of 30 studies examining correlates of functional decline found that between 15 and 76% of hospitalized elders experience diminished performance in at least one ADL at discharge [19]. Of those with decline at discharge, only half will recover function at 3 months post-discharge, and, for many, this decline will result in permanent loss of independent living [20, 21]. Functional decline is considered a "profound marker of morbidity and mortality" [22, 23] resulting in longer lengths of stay, greater costs and increased rate of nursing home placement [24]. Among the ADLs, the ability to walk independently is considered the most critical in predicting health outcomes. Functional Mobility

Decline, defined as new walking dependence, is associated with poor posthospitalization outcomes such as discharge to a nursing home, continued impaired mobility and higher mortality rates [25]. The incidence of functional mobility decline occurs in 15–59% of hospitalized elders [26]. For older hip fracture patients, especially those with cognitive and affective disorders, there is a greater risk of functional decline and new nursing home placement [27, 28].

Table 2 Complications in the older surgical patient[a]

Complication	Hospital factors[b]	Clinical outcome	Cost implications
Functional decline	Immobility Bed rest without medical/ surgical indication Physical restraint Inappropriate medication prescribing New psychoactive drug use Obstacles in the hospital physical environment	Reduced/loss of independence in function (activities of daily living) Reduced/loss of ambulation Pain Increased rate of pressure ulcers, falls, fall-related injuries, and development of contractures	Longer length of stay (LOS) Increased rate of institutional or home-based rehabilitation Nursing home placement
Fall-related injury	Immobility Physical restraint Inappropriate medication prescribing New psychoactive drug use Obstacles in the hospital physical environment	Pain Fracture requiring surgical intervention Reduced/loss of independence in function (activities of daily living) Reduced/loss of ambulation	Medicare will not pay for treatment[c] Surgery Longer LOS Institutional or home-based rehabilitation Nursing home placement
Under/malnutrition	Immobility Inattention to oral care Lack of feeding assistance for those with physical or cognitive impairments	Reduced wound healing Discomfort due nasogastric tube placement Percutaneous enteral access procedures (gastrostomy) Delirium Physical restraint to prevent tube removal Aspiration Functional decline	Longer LOS Surgery Institutional or home-based enteral nutrition therapy
Pressure ulcer	Immobility Physical restraint Under/malnutrition Dehydration	Immobility Sleep deprivation Pain Sepsis Septicemia Surgical debridement Surgical techniques (direct closure, flaps, and skin grafting)	Medicare will not pay for treatment[b] Longer LOS Institutional or home-based skilled nursing treatment
Urinary tract infection (UTI: secondary to catheter use or CAUTI)	Emergency room placement without indication Incontinence treatment No postsurgical monitoring of catheter use	Immobility Pain Delirium Acute pyelonephritis Bacteremia Sepsis Prosthetic joint infection Higher risk for death	Medicare will not pay for treatment[b] Longer LOS Rehospitalization

(continued)

Table 2 (continued)

Complication	Hospital factors[b]	Clinical outcome	Cost implications
Delirium	Physical restraint Inappropriate medication prescribing New psychoactive drugs Urinary catheterization CAUTI Immobility Under/malnutrition Dehydration	Functional decline Persistent cognitive impairment Falls, injuries Undetected infection Sleep deprivation	Longer LOS Rehospitalization Nursing home placement Death

[a]Geriatric syndromes refer to "clinical conditions in older persons that do not fit into discrete disease categories." This may also include other conditions highly associated with aging such as frailty, sleep disorders, self-neglect. For the purpose of this review, these syndromes and potential complications are more narrowly defined

[b]Hospital factors. There is a myriad of patient and hospital factors that contribute to each complication, however, this list provides examples of those specific hospital practices that place the older adults at high risk and which are the focus of geriatric care model interventions

[c]As of October 2008, hospitals will no longer receive payment for 8 hospital-acquired conditions; 3 of these 8 indicated in the table are complications that are known to occur most frequently in older inpatients and have been found to be reduced when geriatric models of care are employed (fall-related injury, pressure ulcer, and catheter-associated urinary track infection)

Fall-Related Injury

Roughly 2–5% of older adults fall during hospitalization [29]. The number of falls per 1,000 patient days is highest in hospital units admitting mostly older adults such as geropsychiatry, rehabilitation, and geriatric medicine. Among hospitalized older adults, falls from bed account for approximately one-third of all falls. Almost one-third of all fall-related injuries occur among persons 85 years of age or older. Approximately 3–10% of falls happening in hospitals result in either serious or minor injuries [30]. Hip fractures, occurring in about 1–4% of hospital falls are particularly significant because older adults are more likely to suffer from a substantial decline in physical functioning and often require longer periods of active rehabilitation services as compared to younger persons [31].

Undernutrition/Malnutrition

Undernutrition and malnutrition are deficiency syndromes caused by inadequate intake or absorption of macronutrients. Malnutrition has long been associated with important adverse outcomes, such as increased morbidity and mortality and decreased quality of life. Weight loss and hypoalbuminemia are both strongly correlated with increased mortality in ill adults [32]. Body weight and body composition have important implications for physical functioning of older persons and the prevalence of malnutrition in older hospitalized patients has been estimated to be between 40 and 60% [33].

Pressure Ulcers

Pressure ulcers continue to present a major health problem for hospitalized adults with reported nosocomial incidence rates between 0.4 and 38% [34]. Pressure ulcers are highly correlated with age [35]. At least a fifth of pressure ulcers will progress to a more advanced stage of deterioration. Most ulcers develop in the sacrum and coccyx areas with rates higher in patients with mobility impairment. Pressure ulcers remain a major cause of morbidity and are associated with longer lengths of hospital stay. Nosocomial pressure ulcers and their progression in severity during hospitalization have been used as a quality care indicator [36].

Urinary Tract Infection

Approximately 4% of patients with urinary tract infection (UTIs) will develop bacteremia which is known to significantly increase in length of stay and is associated with higher mortality in older patients [37]. The major care-associated practice leading to UTI in older inpatients is the overuse of urinary catheters, defined as catheter use for longer than 2 days [38]. Catheter-associated urinary tract infection (CAUTI) is the most common nosocomial infection [39]. A study using a random sample of almost 36,000 Medicare patients undergoing major operations from 2,965 US hospitals reported that 86% had perioperative indwelling urinary catheters and among these 50% had catheters for longer than 2 days postoperatively. These patients' risk of developing a urinary tract infection was twice as likely compared to patients with catheterization [40]. Among another sample of approximately 39,000 Medicare patients undergoing major surgery who were discharged to a nursing home it was found that those patients discharged with catheters were at higher risk for rehospitalization for UTI and death within 30 days than patients who did not have catheters [41].

In addition to infection, catheter use is associated with immobility, delirium, and pain [42].

Delirium

Delirium, a transient state of cognitive impairment, may develop in both cognitively intact and impaired older adults. It is estimated that between 14 and 24% of older persons are admitted to the hospital with delirium, and an additional 6–56% of hospitalized elders will develop delirium during their hospitalization replace especially if they are admitted to an ICU [43]. Postoperative delirium is more likely to occur following hip fracture, cardiac, non-cardiac thoracic, aortic aneurysm, and abdominal surgery. Postoperative delirium is more likely in those deemed vulnerable. Patient vulnerability including presence of previous brain pathology, decreased ability to manage change, impaired sensory function, multiple co-morbidities and changes in pharmacodynamic responses to medications, are all suggested possible causes for delirium. In surgical patients both preoperative (use of narcotic analgesics, history of alcohol abuse and depression) and perioperative (greater intraoperative blood loss, more postoperative transfusions, postoperative hematocrit less than 30%, and severe postoperative pain) risk factors have been identified for delirium postoperatively [44]. Additionally, hospital practices that lead to iatrogenic events including use of physical restraints, malnutrition, more than three medications and urinary catheterization are also significantly associated with delirium [45]. There are no significant differences in incidence of postoperative delirium following general vs. epidural anesthesia.

Despite high incidence, most delirium goes undetected [46, 47] thus contributing to many negative consequences. Delirium is associated with poor hospital outcomes such as higher mortality rates, increased length of hospital stay, increased intensity of nursing care, greater health-care costs as well as increased risk of several adverse outcomes after discharge, including functional decline, persistent cognitive impairment, rehospitalization, and nursing home placement [48].

The occurrence of each of these complications leads to interventions that can often prolong the hospital stay. Following hospital discharge, they frequently contribute to death, institutionalization as well as disproportionately high rehospitalization rates, high emergency department usage, and increased need for rehabilitation therapy services. As illustrated in Table 2, the *interrelationships* among these various complications during hospitalization is obvious and also well documented [12]. The data supporting the importance of prevention, early detection, and treatment of these complications in older surgical patients is described in the ACOVE (Assessing Care of Vulnerable Elders) report, Quality Indicators for Hospitalization and Surgery in Vulnerable Elders [49].

Although patient characteristics, especially multiple co-morbidities, frailty, and cognitive impairment, may increase vulnerability of older inpatient to negative consequences, the hospital environment plays an independent and significant role in determining staff practice and subsequent patient outcomes such as iatrogenic complications. This has led to the development of geriatric models to address these hospital-based or institutional factors that are likely to contribute to complications among older patients. Effective resolution of these negative consequences is dependent on geriatric models that target both patient and environmental (institutional) risk factors.

Geriatric Care Model Objectives

Although geriatric models of care differ in their approach to prevent complications and address care delivery problems that can contribute to complications, all share a common set of general objectives. Although these objectives could be applied to any patient regardless of age, it is how geriatric care models apply these that are age-specific. Table 3 provides examples of processes and interventions to meet these six general objectives.

The six general objectives of geriatric care models are as follows.

Educate Health-Care Providers in Core Geriatric Principles

The complications most frequently encountered among older patients are often due to system-level problems. These include inadequate educational preparation of health-care providers to recognize age-specific factors that increase risk of complications. All geriatric care models require a coordinator or clinician with advanced geriatric education; however, the implementation of any model depends on direct care staff with the knowledge and competencies to deliver safe and evidence-based care to older patients. Thus, the coordinator or other geriatric clinician role includes teaching of other staff through rounds, journal clubs, conferences, and other internal institutional educational venues.

Target Risk Factors for Complications

Given the disproportion of certain complications or geriatric syndromes among hospitalized older adults, the clinical focus of all geriatric models is prevention via risk factor reduction and early detection of these problems. Some models may focus on a particular syndrome; however, the interrelationship of these complications and their shared risk factors often result in a reduction of the other geriatric syndromes. Targeting risk factors requires standardized assessment tools known to be valid and reliable for older adults. See the Hartford Institute's Try This and How to Try This series for examples of assessment instruments (http://www.hartfordign.org/trythis). Implementation of geriatric care models often include institutionalizing these practices such as incorporating these tools in the medical record as well as hospital policies, procedures, and protocols.

Incorporate Patient (Family) Choices and Treatment Goals

All health-care decisions should be guided by the patient's choices. Choices range from decisions about activity level and medication use to more complex issues including advance directives.

Decisions regarding life-sustaining treatment are often influenced by quality of life considerations balanced by the potential length of life. For family members acting in the best interests of patients who can no longer participate in decision-making, this can be a complicated dilemma. Life-sustaining treatments are often employed with very old patients who die in the course of hospitalization although most prefer comfort care. Geriatric models are meant to address this lack of congruence by supporting efforts to provide care that is more consistent with patients' preferences [50]. For this reason, many geriatric models work collaboratively or in conjunction with palliative care programs.

Employ Evidence-Based Interventions

Given that most physicians, nurses, and other health providers have received minimal content in their training regarding geriatrics, it is not surprising that there is a higher complication rate for older

Table 3 Geriatric care models: objectives, processes and interventions

Objective	Examples of processes	Examples of interventions
Educate health-care providers in core geriatric principles	Resident training includes required geriatric rotation *or* mandatory geriatric rotation for residents Institutional continuing education includes geriatric-specific training *or* Geriatric-specific interdisciplinary continuing education programs Geriatric specialist responsible for geriatric training initiatives	Hospital intranet includes geriatric programming Journal club includes geriatric journals and/or articles focusing on geriatric outcomes Medical, surgical, nursing, and interdisciplinary rounds includes geriatric case studies
Target risk factors for complications	Policies, protocols, and documentation system includes assessment tools and practices that identify older adults at risk for complications Assessment tools prompt providers to consult geriatric specialists for evaluation of high-risk problems Geriatric specialist provides individual evaluation of risk factors	Electronic medical record (EMR) provides alerts for medications prescribed that are known to increase fall risk EMR prompts providers to document daily cognitive testing results Hospital policy for daily cognitive assessment of at-risk patients Cognitive assessment indicates delirium that leads to geriatric specialist consultation
Incorporate patient (family) choices and treatment goals	Policies and protocols support and documentation system includes forms that elicit patient choices as well as family involvement in care Geriatric nurses are prepared to coordinate an interdisciplinary evaluation and promote development of *informed* patient/family treatment goals and plan of care Palliative care is consulted and provides informed choices to patients/families in situations of life- threatening illness	Admission history includes evaluation of patient's preferences for postdischarge rehabilitation Unlimited visiting hours and bedside recliners encourage family participation in recovery Patient and family preferences for type and degree of family involvement is documented Patient with Alzheimer's disease who is unable to verbally indicate needs is evaluated by palliative care specialist for pain evaluation/treatment
Employ evidence-based interventions	Policies and protocols integrate geriatric specific implications Education and training for all clinicians include core geriatric content	Hospital protocol for urinary catheter removal within 2 days postsurgery Unit-based mobility program Physical environment reduces injury risk for nonambulatory patients with dementia such as low-height beds and bedside mats
Promote interdisciplinary communication	Medical record facilitates patient information across disciplines Processes in place to encourage face-to-face interaction among disciplines Unit-based and hospital-wide committee includes geriatric specialist representation	Interdisciplinary team rounds held bi-weekly Programmatic initiatives include all applicable disciplines, e.g., physical and occupational therapy in unit-based mobility program Co-manage patients across specialties such as geriatric oncology Collaborate with other programs such as palliative care in providing symptom management
Emphasize discharge planning or transitional care	Documentation system provides comprehensive hospital course information to primary care provider and other postdischarge providers (home care, nursing home, etc.) as well as elicits pertinent information *from* other providers	Patient and caregiver receive comprehensive documentation of hospital treatment, changes in treatment plan, and postdischarge instructions Understanding of instructions is evaluated before discharge Phone follow-up postdischarge to evaluate patient condition and needs

hospitalized patients. Advances in geriatric science, similar to other research-based approaches, are not readily employed in hospital care. Problems with polypharmacy, inappropriate medications (e.g., overuse of psychoactive), overuse of restraints, inadequate detection of delirium, depression, and undermanagement of pain are some of the many hospital factors that can contribute to poor outcomes. Thus, geriatric models promote the use of standardized evidence-based protocols.

Promote Interdisciplinary Communication

Since geriatric syndromes are not just medical problems but represent a complex interaction of medical, functional, psychological, and social issues, other disciplines such as nursing, pharmacy, social work, physical and occupational therapy are needed. Geriatric care models all include interdisciplinary teams, i.e., an approach that facilitates communication among disciplines.

Emphasize Discharge Planning (or Transitional Care)

Many older patients will require rehabilitation or skilled nursing services following hospitalization. Almost a quarter of older hospital patients are discharged to another institution such as a rehabilitation hospital or nursing home and more than 10% are discharged with home care [51]. Older adults are more likely to experience problems associated with discharge planning that can lead to delays in discharge and greater use of emergency service use and hospital readmission. Hospital readmission for older patients is most likely associated with medical errors in medication continuity [52, 53], diagnostic workup, or test follow-up [54]. These poor outcomes are attributed to a lack of coordination among health-care providers that can result in unresolved medical issues [55] and deficient preparation of patients and their caregivers to carry out discharge instructions [56]. One study found wide variations among providers in discharge planning effectiveness; the providers cited their lack of knowledge and experience when not making appropriate home-care referrals [57]. Thus, geriatric models not only focus on the inpatient experience but also the post-hospital care environment and the care transition following hospital discharge. Two of the six models consider the care transition a primary focus of their programs.

Geriatric Models

There are several types of geriatric models that are currently employed in hospitals throughout the USA. In addition to incorporating the original tenets central to comprehensive geriatric assessment (screen for those at high risk for geriatric-specific problems, assess for modifiable risk factors, and implement strategies consistent with the patients' treatment goals), all strive to deliver quality care for older adults in a cost-effective manner. Comprehensive geriatric assessment assumes that the systematic evaluation of a frail older person by a multidisciplinary health-care team will uncover actual or potential health problems. The considerable advances in geriatric health-care science over the last 30 years can then be applied to treating or preventing these conditions and thus result in better health outcomes.

Although the specific mode of intervening may differ among the models, they all address both common health problems and care delivery issues. The geriatric model may consider all geriatric syndromes or target specific ones such as delirium or functional decline. Similarly, the geriatric model may be employed as a hospital-wide approach, unit-based intervention, or focus on specific processes of hospitalization such as admission screening or discharge planning. Regardless of the structure of the geriatric model, all facilitate the general objectives listed in Table 3. Table 4 provides a summary of the clinical foci, unique features, coordination, and interventions for each of the six most commonly employed geriatric models of care.

Table 4 Core components of six geriatric care models

Model type	Clinical outcome focus[a]	Unique features	Program/team coordination	Interventions[b]
Geriatric Consultation	Primary focus can vary depending on composition of consult team & may be specific to a surgical specialty or procedure	Employed by primary provider request	Individual consultant (geriatrician, gero-psychiatrist or geriatric nurse specialist) *or* Interdisciplinary team that is coordinated by geriatric medicine or psychiatry fellow, geriatric nurse specialist or an administrative director	Comprehensive geriatric assessment: medical, psychiatric, functional, and social Recommends interventions based on consultant discipline (medicine, psychiatry, or team that includes nurses, social workers, and others) Primary provider chooses which recommendation to employ
Acute Care for the Elderly (ACE)	Functional decline	Dedicated unit with explicit admission criteria Requires interdisciplinary team Redesign of physical environment to accommodate physical and cognitive needs	Unit directed and/or team coordinated by geriatrician, geriatric nurse specialist, administrator or co-managed by clinician-manager	Physical environment to promote patient mobility, orientation and staff observation Interdisciplinary rounds facilitate care coordination and thus: Identify modifiable risk factors for geriatric syndromes and complications Prevent avoidable discharge delay Promote timely referrals to disciplines or specialists
NICHE: GRN/ACE	Nursing processes related to all geriatric syndromes and potential complications such as avoiding restraint use, initiating urinary catheter removal	Focus on improving nursing care of all geriatric syndromes Prepares staff nurses to take active part in geriatric care management including coordinating or facilitating other geriatric models of care	Program implementation by NICHE Coordinator (usually a geriatric nurse specialist) Geriatric Resources Nurses (staff nurses with additional training) implement protocols Depending on availability, other clinicians (geriatrician, hospitalist, social worker, etc.) work as interdisciplinary team	Nurse-initiated protocols: Restraint and psychoactive drug reduction Functional mobility Fall/injury prevention Pressure ulcer assessment/treatment Prevention of UTI – early catheter removal Delirium assessment/treatment Organizational strategies including measurement schema, performance improvement techniques, and management tools to promote implementation of above protocols

(continued)

Table 4 (continued)

Model type	Clinical outcome focus[a]	Unique features	Program/team coordination	Interventions[b]
HELP	Delirium prevention and early management	Requires use of volunteers	Elder Life Nurse Specialist or Elder Life Specialists coordinates interdisciplinary team (geriatrician, recreation therapy, physical therapy, etc.) and trained volunteers	Delirium risk factor protocols: Mental orientation Therapeutic activities Early mobilization Vision and hearing adaptations Hydration and feeding assistance Sleep enhancement
APN Transitional Care Model	Reducing complications specific during the transition from hospital to home	Requires advanced practice nurse coordinator to follow patient in hospital and following discharge	Advanced Practice Nurse (nurse practitioner or clinical nurse specialist)	Protocols to assess/ intervene with: Medication discrepancies and inappropriate medication usage Case management and APN surveillance across settings
The Care Transitions Intervention	Reducing complications specific during the transition from hospital to home, such as preventing posthospital medication discrepancies, increase likehhood of patient/ caregiver detection of worsening condition	Requires nurse transitions coach to follow patient in hospital and following discharge	Transition Coach (nurse or advanced practice nurse) empowers patient and caregiver	Personal Health Record includes data elements essential to promote productive patient–provider encounters across settings Discharge Preparation Checklist to facilitate patient's knowledge of discharge instructions Medication Discrepancy Tool used by transition coach to identify medication issues

[a]All programs are meant to address geriatric syndromes and potential complications. Geriatric syndromes refer to "clinical conditions in older persons that do not fit into discrete disease categories." This may also include other conditions highly associated with aging such as frailty, sleep disorders, self-neglect. For the purpose of this review, these syndromes and potential complications are more narrowly defined to 6 of the most common complications

[b]Interventions are guided by the use of standardized assessment tools known to be valid and reliable for older adults. See the Hartford Institute's Try This and How to Try This series for examples of assessment instruments (http://www.hartfordign.org/trythis)

Geriatric Consultation Service

Geriatric Consultation Service provides a geriatrician, a gero-psychiatrist, a geriatric clinical nurse specialist or an interdisciplinary team of geriatric health-care providers to conduct a comprehensive geriatric assessment or evaluate a specific condition (delirium), symptom (patient dislodges or removes treatment), or situation (adequacy of family support for discharge back to community setting). The consultation may be requested by another primary service for an individual patient or may be initiated by a hospital policy for all patients that are screened at high risk for geriatric-related complications or are admitted from a homebound program or a nursing home [58].

Outside of academic medical centers, few hospitals have geriatric departments that can provide geriatricians or a geriatric consultation team. Although geriatric nurse specialists may be more prevalent in hospitals than geriatricians, many function without the benefit of a geriatric team or a geriatrician. Similar to geriatricians, it is difficult to evaluate their effectiveness when their practice is limited to a consultative role in which recommendations may not be followed or institutional resources are not adequately available for staff to implement [59].

Acute Care for the Elderly Units

Acute Care for the Elderly (ACE) Units are discrete geriatric care-focused units. Originally developed in the 1970s within Veterans Administration Hospitals, Geriatric Evaluation and Management (GEM) Units were meant to provide comprehensive geriatric assessment delivered by a multidisciplinary team with a focus on the rehabilitative needs of older patients. Multidisciplinary team rounds and patient-centered team conferences are considered the hallmarks of care. The core team includes a geriatrician, clinical nurse specialist, social worker as well as specialists from other disciplines providing consultation: occupational and physical therapy, nutrition, pharmacy, audiology, and psychology. GEM units usually have been redesigned to facilitate care of the older patient, which, in contrast to geriatric consultation services, have direct control over the implementation of team recommendations. Research conducted in the 1980s and 1990s have documented significant reductions in functional decline and suboptimal medication use as well as return to home postdischarge and, more recently, decreased rate of nursing home placement [60] among hospitalized veterans on GEMUs compared to general medical units.

Beginning in the 1990s, Acute Care of Elders (ACE) Units have been implemented in non-VA hospitals although they generally focus on more acutely ill patients than GEM units. These units utilize staff with geriatric expertise working collaboratively in an interdisciplinary team (fostered by care processes such as team rounds and family conferences) in a physical environment with adaptations to addresses age- related changes (e.g., flooring to reduce glare and low-height beds to reduce fall-related injury), promote orientation (clocks and calendars) and facilitate staff observation (e.g., alarmed exit doors, windows inserted in walls and communal space for meals). The interdisciplinary team (led by geriatricians and/or geriatric nurse specialists) aims to facilitate care coordination and thus identify modifiable risk factors for geriatric syndromes and complications, prevent avoidable discharge delay, and promote timely referrals to disciplines/specialist.

Palmer et al. designed the first ACE unit at the University Hospitals of Cleveland [61]. A randomized controlled trial of Acute Care for Elders in an academic medical center reported improved functional status (ADL or activities of daily living, instrumental ADLs and ambulation) at discharge of patients hospitalized on the ACE unit compared to those on other units. Fewer patients from the ACE group were discharged to nursing homes. These beneficial effects were achieved without increasing in-hospital or postdischarge costs. There were no significant differences in mortality, length of stay, readmission, or hospital costs between the two groups [62]. In another randomized trial conducted in a community hospital, patients were randomly assigned to either ACE care or a regular care unit. Positive outcomes of the ACE intervention was demonstrated in several processes of care including a reduction in restraint use, days to discharge planning and use of high-risk medications. They also found benefit in a composite outcome of ADL improvement and nursing home placement but not in discharge ADL levels alone. There was no significant reduction in length of stay, hospital costs, or mortality in the ACE unit subjects compared to the regular unit subjects [63]. These savings are recognized in integrated health-care delivery systems such as the VA, Kaiser, and PACE (Program of All Inclusive Care of the Elderly); however, our current "silo-based" reimbursement system to individual hospitals does not provide incentives for postdischarge reductions in health services usage [64].

Since one unit cannot provide care for all older patients within a hospital, many hospitals use this unit for patients at highest risk for age-related complications. The unit is an excellent environment for training of all disciplines. ACE staff may also provide consultation throughout the hospital to export ACE principles throughout the health system.

Nurses Improving the Care of Health System Elders

Nurses Improving the Care of Health System Elders (NICHE; http://www.nicheprogram.org) is a national program aimed at system improvement to achieve positive outcomes for hospitalized older adults. NICHE has two main goals: improving the quality of care to patients and improving nurse competence. This is accomplished by "modifying the nurse practice environment with the infusion of geriatric-specific: (a) core values into the mission statement of the institution; (b) special equipment, supplies, and other resources; and (c) protocols and techniques that promote interdisciplinary collaboration." [65] NICHE includes several approaches, each of which facilitates transfusion of evidence-based geriatric best practices into hospital care. A geriatric nurse specialist as the NICHE Coordinator functions in both a "primary care" role (evaluating and managing patients directly) and in a leadership role (teaching and mentoring others and changing systems of care)." [66] Foundational to NICHE is the Geriatric Resource Nurse Model (GRN) which is an educational intervention model that prepares staff nurses as the clinical resource person on geriatric issues to other nurses on their unit. The GRN model provides staff nurses, via education and modeling by a NICHE coordinator, with specific content for improved knowledge of care management for geriatric syndromes. Clinical protocols and organizational strategies provide necessary tools to apply evidence-based practice. For example, in one NICHE orthopedic unit, GRNs received intensive education on the prevention and detection of delirium in a unit where the primary diagnoses were joint replacement and hip fracture repair. Utilizing a combination of standardized assessment of cognition and focused interventions to prevent post-op delirium, the unit realized a significant reduction in the incidence of delirium. Other systemic interventions utilized by the GRNs include a revised nursing database and delirium-specific order sets [67]. An evaluation of responses of 9,802 direct-care registered nurses from 75 acute care hospitals participating in NICHE found that a positive geriatric nurse practice environment was associated with positive geriatric care delivery. The independent contribution of all three aspects of the geriatric nurse practice environment (resource availability, institutional values, and capacity for collaboration) influences care delivery for hospitalized older adult patients. The study findings demonstrate that a nurse practice environment that provides adequate geriatric-specific resources (continuing education, education, specialty services), promotes interdisciplinary collaboration, and fosters patient, family, and nurse involvement in treatment-related decision-making is associated with quality geriatric care [64]. In single site studies, NICHE hospitals demonstrate improved clinical outcomes, rate of compliance with geriatric institutional protocols; cost-related outcomes; and nurse knowledge. In a study of eight hospitals, nurses reported higher quality of geriatric care following NICHE implementation [68].

NICHE also promotes a unit-based ACE model. The ACE model within NICHE emphasizes: (1) implementation of nurse-driven protocols, (2) geriatric training of all nursing staff, and (3) utilization of geriatric-specific units within a health system's overall geriatric care programming. Similar to other ACE studies, a NICHE-ACE unit in which the majority of the staff nurses were nationally certified in geriatric nursing reported lower fall and pressure ulcer rates, and lower length of stay when compared to overall hospital [69].

Since NICHE is a system-level approach it provides a structure for nurses to collaborate with other disciplines and to actively participate or coordinate other geriatric care models. For example, in hospitals with a geriatric department or consultation service, GRNs screen for appropriate referrals to these services and can effectively implement geriatric service recommendations with support from the NICHE coordinator. The models enhance NICHE program effectiveness by expanding the scope of geriatric programming within a health system.

The Hospital Elder Life Program

The Hospital Elder Life Program (HELP; http://elderlife.med.yale.edu/public/public-main.php) is a program designed to implement protocols that target six delirium risk factors: mental orientation, therapeutic activities, early mobilization, vision and hearing adaptations, hydration and feeding assistance, and sleep enhancement. These protocols were tested in several well-designed clinical trials and demonstrated significant reduction in the incidence of new delirium. Further, among those who did develop delirium, these protocols are associated with a significant reduction of total number of episodes and days with delirium, functional decline, costs of hospital services, and reduction in use of long-term nursing home services [70, 71].

HELP employs geriatric specialists of various disciplines (geriatrician, geriatric nurse specialist, recreation therapy, and physical therapy) working together as an interdisciplinary team with trained volunteers. The program is coordinated by Elder Life Specialists, typically an Elder Life Nurse Specialist who has advanced geriatric nursing education and is responsible for implementing nursing-related assessments and tracking of delirium risk factor protocol adherence. The latter depends on the involvement of well-trained and supervised volunteers in patient-care interventions [72]. The research-tested protocol was made available to hospitals in 2000. Implementation in many hospitals has been adapted based on hospital resources. This has led to wide variations in adherence to the intervention protocol. Although higher levels of adherence have been associated with lower rates of delirium, these adapted protocols continue to provide positive results [73].

Transitional Care Models

An American Geriatric Society Position Statement defines transitional care as a set of actions designed to ensure the coordination and continuity of health care as patients transfer between different locations or different levels of care within the same location [74]. Older adult patients with complex medical and social needs and their caregivers require assistance to effectively navigate the health-care system, including recovery from surgery and return to pre-morbid health and living arrangements. Two models have emerged that have demonstrated improved outcomes for older adults hospitalized for both medical and surgical interventions.

APN transitional care model utilizes advanced practice nurses (APNs) whose primary responsibility is to optimize the health of high-risk, cognitively intact older adults with a variety of medical and surgical conditions during hospitalization and for designing and overseeing the plan for follow-up care following discharge [75]. The APN work collaboratively with the older adult, family caregiver, physician, and other health team members and are guided by evidence-based protocols. The same nurse implements this plan after discharge by providing traditional home-care services and by phone availability 7 days a week. Three federally funded, randomized, controlled trials consistently demonstrated that this model of care improves older adults' satisfaction, reduces rehospitalizations, and decreases health-care costs [76–78].

Care transitions coaching or *care transitions intervention* (see http://www.caretransitions.org/index.asp) employs a nurse or "transitions coach" to encourage older patients and their family caregivers to assume more active roles during care transitions by facilitating self-management and direct communication between the patient/caregiver and primary care provider. The four content areas or "pillars" of the patient/caregiver intervention are as follows: (1) medication self-management, (2) a patient-centered record, (3) primary care and specialist follow-up, and (4) knowledge of "red flags" warning symptom or sign indicative of a worsening condition

[79]. The Personal Health Record includes data elements essential to promote productive patient–provider encounters across settings such as an active health problem list; medications and allergies; a list of warning symptoms or signs that correspond to the patient's chronic illnesses; a checklist of activities that need to take place before and following discharge. This record is maintained by the patient and caregiver with assistance from the transition coach. The 4-week intervention begins in the hospital and continues through home visits and/or phone follow-up after discharge.

Several studies, including a randomized, controlled trial, found that patients who received this intervention had lower all-cause rehospitalization rates 30 and 90 days after discharge compared with control patients. Intervention patients also had lower rehospitalization rates for the same condition that they were admitted for in the index hospitalization at 90 and at 180 days than controls. Mean hospital costs were approximately $500 less for patients in the intervention group compared with controls [80].

New Specialty Models

In some hospitals, multiple geriatric models are employed. For example, a hospital may begin with NICHE. The NICHE coordinator, a geriatric nurse specialist, will then become an Elder Life Specialist to implement HELP hospital wide or within a discrete ACE unit. Often the core geriatric interdisciplinary team of any geriatric program screens patients for other related services such as palliative care, rehabilitative services, or pain management programs. Some have developed dual-function units such as merging an ACE unit with a palliative care unit [66]. Others have developed programs that merge geriatrics with other specialties. Examples include hip fracture, trauma, and oncology.

The American Academy of Orthopedic Surgeons recommends coordination of care and communication by providers as important aspects of quality care for hip fracture patients [81]. In response, several hospital programs that incorporate geriatric co-management of hip fracture patients have been developed. The expectation is that involvement of geriatricians in care management will avoid iatrogenic problems. For example, one program focuses on minimizing time to surgery and employment of standardized orders and protocols [82]. These programs have been shown to reduce delirium by over one-third, reduce severe delirium by over one-half, decrease predicted length of stay, readmission rates, complication rates, and mortality [83]. Others have developed a geriatric trauma team that include a geriatrician and geriatric advanced practice nurse who evaluate older trauma patients and share recommendations in weekly multidisciplinary rounds and performance improvement meetings of the trauma service. Most (91%) geriatric recommendations were followed and included: advanced care planning, disposition decisions to promote function, decreased inappropriate medications, and pain management [84].

Similarly, oncology programs have either developed geriatric – oncology consultation team or have developed geriatric – oncology units, some of which are part of an existing ACE unit [85, 86]. These programs report that older oncology patients have more complex medical and social needs than adult oncology patients and thus require input from both perspectives [87].

Conclusion

Although these models use different strategies, all share common goals of treatment. Each hospital or health system chooses a model based on the unique needs of that hospital's patient population, the resources available (geriatric specialists, bed capacity to support separate unit, volunteers, etc.) and especially senior administrator's commitment to geriatric programming. Since there is no direct reimbursement for many components of these models (interdisciplinary rounds, geriatric nurse specialist, volunteers, etc.) administrators seek external (grants, donor gifts) and internal funding (hospital foundation grants). They are motivated by the model's alignment to the hospitals strategic plan (e.g., excellence in senior care), the institution's mission, patient/family satisfaction, relationship with the community, and costs savings (i.e., reduction of complications). All of the models have demonstrated positive outcomes and each have been implemented in at least 50 hospitals; however, this still only represents a small proportion of American hospitals. Each model was originally developed with government and/or foundation support. Future survival of these models may depend on advancing the unique contributions of each within an integrated model that will enhance the hospital experience of the older patient.

Another problem influencing geriatric model implementation is availability of geriatric clinicians. Since significant geriatric medicine input is needed for many of these models, they generally are limited to academic medical centers, which only represent a small proportion of US hospitals. All of these models require providers with knowledge of core concepts in geriatrics; however, there is a significant shortage of fellowship-trained geriatricians, geriatric psychiatrists, master's prepared geriatric nurse specialists, as well as other disciplines [88]. In addition to efforts to increase the training of geriatric specialists, several initiatives are underway that involve specialty organizations, medical schools [89], and resident training programs [90, 91] to integrate principles of geriatric care into curriculums and practice. As more geriatrics is being integrated into undergraduate medical training and surgical resident training, knowledge of geriatric care principles and collaboration with geriatric models will enhance outcomes of the older surgical patients. The Council of the Section for Surgical and Related Medical Specialties in the American Geriatrics Society program provides the Geriatrics Syllabus for Specialists; a useful guide (lectures, PowerPoint presentations, etc.) geared toward providing vital information for surgeons caring for older patients as well as faculty leadership training to promote geriatric training and research within their disciplines. The initiative also enables surgical professional certifying bodies and societies to build the capacity of their members to provide better care of older adults [92].

Financial and administrative barriers deter the implementation of geriatric models. Medicare payment system focuses on provider-specific reimbursement and thus limits payment for organizational redesign, multidisciplinary teams or nurse-coordinators. The new CMS financial incentives that will not reimburse for nosocomial "never" events such as pressure ulcers, catheter-associated infections, and fall-related injury, may eventually encourage the use of these models [15]. A recent IOM report recommended that "payers should promote and reward the dissemination of those models of care for older adults that have been shown to be effective and efficient." [87] Incentives suggested included elimination of Medicare's co-payment disparity for mental health and enhanced payments for services under these models.

Finally, most of the research documenting complications of the older patient are based on studies combining both medical and surgical patients, thus future research should address the risk factors of these complications specific to surgical patients. Further, with the exception of hip fracture and cardiac surgery, additional studies should also identify complications within specific types of surgical procedures. This may provide important data to tailor models to specific surgical populations.

Intensive Care in Older Adult Surgery Patients

25

Teresa S. Jones and Thomas Robinson

Contents

Abstract

Elderly patients account for the majority of inpatient and ICU admissions. Although mortality is higher compared to younger patients, older patients who survive their ICU stay can have an excellent quality of life and functional

status. With age come physiologic changes in the body that can alter treatment in an acute setting. In this chapter, we review the changes and treatment options for the most frequently encountered ICU complications.

Keywords
Intensive care · Delirium · Shock · Acute kidney injury

Introduction

Patients >65 years old now account for up to 50% of intensive care unit (ICU) admissions and up to 60% of all ICU days [1–4]. In addition to medical advances that have prolonged life expectancy, there is now improved understanding of the different physiology that develops as patients age. Refusal of ICU admission is common in some countries, but the data now shows that elderly patients have a greater survival benefit from ICU admission compared to younger patients [5]. A geriatric patient's admission to the ICU requires a commitment of resources; however, it also represents a life-saving intervention now for the majority of medical and surgical patients.

Outcomes

Mortality has traditionally been the primary outcome used to assess health care delivery. Mortality among geriatric patients after hospital discharge remains high. In a study of medical and surgical patients ≥70 years, 1-year survival was 56% in patients age <85 years and 27% in those ≥85 years, rates markedly lower than in a matched population (93%) [6]. Age remains an independent variable in many prognostic scoring systems such as Acute Physiology and Chronic Health Evaluation (APACHE) II, APACHE III, and the Simplified Acute Physiology Score (SAPS) II. However, the impact of age on mortality weakens as the severity of the acute illness or physiologic derangement increases in both surgical and medical patients [7–10]. In addition to severity of their acute illness, preexisting conditions in older patients, particularly signs of frailty, are associated with poor prognosis [11, 12]. In one study, patients >75 years of age who had functional limitations were six times more likely to die in the hospital than those aged 50–64 years without limitations. Among patients without functional limitations, there was no difference in mortality between the youngest and oldest group [13, 14].

While overall mortality is high, the evidence demonstrates a clear benefit for geriatric patients who survive their ICU admission. In the largest single-center outcome study of geriatric patients who survive ICU admission, Kaarlola and coinvestigators evaluated 883 elderly ICU survivors and 1827 controls [15]. They found that cumulative 3-year mortality was higher among the older patients (57% vs. 40% in the control group). Most (66%) elderly nonsurvivors died within 1 month of ICU discharge. However, 97% of the geriatric survivors lived at home. Of those patients, 88% described their present state of health as good or satisfactory. In fact, 66% found it similar or better than 12 month prior, and 48% found it similar or better than before ICU admission. Additional prospective cohort studies have shown that patients who survive their acute intensive hospitalization can have excellent function in their activities of daily living (ADL) [16]. Therefore, despite the high overall mortality, we believe that older patients can benefit from an ICU admission. In the rest of this chapter, the goal will be to examine common ICU-related problems as they relate to geriatric patients: delirium, respiratory failure, shock, acute kidney injury, and malnutrition.

Delirium

Evaluation

Delirium is an acute state of confusion that develops over a short period and fluctuates over time. It is often the result of underlying organic derangements, such as infection, medical illness, and drug use or withdrawal. Delirium can be distinguished from dementia by its acute onset and fluctuating course.

The assessment of acute changes in cognition is difficult in the ICU setting due to the severity of underlying disease and the frequent loss of verbal communication due to mechanical ventilation. One tool for assessment of delirium in the ICU, which was adapted from the Confusion Assessment Method (CAM), is the CAM-ICU [17]. It has been validated in several studies as being both highly sensitive and specific for delirium [17, 18]. Using CAM-ICU, delirium is diagnosed in two steps. First, a standardized sedation scale, such as the Richmond Agitation-Sedation Scale [19], is used to determine the level of consciousness. Any patient not determined to be comatose is then assessed for four features of delirium: (1) acute onset of mental status changes or a fluctuating course, (2) inattention, (3) disorganized thinking, and (4) an altered level of consciousness. A diagnosis of delirium is made with the presence of both features (1) and (2) in addition to either feature (3) or (4) [18].

There is little doubt that as the elderly population ages, the prevalence and burden of delirium in the ICU will grow. Milbrandt and colleagues studied patient charges in 275 consecutive, mechanically ventilated ICU patients and found the presence of delirium to be associated with 39% increased ICU cost (95% CI, 12–72%) and 31% higher hospital cost (95% CI, 1–70%) [20]. In surgical patients, development of delirium increased ICU and overall hospital stay, cost, rate of postdischarge institutionalization, and mortality at 30 day and 6 months [21]. Prevention and treatment of delirium is critical not only to hospital survival but also long-term outcomes for elderly patients.

Prevention

The risk factors for delirium are divided into host factors, which are present on admission to the ICU, and precipitating factors, which occur during the course of illness. In a recent study of elderly patients admitted to the ICU, the rates of delirium were found to be >70% during their hospitalization, and patients with dementia had a 40% higher overall rate of delirium during hospitalization than those without dementia [22]. Other factors present on admission most commonly associated with the development of delirium are age greater than 65, poor vision, severe illness, and presence of infection [23]. It is difficult to modify these preadmission factors; therefore, it is the precipitating factors that develop during a hospitalization that are potentially modifiable and therefore the target of prophylactic and therapeutic intervention [24, 25].

The use of sedative and analgesic medications deserves special attention. Pain control is a critical issue in management of elderly patients and nearly all patients in the ICU receive these medications. Elderly patients are more sensitive to the effects of benzodiazepines and opioids due to both a decrease in the number of receptors and a decrease in affinity of receptors for neurotransmitters [26]. Cardiac output and hepatic and renal outflow all decrease with age, and overall decrease in lean body mass and total body water and increase in fat causes redistribution of drugs and interfere with appropriate metabolism and clearance [27]. These changes should motivate a multimodal strategy for pain management and sedation to prevent delirium.

To prevent or minimize the impact on mental status, choice and dosing of medications should be decided carefully. Benzodiazepines and anticholinergics have been consistently linked to delirium in the elderly [28]. Pisani and coworkers recently published data showing that use of a benzodiazepine or an opioid was associated with increased delirium duration, especially the first episode (relative risk of 1.64 with a 95% confidence interval of 1.27–2.10) [29]. Meperidine is consistently linked to the development of delirium, especially in the aged [30–32]. Trials of newer sedation agents have shown some promise. In a 2007 trial by Pandharipande et al., the use of dexmedetomidine (an alpha 2 agonist) was compared to lorazepam in mechanically ventilated patients. The use of dexmedetomidine was associated with more delirium-free days than lorazepam [33]. In a 2016 trial that randomized patients 65 years and older to dexmedetomidine vs. placebo, low dose dexmedetomidine significantly decreased the occurrence of postoperative delirium [34]. Choice of sedation may be limited due to cost as well as hemodynamic effects. With any medication choice, daily interruption of sedation and the use of intermittent as opposed to continuous dosing are two methods used to minimize the impact on mental status and the ability to assess for delirium [35].

The data regarding the use of opioids is less clear. A study by Ouimet and coworkers demonstrated higher daily use of opioids in ICU patients without delirium [36]. Similarly, in a study of hip fracture patients, Morrison and coauthors found that patients treated liberally with opioid analgesics were less likely to develop delirium than those who received less analgesia [37]. These findings point to the need for careful use of these agents with attention to providing adequate pain relief while avoiding oversedation. In general, narcotics are associated with more frequent respiratory disturbances following surgery and the use of nonnarcotic analgesics should be implemented if possible [38]. Nonsteroidal pain relief is useful but in practice, many elderly patients have absolute or relative contraindication to their use due to increased GI bleed risks with ventilation [39]. Regional techniques including epidurals or paravertebral blocks should be considered, but in the ICU setting, coagulopathy, respiratory depression, and hemodynamic effects can also limit their use [40].

Delirium prevention can reduce the incidence of delirium up to 30–40%. The American Geriatric Society currently recommends multicomponent interventions to prevent delirium in the postoperative patients including: cognitive reorientation, sleep enhancement, early mobility, adaptations for visual and hearing impairment, nutrition and fluid repletion, pain management, appropriate medication usage, adequate oxygenation, and prevention of constipation [41]. These measures should be monitored by a multidisciplinary team for adherence.

Treatment

Once delirium is diagnosed, treatment must be implemented. The first step is to rule out an underlying organic source. Altered mental status may indicate infection, metabolic and electrolyte abnormalities, or medication exposures; all risk factors for delerium must be addressed prior to intervention. If all critical illness-related factors are ruled out, nonpharmacologic approaches should be implemented first that are similar to those recommended in the AGS preventative guidelines. After the use of nonpharmacologic strategies, consideration should be given to the use of pharmacologic agents to manage the symptoms of delirium. Currently, the Society of Critical Care Medicine recommends haloperidol as the drug of choice for treatment of delirium in the ICU [42]. This recommendation holds true for the geriatric patients [43]. Using intermittent intravenous injection, a 2-mg dose, is recommended. Repeated doses are administered if symptoms are not controlled, doubling the previously administered dose every 15–20 min until agitation resolves. Once controlled, scheduled doses are given every 4–6 h and then tapered over several days. Side effects of haloperidol include QT interval prolongation, extrapyramidal symptoms, and neuroleptic malignant syndrome. Routine EKG monitoring is suggested to detect any QT prolongation [42]. Atypical antipsychotics, such as risperidone quetiapine, and olanzapine may also have a role in the management of delirium but the data is not yet conclusive [44]. Dexmedatomidine has also been used as a rescue medication when patients are refractory to Haldol with good effect [45].

Respiratory Failure

Changes in Pulmonary Function Associated with Aging

The aging process affects every aspect of respiratory physiology and oxygen transport with important consequences for the geriatric patients with critical illness [46]. Age-related changes include decrease in vital capacity, forced expiratory volume in 1 s, arterial oxygen tension, and maximal oxygen consumption. Ventilation is impaired due to blunted responses to both hypoxia and hypercarbia. Aspiration risk is high due to decreased airway sensitivity, impaired mucocilliary transport, and decreased cough strength. All of these changes make pulmonary complications very common in elderly patients, even following elective surgical procedures [38, 47–49].

Management

In the nonintubated patient, aggressive early management is critical to prevent need for mechanical ventilation. Pain management should be initiated early and in a preventative fashion. This allows elderly patients to mobilize as soon as possible. Even just assuming an upright position can increase functional residual capacity and lessen the closure of small airways caused by the supine position. It has been demonstrated that oxygen consumption following thoracotomy is lower in the seated rather than the supine position, suggesting that the work of breathing may be lessened when a patient is upright [50]. Lung recruitment maneuvers including incentive spirometry (IS) can complement patient mobility and pain management. Ideally, patient should start with IS every 6 h. If patients are unable to attain volumes of at least 8–10 ml/kg ideal body weight on IS, then noninvasive lung expansion therapy should be considered.

Techniques of mechanical ventilation and weaning do not differ in the elderly, but they may require a longer period of support, given the impairments imposed by age, comorbidities, and acute illness. Parameters used to predict successful weaning from mechanical ventilation in younger patients may also be less reliable in the elderly [51]. The ARDSnet investigators examined age as a factor affecting outcome from acute lung injury and acute respiratory distress syndrome [52]. They found that although patients >70 years of age were able to breathe spontaneously for 2 h without ventilator assistance, which was a common similar time point to younger patients, the older patients had higher reintubation rates, longer ICU and hospital stays, and lower survival rates at 28 days. Caution should be exercised when liberating elderly patients from mechanical ventilation even if they achieve weaning parameters.

Shock

Changes in the Cardiovascular System Associated with Aging

Structural and functional changes occur with the heart and peripheral vasculature that can seriously alter the management of shock in an elderly patient. Compliance of the peripheral vasculature decreases, which leads to an increase in afterload. To compensate, patients develop left ventricular hypertrophy and decreased diastolic compliance. This decrease in compliance results in a nearly 50% reduction in early diastolic filling, making elderly patients more reliant on atrial contraction for ventricular filling. Cardiac output is then more reliant on preload, making older patients more sensitive to hypovolemia and atrial arrhythmias. In addition to structural changes to the heart, the presence of coronary artery disease should always be suspected in the setting of hypotension. The Framingham Heart Study found that myocardial infarction was silent or unrecognized in over 40% of patients aged 75–84% [53].

Evaluation

Shock is best defined as a state of inadequate tissue perfusion. In the uncompensated state, it is easily recognized by tachycardia, oliguria, and hypotension. The initial monitoring of the critically ill patients should include close attention to the physical exam, vital signs, and urine output. These parameters, and more importantly their change over time, are the most useful in determining response to resuscitative efforts, but they also can fail to detect ongoing tissue hypoperfusion and hypoxia [54]. Even after hypotension has been corrected and urine output restored, a state of "compensated shock" may remain. Hypoxia forces tissue to utilize anaerobic pathways, resulting in lactic acid production and large amounts of hydrogen ions. Base deficit and lactate levels are frequently used to assess both the initial state of shock and monitor the effects of ongoing resuscitation. Clearly, no single end point is applicable to every scenario, and it is important to repeatedly examine patients to determine success or inadequacy of resuscitation.

The optimal way to monitor resuscitation is still debated. Central venous pressure (CVP) can be continuously monitored off of a central venous catheter. Changes in CVP can be used to assess response to fluid challenges or diagnose severe hypovolemia, but it is known that CVP correlates poorly with changes in cardiac output [55]. Monitoring resuscitation with pulmonary artery catheters (PAC) is also no longer stand practice since there has been no prospective evidence that supports their use. In a large meta-analysis, Shah et al. evaluated 13 randomized clinical trials and concluded that in critically ill patients, the use of PACs neither increased mortality or hospital days nor did it confer benefits. One of the reasons no benefit is seen may be the lack of any clear guidelines for treatment based on data collected from a PAC [56]. Regardless, an important indication for a PAC is the differentiation between distributive vs. cardiogenic shock; however, that differentiation can also be made with echocardiography, if available.

Mixed central venous oxygen saturation (SCVO2) and blood lactate levels may be a useful adjunct in determining the adequacy of oxygen delivery and resuscitation. A value of >70% is considered to be normal for ScVO2. Lower values are consistent with flow-dependent delivery of oxygen, and a variety of strategies have been published using SCVO2 as an end point for resuscitation. An early goal-directed resuscitation strategy aimed at achieving an SCVO2 of 70% in patients presented to the emergency department in septic shock resulted in a significant decrease in mortality (46.5% in the control group vs. 30.5% in the treatment group) [57]. Of interest to this chapter, the mean age in the treatment group was 67.1 years (±17.4 SD). To obtain true mixed central venous oxygen saturation, a PAC catheter must be used, but central venous oxygen saturation (ScVO2) can be used as a surrogate, with the understanding that ScvO2 may be slightly less than the true SvO2 [58]. Lactate has been similarly shown to accurately risk stratify patients, and lactate clearance has been associated with improved survival [59]. In a RCT comparing the lactate clearance vs. ScVO2 was goals for resuscitation; there was no significant difference in hospital mortality when patients were treated for either [60].

Newer monitoring devices include pulse contour analysis, which calculates stroke volume from analysis of arterial pressure or oximeter waveforms. While less invasive, these devices have significant limitations on reliability based on patient parameters and should be used with caution at this time.

Management

Resuscitation with crystalloid, blood, and the administration of vasopressors are all methods to improve tissue oxygen delivery. Guidelines for the optimal use of these techniques are varied, and each approach is not without complications. Early restoration of circulating blood volume with blood products and crystalloid is crucial, especially in the elderly who are preload dependent to maintain ventricular filling and cardiac output. In the early phase of resuscitation, fluids are probably superior to vasopressors for the maintenance of blood pressure [61]. Care, however, must be taken to avoid excessive amounts of crystalloid as this has been linked to cardiac and pulmonary complications, coagulopathy, and acid–base disturbances [62]. Transfusion of blood to restore adequate oxygen carrying capacity is vital in cases of frank anemia, but exact triggers for transfusion in the elderly are still debated. The Hebert study suggests a transfusion threshold value of <7 g/dl of hemoglobin, and this recommendation has been widely adopted. This study, however, excluded patients with chronic anemia, ischemic heart disease, or any patient in whom the attending physician was unwilling to tolerate a transfusion trigger of <7 g/dl [63]. In elderly patients with acute myocardial infarction, a lower 30-day mortality was associated with blood transfusion for hematocrit values <30% [64]. Other studies have documented increased myocardial ischemia when intraoperative or postoperative hematocrit fell below 28% [65, 66]. Given the high incidence of ischemic cardiac disease – often silent in the elderly – care should be taken in setting a "one-size-fits-all" transfusion trigger in the geriatric population.

Once effective volume has been restored, inotropes and vasopressors may be required to augment oxygen delivery. In elderly patients, the response to b-agonists declines, with subsequent reduction in the inotropic, chronotropic, and vasodilatory effects of these medications. With these changes, nonadrenergic effects may be more pronounced. With the geriatric patient, inotropic support may be required in atypical clinical settings such as septic shock. In cases of severe sepsis, norepinephrine is advocated as the initial vasopressors recommended in the Surviving Sepsis Guidelines, with a target mean arterial pressure of 65 mmHg [67]. However, Viellard-Baron and coauthors found a high incidence of global left ventricular hypokinesia, defined as an ejection fraction of <45%, in a mixed group of patients presenting with septic shock (mean age 65 years). Hypokinesia was often present on initial evaluation, and further cases were unmasked after 24–48 h of therapy with norepinephrine, bringing the total incidence to about 60% [68]. This hypokinesia can be counteracted by the addition of inotropic agents such as dobutamine [67]. Finally, the stiffened aorta should also be taken into account, and the addition of afterload reducing agents may be useful for refractory cases [69].

In summary, the clinician caring for the elderly patient with shock must walk a fine line, using both fluids and inotropes, while paying close attention to changes in their clinical status. Frequent adjustments will be required as the clinical situation evolves.

Acute Kidney Injury

Changes in the Renal System Associated with Aging

Changes in renal function related to advancing age are significant in the management of critical illness. There are predictable declines in the glomerular filtration rate (GFR) and creatinine clearance. These declines, while significant, have little impact on the measured serum creatinine level, as there is a parallel reduction in the amount of creatinine produced due to overall decrease in lean muscle mass.

With aging, homeostatic mechanisms become less capable of dealing with the fluid losses, acid–base disturbances, and electrolyte abnormalities. Insensible losses are increased through surgery, wounds, and mechanical ventilation. The aging kidney is less able to concentrate urine and compensate for these losses. In addition, the normal thirst mechanism is often impaired in the geriatric patient. The net result is an increased propensity for hypovolemia, which can be particularly harmful in the elderly who rely on preload to maintain cardiac function. Poor bicarbonate elimination also hampers renal compensation in acid–base disturbances. Compounding this problem is the diminished capacity of the kidney to excrete acute salt and water loads, which can manifest as pulmonary insufficiency secondary to acute volume overload. The key factors to successful management include meticulous attention to detail, frequent laboratory and physical assessment, and appropriate fluid administration to avoid any large or rapid changes in volume status, electrolytes, or acid–base loads.

Evaluation

The incidence of acute kidney injury (AKI) increases with age and is 3.5 times more prevalent in those >70 years of age [70]. The 2012 Kidney Disease: improving Global Outcomes Clinical Practice Guidelines for Acute Kidney injury defined AKI as one or more of three criteria: a rise in creatinine of at least 0.3 mg/dl over a 48 h period; an increase of ≥1.5 times of the baseline creatinine value within the seven previous days; urine volume ≤0.5 ml/kg per hour for 6 h [71]. The causes of AKI are no different in geriatric patients as compared younger ICU patients, but age itself remains a major risk factor for the development of AKI in the ICU [72]. This may be due to the increased incidence of diabetes, hypertension, and underlying chronic kidney diseases in the elderly population.

The etiology of AKI is usually divided into three categories: prerenal, intrinsic, and postrenal. Prerenal causes include fluid losses, decreased intake, diuretic treatment, and reduced effective circulating blood volume secondary to impaired cardiac output, systemic vasodilatation, and renal artery stenosis. The elderly are especially vulnerable to prerenal AKI due to impaired autoregulation and high risk of hypovolemia. Intrinsic causes include ischemia, sepsis, and nephrotoxins, otherwise known as acute tubular necrosis (ATN) and can account for up to 76% of cases of AKI in the ICU [73]. Postrenal causes in older patients usually are due to mechanical blockages due to malignancy.

The diagnostic approach to AKI should include a history and examination. A review of medications should focus on potential sources of kidney injury such as NSAIDs, intravenous contrast, diuretics, and angiotensin-converting enzyme inhibitors or angiotensin receptor blockers. Laboratory examination should include serum creatinine, urinalysis, urine electrolytes, urine creatinine, and osmolarity. These values can be used to determine the glomerular filtration rate and the fractional excretion of sodium. As a diagnostic tool, fractional excretion of sodium is often confounded by diuretics in the elderly. In that cause, fractional excretion of urea may be more accurate to distinguish between prerenal and intrinsic causes. Urine osmolarity, when <300 mOsm/kg, is indicative of intrinsic renal failure.

Clinical Management

Management of AKI should first involve the treatment of life-threatening complications, such as electrolyte abnormalities, pulmonary edema, and metabolic acidosis. Second, all nephrotoxic agents should be discontinued. Finally, fluid and hemodynamic status should be optimized.

Although still employed, medications to prevent AKI have not demonstrated a long-term benefit. Renal-dose dopamine and continuous fenoldopam have not shown to prevent need for renal replacement therapy or improve mortality [74, 75]. Furosemide may improve urine output, but it has no influence on return of renal function or survival, thus its utilization should be limited to maintaining fluid balance [76]. Mannitol has also been shown to have no efficacy in renal protection [76].

Outcomes: Renal Replacement Therapy

Renal replacement therapy (RRT) is required in approximately 85% of patients with oliguric renal failure and about 30% with nonoliguric renal failure [77]. Like tracheotomy, the initiation of RRT in the elderly is a significant decision point in the care of the elderly patient and should be approached with deliberation. Multiple recent studies have examined prognosis and outcomes following RRT during the course of critical illness. In a meta-analysis by Bagshaw, the mortality of ATN treated with RRT was reported at 46–74%. In studies confined to the critically ill, mortality was nearly 60% at 90 days. In the same analysis, quality of life was addressed, and studies consistently demonstrated lower global quality of life scores. However, survivors generally rated their quality of life acceptable [78].

In addition to survival, return of renal function, defined as freedom from RRT, is another important outcome measure. Schmitt and coworkers undertook a meta-analysis addressing recovery of kidney function after AKI in the elderly. They reported that 31.3% of the elderly did not recover function compared to 26% in younger patients (pooled RR, 1.28, 95% CI, 1.06–1.55). An interesting finding in their review was that the relative risk of nonrecovery was only slightly increased in the elderly when continuous RRT was used; however, this did not achieve statistical significance [79]. A multidisciplinary approach to this decision may help determine if RRT is in line with patient's goals of care, particularly after hospital discharge.

Nutrition

Body composition changes over the course of aging. Lean muscle mass is reduced up to 40% by the age of 80 with simultaneous increase in body fat. There is a corresponding decrease in muscle strength and decrease in resting energy expenditure by up to 15% [69]. As a result of this loss of muscle mass, the elderly patient may rapidly develop protein–energy malnutrition in the setting of acute illness and surgery. Malnutrition is reported in more than half of geriatric patients at the time of hospital admission, a proportion that is even high among patients who come from nursing homes [80]. On the other hand, obesity is not associated with an increase in mortality in the ICU, but is associated with increases in the duration of mechanical ventilation and ICU length of stay [81].

Ideally, nutritional support should be initiated within 24 h of admission to the ICU. An audit of feeding practices by Taylor found that in patients greater than 64 years of age prolonged starvation (>5 days) resulted in higher mortality than those without nutrition 0–5 days, which was not found in younger patients. This suggested a greater susceptibility to starvation in the elderly [82]. We routinely initiate "trickle feeds" as soon as vasopressor doses have stabilized and lactate levels are decreasing. Our preferred method of nutrition is the enteral route, with the choice of tube and position (gastric or postpyloric) determined by the clinical scenario. The use of early enteral nutrition in surgical patients has demonstrated reduced infection rates. No increase in the incidence of anastomotic failure has been documented, and there is a trend toward reduced mortality [83]. Deficiencies in micronutrients are common, and supplementation should be routine. It is important to be aware that caloric requirements are reduced in the elderly; overfeeding results in excess CO_2 production, mandating higher minute ventilation and should be avoided. Overfeeding will not decrease the amount of lean tissue loss, can increase fat synthesis, aggravated hyperglycemia, and can delay weaning from mechanical ventilation [84].

Parenteral nutrition (PN) should also be considered in malnourished older patients. PN can support improvement in function status, albeit at the lower margin than in younger patients [85]. Complications occur at the same rate as younger patients, but overall mortality is higher in older adults who received PN vs. younger. This rate is potentially due to underlying disease and prognosis. Parenteral nutrition should be considered a medical treatment, and its use should be balanced against a realistic change of improvement in condition [86].

Impaired glucose tolerance increases with aging, and nearly 40% of the US population over age 60 has either type 2 diabetes or impaired glucose tolerance. The mechanism of impaired glucose tolerance is a lifelong decline in insulin secretion by B-cells at a rate of 0.7% per year. No specific change in insulin sensitivity, as previously thought, has been identified [87]. Early evidence suggested that strict glycemic control may be beneficial for patients in the ICU with a decrease in mortality, especially when employed for more than 3 days [88, 89]. These initial findings generated controversy and concern over the risk of hypoglycemic events that occur during insulin therapy. The NICE-SUGAR study was undertaken to determine the best target for glycemic control in critical illness. In a study of over 6000 ICU patients, subjects were randomized to intensive control or conventional control of blood sugar. The incidence of hypoglycemia was significantly greater in the intensive-control group (6.8% vs. 0.5%, $p < 0.001$). Mortality in this study was greater in the intensive control group as well (27.5% vs. 24.9%, $p = 0.02$). The authors concluded that a blood glucose target of 180 mg/dl or less resulted in lower mortality than did a target of 81–108 mg/dl [90].

Caring for Dying Patients

Caring for dying patients is a natural part of working in the ICU, even more so with geriatric patients. A more complete discussion of palliative care and end-of-life decision-making is presented in ▶ Chap. 17, "Traumatic Injury in Older Adults." However, this is such an integral part of caring for the geriatric ICU patient that it bears some repetition. Cook and coworkers writing for the Canadian Critical Care Trials Group prospectively followed 851 patients with a mean age of 61.2 years who were receiving mechanical ventilation. Of these patients, 166 (19.5%) had mechanical ventilation withdrawn. Rather than age or the severity of the illness and organ dysfunction, the three strongest determinants of withdrawal of ventilation in critically ill patients were the physician's perception that the patient preferred not to use life support (hazard ratio, 4.19), the physician's prediction that the patient's likelihood of survival in the ICU was less than 10% (hazard ratio, 3.49), and a high likelihood of poor cognitive function (hazard ratio, 2.51) [91]. Surprisingly, Cook and coauthors did not find a significant relationship between withdrawal of ventilation and age, previous functional status, severity of illness, or severity of organ dysfunction. It should be concerning to all of us rendering care for elderly patients that the strongest determinate of withdrawal from mechanical ventilation was physicians' perception of patients' wishes. Unfortunately, we know that patients' wishes regarding ICU admission or initiation of ventilation are frequently unknown at the time of ICU admission [92]. In addition, these wishes may not correspond with the family members' understanding their advance directives [93]. Finally, patients' assessments of their quality of life does not necessarily correlate with their wishes regarding life-sustaining therapy.

Knowing these potential conflicts, it is essential upon admission to the ICU to assess the patient's goals of care, either with the patient or the family. When we feel that further critical care is unlikely to achieve a quality of life that would be acceptable to the patient – as previously defined in our discussions with patients when available or families and surrogates if not – we involve our palliative care colleagues early to help give families a better perspective on expectations after an ICU admission. Often, these decision points occur with acute events, such as need for reintubation, initiation of RRT, need for surgery, etc. The vast majority of families do not want to assume responsibility for a decision that they perceive as leading to the death of their patient, when in reality, it is often that the patient's disease process dictates the outcome. The decision surrogates are faced with is not whether death will occur, but how that death will happen. Occasionally, we are unable to reach a clear consensus with the family or surrogate decision makers. In these situations, we continue supportive therapy – usually with limitations about escalation – and reconvene the discussion in the near future. End-of-life discussions are almost never concluded in a single setting and generally mature over time as the disease process and the patient's physiologic response becomes clear to both physician and family.

Through experience, we have found that establishing consensus, providing open communication, and focusing on goals of therapy are effective tools in our daily practice. Involving other specialties, particularly palliative care, can give families the information they need to make an informed decision.

Conclusion

Critical care of elderly patients both compares and contrasts with that of younger patients. It is different in that age has multifarious effects on all organ systems, and these age-related changes influence the way elderly patients respond to their critical illness and to treatment. It is similar in that the principles, procedures, techniques, and devices used to support organ system insufficiency or failure are the same and that with a comprehensive approach to care and close attention to detail many can survive their critical illness and resume a valued and enjoyable life.

Abstract

Chronic wounds in older individuals are among the most devastating and difficult to treat age-related ailments and are strongly intertwined with a sense of self-worth and quality of life. As the population ages, it is increasingly clear that there is a subset of older adults that is disproportionately vulnerable to developing chronic wounds and is at especially high risk for iatrogenic complications with wound care interventions. In these frail older individuals, wounds are usually

R. A. Rosenthal et al. (eds.), *Principles and Practice of Geriatric Surgery*,
https://doi.org/10.1007/978-3-319-47771-8_27

caused by decline in more than one domain of function, in contrast to younger individuals. New or difficult to treat wounds in older individuals can therefore be a sign of medical illness and like other geriatric syndromes should trigger a comprehensive evaluation. The aim of this chapter is to review the approach to older adults with wounds including comprehensive risk and functional assessment, identification of red flags, medications, special considerations for management of wounds in frailty, the role of palliative care and wound rehabilitation programs, counseling, and compensatory strategies.

Frailty · Chronic wounds · Exudate · Odor management · Pain control · Medication debridement · Pressure ulcer · Neuropathic foot ulcer · Wound palliation · Wound finances

Key Facts

- 8.5 percent of people worldwide (617 million) are over the age of 65 with projections that it will rise to 17 percent of the world's population by 2050.
- Aging is associated with thinning of the epidermis, degeneration of collagen, fracture of the dermal layer, and atrophy of subcutaneous fat.
- The incidence of venous leg ulcers is 3–4 times higher, and of pressure ulcer is 5–7 times higher in persons older than 80 years compared with persons aged 65–70 years.
- Care for chronic wounds in older adults costs about $10 billion annually.

Introduction

Wound healing is a complex process that can be derailed by multiple factors including obesity, diabetes, smoking, vascular disease, infection, renal failure, and malnutrition. The current incidence of chronic nonhealing cutaneous wounds is estimated at 5–7 million in the United States, with total annual wound care expenditures exceeding $25 billion [1]. We are now entering a "perfect storm" in which there is rapid expansion of the population over 65 years of age, combined with an exponential increase in diabetes and obesity worldwide. The fastest growing segment of this population, those over 85 years of age, is also the cohort with the highest incidence of chronic wounds, particularly venous leg ulcers and pressure ulcers [2–4]. Meanwhile, older adults have significantly higher rates of surgical procedures, with increased potential for wound complications [5]. The full impact of caring for chronic wounds includes direct costs (wound care supplies, hospital and nursing costs), indirect costs (lost wages for patient or unpaid caregivers), and intangible costs (pain and suffering). Thus, in addition to the effect on morbidity and mortality, we can expect that chronic wounds in the elderly will account for a disproportionate share of our nation's healthcare expenditures.

Despite universal age-related changes in skin which include thinning of the epidermis, degeneration of collagen, fracture of the dermal layer, and atrophy of subcutaneous fat [6], it is becoming increasingly clear that the development of chronic wounds and the trajectory of rate of wound healing or the development of iatrogenic complications cannot be solely defined or constrained by chronological age or presence of comorbidities [7]. Data suggest that there is a subset of older individuals at significantly higher risk for adverse health outcomes, including falls, hospitalization, institutionalization, and mortality [8, 9]. Identification and risk stratification of these individuals by the wound care team is of critical importance in order to provide quality and cost-effective treatment and to avoid adverse outcomes that are associated with some wound treatment modalities. Optimizing care for the frail older individual with wounds requires a systematic multidimensional approach, focusing on somatic, functional, psychological, and social features [10].

Key Basic Pathophysiologic Changes in Chronic Wounds

- Oxidative damage
- Impaired cell proliferation
- Protein modification
- Impaired bioenergetics
- Dysregulated inflammation
- Catabolic/anabolic hormonal imbalance

Pathophysiology of Chronic Wounds in the Aging and the Frail

There is no uncertainty that cellular damage is a unifying feature shared between younger and older individual with wounds. Reduced ability to respond to this cellular damage by increasing repair and maintain homeostasis is what sets apart frail older adults from young and robust older individuals. In such frail older adults, *homeostenosis* (decreased ability to maintain homeostasis in times of acute stress) explains the lack of ability of these older adults to meet the increased demand imposed on them by the wound (great challenge and low reserve) [11]. Several basic pathophysiologic factors contribute to this homeostenosis including the continuous demand on aging cells to respond to oxidative damage, chronic inflammation burden, hormonal imbalance between catabolic and anabolic hormones, oxidative stress damage, and mitochondrial exhaustion limiting the ability of the "frail cells" to respond to challenge precipitated by the newly developing wound.

It is also widely accepted that the healthy octagenarian with a traumatic or surgical wound normally heals at a slower rate than a healthy young adult. This effect of "pure aging" is clinically apparent by age 60 and becomes statistically significant at age 70 [12]. However, because wound healing is a complex, highly orchestrated process, disruption of even a single aspect of that process can delay healing [13]. The development of chronic wounds is multifactorial and depends upon both intrinsic and extrinsic factors. The four principle aging processes are changes in body composition, energy imbalance, homeostatic disequilibrium, and neurodegeneration. These "intrinsic" factors can have a major effect on wound healing. Specifically, alteration of the skin architecture with loss of elasticity, thinning of the dermis, and reduced capacity of keratinocytes to proliferate and migrate make the skin vulnerable to even minor trauma. A recent study using an ex-vivo model demonstrated that application of a compressive load to ischemic aged skin resulted in subepidermal separation and altered orientation of the collagen fibers similar to that seen in patients with pressure ulcers [14]. Other changes in body composition include an increase in fat mass (FM) and decline in fat-free mass (FFM). Healthy, weight stable men and women, between the ages of 68 and 78, lose approximately 1% of FFM per year. This loss of lean muscle translates to a threefold loss of strength and is a primary predictor of disability [15]. Age-induced dysregulation of energy intake and utilization is brought about through a combination of reduced perception of hunger, early satiety, changes in the hormonal mediators associated with energy balance, and reduced energy expenditure [16]. The net effect in terms of weight gain or loss depends on a number of factors, including the overall health of the individual. However, all aspects of wound healing increase protein and energy requirements. In an older adult who is already at high risk for malnutrition, the presence of a wound can tip the balance toward involuntary weight loss, development of sarcopenia, impaired immunity, and increased risk of infection [17]. Sarcopenia, reduced functional ability, and malnutrition, combined with the inability of aged skin to distribute a pressure load substantially increase the vulnerability of older adults to developing pressure ulcers.

Alterations in the homeostatic balance include increased pro-inflammatory markers, decreased antioxidants, decreased anabolic hormones, and increased catabolic hormones and insulin resistance. All of these factors contribute to impaired wound healing and affect the skin's ability to function as an immune organ. Finally, neurodegeneration combined with impaired cognition, gait imbalance, and slow reaction times contributes to immobility and decreased ability for self-care [18].

Management of Chronic Wounds in Frail Older Adults

A holistic, multidisciplinary approach is critical aspect of geriatrics wound care management and recognizes that every individual may be different, extending beyond the physical manifestations of disease to consider personal circumstances and emphasizes that "it is more important to know the patient that has the wound than to know the wound that has the patient" (paraphrase of original quote by Sir William Osler).

Key goals of a comprehensive successful geriatrics wound care management include risk factor assessment, functional status determination, prognostication, promoting a healing environment, medication and wound debridement, dressing, antimicrobial use, and setting priorities for wounds that won't heal.

Key Risk Factors

- Advanced age
- Frailty and postoperative immobility
- Low or high body weight
- Incontinence
- Nerve damage
- Altered mental status
- Sedative drugs
- Vascular insufficiency
- Malnutrition
- Dehydration

Risk Factors and Red Flags

While intrinsic factors clearly increase the risk for developing wounds, the most vulnerable patients are those with multiple concurrent illnesses. Data from the US Wound Registry indicate that patients in outpatient wound centers have an average of six comorbid conditions, including a high prevalence of patients with renal failure, peripheral vascular disease, diabetes, and malnutrition [19]. Multimorbidity, defined by the National Quality Forum as "two or more chronic conditions that collectively have an adverse effect on health status, function, or quality of life," is known to be associated with an increased risk of death and disability. The complexity of these wound care patients is made evident by considering that only 14% of Medicare beneficiaries have six or more chronic conditions [20].

Obesity, defined as body mass index greater than 30, is a major public health problem that is not included in the indices of multimorbidity. The incidence of obesity in the United States increased dramatically between 1980 and 2008, doubling for adults and tripling for children· [21]. Although not often thought of as being a problem of aging, the startling reality is that more than one third of adults over the age of 65 are obese. What is concerning is that between 1990 and 2010 there has been a linear increase in the prevalence of obesity in older men. Thus, the prevalence of obesity has increased from 31.6% to 41.5% among men aged 65–74, while the prevalence among men 75 and older has increased from 17.7% to 26.5%· [22]. This alarming trend comes at great cost, with a health burden that includes an increased risk of diabetes, cardiovascular disease, osteoarthritis, stroke, and cancer, all comorbidities that impact wound healing [23]. Furthermore, obesity increases the risk of some of the most difficult wound healing problems: lymphedema and venous insufficiency [24, 25]. Presenting with chronically erythematous, edematous, and weepy legs, these patients are often admitted to the hospital for treatment of "cellulitis" and account for approximately 50% of visits to outpatient wound centers. Because bilateral lower extremity erythema and edema is more likely to be related to an exacerbation of congestive heart failure than acute infection, treatment requires a multidisciplinary approach, particularly in older adults who are at high risk for complications from repetitive antibiotic administration, fluid overload, and progressive disability. Older adults who are obese are also at risk for sarcopenia as fat replaces muscle mass. Intake of a calorically dense diet with increased carbohydrates and fat at the expense of protein, vitamins, and minerals, paradoxically puts obese individuals at high risk for malnutrition. Involuntary weight loss occurs disproportionately in older obese individuals and is associated with high mortality [16].

Diabetes is one of the most common comorbidities among people presenting to wound clinics. As our population lives longer and grows heavier, the prevalence of type 2 diabetes is steadily increasing. Current estimates are that over one quarter of individuals over the age of 65 are diabetic (*National Diabetes Statistics Report: Estimates of Diabetes and Its Burden in the United States*, 2014). Although the risk of type 2 diabetes is increased by obesity, both insulin resistance and reduced pancreatic islet cell function are age-related changes that can result in diabetes in older adults of normal weight [26]. Diabetes accelerates the normal rate of aging in a wide variety of physiological processes. Diabetes management is more complex in the older adult with multiple comorbidities, impaired nutrition, polypharmacy, and functional disabilities. The combination of peripheral neuropathy and peripheral vascular disease greatly increases the risk of wound healing complications, foot ulcers, and lower extremity amputations in the elderly patient with diabetes. Coexisting visual impairment and impaired cognitive function may lead to delayed presentation with greater severity and more difficult management. The good news is that the rate of hospital admissions for diabetics with lower extremity amputation and ulcers declined between 1988 and 2007. Although the discharge rate in 2007 for lower extremity conditions (peripheral arterial disease, ulcer/inflammation/infection, and neuropathy) as the first-listed diagnosis among diabetics aged 75 years or older was 21.6%, the rate has been steadily declining (http//:www.cdc.gov). The rate of nontraumatic lower extremity amputation in diabetics has steadily declined since 1996, particularly for those over 75 (dropping from 19.4% in 1996 to 3.7% in 2009). One interpretation is that outpatient care is improving, preventing the necessity of hospital admission.

Measurement Tools

- Activities of Daily Living
- Frailty Calculator
- Mini-Cog or MMSE
- Geriatrics Depression Scale
- Braden Scale to determine risk of future pressure sores

Functional and Cognitive Status Determination and Frailty Assessment

Frailty is considered to be highly prevalent with increasing age; it is estimated that 10–15% of older adults over the age of 65 are frail. The prevalence of frailty rises up to 25–50% of individuals older than 85. Frailty is a clinical state of weakness and susceptibility to stress arising from low physiological reserve across neuromuscular, metabolic, and immune systems. This low reserve increases an individual's vulnerability for adverse health outcomes.

As mentioned above, wounds and different wound care modalities including debridement and grafting are significant stressors that may further lower the physiological reserve; therefore, frailty has a clinical significance for older patients with wounds where potential exists to alter treatment options and adjust expectations (patient's and provider's) for cure [9].

Key Facts

- Frailty is a biologic syndrome of decreased reserve and resistance to stressors.
- Frailty is strongly linked to adverse outcomes after surgical interventions.
- Frailty index can serve as powerful predictor of outcomes.

Although studies of the association between frailty and wound intervention outcomes are lacking, some clues may be gleaned from prior work demonstrating worse surgical outcomes in frail patients, including mortality, delirium, and delayed discharge after elective general, thoracic, and cardiac surgery. Some early preliminary reports indicate that initial wound size is significantly correlated with frailty status [27]. Furthermore, it has been suggested that frail older adults with wounds experience more pain and have higher incidence of depression compared to age matched nonfrail older adults with wounds [27].

Diagnostically, it is difficult to discern frailty status based on lab tests. Evidence suggest that frail older adults with wounds will have similar erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), ankle-brachial index (ABI), and hemoglobinA1cC values as nonfrail older adults with wounds [27]. In geriatrics, the frailty index is widely used to determine frailty status and the score is used to prognosticate outcomes, provide a personalized approach to medical care, and enhance the patient's quality of life. The value of the frailty index has been proven in geriatric medicine and is being increasingly used in some surgical subspecialties [8].

Prognostication: Does This Wound Have the Potential to Heal in a Normal Time Frame?

Determining whether a wound has the potential to heal in a "normal" time frame is largely dependent on the underlying etiology, medical comorbidities, and duration and size of the wound [28–30]. Aside from those living with spinal cord injury, pressure injuries tend to occur in frail older adults. Venous leg ulcers may be accompanied by decompensated heart failure or immobility. Neuropathic foot ulcers can occur even in wheelchair users due to poorly fitting shoes or a malpositioned foot pedal. Concomitant ischemic changes secondary to a long duration of diabetes mellitus may impede wound healing even further.

Several retrospective cohort pressure injury studies suggest that many Stage 2 pressure injuries will close, even amongst frail long-term care patients [31–33]. It is important to note that these studies are heterogeneous both with regards to time followed (3–6 months) and location. The studies combined outcomes from coccyx, ischium, sacrum, and heels. Heel pressure injuries are more complex in that they have little subcutaneous tissue and may be complicated by inadequate arterial supply leading to lower tissue tolerance to pressure. Full thickness (unstageable and Stage 3 or higher) pressure injuries will take weeks to months to heal in those patients who can receive adequate nutrition, offloading, and local wound care. For those patients with an advanced illness, healing may not be the goal because there may not be enough time to heal the pressure injury prior to the patient's death [34].

Wound size and wound age are important prognostic signs for venous ulcer healing with standard compression therapy. A sophisticated cohort study that used modeling prognostic algorithms on 20,000 patients found a cut point with venous leg ulcers that were 10cm^2 and present for greater than 1 year. Those less than these parameters had a 70% chance of healing in 6 months, while those greater than these parameters had a 30% chance of healing in 12 months [29]. Likewise if there is early healing with standard compression therapy, then usually there will be closure within 3 months. A venous leg ulcer that is not showing evidence of healing in 6 weeks with standard compression therapy should raise the index of suspicion for an incorrect diagnosis, including the possibility of malignant transformation and warrants biopsy. Multiple punch biopsies that include skin at the wound edge may be required to achieve a correct diagnosis.

Neuropathic foot ulcers also have prognostic data for wound healing based on size and duration. A similar cohort study with modeling prognostic algorithms from 20,000 patients determined that those wounds greater than 2cm^2 that were present for greater than 2 months and showed evidence of osteomyelitis or abscess had a less than 25% chance of healing in 5 months. For those ulcers that show early healing by 1 month, a 53% reduction in size by 3 months is expected. This data was extracted from patients who were not treated with total contact casting, a therapy that has become a game-changer in healing these wounds [35]. However, because of the technical expertise and time involved and patient factors, real-world medicine has found that total contact casting is not often used despite its efficacy [36].

Promoting a Healing Environment

Nutritional Support

The nutritional impact of healing a chronic wound should not be underestimated. Caloric needs decrease with age, as does lean muscle mass and metabolic rate. Older adults frequently suffer from protein calorie malnutrition – 5% in community living adults and as high as 60% in those living in long-term care [37]. The protein requirement of patients with chronic wounds increases significantly. A patient can lose 12–25 grams of protein a day from a highly exudative wound [38]. Patients living with advanced illness will have difficulty with appetite, nausea, and swallowing function. Forcing them to eat can cause further suffering. While enteral supplementation can promote wound healing, feeding tubes are not recommended for patients with advanced dementia and pressure ulcers. Cohort studies have suggested that these patients are actually less likely to heal than those without feeding tubes and have an increased risk of pressure ulcer development [39]. Instead the provider should focus on the patient's goals of care – what foods do they like and can they be enriched in calories and protein? Several small meals through the day and focusing on oral care to reduce pain and improve taste may also be strategies to improve nutrition (Langemo 2010 NPUAP paper). Consulting a dietitian to calculate caloric, protein, and vitamin/mineral needs may be helpful in generating creative ideas to improve the nutrition.

Risk Factor Modification

Wounds are less likely to heal when the underlying cause cannot be reversed. Patients with complex contractures in the setting of advanced dementia may not be able to offload a pressure ulcer regardless of the repositioning. Nutritional deficiencies in that setting are also quite challenging. Sedentary patients whose legs are constantly in a dependent position and who cannot or will not wear compression wraps or garments are unlikely to heal their venous leg ulcers. Patients with neuropathic foot ulcers who are unable to offload their foot because of extenuating circumstances at home or work are also unlikely to heal. And for all of these wounds, if arterial insufficiency remains after the patient has received maximal revascularization or if there are no options for revascularization, then it is unlikely that the wound will heal. It is important to obtain a thorough social and functional history of the patient – inquiring about support at home, access to high quality/high protein foods, sleep habits, daily activities, ability to perform self-care, including wound care, and any depressive symptoms that may be occurring [40].

Physical Rehabilitation

Despite the low potential for some chronic wounds to heal, it is still important to keep the patient engaged and active to reduce functional decline. Especially those patients with arterial and venous disease, they will benefit from a walking program. Determining what the patient is already doing at baseline – maybe it is walking around the apartment – can help the provider motivate the patient to set goals for more walking in and around their home. Collaborating with physical and occupational therapy professionals is key to setting a self-care program that will minimize functional decline.

Medication Debridement

Almost 90% of older adults over the age of 75 are on chronic medications, a third of which are on three or more medications. On average, nursing home patients are on 7–8 medications. Some medications prescribed for older adults may indirectly (e.g., decreased alertness, falls, or impaired nutrition) or directly (interfere with coagulation, inflammation, matrix remodeling, or tissue perfusion) contribute to impaired wound healing. Medications should be regularly reviewed and discontinued if risk outweighs benefit. Special attention should be given to immunosuppressants, corticosteroids, NSAIDS, and anticoagulants as they have been shown to have the strongest effects on impairing wound healing. These and other medications that are commonly used in older population that may also contribute to slower wound healing are listed in Table 1 [41–44].

Table 1 Potentially high risk medication in older adults with wounds

Class	Common drug name	Mechanism	Wound specific effects	Recommendation
Anticoagulants	Warfarin, heparin, low molecular weight heparin	Inhibit coagulation cascade intrinsic and extrinsic pathways	Prevents fibrin deposition and impairs clotting, and resultant hematoma formation has been shown to cause mechanical disruption and may increase wound infection	Home safety check for clutter and risk fall, falls risk assessment
Antiplatelet drugs	Aspirin, nonsteroidal anti-inflammatory drugs, ticlopidine, dipyridamole	Inhibit platelet aggregation Inhibit arachidonic acid pathway	Affects wound hemostasis Interrupts inflammatory phase of wound healing and impairs epithelialization	Review indication and stop if possible, reduce dose/frequency if unable to stop
Cardiovascular drugs	Ramipril, lisinopril, captopril, irbesartan, candesartan Hydralazine, bendroflumethiazide, bumetanide, indapamide, furosemide, amiloride, spironolactone, metolazone Beta-blockers – doxazosin, alfuzosin, terazosin, tamsulosin	Bradycardia, hypotension, orthostatic hypotension, syncope	Both abnormal electrolyte states, especially in combination with epinephrine use and a diseased heart, can predispose the patient to poor wound blood flow. Some of the drugs in this category have anti-inflammatory effects that can impair/delay wound healing	Check laying and standing BP, review indication, and use alternative if possible
Gout medications	Colchicine, allopurinol, pegloticase	Inhibition of microtubule formation	Decrease cytokine release/ formation, decrease granulocyte migration, decrease blood supply from vasoconstriction, decrease fibroblast activity, interrupted excellular transport of, procollagen, increase collagenase synthesis	Review indication, stop if possible

(continued)

Table 1 (continued)

Class	Common drug name	Mechanism	Wound specific effects	Recommendation
Steroids		Inhibition of gene expression	Decrease inflammatory mediators, decrease platelet adhesion, decrease WBC recruitment and phagocytosis, decrease tissue formation, decrease tissue remodeling	Review indication, stop if possible, consider Vit A supplementation Of all the systemic corticosteroids, cortisone acetate is the least harmful in this regard. Doses less than the equivalent of 10 mg/day of prednisolone may have little effect on wound healing
Sedatives and hypnotics	Short- and intermediate-acting: alprazolam, estazolam, lorazepam, oxazepam, temazepam, triazolam Long-acting: chlorazepate, chlordiazepoxide, chlordiazepoxideamitriptyline, clidinium-chlordiazepoxide, clonazepam, diazepam, flurazepam, quazepam	Older adults have increased sensitivity to this class causing orthostatic hypotension, sedation, lightheadedness, slow reactions, impaired balance, and confusion	Alter alertness, difficulty meeting nutritional goals, may impair wound blood flow. Oversedation may lead to patient not repositioning self during sleep in bed or chair, making offloading more challenging	Avoid use Stop if possible Long-term use will need slow, supervised withdraw
Antipsychotics, first- (conventional) and second- (atypical) generation, tertiary TCAs, alone or in combination	Chlorpromazine, haloperidol, lithium,promazine, trifluoperazine, quetiapine, alanzapine, risperidone	Highly anticholinergic, sedating, and cause orthostatic hypotension; the safety profile of low-dose doxepin (≤6 mg/day) is comparable to that of placebo, slow reflexes, and Parkinsonian symptoms	Alter alertness, difficulty meeting nutritional goals	Avoid use for behavioral problems of dementia unless nonpharmacologic options have failed and patient is threat to self or others. Review indication and stop if possible Consider reducing dose
Antidepressants	Amitriptyline, amoxapine, clomipramine, desipramine, doxepin, imipramine, nortriptyline, paroxetine, protriptyline, trimipramine	Highly anticholinergic, sedating, and cause orthostatic hypotension; falls, drowsiness, blurred vision, constipation, urinary retention	Alter alertness, difficulty meeting nutritional goals	Avoid use. Review indication and stop if possible Consider reducing dose

(continued)

Table 1 (continued)

Class	Common drug name	Mechanism	Wound specific effects	Recommendation
Analgesics	Codeine, pentazocine, tramadol, morphine, oxycodone, meperidine	Drowsiness, confusion, hallucinations, orthostatic hypotension, apathy	Directly stimulate the sensation of nausea and delay gastric emptying; this can compromise the patient's ability to maintain oral fluids and diet	Review indication and stop if possible Consider reducing dose
Anti-epileptics	Amobarbital, butabarbital, butalbital, mephobarbital, pentobarbital, phenobarbital, secobarbital, pregabalin, carbamazepine, phenytoin, primidone, sodium valproate, gabapentin, lamotrigine, topiramate, levatiracetam	Unsteadiness and ataxia if levels high Phenytoin – permanent cerebral damage and unsteadiness in long-term use	Animal studies suggest poor wound healing	Review indication and stop if possible Consider reducing dose

A Different Focus on the Wound That Will Not Heal

After a patient has been informed that the wound most likely will not heal, they must be reassured that there are other areas on which to focus for wound care. Goals such as control of pain, exudate, odor, and bleeding are all important to the patient and can improve their quality of life. Much of the research with regards to palliative wound management has focused on pressure ulcers at the end of life. We have extrapolated that information to apply to all chronic wounds.

Pain Management

Pain associated with chronic wounds can be debilitating and a significant source of stress, further impairing the healing process [45]. The pain may be episodic – occurring with dressing changes or debridement, or it may be constant. Distinguishing in what situations and how often the pain occurs is important for management. Patients with a serious advanced illness, in whom repositioning may be painful, or patients with constantly painful wounds should receive premedication with nonsteroidal inflammatory medications or opiates 30 min prior to dressing changes and possibly afterwards as well. For those patients with pain due to dressing changes, determine whether it is the tape or the product removal that causes pain. Simply using skin adhesive remover can greatly relieve tape removal pain. Consider changing the wound product if it is sticking to the wound and causing pain, and choose a product with longer wear time so as to reduce the frequency of dressing changes. Periwound skin can become very irritated with dressing changes and there are skin preparations that can reduce tape trauma. Consider "window paning" a wound with a hydrocolloid – tape the dressing to the hydrocolloid and only change the hydrocolloid once a week to reduce periwound trauma. With regards to the dressings themselves, wet to dry dressings are not the standard of care. To be done properly they must be applied four times per day and are known to indiscriminately mechanically debride upon removal. Wet to dry dressings do not facilitate achieving moisture or bacterial balance, are very painful, and have no place in chronic wound care. Pain can be alleviated by applying liquid lidocaine 4% (moistened in fluffed gauze) or in a topical gel to the open wound for 5–10 min prior to conservative sharp debridement or if the patient states there is pain with dressing removal. Distraction techniques such as music, position changes, and guided imagery may be helpful. Lastly, always inform the patient that they are in control and can request a time out during a debridement or dressing change [34, 45].

Discharge and Exudate Management

Wound exudate can denude the surrounding skin and cause further pain and frustration. Thus it is important to assess the amount of exudate and adjust the dressing regimen accordingly (Table 2). One way to do this is to train the clinical staff or patient to put the soiled dressings on a separate surface so that you can assess amount and appearance of the exudate. Ask the patient and/or caregiver when it was last changed and assess the outside of the dressing for strikethrough (drainage that is visible from the outside). When considering dressings for exudate management, be mindful of

Table 2 Dressing options arranged by wound characteristics

Wound characteristic	Dressing category	Action	Common examples	Limitations/indications
Dry, shallow	Films	Moisture retentive, semi-occlusive. Keeps bacteria out, moisture in	Tegaderm® Opsite®	Cannot use on infected or draining wounds, may irritate skin
Dry, shallow	Impregnated gauze	Nonadherent, provides moist environment	Xeroform® Adaptic® Aquaphor®	Requires secondary dressing
Dry, shallow	Nonadherent gauze	Nonadherent, breathable	Telfa®	Adhesive and nonadhesive
Dry, shallow	Nonimpregnated, nonadherent	Prevents dressing adherence	Wound veil® Mepitel®	No active ingredients
Dry, minimal depth	Hydrogel	Polymer with high water content. Maintains moist environment, enhances autolysis	Normlgel® Carrasyn V® Solosite®	Viscosity varies
Low exudate, granulating	Hydrocolloid	Sheet dressing, promotes autolysis, may protect periwound skin	DuoDerm® Comfeel® Replicare® Restore®	May macerate or produce strong odor
Moderate drainage, shallow to deep	Alginate, derived from seaweed	Sheets and ropes, may have gelling properties, absorbs drainage while maintaining moist environment. May combine with honey or silver	Algisite® Kaltostat® Sorbsan® Curasorb® Melgisorb	May harden into “brick.” May create pressure if used for packing, requires semipermeable secondary dressing. It is bioabsorbable (OK to leave particles behind in the wound)
Moderate to high drainage, shallow to deep	Hydrofiber, synthetic from carboxymethyl-cellulose	Sheets and ropes, vertical wicking, ropes will not fall apart, absorbs and gels in the wound. May combine with silver	Aquacel® Drawtex®	Not bioabsorbable
Moderate to high drainage, shallow to deep	Polyurethane foam	Absorbent, wicking. May have silicone backing and border, sheets or cavity filling	Allevyn®, Mepilex® Cutimed®	May have gentle border for fragile skin; may combine with silver (expensive)
Moderate to high drainage	Composite	Attributes of alginate or hydrofiber combined with foam	Allevyn Life®	Expensive
High odor	Charcoal	Odor absorbent	Actisorb® Carboflex® Carbonex®	Activated charcoal binds bacteria but is not bactericidal. May be combined with silver

how to protect the wound edge. Skin preparations or barrier creams with zinc may be effective. Highly absorbent dressings that wick away moisture such as alginates, hydrofibers, or foams will increase wear time and protect periwound skin. There is a wide variety of dressings available, many of which are designed for fragile skin. In general, brand names are less important than matching the category of dressing with the wound characteristics.

For highly exudative leg wounds, consider using an incontinence undergarment (rather than a baby diaper). The incontinence undergarment is cost effective, super absorbent, and often does not have skin irritating deodorizers and perfumes that baby diapers may contain. Negative pressure wound therapy (NPWT) can be helpful for exudate management and to facilitate wound contraction. Hospice agencies will not pay for the treatment because CMS reimbursement mandates that the wound show evidence of closure. This is unfortunate for those patients living with serious advanced illness as NPWT can be very effective at controlling drainage and minimizing the frequency of dressing frequency changes, further reducing the need for painful repositioning [28, 34]. Data regarding the cost efficacy of NPWT compared to standard dressings, including personnel time combined with quality of life measures may be helpful in convincing payors to make exceptions for patients who require a palliative approach.

Odor Control

Wound odor primarily occurs due to heavy bacterial burden (anaerobes) and sometimes due to the wound product. Ask the patient and/or caregiver whether they notice wound odor. Determine whether you can smell odor – outside of the clinic room, only in the clinic room, in close proximity to the wound, or only with dressing removal. Remove the dressings and thoroughly cleanse the wound before reassessing. Hydrocolloid dressings tend to cause odor, and the patient and/or caregiver should be warned in advance so as to not confuse the odor with infection. Conservative sharp debridement to reduce the amount of necrotic tissue will aid in odor management. Short-term use of antiseptics for cleansing, such as 0.125 or 0.25% Dakin's solution or hypochlorous acid, can also reduce odor. Using these solutions longer than 2 weeks should be avoided. Topical metronidazole with each dressing change has been used for odor control. Crushed tablets are more cost effective than creams or ointments. Composite dressings that contain silver, cadexomer iodine, or honey and an absorbent component will further reduce the bacterial burden, thereby reducing odor. Patients and caregivers might find charcoal dressings, kitty litter under the bed, coffee grounds in the room, or other external deodorizers helpful [28, 34].

Hemostasis

Bleeding can be very frightening to the patient and to the caregiver. Bleeding in chronic wounds typically occurs due to high bacterial burden or a traumatic dressing. This can be alleviated simply by changing dressing types to reduce the bacterial burden or adding a nonadherent component such as an impregnated gauze, wound veil, or silicone dressing to prevent trauma to the wound bed during dressing changes. Bleeding occurs briskly in malignant wounds, as they tend to be hypervascular. Patients and/or caregivers should be given an action plan if brisk bleeding should occur. There are highly expensive hemostatic dressings on the market, but these can be used on an as-needed basis to prevent an emergency room visit before the Hospice nurse can arrive to advise changes in the wound treatment plan. Dark towels, which mask the appearance of bleeding, can be used to hold pressure and may further reduce anxiety. Cold compresses can promote vasoconstriction, but may be uncomfortable for the patient.

Quick Tips

- Code all procedures including HCPCS codes
- Take pictures and measurements
- Document wound requirements
- Make sure that products ordered meet the definition of durable medical equipment, prosthetics, orthotics, and supplies
- Promptly sign and date your wound notes

Financing Wound Care

In 1965 the US government enacted federal legislations to provide health insurance for the old, disabled, and poor. Today Medicare and Medicaid programs cover most healthcare expenditures for adults age 65 and older including physician office visits, home visits, early post-acute care through Medicare part B as well as a specific and more comprehensive Medicare part C coverage, and prescription drug coverage (Medicare part D).

In the wound healing field, Medicare covers 80% of the costs but requires clear and detailed documentation of wound dimensions and including supplies that are deemed medically necessary for treatment. Promptly dated and signed wound notes are essential to avoid reimbursement decline [46]. In general Medicare covers the following broad categories:

I. **Dressings:** under Medicare part B, almost all surgical dressings are covered for wound patients. Deductible and copayment should be considered when ordering these dressings.
II. **Compression stockings:** limited to venous or lymphedema wounds that are open and measurable. Ordering the compression garment when the wound is still open but near closure will help prevent wound recurrence and meet insurance requirements.
III. **Home nursing and wound care:** including home nursing to change dressing, clean wounds, and topical or systemic application of medications. This coverage is included with Medicare part A**.**
IV. **Out-patient care:** essential to this coverage that clinicians carefully document with each visit wound size, depth and if drainage is required.

Clinical Vignette

The Impact of Frailty on Stage 4 Pressure Ulcer Healing

The following scenario describes two patients who presented with very similar pressure ulcers. Both are wheelchair bound. Patient #1 is 71 years old with a 26 year history of multiple sclerosis. She has multiple chronic diseases including chronic obstructive pulmonary disease and has had multiple admissions for respiratory insufficiency. She was admitted to the hospital with pneumonia and was noted to have an unstageable right ischial pressure ulcer. There are four specialists involved in her care including infectious disease, nephrology, pulmonology, and palliative care. Her home medication regimen included seven medications, not including the antibiotics prescribed in the hospital. The right ischial pressure ulcer developed at home prior to admission. Her albumin was 2.5, prealbumin 26. Patient #2 is an 82-year-old paraplegic of 50 years duration after a motor vehicle crash. She has no other medical problems. She has a primary care physician and has no specialists involved in her care. She takes analgesics for chronic back pain. Admission albumin and prealbumin were 3.0 and 31, respectively. She also was admitted with pneumonia and noted to have a preexisting right ischial pressure ulcer that was unstageable at the time of consultation.

Based on the number of medications, the number of specialists, and the number of prior falls or hospitalizations, patient #1 meets criteria for frailty while patient #2 does not (Fig. 1).

This side-by-side comparison illustrates the complexity of caring for a frail older adult with multiple comorbid illnesses and a Stage 4 ischial pressure ulcer complicated by osteomyelitis. Both patients require intravenous antibiotics based on intraoperative bone cultures if available. Both patients require exudate management with appropriate moisture retentive dressings. Both patients require vigilant periwound skin care and offloading to improve tissue perfusion and prevent progression of pressure injury. Both patients require an involved caregiver who can help manage fecal and urinary incontinence. Both patients require nutritional supplementation.

In this scenario, the frail older adult required three times as long to reach the same level of healing as the nonfrail older adult.

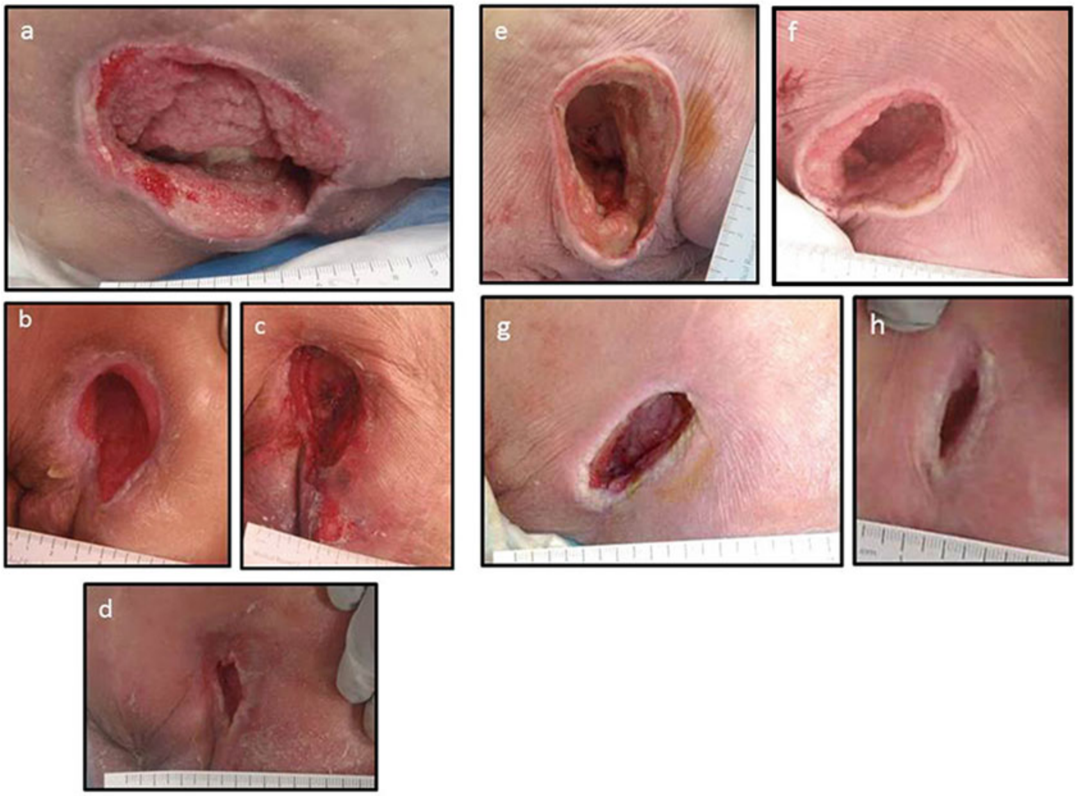

Fig. 1 Impact of frailty on healing in older adults with stage 4 pressure ulcer. (**a**) Patient #1 is a 71-year-old with multiple chronic illnesses who underwent operative debridement. After debridement the wound measured 6.5 × 5.5 cm, 3.6 cm deep. The patient was treated with intravenous antibiotics for osteomyelitis based on intraoperative bone culture. (**b**) 5 months after debridement and treatment with negative pressure wound therapy the wound is 5.5 × 3 cm, 1 cm deep. (**c**) There was marked improvement until admission for respiratory insufficiency. Upright posture is required for respiratory toilet and the wound waxes and wanes depending upon respiratory status. 11 months after debridement the wound measured 7 × 2 cm, 1.5 cm deep. (**d**) Negative pressure wound therapy is continued with the occlusive drape protecting the wound from fecal contamination. Time out of bed to chair is about 3 h per day and respiratory complications have been minimal. 18 months after debridement the wound measures 3 × 1cm, 0.5 cm deep (**e**) Patient #2 is an 82-year-old paraplegic with minimal past medical history who underwent operative debridement. After debridement the wound measured 6 × 5 cm, 3 cm deep. The patient was treated with intravenous antibiotics for osteomyelitis based on bone culture. (**f**) 2 months after debridement the wound measures 5.5 × 4.3 cm, 2 cm deep. Negative pressure wound therapy was discontinued because of difficulty maintaining a seal when getting out of bed to the chair. (**g**) 3 months after debridement the wound measures 4.5 × 1.7 cm, 1.5 cm deep. (**h**) 7 months after debridement the wound measures 2 × 0.5 cm, 0.5 cm deep and has minimal drainage

Conclusion: Putting It All Together

From the foregoing discussion it should be clear that care of the patient with chronic wounds requires a multidisciplinary approach and that this is even more critical in older adults. Many of these wounds require specialty care that is beyond the scope of what the primary care physician can provide. Specialized wound centers have been developed to facilitate healing of the most difficult wounds and need to be prepared to manage the complexities of the frail and older patient. Additionally, providers trained in geriatrics and palliative care are often involved in the care of these complicated patients to assist with symptom management, goals of care clarification, and to prevent functional decline, polypharmacy and to maximize quality of life. The goal of the comprehensive wound center is to promote wound healing through evidence-based protocols. An early and aggressive approach to wound closure reduces cost, improves quality of life, and prevents re-admission to the hospital. The wound care clinician will assist with the diagnosis, provide appropriate debridement to remove necrotic tissue and prescribe treatments that move the wound toward bacterial balance and promote healing.

However, older adults have additional special needs that merit multidisciplinary care and comprehensive assessment. According to the US

Table 3 Treatment modifications for older adults

Wound type	Offloading	Edema control	Moisture management
Pressure ulcer	Use friction reducing devices (FRDs) for transfers to reduce friction/shear on frail skin. Do not use heel offloading boots if the patient gets out of bed without assistance – increased risk of falls	N/A	Avoid use of foley catheters for sacral/coccyx/ischial pressure ulcers – increase risk of delirium Avoid wearing plastic incontinence garments at night that might trap moisture. Better to have highly absorbent pad under patient
Venous leg ulcer	Ask about positioning in bed, as pressure from bed or recliner on leg wound can retard wound healing	Assuming adequate arterial supply (ABI >0.8) start low compression wrapping (two layer) and increase weekly to four layer if patient tolerates Gradient compression wrap, nonelastic better than compression stockings. Indications are obesity, fragile skin, limited mobility or grip strength, limb shape not conducive to traditional stockings. Medicare will only pay when there is an active ulcer Consider intermittent pneumatic compression pumps if patient unable to don any stockings. May have to prove failure of compression stockings first Avoid long-stretch elastic wrap (e.g., ACE) as this will tourniquet and cause further skin injury Avoid thromboembolic deterrent stockings (TEDS) for edema control – they cause pedal edema as the strongest amount of compression is at the calf Consider PT consult for walking program to further reduce edema	For patients with highly exudative wounds not easily managed with wound products, consider use of incontinence undergarment. Avoid use of baby diapers/sanitary napkins (have perfumes)

(continued)

Table 3 (continued)

Wound type	Offloading	Edema control	Moisture management
Neuropathic foot ulcer	Total contact cast, CROW, forefoot offloading shoe, or knee scooter. These devices may not be a consideration if patient is at risk for falls. Older adults may not have sufficient shoulder strength for crutches Consider wheelchair, but with caution of coccyx/ischial pressure ulcer prevention. Need exercise plan to avoid deconditioning (hand pedal bike)	Address edema in patients with neuropathic foot ulcers – neuropathy affects the lymphatic system and can cause swelling that will impair wound healing	Wet wounds Foams Cadexomer iodine Hydrofiber Alginate Dry wounds Hydrogel Hydrocolloid (but can macerate skin)
Arterial ulcer	Consider vascular lambs-wool lined boot for offloading, protection, and warmth	Leg elevation Consider PT consult for walking program to increase arterial collateral flow and reduce edema. Challenging if patient is to remain nonweight bearing	Goal is to keep clean and dry until after revascularization (if an option). Can consider antiseptics (betadine) in this case

Census Bureau, 20% of people over age 65 have some chronic disability with 8% having significant cognitive impairment and 30% having difficulty with mobility. More than 40% of individuals over the age of 85 living in the community have difficulty performing activities of daily living and one in six report cognitive limitations (Rising demand for long-term services and supports for elderly people, 2013. www.cbo.gov/publications/4240. Retrieved August 18, 2015). Further assistance in activities of daily living may be required for patients who have been told to stay off of their neuropathic foot ulcer or limit time in the chair to promote pressure ulcer healing. Some older adults with wounds require more emphasis on palliation with control of symptoms and avoidance of infectious complications. Interestingly, more than 50% of wounds treated with a palliative approach ultimately heal [28]. Wound specialists have an in-depth knowledge of and access to advanced wound care modalities that promote healing, reduce odor, and increase comfort. The multidisciplinary approach emphasizes optimization of medical management, nutrition, mobility, pressure reduction, and perfusion while exploring barriers to care. Furthermore, best practice, evidence-based wound healing modalities such as diabetic foot offloading and compression wrapping need to be modified for the elderly patient with gait disturbances, risk of falls, or congestive heart failure (Table 3).

Other barriers for the older adult may include financial stress and lack of social support. The patient and caregiver may feel overwhelmed with tracking what treatments have worked best and what have caused problems. Getting to frequent appointments with a wound care provider can also be burdensome. An outpatient clinic setting can give a caregiver a break from dressing changes for a few weeks, but increases the burden of appointments. Skilled home health services can be a blessing; unfortunately, the patient may be discharged if the wound is not progressing. The provider will need to advocate for the patient, stating that the wound will make very slow progress due to underlying conditions. Teamwork is critical to facilitate care across the continuum and requires coordination with the family, with home health services and with the primary care physician. The $5 billion global market for "advanced wound management" is expected to triple in the next 10 years. Our nation's older adults will receive a disproportionate share of this advanced care. With a concerted interdisciplinary approach with the patient at the center of the algorithm, we can anticipate improved outcomes and better utilization of limited resources.

Abstract

The vast majority of older patients undergoing surgical procedures are medically complex with multiple chronic medical conditions, which poses significant challenges during transitions of care. Older patients frequently require specialized care coordination as they transition between surgical and nonsurgical healthcare providers located in different care settings following surgery. Transitional care at the time of hospital discharge is a critical period to ensure that appropriate information is exchanged between inpatient and outpatient healthcare providers and ensure that patients receiving appropriate follow-up care and the best outcomes. There are several different types of interventions that can be carried out before and after patients leave the hospital after surgery to achieve these goals. In this chapter, we will review the challenges facing older patients during transitions of care after surgery and the spectrum of evidence-based interventions available to healthcare providers for improving transitional care. Applying these strategies can significantly improve the quality of care and outcomes for older patients undergoing major surgery.

Keywords

Care transitions · Surgery · Discharge planning · Care coordination · Post-discharge · Multimorbidity · Geriatric

Introduction

It is estimated that over eight million inpatients surgical procedures are performed annually in US hospitals across all surgical specialties [1]. Nearly half of these surgical procedures are performed in adults aged 65 years and older [2]. The vast majority of older surgical patients meet criteria for multimorbidity with two or more chronic medical conditions such as cardiovascular, pulmonary, or renal disease. Moreover, at least 20% of older patients have five or more chronic conditions and take >6 prescribed medications that require close medical surveillance [3]. Older patients with multimorbidity are considered *medically complex* and require extra steps to ensure that their care is highly coordinated during transitions of care.

Transitional care has been broadly defined as the set of actions taken to ensure that patients have coordination and continuity of healthcare as they transition between different care settings, healthcare providers, and/or different levels of care within a given healthcare setting [4]. This involves the deliberate organization of patient care activities and sharing information among all providers concerned with delivering care to an individual patient across transitions of care [5, 6]. This can be particularly challenging for medically complex older patients undergoing major surgical procedures. Care is often incomplete or fragmented given that patients frequently transition from the primary care provider who knows them well to surgical specialists whom are not familiar with a patient's chronic care plan [7]. Differences in organizational practices, clinical preferences, as well as cultural differences between surgical and nonsurgical healthcare providers all may contribute to poor communication and/or fragmented care coordination during transitions.

Poor coordination of care during transitions is estimated to effect the quality of care and outcomes in over a quarter of discharged patients [8]. Specifically, the failure of providers to communicate effectively and share a "mental model" of clinical goals has been identified as the primary root cause in 85% of adverse events that occur in the outpatient setting after patients have left the hospital [9]. These gaps in care coordination lead to a significantly higher risk for older patients to experience a medical error or adverse event and require hospital readmission [9]. Moreover, when post-discharge complications occur in older patients and they require readmission, the lack of care continuity with healthcare providers who performed their surgery has been associated with a 25% higher risk for mortality [10, 11]. These different types of breakdowns in care coordination also lead to increased costs of care [12].

As such, it is well recognized that care coordination needs to be optimized for older patients at the time of hospital discharge to achieve the best clinical outcomes. The Joint Commission, the Centers for Medicare and Medicaid (CMS), and the Institute of Medicine (IOM) have all identified care coordination during transitions of care as one of the keys to improving the effectiveness and safety of our US healthcare system [13]. Furthermore, transition care programs for vulnerable patients were incentivized by passage of the Patient Protection and Affordable Care Act of 2010 [14]. This has resulted in the development of multiple strategies to improve care coordination during transitions between outpatient and inpatient settings for older patients with multiple chronic disease conditions [15]. But while multiple strategies have been proposed to improve care coordination for medically complex older patients during transitions of care, it is unclear what strategies are most effective for patients following surgery.

In this chapter, we will review factors that place older patients at risk for fragmented care during transitions following surgery and the different transitional care strategies that have been developed to prevent adverse events and improve patient outcomes. Transitional care interventions have been found to be most effective among people older than 60 years of age, although most have not been designed to be specific for surgical patients [16]. It is critical to understand what strategies can be applied to surgical patients at different stages during an episode of surgical care, including pre-admission, during the surgical hospitalization, and post-discharge (Fig. 1). We will discuss specific interventions that can be used for improving care coordination (1) before patients leave the hospital (pre-discharge), (2) after patients leave the hospital (post-discharge), and (3) across the care continuum to bridge the transition between inpatient and outpatient care. The success of transitional care for many older adults relies upon applying multiple interventions, and many strategies involve bundling separate components in different combinations. It is hoped that this overview of transitional care interventions will help surgical providers and health systems guide implementation of strategies that can improve the quality of care and outcomes for older patients following major surgery.

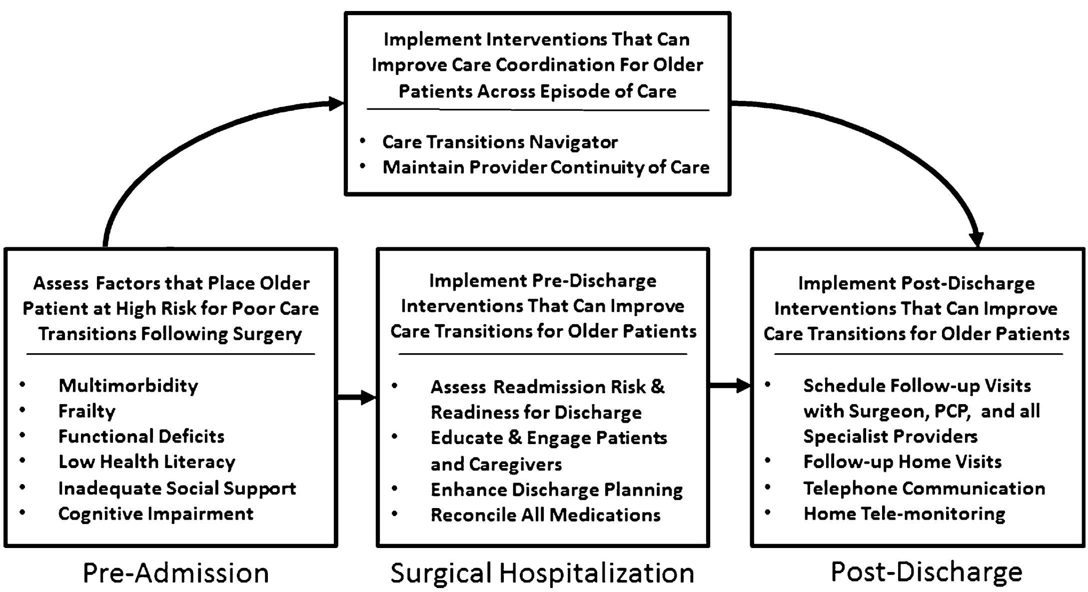

Fig. 1 Conceptual model of transitional care strategies during episode of surgical for older patients. Various interventions to improve surgical care transitions can be applied before admission, during hospitalization, and following discharge

Patients at Risk for Poor Care Transitions Following Surgery

There are multiple factors that place older patients at risk for fragmented care and poor outcomes during care transitions following surgery. This includes a spectrum of variables related to chronic medical conditions, socioeconomic status, as well as factors that are specific to their surgical procedure and postoperative care. Moreover, many older patients have components of frailty such as functional or cognitive deficits that limit their ability to respond to surgery. It is important to recognize these different types of risk factors for poor care transitions and the assessment tools that can be used to identify them before and after surgery (Table 1). Identifying risk in older patients can help providers target additional interventions during the discharge planning process to prevent unplanned readmissions.

Table 1 Risk factors for poor care transitions following surgery

Variable	Examples of available assessment tools
Multimorbidity	• Predicting Emergency Admissions Over the Next Year (PEONY) • Q-Admissions Risk Calculator • Gagne Index • Multimorbidity (MM) Index • National Surgical Quality Improvement Program (NSQIP) risk calculator • Charlson Comorbidity Index
Frailty	• Fried (Hopkins) Frailty Score • Comprehensive Geriatric Assessment • Risk Analysis Index (RAI) • Modified Frailty Index (mFI) • Vascular Quality Initiative Frailty Index (VQI-FI) • Clinical Frailty Scale (CFS) • Frail Non-Disabled (FiND) Instrument • Tilburg Frailty Indicator • SHARE Frailty Index
Functional deficits	• Hospital Admission Risk Profile (HARP) • Katz Index of Independence in Activities of Daily Living • Lawton Instrumental Activities of Daily Living (IADL) Scale • Activity Measure for Post-Acute Care (AM-PAC)
Low health literacy	• Short Assessment of Health Literacy (SAHL) • Rapid Estimate of Adult Literacy in Medicine (REALM) • Test of Functional Health Literacy in Adults (S-TOFHLA) • BRIEF Health Literacy Screening Tool (BRIEF)
Inadequate social support	• The Social Provisions Scale (SPS) • Perceived Social Support Scale (PSSS) • Social Support Questionnaire (SSQ) • Multidimensional Scale of Perceived Social Support (MSPSS)
Cognitive impairment	• Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE) • General Practitioner Assessment of Cognition (GPCOG) • Memory Impairment Screen (MIS) • Mini-Cog Assessment • Mini-Mental State Examination (MMSE)

Multimorbidity

Comorbid medical conditions are one of the central factors that place older surgical patients at risk for difficult care transitions. Up to 90% of older patients meet diagnostic criteria for *multimorbidity* with co-occurrence of two or more chronic diseases [17]. And approximately a quarter of patients over 65 years old have five or more long-term health conditions that require more than six or more prescribed medications on a daily basis [3]. Patients with multimorbidity become increasingly difficult to manage when they transition across care settings, particularly when being referred to surgical specialists for evaluation and operative management. This results in large part from the inefficient exchange of complex health information between primary care and surgical providers and inability to share a mental model of how care should be coordinated. Furthermore, primary care providers do not always have a clear sense of what their role should be in the immediate post-discharge care of patients following surgery.

There are a variety of tools available to assess the degree of multimorbidity and corresponding degree of risk in older patients undergoing surgery. Table 1 shows a sample of the different risk calculators that have been developed and validated in medical and surgical populations using patient comorbidity data. They are available to predict risk for short-term outcomes such as unplanned readmission or need for post-acute care settings, as well as long-term outcomes and mortality. Moreover, many of these tools can be adapted and automated within EHR systems or found on publicly available websites to provide healthcare providers risk data at the point of care.

Most comorbidity risk assessment tools are not specific to surgical outcomes with the exception of the American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) risk calculator. This tool is available online (http://www.riskcalculator.facs.org/) and can be used to assess a patient's risk for a number of different outcomes based on their specific surgical procedure and 19 different comorbidity variables. Another risk tool able to be calibrated for surgical populations is the Charlson Comorbidity Index, which can be used to predict an individual's mortality risk from a list of 30 different categories of comorbidities. However, this risk index is most commonly used for comorbidity adjustment in surgical databases and not typically used for prospective risk assessment.

Frailty

An older patient's degree of frailty is another measure that can be used by surgical providers to estimate risk for poor outcomes during transitions of care after surgery. Frailty is a multidimensional syndrome independent of age that is defined as a patient's loss of physiologic resilience to stress. As frail patients have a limited ability to respond to a major stress such as surgery, it is not surprising that frailty measures also correlate with postoperative morbidity and mortality [18].

Frailty can be measured in older patients undergoing surgery using several different approaches, broadly classified as *phenotypic frailty models* and the *accumulated deficits model (ADM) of frailty*. Phenotypic models focus on recognition of somatic or physical characteristics that are associated with frailty. The Fried or Hopkins Frailty Score is one of the most widely recognized phenotypic models of frailty, which measures five domains: unintentional weight loss, self-reported exhaustion, weakness as measured by grip strength, slow walking speed, and low physical activity [19]. The Fried Frailty Score has been validated for predicting postoperative outcomes among a variety of different surgical populations [20]. Other phenotypic methods used to assess frailty include measurement of nutritional status (e.g., serum albumin), triceps skinfold thickness, and sarcopenia. In particular, it has been suggested that computed tomography (CT) measurements of psoas muscle size can be used to quantify sarcopenia and serve as a preoperative measure of frailty [21].

The other main approach that can be used by healthcare providers to assess frailty is the ADM. This assessment tool originated from the Canadian Study of Health and Aging and probes 70 different items within physical, medical, cognitive, and functional domains as part of a Comprehensive Geriatric Assessment (CGA). While the CGA has been deemed too time-consuming to undertake in routine surgical practice, truncated versions of this model have been developed for surgical patients [20]. This includes the Clinical Frailty Scale, which is a simplified assessment tool using schematics to represent progressive degrees of frailty based on the ADM. Other models based on the ADM include the modified frailty index (mFI) and the Vascular Quality Initiative Frailty Index (VQI-FI). These last two frailty indices utilize data that is routinely collected as part of surgical quality improvement registries such as NSQIP or the Vascular Quality Initiative (VQI) and have been used to estimated risk associated with 30-day and 1-year mortality outcomes following different general and vascular surgery procedures.

Functional Deficits

Beyond assessing comorbidity data, other specific risk factors can be used to identify older patients who are at risk for having difficult care transitions following surgery. One significant factor to recognize and measure is whether older patients have any *functional deficits*. This is defined as any limitation or impairment in physical ability that results in lack of mobility or inability to independently complete their activities of daily living. Functional deficits directly impact a patient's ability to care for themselves after surgery and place patients at a greater risk for adverse postoperative events such as falls in the outpatient setting. Recent studies have shown that functionally dependent surgical patients have a significantly increased risk of discharge to post-acute care facilities, irrespective of whether postoperative complications occurred [22]. Loss of independence during the postoperative period is also associated with an increased risk for readmission and death following hospital discharge [23].

There are a wide range of tools that can be used to screen for functional deficits and risk for loss of independence in older patients before and after surgery (Table 1). Standardized tools that can be applied in the preoperative setting include the Hospital Assessment Risk Profile, the Katz Index of Independence in Activities of Daily Living, or the Lawton Instrumental Activities of Daily Living (IADL) Scale. In particular, these instruments are useful for assessing whether an older patient can perform daily tasks necessary to live independently in the community after surgery. The information provided from functional assessment tools can also provide objective data to assist with targeting individualized patient needs following discharge including in-home services such as meal preparation, nursing care, homemaker services, personal care, or continuous supervision.

During the postoperative period, it is important to re-evaluate older patients' functional status and assess needs for post-discharge care. Tools such as the Activity Measure for Post-Acute Care (AM-PAC) are useful for assessing activity limitations in older patients across post-acute care settings. In particular, the AM-PAC "6-Clicks" Basic Mobility Short Form is a simple measure used by physical therapists (PT) to assess mobility in the inpatient setting and can be used to predict when patients might benefit from further PT services in the outpatient setting [24].

Low Health Literacy

Low health literacy is found in up to a third of the US adult population and places older patients at risk for adverse events during transitions of surgical care [25]. Health literacy is defined as the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions. This includes specific skills needed by patients to navigate the healthcare system and allow clear communication with their healthcare providers. Older surgical patients in particular need to be able to access information and resources that are specific to their surgical condition following discharge. Adverse events may occur when patients don't understand their medications, discharge instructions, or warning signs following hospital discharge after surgery.

There are a wide variety of instruments available to healthcare providers for assessing health literacy in older patients undergoing surgery (Table 1). This includes tools that have been designed to objectively test an individual's health literacy or alternatively rely upon the elicitation of self-reported abilities [25]. Using the objective measurement approach, patient abilities are assessed by solving tasks dealing with print literacy, numeracy, or oral literacy. In comparison, the self-report approach is characterized by how a patient perceives their ability to interpret medical terminology in multiple domains. Many health literacy tools have been designed to be administered for non-English-speaking adults, and some can be administered in as little as 2 min. These can be quickly administered during the preoperative or postoperative period and can help surgical providers *personalize* an older patient's transition of care after surgery.

Inadequate Social Support

Many older adults undergoing surgery are found to have an inadequate social support network, which increases their risk for poor transitions of care. Social support is both the perception and actuality that patients have assistance or resources provided from other people, which may include caregivers, family, friends, neighbors, or other members within their community. The supportive resources provided by these individuals can be categorized by the form of aid provided and includes instrumental, informational, and emotional support [26]. Instrumental support refers to the availability of people who can provide functional aid in completing daily tasks, such as making meals or providing transportation if needed. Informational support refers to the availability of people who can provide information or advice needed to solve problems that arise. And emotional support refers to the availability of people to listen to a patient's problems and provide empathy, caring, and understanding. All of these forms of social support can influence a patient's ability to thrive during transitions of care following surgery.

There are multiple tools available for surgical providers to assess a patient's perception of their social support network (Table 1). While these instruments contain different questions, they are all designed to assess components of instrumental, informational, and emotional social support domains. Most of these questionnaires can be administered rapidly within the preoperative or postoperative periods and used to determine how much support older patients can count on from people around them following hospital discharge. They can also be used to help patients and healthcare providers identify specific individuals who can provide assistance with their post-discharge care plan. This is particularly important when older patients have outpatient wound care or physical therapy needs following surgery.

Cognitive Impairment

Cognitive impairment may be present at varying degrees in a high percentage of older patients undergoing surgery and influence their ability to transition successfully after surgery. This is defined as impairment of mental processes that limit a patient's acquisition of information and knowledge and influences how they understand and interact with their environment. Mild cognitive impairment is estimated to be present in up to 40% of patients older than 65 years of age who present for surgery, whereas dementia is found in up to 7% of patients [27]. Older surgical patients with cognitive impairment at baseline are also at high risk for postoperative delirium and postoperative cognitive dysfunction (POCD) [28]. POCD is typically a short-term decline in cognitive function, especially in memory and executive functions, which may last from a few days to a few weeks after surgery. The symptoms vary from mild memory loss to an inability to concentrate or process information.

Any type of impairment in cognitive function during care transitions places older patient at risk for poor outcomes after discharge. Surgeons caring for older patients should be aware of the various tools available to screen for cognitive impairment (Table 1). Most of these tools need 10 min or less to administer and can be performed by a mental health consultant working with the surgical team. While the evaluation of baseline cognitive function is not part of routine preoperative evaluation, nevertheless it is important to identify older patients who should undergo screening. Cognitive screening tools can help risk stratify patients who would benefit from close surveillance and interventions to support care transitions. Moreover, these measurements may help guide decision-making and customize both surgical treatments and post-discharge plans for older patients.

Interventions to Improve Care Transitions Before Hospital Discharge

Assessment of Readmission Risk and Readiness for Discharge

Roughly 20% of older patients who undergo major surgery will be readmitted to the hospital within 30 days after discharge [29]. The various risk factors defined above all place older patients at risk for poor care transitions and adverse events after discharge, which often require the need for readmission. As such, it is important to systematically assess a patient's readiness for discharge and identify risk factors for readmission before discharge so that the hospital team can work to begin to mitigate those risks while surgical patients are still inpatients. Assessing how well an older patient is prepared for discharge and their risk for readmission can also help clinicians identify older patients who might benefit from more intensive post-discharge care.

While assessment tools defined in Table 1 can be used to evaluate individual risk factors, they are not specific to calculating an older patient's risk for readmission. However, several clinician friendly readmission risk assessment tools have been developed and validated to meet this need (Table 2). The Length of stay, Acuity, Comorbidity, and Emergency department use (LACE) index is one of the most well-known tools and calculates risk for readmission based on an algorithm that combines a patient's length of stay, acuity of admission, comorbidities, and ER visits within the prior 6 months [30]. This model was derived using medical and surgical patients of all ages and has moderate discriminative ability to predict unplanned readmissions. Another risk index for predicting 30-day potentially avoidable readmissions among patients hospitalized for medical conditions of all ages is the HOSPITAL score [31]. This score is calculated using eight different patient risk factors and has a slightly greater discriminatory power to predict readmissions, but at the cost of needing to collect more variables. The Pra instrument is an eight-item questionnaire that can be used to screen older adults readiness for discharge and assess risk for readmissions and need for post-discharge outpatient healthcare services [32]. While this tool requires survey administration and has lower predictive power, nevertheless it is designed specifically for older patients. Finally, the TCM discharge screening and BOOST 8P tools define different risk factors that providers can use to categorize older adults at high risk for adverse events during transitions of care at the time discharge. Readmission risk is calculated by the severity of these risk factors and can be used to stratify patients prior to leaving the hospital [33].

The ACS-NSQIP risk calculator previously mentioned can also be used to estimate 30-day readmission likelihood using both patient and procedure-level data. This nomogram calculates readmission risk based on five patient-level variables and five procedure-related variables and has moderate discriminative power to predict unplanned readmission [34]. Using this tool, early 30-day readmission following both general and vascular surgery procedures has been found to be strongly associated with postoperative complications [35–37].

Education and Engagement of Patients and Their Caregivers

A central component of most care transitions interventions is a focus on education and engagement of patient and their caregivers. Many studies have shown that patients who are better educated and engaged about their health condition are more likely to participate in preventative and healthy behaviors, self-manage their health condition, have better healthcare experiences, and achieve better clinical outcomes [38]. It is recognized that patient and their caregivers or families must actively participate in informed decision-making and receive appropriate education prior to hospital discharge for self-care management. This includes recognition and understanding of important health issues, medications, as well as early identification and response to potential problems to prevent decline in health condition. Developing a patient-centered care plan individualized to specific post-discharge needs is a core part of several care transitions interventions. Furthermore, patients and caregivers need to be aware of resources that are available to them in the post-discharge outpatient setting.

In order for education and engagement practices to be effective during transitions of surgical care, they need to be patient-centered and tailored to the risk profile of the individual patient. For example, an older patient with low health literacy or who doesn't speak English will need resources that are specific to their level of comprehension and delivered in a language they can read. It is recommended that providers use "teach-back" methods to have patients recite what they have

Table 2 Readmission risk assessment tools

Risk assessment tool	Variables assessed using tool	Patient population and ages	Discriminatory or predictive power
LACE	Length of stay Acuity of admission (i.e., inpatient or outpatient) Comorbidities ER visits within previous 6 months	Surgical and medical; all age ranges	c-statistic – 0.70
HOSPITAL	Hemoglobin level Oncology (i.e., discharged from oncology service) Sodium level Procedure Index admission type No. of admissions in the past year Length of stay	Medical; all age ranges	c-statistic – 0.72
Probability of repeated readmission (Pra) instrument	Survey questions In general, how would you say your health is? In the previous 12 months, have you stayed overnight as a patient in a hospital and how many times? In the previous 12 months, how many times did you visit a physician or clinic? In the previous 12 months, did you have diabetes? Have you ever had coronary heart disease, angina pectoris, a myocardial infarction, or a heart attack? What is your sex? Is there a friend, relative, or neighbor who would take care of you for a few days, if necessary? What is your date of birth?	Medical; patients >65 years	AUC – 0.64
TCM hospital discharge screening criteria	Being age 80 or older Moderate to severe functional deficits More active coexisting health conditions Six or more prescribed medications Two or more hospitalizations in the past 6 months or hospitalization in the past 30 days Inadequate support system Low health literacy Documented history of nonadherence to the therapeutic regimen Cognitive impairment such as diagnosis of dementia or positive screening assessment using standardized tools	Surgical and medical; all age ranges	N/A
BOOST 8Ps	Problem medications (e.g., warfarin, insulin, etc.) Psychological (e.g., depression) Principal diagnosis (e.g., cancer, stroke, etc.) Polypharmacy (>5 medications) Poor health literacy (i.e., inability to teach back) Patient support (i.e., absence of caregiver) Prior hospitalization (nonelective, prior 6 months) Palliative care (progressive serious illness)	Surgical and medical; all age ranges	N/A
ACS-NSQIP risk calculator	Patient variables ASA class Steroid use Dialysis dependence Diabetes Cancer Procedure variables Wound class Operative time Urgent surgery Inpatient procedure Discharge destination	Surgical patients; all age ranges	c-statistic – 0.70

LACE, Length of stay, Acuity, Comorbidity, and Emergency department use; AUC, area under the receiver operating curve; ER, emergency room; ASA, American Society of Anesthesiologists; DM, diabetes mellitus; COPD, chronic obstructive pulmonary disease; N/A, not available learned and confirm what has been explained to them. Moreover, it is recommended that patients and caregivers have access to high-quality educational resources specific to their surgical condition using a combination of different mediums or delivery formats. This includes print materials, Internet websites, videos, communication with other patients with similar health conditions, or resources that facilitate direct communication with healthcare providers. And at least one care transitions intervention advocates for the use of computerized bedside education systems consisting of a virtual nurse as the most effective way to engage and educate patients about their post-discharge self-care plan [39]. While these various types of computerized technology can help facilitate information delivery, it is important to ensure that older patients are comfortable with using them.

For older patients who have undergone major surgery, education and engagement activities typically need to be customized to their specific postoperative care plan. First, almost all surgical patients will have specific education needs related to the care of their incisions and surgical wounds. It is critical to provide surgical patients and their caregiver's in-depth instructions regarding specific wound care and/or dressing changes, as well as education on early identification and response to problems such as surgical site infections. This may come in different combination of print and visual media. Second, surgical patients are commonly prescribed new medications during the surgical encounter, including those for pain control or to help manage a complication. Patients and caregivers require detailed education pertaining to any new medications, including side effects and plans for dose titration. In cases where medications are intended to be taken long term, communication with the patient's primary care provider is needed to ensure they are continued and at the correct dose. Finally, it is equally important for patients to be educated and engaged in their care plan when receiving post-discharge care from a home care nurse or post-acute care provider. Many times patients serve as a key intermediary to ensure that health information is accurately communicated between inpatient and outpatient healthcare providers.

Enhanced Discharge Planning

Enhanced discharge planning is one of the most common strategies undertaken to improve transitional care at the time of hospital discharge and reduce readmissions. This includes strategies designed to *enhance* the organization of routine discharge planning, as well as efforts to make it more patient-centered. This intervention is generally undertaken by a nurse care coordinator or case manager and includes the development of a personalized or patient-centered care plan for each patient who is leaving the hospital. The patient-centered care plan considers their hospital course in the overall setting of comorbidities, functional status, cognitive status, health literacy, and social support. Enhanced discharge planning also intends to ensure that patients leave the hospital at an appropriate time in their care and that the coordination of post-discharge care is well-organized, including scheduling of follow-up appointments with specialists and outpatient providers.

There has been moderate strength evidence showing that enhanced discharge planning is effective at reducing hospital readmissions for older adults. A total of 30 different randomized controlled trials (RCTs) have been undertaken so far to evaluate enhanced discharge planning, including 21 studies that focused on older patients and 5 studies that recruited surgical patients. A recent Cochrane meta-analysis of these RCTs demonstrated that enhanced discharge planning reduced hospital length of stay by 27% and readmission rates by 13% (RR: 0.87, 95% CI: 0.79–0.97) relative to control groups [40]. Coordinated discharge efforts were also associated with increased satisfaction for patients and healthcare professionals in six different studies. The greatest improvements associated with this intervention were in participants' perception of the discharge process, continuity of care, and nonfinancial access to medical care.

Enhanced discharge planning strategies are very applicable to most older patients who undergo major surgery. The preponderance of older surgical patients has multimorbidity and other risk factors that place them at risk for poor care transitions following discharge and require more detailed discharge planning. Implementing enhanced discharge planning can help improve the efficiency and quality of care coordination for surgical patients during their transition from inpatient to outpatient care, without a significant investment to the healthcare system. In particular, the development of an individualized discharge plan can significantly help facilitate transitions to the post-discharge setting by providing information to patients about their surgical condition and establishing a post-discharge care plan that includes follow-up responsibilities for both surgical and nonsurgical providers.

Medication Management and Reconciliation

Another core component of care transitions interventions are specific efforts directed at optimizing medication management and reconciliation across different care settings. Most of these interventions are led by pharmacists and include strategies to ensure that patients are on the appropriate medication at the correct dose or frequency and do not have duplicated prescriptions when they transition to outpatient care settings, including home and post-acute care facilities. Nearly a quarter of the adult population over 65 years of age takes more than five different medications and are at high risk of experiencing such as medical errors or other adverse drug events (ADEs) during transitions of care [3]. ADEs occur most frequently following hospital discharge among older adults taking multiple medications, particularly when new drugs are started or chronic medications are stopped during their acute hospitalization. Reconciliation efforts may help to prevent ADEs by systematically comparing patient medication records across the different care settings and ensuring they are concordant with physician orders in both inpatient and outpatient settings.

The effect of pharmacist-led medication reconciliation strategies on patient outcomes during transitions of care has been well-studied. A total of five different RCTs and multiple observational cohort studies have been completed to date that have examined the effects of medication reconciliation at the time of hospital discharge on patient outcomes. When this pre-discharge intervention is combined with post-discharge follow-up efforts to ensure that outpatient medications are reconciled, there is solid evidence underscoring its effectiveness. A recent meta-analysis of eight RCTS found that medication reconciliation reduced drug event-related hospital revisits by 67% (RR 0.33; 95% CI 0.20–0.53), ED visits by 28% (RR 0.72; 95% CI 0.57–0.92), and 30-day readmissions by 23% (HR: 0.81; 95% CI: 0.70–0.95) when compared to control groups [41]. This evidence highlights the effectiveness of medication reconciliation for improving patient outcomes and post-discharge hospital utilization.

Medication reconciliation during surgical care transitions is particularly important for older patients with multimorbidity who have undergone major surgical procedures. There is a high likelihood that one or more chronic medications in these patients have been either stopped or had dosages altered during the postoperative period. This is a routine practice for high-risk medications, such as those used for anticoagulation (e.g., warfarin), diabetes (e.g., metformin), or heart failure (e.g., furosemide). However, some other types of chronic medications may also need to be held following surgery due to hemodynamic instability or as a result of varying degrees of organ failure during the perioperative period. In addition, many older surgical patients also require the addition of new medications during the postoperative period such as a narcotic for pain management. Furthermore, some surgical patients will require new medications to treat a postoperative complication such as anticoagulation for postoperative deep venous thrombus or an antibiotic to treat a surgical site infection. It is important to ensure that all medications for chronic and acute conditions are managed appropriately during the post-discharge period after surgery.

Interventions to Improve Care Transitions Following Hospital Discharge

Scheduled Early Follow-Up Visits with Healthcare Providers

One of the most common and important strategies employed to improve care transitions at discharge for older patients is directed at scheduling early follow-up visits with their healthcare providers and then making sure patients arrive at these appointments. This includes follow-up visits with members of their primary care medical home as well any specialty providers such as surgeons that cared for them during the recent hospitalization. The early follow-up visit is an opportunity for the patient and caregiver to be examined by their healthcare provider and have any outstanding questions clarified. This may include obtaining additional education or resources to supplement their outpatient care. From the perspective of the healthcare providers, this visit allows them to assess changes in health status since discharge and review or make any changes the post-discharge care plan. For many older patients, this requires coordination with home health nurses, case managers, or post-acute care facilities. The follow-up visit is also another opportunity to use *teach-back* strategies to ensure that patients and caregivers comprehend their care plan and are aware of the warning signs or symptoms that indicate a worsening condition.

Early follow-up visits with primary care providers (PCPs) after hospital discharge have been associated with improved outcomes among older patients hospitalized for both high-risk medical and surgical conditions. In a recent large observational study, adults 65 years or older who received PCP follow-up within 7 days of hospitalization for heart failure complications had a significantly reduced rate of 30-day readmissions compared to patients with longer follow-up. Another prospective cohort study enrolling patients with multimorbidity found that individuals lacking PCP follow-up within 30 days after discharge for a medical condition were ten times more likely to be readmitted ($P < 0.05$). Finally, early follow-up with a PCP also was also found to be associated with a significantly lower risk of 30-day readmission among medically complex surgical patients undergoing thoracic aneurysm repair, particularly when a perioperative complication occurred (20% vs. 35%; $p < 0.001$). This finding was supported by risk-adjusted regional analyses, where PCP follow-up reduced the likelihood of 30-day readmission following thoracic aneurysm repair by over 31% (risk-adjusted OR: 0.68; 95% CI: 0.55–0.85; $P < 0.01$).

There are several potential benefits associated with having older patients' follow-up with their PCP in addition to their surgical team within a short time period following hospital discharge after undergoing a major surgical procedure. First, the majority of older patients undergoing major surgery have at least one or more chronic medical conditions, including chronic obstructive pulmonary disease (COPD), diabetes, stroke, renal insufficiency, and heart failure. These conditions are all independently associated with an increased risk of readmission and may be exacerbated by surgical stress during the postoperative period [42]. The patient's PCP is typically in the best position to evaluate and treat the patients if any health condition has deviated from baseline. Second, many older patients take one or more medications that need to be stopped or titrated during the postoperative period. The PCP is generally in charge of managing an older patient's medication regimen and is the best provider to titrate or make changes necessary for long-term drug maintenance. A clinic visit with a PCP during the 2-week period after surgery will facilitate this. Finally, early follow-up visits with both primary care and surgical providers after surgery can help detect many complications that occur in medically complex older patients at an early stage before their condition deteriorates. This is supported by a retrospective review by Saunders et al. who noted that in many cases, outpatient follow-up did not occur early enough in the postoperative period to treat complications before patients required hospital readmission [43].

Home Visits

A home visit by a healthcare provider following hospital discharge is a component of several transitional care strategies used for older high-risk patients. This type of intervention is designed to evaluate any signs of deterioration in clinical status since discharge, as well as an opportunity to re-engage and educate the patient within their home setting. This includes reinforcing medication adherence, wound care, or any aspect of their post-discharge care plan. As such, home visits are typically conducted within a short time period after discharge (i.e., 1 week) by providers who are familiar with the patient's recent hospital course. This visit may be conducted by different members of the healthcare team, including nurses, advanced practice clinicians (e.g., nurse practitioners or physician assistants), pharmacists, or a specialized care navigator.

While home visits are a component of many care transitions interventions, the effect of this intervention on clinical outcomes has not been consistent across groups of older patients with chronic medical disease. One RCT that evaluated the effect of a single nurse home visits on outcomes in patients with heart failure found a significant reduction in readmissions and lower rates of out-of-hospital mortality [44]. But, this finding was not consistently replicated when including other types of patients with medical conditions. At least one meta-analysis that including all general medicine patients who had received at least one home visit did not find a significant effect on readmission rate. However, another recent meta-analysis found that medical patients who received two or more post-discharge home visits had the lowest likelihood of readmission [45].

Among older high-risk surgical patients, home visits have shown promise as a means to reduce readmissions in a few studies. The "Follow Your Heart" study enrolled older patients who underwent cardiac surgery to receive two home visits within 10 days of hospital discharge by a cardiac nurse practitioner (NP) who was familiar with the patient's hospital course [46]. When compared to patients who received a home visit from a home health agency, this study found that cardiac surgery patients who were visited by the cardiac NP had a significant reduction in hospital readmissions (3.9% vs. 11.5%; $P < 0.05$). Another cohort study found that cardiac surgery patients who were visited by a physician assistant with cardiothoracic training on days 2 and 5 following discharge had a significant decrease in the rate of infection-related readmissions [47]. Together, these studies support the effectiveness of in-home visits by providers who know the patient and have specialized training to manage postoperative conditions. The authors of both studies similarly concluded that providers familiar with the postoperative care of cardiac surgery patients were less likely to send patients to the emergency department because of their ability to manage complications in the outpatient setting.

Follow-Up Telephone Communication

A common component of care transitions interventions after discharge is some form of telephone communication between the patient and healthcare providers. This includes follow-up phone calls by members of the healthcare team or patient-activated telephone hotlines that patients can contact on their own. Follow-up telephone calls to patients may be personalized or involve generalized call scripts that inquire about new symptoms patients might be having since discharge, plans for ambulatory follow-up, use of prescribed medications, and any warning signs for impending adverse events. During follow-up calls, patients are also usually provided information on resources to help support post-discharge care. Both follow-up telephone calls and telephone hotlines aim to identify and remedy possible gaps in care that may occur after hospital discharge, allowing patients to get their questions answered while giving providers an opportunity to reinforce key elements of the discharge instructions.

While follow-up telephone calls are among the most commonly used transitional care interventions used in practice, the evidence supporting their effectiveness as a solitary post-discharge intervention has been mixed. Among patients with chronic disease, recent systematic reviews have found inconclusive evidence that a single follow-up telephone calls by themselves are effective in reducing 30-day readmissions [48]. Similarly, the effectiveness of post-discharge telephone calls in surgical patients is unclear. A recent RCT known as the CONNECT trial randomized patients who underwent colorectal surgery to post-discharge telephone calls by a nurse provider, but found no significant difference in 30-day readmissions compared to patients who didn't receive the intervention [49]. However, another recent meta-analysis found that interventions involving multiple follow-up telephone calls during the post-discharge period had the lowest likelihood of readmission [45].

The variability in effectiveness of post-discharge telephone calls for older patients following surgery may depend on several factors. First, the ability to contact an older patient by phone during the post-discharge period can be variable. While telephone calls are made to a number provider by the patients, studies have shown that only a fraction of patients are able to actually answer a telephone call. It is important to have contact information for the patient or caregiver, but also other members of their social support environment such as family or neighbors. Second, there needs to be a mechanism for addressing any problems that are identified during a follow-up call in order to prevent a potential readmission. If the provider making the telephone call does not have the medical training to answer patient questions or triage clinical issues, the benefit of telephone follow-up may not be maximized. Finally, the results of systematic reviews suggest that follow-up calls need to be combined with other transitional care interventions in order to adequately impact clinical outcomes. This includes combing follow-up calls with home visits or early follow-up with their provider to reinforce the post-discharge plan.

Home Telemonitoring

Another emerging technology-driven strategy for care transitions is the incorporation of home telemedicine or telemonitoring into follow-up care after hospital discharge. Telemonitoring has been defined as the process of transmitting data concerning a patient's health status from home by a patient or their caregiver back to a healthcare provider or healthcare setting. This strategy encompasses the use of several different types of technologies to monitor a patient's health status from a distance, including video consultation; mobile phone; automated device-based, interactive voice response; and web-based telemonitoring. These strategies may include remote transfer of physiologic data between patients and providers, such as vital signs, images to document a disease state, or confirmation of medication or treatment compliance. This strategy may also involve partnering with home health agencies to improve gaps during the discharge transition process [50].

Telemonitoring has shown promise as a transitional care strategy for older patients with different types of chronic disease conditions. Multiple studies have shown an effect between different telemonitoring interventions and significant reductions in mortality, readmissions, and healthcare utilization for older patients with chronic conditions including heart failure, COPD, and asthma [51]. Telemonitoring has also been shown to improve patient-reported quality of life and satisfaction with care [52]. In particular, the benefit of these interventions has been correlated with increased knowledge of self-care behaviors that prevent complications in the outpatient setting.

While telemonitoring strategies have not been specifically studied in older surgical patients, nevertheless they can also be expected to benefit from these types of interventions during transitions following hospital discharge. Telemonitoring is well suited for older surgical patients who live far from the hospital and have specialized postoperative care needs such as wound care. For example, the ability to remotely monitor surgical wounds for healing and or development of surgical site infections (SSI) can help decrease the need to see a patient back in clinic. There have been several smartphone applications developed over the past couple of years that allow patients or home health nurses to take a wound photograph and transmit it through secure web-based platforms to healthcare providers. This exchange of wound images allows providers to remotely assess for evidence of SSI or wound breakdown and determine if an in-person visit is needed, many times saving the patient an obligatory visit back to the hospital.

Interventions to Improve Care Transitions Across Episode of Care

Maintaining Continuity of Provider Care

Maintaining continuity of provider care is an important part of care coordination and a strategy for improving transitions across episodes of care for older patients. The ideal concept of *continuity* is having a patient's healthcare managed by a single provider who knows every aspect of their medical and surgical history and is responsible for coordinating all aspects of chronic health maintenance. This type of strategy helps establish and maintain strong patient-provider relationships and minimizes the potential for gaps in information exchange when patients are cared for by multiple providers in a health system.

Although the ideal notion of a single provider is not feasible in most modern healthcare systems, particularly for patients with multimorbidity, there are still models of care continuity that can be applied to older patients. For example, hospitals with integrated post-hospital care delivery where patients are seen by their same primary care or specialist provider have been shown to reduce readmissions for patients with acute and chronic medical conditions, such as pneumonia, urinary tract infections, heart failure, and COPD [53]. Moreover, continuity of care has been reported to reduce complications and reduce overall healthcare costs for patients with chronic diseases [54]. This benefit is maintained when patients are cared for by teams within the same healthcare setting, regardless of whether the same providers are involved with every episode of care.

There is accumulating evidence showing that continuity of care is also critical for the management of older patients during the post-discharge period following surgery [10, 11]. Specifically, older patients who experience a postoperative complication following surgery and then return to the same index hospital for management have significantly improved outcomes when compared to patients who are readmitted to different hospitals. A recent study by Brooke et al. showed that returning to the index hospital where surgery occurred was associated with a 26% lower odds of 90-day mortality (OR: 0.74; 95% CI: 0.66–0.83) [10]. Moreover, this study found that the decrease in mortality risk was greatest for patients readmitted for surgical versus medical complications, and there was a dose-dependent reduction in mortality when patients were managed by the same surgical providers who performed their initial operation. These data support the importance of continuity in surgical care at both the hospital and provider level and suggest that maintaining continuity of care following surgery can be used as a metric of care quality.

Care Transitions Navigators

One of the major issues facing older patients undergoing surgery is how to navigate the complexity of the healthcare system during care transitions before and after their operation. Care transitions navigators are individuals whose specific job is to assist patients in this capacity, as well as provide continuity across the episode of care. This role is a central component of several different care transitions programs and typically involves a healthcare professional with some form of advanced training in nursing or social work. Care navigators function as another set of "eyes and ears" for patients or caregivers to bridge the gap between inpatient and outpatient care. This includes helping them understand their care plan, new medications, follow-up appointments, or the myriad of questions that pop up as they transition back to their primary care team. The navigator also helps the patient coordinate any needed outpatient care, including pending labs and imaging studies, and following up with patients' primary care providers to relay updated problem lists and treatment plans. They also work closely with discharge planners and case managers in addressing the essential aspects of care coordination before, during, and after the time of hospital discharge.

Care navigation has been shown to be an effective transitional care strategy for improving outcomes among patients with various medical and surgical conditions. A recent meta-analysis of 25 different RCTs found that patients assigned to care navigators were significantly more likely to access health resources and adhere to follow-up treatment plans when compared to usual care [55]. Many of these studies found that care navigators were most effective among older female patients and those from disadvantaged socio-demographic backgrounds. Furthermore, care navigation was found to be associated with a significant improvement in patients' overall satisfaction with their care delivery.

Care navigators are well-suited to assist older patients undergoing different types of major surgery and provide assistance with care transitions extending across the entire episode of surgical care (Fig. 1). Starting during the pre-admission period, navigators can help patients and caregivers prepare for surgery and the recovery period, which often is a new or foreign experience. Through the coordination of care with primary care and surgical teams as well as helping patients obtain educational resources, navigators can smooth the transition from outpatient to inpatient care. This may include helping patients develop a patient-centered care plan that outlines their personal goals and expectations of surgical care. During the postoperative period, navigators continue to be a source of education to the patient and their family and work with different care teams to ensure that the patient-centered care plan is reinforced. This includes helping with discharge planning and then ensuring that the care plan is understood and maintained by outpatient providers. Care navigators are another resource to ensure that older patients have continuity of care into the post-discharge period.

Bundled Care Models for Transitional Care

There have been multiple transitional care models developed over the past several decades seeking to maximize patient benefit through bundling different combinations of the care intervention described above (Tables 3 and 4). While the data supporting the effectiveness of single interventions isolated to either the pre- or post-discharge settings, bundled care models for transitional care have been rigorously tested in well-designed clinical trials and found to improve care coordination at the time of discharge and reduce hospital readmission. Moreover, a common element of these care transitions strategies is that they have all been designed to promote patient-centered care by using techniques to engaging patients and their caregivers across care settings.

Transitional Care Model

The Transitional Care Model (TCM) is a multidisciplinary approach to transitional care championed by Mary Naylor and colleagues at the University of Pennsylvania [3, 56]. This model is designed as a comprehensive approach to transitional care at the time of hospital discharge for medically complex older adults and includes different types of strategies as shown in Table 3. This includes a major emphasis on engaging patients and their caregivers in the self-care of their health issues and the early identification and response to potential problems to prevent decline in health status. In addition, the TCM assigns patients to nurse-trained *transitional care navigators*, who provide continuity of healthcare to the

Table 3 Evidence-based care transitions strategies using multiple components

Care transitions models	Components	Key findings from clinical trials
Transitional Care Model (TCM)	1. Use of advanced knowledge and skills by a transitional care nurse (TCN) to deliver and coordinate care 2. Comprehensive, holistic assessment of each older adult's priority needs, goals, preferences 3. Collaboration with older adults, family, caregivers, and team members in implementation of a streamlined, evidenced-based plan of care 4. Regular home visits by the TCN with available, ongoing telephone support through an average of 2 months 5. Continuity of healthcare between hospital, post-acute, and primary care clinicians facilitated by the TCN accompanying patients to visits to prevent or follow-up on an acute illness care management 6. Active engagement of patients and family caregivers with a focus on meeting their goals 7. Emphasis on patients' early identification and response to healthcare risks and symptoms to achieve *longer-term* positive outcomes and avoid adverse and untoward events that lead to acute care service use 8. Multidisciplinary approach that includes the patient, family caregivers, and health-care providers as members of a team 9. Strong collaboration and communication between older adults, family caregivers, and healthcare team members across episodes of acute care 10. Ongoing investment in optimizing transitional care via performance monitoring and improvement	Naylor et al. *JAMA* 1999: Older patients with multimorbidity randomized to receive TCM at discharge were less likely than control group patients to be readmitted once within 6 months (20.3% vs. 37.1%; $P < 0.001$) or have multiple readmissions (6.2% vs. 14.5%; $P = 0.01$). The TCM intervention group had fewer hospital days per patient (1.53 vs. 4.09 days; $P < 0.001$), and after 6 months, total Medicare reimbursements for health services were significantly lower about in the intervention group (\$0.6 million vs. \$1.2; $P < 0.001$) Naylor et al. *J Am Geriatr Soc*. 2004: Older patients with heart failure randomized to receive TCM at discharge have significantly longer time to readmission ($P < 0.05$) as well as fewer readmissions ($P < 0.05$) and lower mean total costs (\$7636 vs. \$12,481, $P < 0.01$) within 52 weeks after intervention
Care Transitions Intervention (CTI)	Four pillars of transitional care and transitions coach 1. Medication self-management 2. Dynamic patient-centered record 3. Scheduled follow-up with PCP and specialist providers 4. Patient education and knowledge of "red flags" and how to respond 5. Transitions coach* *Patients work with a nurse-trained transitions coach to help navigate the pre- and post-discharge process. This includes providing continuity across care settings and ensuring that their needs are met irrespective of the type of care settings. The transitions coach also conducts one home visit and at least three follow-up phone calls	Coleman et al. *Arch Intern Med.* 2006: Older patients with multimorbidity randomized to receive the CTI had a significant reduction in readmission rates at 30 days (8.3% vs. 11.9%; $P < 0.05$) and 90 days (16.7% vs. 22.5%; $P < 0.05$) when compared to usual care. Patients receiving the CTI also had significantly lower readmission rates for the same condition that precipitated the index hospitalization at 90 days (5.3% vs. 9.8%; <0.05) and at 180 days (8.6% vs. 13.9%; $P < 0.05$) than controls. Finally, the mean hospital costs were lower for intervention patients (\$2058) vs. controls (\$2546) at 180 days (log-transformed $P < 0.05$)

Table 3 (continued)

Care transitions models	Components	Key findings from clinical trials
Project Re-Engineered Discharge (RED)	1. Ascertain need for and obtain language assistance 2. Make appointments for follow-up medical appointments and post-discharge tests/labs 3. Plan for the follow-up of results from lab tests or studies that are pending at discharge 4. Organize post-discharge outpatient services and medical equipment 5. Identify the correct medicines and a plan for the patient to obtain and take them 6. Reconcile the discharge plan with national guidelines 7. Teach a written discharge plan the patient can understand 8. Educate the patient about his or her diagnosis 9. Assess the degree of the patient's understanding of the discharge plan 10. Review with the patient what to do if a problem arises 11. Expedite transmission of the discharge summary to clinicians accepting care of the patient 12. Provide telephone reinforcement of the discharge plan	Jack et al. *Ann Intern Med*. 2009: Older patients on medical service at single institution randomized to receive RED intervention had a lower 30-day rate of hospital utilization including ED visits and readmissions (31% vs. 45%; $P < 0.01$) than patients receiving usual care
Project Better Outcomes by Optimizing Safe Transitions (BOOST)	BOOST toolkit includes 1. 8P risk assessment 2. General Assessment of Preparedness (GAP) for discharge 3. Written discharge instructions 4. PASS 5. DPET (Discharge Patient Education Tool) 6. Teach-back 7. Follow-up telephone calls 8. Scheduled follow-up appointments 9. Inter-professional rounds 10. Post-acute care transitions 11. Medication reconciliation	Hansen et al. *J Hosp Med*. 2013: A pre-post study was conducted within 11 different hospital units consisting of both medical and surgical patients before and after implementation of the BOOST toolkit. Among hospital units that implemented BOOST, the 30-day readmission rate was significantly lower (12.7% vs. 14.7%; $P = 0.01$) when compared to site-matched control units

Table 4 Components of bundled transitional care strategies

	Intervention used in bundled care transitions model			
Intervention	TCM	RED	TCI	BOOST
Assessment of patient risk and readiness for discharge	X	X	X	X
Education and engagement of patients and caregivers	X	X	X	X
Enhanced discharge planning	X	X	X	X
Medication management and reconciliation	X	X	X	X
Scheduled early follow-up with providers		X	X	X
Post-discharge home visits	X		X	
Follow-up telephone communication		X	X	X
Maintaining continuity of provider care	X		X	X
Care transitions navigator	X		X	

patient between hospital and post-acute care settings. This role includes accompanying patients and caregivers to follow-up visits with primary care providers and specialists for a total of 2 months after discharge. Care navigators are also available to provide ongoing telephone support to patients during this post-discharge time period.

The TCM has been evaluated in several large multi-site RCTS among a mixture of different medical and surgical patient populations [3, 56, 57]. These studies all enrolled patients 65 years and older with different types of chronic health conditions who were admitted for both medical and surgical reasons. Among patients randomized to the TCM intervention, there was a significantly less likely to be readmitted within 6–12 months after hospital discharge and less likely to have multiple readmissions within this time period (Table 3). These studies also found that Medicare reimbursements and mean costs were significantly lower in the patient cohorts receiving TCM versus usual care.

Care Transitions Intervention

The Care Transitions Intervention (CTI) is a model championed by Eric Coleman at the University of Colorado and is one of the most widely recognized evidence-based bundled care transitions strategies [58]. The CTI model recognizes that care coordination is often fragmented during transitions of care, and patients and their caregivers are often the only common thread across different care settings. As such, this model focuses on providing patients and their families different support tools discussed in this chapter, which help self-management of their conditions after discharge from the acute care setting (Table 4).

The CTI is a 4-week intervention focused on the *four pillars* or conceptual domains of transitional care in addition to a care transitions navigator, which have all been discussed previously in this chapter. As shown in Table 3, these domains are (1) assistance with medication self-management, (2) utilization of a patient-centered record that is maintained by the patient to facilitate cross care setting information exchange, (3) patient empowerment to schedule timely follow-up visits with their primary and specialty care physicians, and (4) patient education of red flags to include signs that their health condition is worsening. In addition, each patient within the CTI is assigned a nurse-trained care navigator known as a *Transitions Coach*. This person visits the patient in the hospital as well as their home and conducts frequent follow-up phone calls to help the patient navigate the pre- and post-discharge process. This includes coaching patients and caregivers on ways to take a more active role in their post-discharge care.

The CTI model was shown to have a significant impact on reducing readmissions in a large single-center RCT among adults 65 years or older admitted with chronic medical conditions [58]. Among patients randomized to the CTI strategy, there was a significantly lower rate of readmission at 30 days and at 90 days when compared to control subjects with usual care (Table 3). Patients who received the intervention also had a significantly lower rate of readmission at 90 days and 180 days following discharge than control patients for the same condition that precipitated the index hospitalization controls. Finally, this study also found that mean hospital costs were lower for older patients receiving the CTI versus controls at 180 days following discharge.

Project RED

Project Re-Engineered Discharge (RED) is a bundled model focused on enhancing the transitional care at the time of discharge, which has been championed by Brian Jack and colleagues at Boston University [39]. This approach is unique in that it advocates for a *virtual patient advocate* discharge approach using computer-generated patient instructions, in addition to a nurse discharge advocate who focuses on enhanced discharge planning.

There are 12 separate components of the RED intervention that are focused at the time of hospital discharge at shown in Table 3. This includes bundled interventions such as routine risk assessment, scheduling follow-up appointments, medication reconciliation, development of a patient-centered discharge care plan (with education and teach back principals), identification of warning signs, and communication with the outpatient providers including follow-up telephone calls. The implementation of RED also includes components that can be customized for older adults, which includes an assessment of health literacy and tools to make it appropriate for sociodemographic diverse patient populations.

The bundled approach used in Project RED has been shown to be an effective strategy for improving care transitions and patient outcomes in a single-center RCT [39]. Older patients hospitalized for medical conditions randomized to receive the RED intervention were found to have a significantly lower 30-day rate of hospital utilization including ED visits and readmissions than patients receiving usual care (Table 3). In addition, patient receiving the RED intervention could identify their index discharge diagnosis, and PCP name more often than control patients. Finally, the total costs associated with post-discharge care among patients receiving RED were substantially lower than control patients, which underscored its overall effectiveness.

Project BOOST

Project Better Outcomes for Older Adults through Safe Transitions (BOOST) is a care transitions program that was developed by the Society of Hospital Medicine to target the discharge process from hospital to home. This program consists of multiple evidence-based interventions reviewed in the chapter that help optimize the safety of care transitions (Table 4). BOOST has bundled these different interventions shown in Table 3 into a *toolkit* for healthcare providers, with individual components addressing multiple aspects of hospital discharge and follow-up process. In particular, this model is focused on improving patient satisfaction with the discharge process, improving the flow of information between hospital and outpatient healthcare providers, and identifying patients at high risk for readmission and mitigates the risk for readmissions before discharge. This includes the use of teach-back methods to increase patient and caregiver learning. The BOOST program is also focused on providing healthcare systems the necessary support to implement these bundled care transitions interventions within their own clinical settings.

While the BOOST program was designed as a quality improvement initiative, its effectiveness in clinical practice has been supported by a recent clinical implementation study [59]. A pre-post assessment was conducted within medical and surgical units at 11 different community and academic hospitals before and after implementation of the BOOST toolkit. Among hospital units that implemented at least two of the BOOST care transitions tools, the 30-day and 1-year readmission rate was found to be significantly lower when compared to site-matched control units (Table 3). However, there was no difference in hospital length of stay between BOOST and control units. While this study was not randomized, nevertheless the data supports comprehensive care coordination as an effective real-world strategy for optimizing outcomes in older adults.

Conclusion

Older patients undergoing major surgical procedures are exposed to many different factors that place them at risk for fragmented care during transitions of care after surgery. Improving care coordination at the time of discharge for these patients is essential to achieving optimal outcomes, including the prevention of avoidable readmissions and improving patient satisfaction with care. The various care transitions interventions discussed in this chapter are different types of strategies to help accomplish this goal. Successful care transitions interventions are more likely to be “bundled” together, address multiple components of the discharge process, and span different care settings. While many interventions have not been specifically designed for older surgical patients, they are nevertheless well-suited for this vulnerable patient population. It is critical for surgical providers to understand and apply appropriate evidence-based transitional care strategies in order to achieve high quality of care and outcomes for their older patients who undergo major surgical procedures.

28 Postoperative Recovery and Rehabilitation

Simon Bergman and Laura M. Drudi

Contents

Abstract

Surgical recovery is a concept which has traditionally been poorly defined and poorly measured. The expectations of elderly patients with regards to their postoperative outcomes, including what they consider a success, may be very different when compared to the expectations of their younger counterparts or of their surgeons. In this chapter, the authors review the impact of surgery on a patient's functional status, on how they report their symptoms, and how they perceive their health and their quality of life. Important risk factors for a prolonged recovery, such as complications, malnutrition, and frailty, are described. Finally, strategies for optimizing recovery are discussed, starting with the preoperative period (comprehensive geriatric assessment, pre-habilitation), followed with hospitalization (enhanced recovery pathways, multidisciplinary intervention

teams and programs), and finally with rehabilitation in the postoperative period.

Clinical Vignette

The surgery was a success, but. . .

Mrs. K is an 87-year-old woman who undergoes a laparoscopic anterior resection for sigmoid colon carcinoma. The surgery is uneventful, and she does quite well postoperatively "for someone her age." Her urinary catheter is kept in for 2 days because of a low urine output, which eventually resolves following several fluid boluses. During this time, she has become confused and uncooperative, most likely due to some degree of delirium. Consequently, she does not start ambulating until the fourth postoperative day when she is helped out of bed by a physiotherapist. She is eventually discharged home 8 days after surgery. She returns to the emergency department 4 days after discharge, when her niece reports that the patient has fallen, has difficulty feeding herself, and is generally too weak to manage on her own. The patient is readmitted until a bed is available in a specialized nursing care facility, where she "recovers" for 3 weeks, before returning home. Six months later, during a visit to her family doctor, the patient reports that she is still too weak to go to the shopping mall, to attend her usual weekly card games, or to travel to visit her family and friends.

Introduction

The satirical phrase "The surgery was successful, but the patient died" could well be rephrased to "The surgery was successful, but the patient was transferred to a specialized nursing care facility, became dependent, and never fully returned to his or her previous way of living." There is no doubt that, regardless of age, when discussing the success of a surgical procedure, traditional outcomes such as complications, length of stay, and mortality are now complemented by what some might call patient-centered or patient-reported outcomes, such as quality of life, functional status, and return to professional or social activities, to name a few. It is increasingly clear that these types of outcomes, which have a medium- to long-term impact, are of particular importance to elderly patients, a patient population that generally has very different goals and expectations when it comes to surgical recovery.

In the vignette above, the surgeon may have been quite satisfied with an uneventful surgery, with seemingly good oncological outcomes, and a patient discharged home in a very acceptable time frame. The patient, on the other hand, may have seen things in quite a different light. This is well illustrated by a study by Terri Fried et al. in which over 226 elderly patients with a severe medical illness (cancer, chronic heart failure, or chronic obstructive pulmonary disease) were asked how likely they would be to undergo a life-saving procedure if this procedure resulted in cognitive or functional impairment. As the risk of dependency increased, fewer patients chose the procedure. In fact, if the outcome was survival associated with functional impairment, 74% of patients chose death. As many as 89% of patients refused the life-saving procedure when the outcome was survival with severe cognitive impairment [1]. In a study of elderly patients considering orthopedic surgery, a list of all potential concerns was established in semi-structured patient interviews. 155 out of 164 concerns (70%) had to do with anticipating postoperative quality of life (mainly with respect to perceived threats to physical and social well-being) and their capacity to cope with surgery and the postoperative recovery. Perhaps not surprisingly, only a little over 50% of these concerns were addressed with the surgeon [2]. Considering the fact that 80% of studies in gastrointestinal surgery only report morbidity and mortality [3], it seems clear that there remains a significant disconnect between traditional surgical goals and the treatment preferences and expectations of functional preservation that are valued by elderly patients [4].

Understanding what can be expected after surgery following hospitalization is important to the surgeon when he or she counsels the patients regarding perioperative outcomes. For patients and their caregivers, only with a true understanding of recovery is it possible to make a judgment on how the benefits of the procedure measure up to the risks. It allows them to align their expectations with realistic goals and to plan accordingly. A better understanding of recovery may be useful information for the surgeon or primary care physician in understanding when a patient has fallen off the normal recovery curve and at what point that deviation from normal may indicate the need for further investigations. In addition, from a professional development or physician-centered point of view, surgeons would likely benefit from recognizing and integrating the importance of longer-term functional outcomes in the context of personal practice audits, of measuring intervention effectiveness, or even in comparing new procedures or approaches. Finally, notwithstanding the impact on the patient and on the caregivers, loss of independence after surgery is independently associated with healthcare costs [5].

In general, surgeons understand recovery to be the period of time following surgery during which patients return to or exceed their preoperative state. But because it is such a complex, multimodal concept that can be measured and interpreted in many different ways, there does not exist a uniformly accepted definition. Perhaps the best definition of recovery is that suggested by the surgical pioneer, Dr. Francis Moore, who, in 1958, wrote that recovery was "the interlocking physical, chemical, metabolic, and psychological factor commencing with the injury, and terminating only when the individual has returned to normal physical well-being, social, and economic usefulness, and psychological habitus." [6]

The outcomes used to describe recovery can be categorized using a pre-defined framework, the Wilson-Cleary model [7], which captures the elements of Moore's definition. It establishes a relationship between clinical interventions, biological and physiological impairment, and the resulting effects on four health status domains: symptom status, functional status, general health perception, and quality of life [8, 9]. This model underlines the shift in modern therapeutic goals from improving physiological impairment and survival to improving patient function and well-being [10, 11].

Table 1 Definition of health status domains and validated measures of recovery

Functional status: ***Ability to perform physical or cognitive tasks***
Katz index [12]
Abbreviated mental test [13]
Mini- Mental Status Exam [14]
Short physical performance battery [15]
Handgrip strength and gait speed [16]
Symptoms status: ***Perception of an abnormal feeling in the patient's body***
Visual analogue pain scale [17, 18]
Verbal descriptive pain scale [18]
General health perceptions: ***Subjective assessment of how patients view their overall health***
Geriatric Depression Scale [19]
Quality of life: ***Defined by Emerson as the "satisfaction of an individual's values, goals, and needs through the actualization of their abilities or lifestyle"*** [20]
Short Form 36 [21]

Definitions of the health domains and examples of measures of recovery which have been validated for use in elderly patients are found in Table 1. The following discussion focuses on the general outcomes of surgical recovery, as opposed to procedure-specific outcomes, such as limb function after orthopedic surgery or exercise capacity after cardiac surgery, for example, which are outside the scope of this chapter.

Functional Status

The idea of a return to preoperative functional status is central to the majority of surgical recovery studies. It is of particular clinical importance, being one of the health domains, that takes longest to return to baseline [22]. Examples of outcomes assessing functional status include the ability to perform basic physical activities independently or to perform a cognitive task. In this patient population, the most commonly used clinical tools to assess physical function and dependency are the activities of daily living

Table 2 Activities of daily living and instrumental activities of daily living

Activities of daily living	Instrumental activities of daily living
Feeding	Using the telephone
Continence	Shopping
Transferring	Preparing food
Toileting	Housekeeping
Dressing	Doing laundry
Bathing	Using transportation
	Handling medication
	Handling finances

(ADL) and instrumental activities of daily living (IADL), which are described in Table 2. Although some authors have shown that elderly patients can recover completely at 3 months following surgery [23], this seems to be the exception rather than the rule. In the general elderly surgical population, there is a persistent impairment in ADL in less than 10% of patients at 6 months [22, 24]. However, in the more vulnerable geriatric patients, such as those above the age of 80, there is 58% dependency in an equivalent time frame [25]. Similarly, a population-based study by Finlayson et al. of 6822 nursing home patients undergoing colon surgery for cancer demonstrated functional decline in 42% of patients at 3 months, 28% at 6 months, and 24% at 12 months [26]. Furthermore, there is considerable dependency in IADL noted in 19% of geriatric patients at 6 months following major abdominal surgery [22]. In elderly critically ill patients, most of which had undergone surgery, at a median follow-up of 21 months, 13% had increased their dependency, and an additional 4% had become completely dependent [27]. When using objective physical performance measures, such as timed walk, functional reach, and hand grip strength, as many as 58% of patients had not return to baseline after 6 months [22]. Such studies raise the important question of whether, in patients who have not yet returned to baseline at 6 months, 12 months, or 24 months, recovery is still actively progressing or whether it has reached a plateau and permanent disability has led to a new baseline state.

From a cognitive standpoint, there is a significant incidence of postoperative delirium, which varies between 5% and 40%, depending on the type of surgery. By definition, this is usually transient in nature and limited to the hospitalization period [28, 29]. In general, based on older studies, it was thought that approximately 8–10% of patients undergoing non-cardiac surgery suffered from cognitive dysfunction, detectable as early as 3–6 months after surgery and possibly persisting for several years [30, 31]. Postoperative cognitive dysfunction has been poorly defined and its etiology is unclear. It may simply represent a preexisting chronic state uncovered by the acute stress of surgery. More recent studies have reported an improvement in MMSE scores at 3–6 months, when compared to preoperative values, possibly related to the overall improvement in patients' medical status following surgery [22]. The data on this important topic are too conflictual and vague to effectively synthesize in order to properly counsel patients with regards to long-term cognitive risk. In general terms, it seems fair to say that, for the vast majority of patients, cognitive functional status seems to be preserved following surgery.

Symptoms Status

Symptoms are usually reported by the patient, and protracted symptoms represent the expression of the patient's underlying ill-being. These symptoms may include the perception of heightened pain, fatigue, or nausea. Generally, unless complications occur, resolution of pain or nausea following surgery will occur within days to weeks, sometimes even during hospitalization. The symptom which seems to persist for weeks or months is a patient's fatigue, even following relatively minor procedures. In several studies of elderly patients undergoing colorectal surgery, fatigue persisted for at least 1 month [23, 32, 33].

General Health Perception

The subjective perception of fatigue, pain, and depressive symptoms have been found to be important factors to acknowledge in elderly patients undergoing surgery. In a study by Zalon et al., it was found that patients perceived to be 33% recovered at 1 month and 92% at 3 months [34]. They found that depression, along with symptoms of pain and fatigue, also improved, but persisted past 3 months. These symptoms contributed significantly to the patients' perception of their own health.

Quality of Life

Quality of life is highly correlated with the health domains describe above, with the addition of the concept of patient satisfaction. Although it seems intuitive that surgery would have an undeniable impact on quality of life, it seems to be minimal, usually with a mild attenuation in the first several weeks after surgery and a return to baseline within 3–6 months [24, 35]. This may be more related to the physical component of the quality of life construct, as the mental component does not seem to be affected negatively by surgery or by critical illness [27, 35]. In fact, some studies have shown that the mental component score of the Short Form 36 quality of life questionnaire may sometimes even surpass baseline scores [36, 37], which is a phenomenon that has also been described in a younger patient population. It is postulated that perhaps, beyond the physical manifestations of the recovery process, the satisfaction of having gone through the procedure, having survived, returned home and begun a life free of the morbidity that prompted the surgery, is enough to improve the patient's overall condition.

For any given outcome, a patient can be imagined to progress along the hypothesized recovery trajectory developed by Feldman et al. [10] and reproduced in Fig. 1. The patient starts at their baseline or preoperative state. When surgery occurs, the surgical trauma and resultant hospitalization begin the deterioration phase, in which the curve of the outcome in question slopes down. This usually takes place during hospitalization. Eventually, usually as the patient returns home and starts reintegrating their pre-procedural life, the rehabilitation phase begins. This can last anywhere between a few weeks and several months. As suggested by Moore, recovery ends when the patient has returned or exceeded their preoperative state [6]. In this figure, the dotted line represents the minimum level of functioning. Protracted recovery can occur when the baseline curve starts at a lower level than expected or is oriented downwards as might be the case in someone who becomes sedentary because of progressive leg pain while awaiting vascular surgery. Conversely, a patient on a pre-habilitation program may benefit from an upward baseline curve. Similarly, the deterioration curve may be steeper than expected in a patient who is not well mobilized after surgery. That same curve would be made less steep if a patient was recruited to an enhanced recovery pathway. Finally, the rehabilitation curve may be modified negatively by a patient with chronic pain after surgery

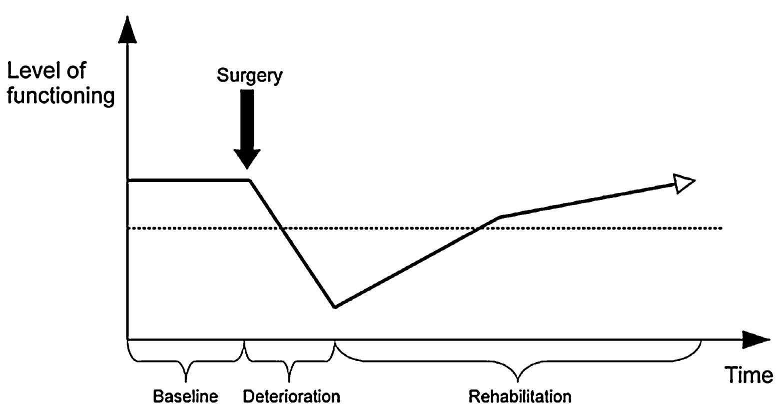

Fig. 1 The hypothesized trajectory of recovery [10]

or positively if undergoing rehabilitation after discharge. Some of the more important risk factors for protracted recovery as well as the strategies to optimize recovery are discussed below.

Risk Factors for Protracted Recovery

Postoperative complications have consistently been shown to be predictors of a slower recovery [26, 38]. This was described by Tahiri et al. who reported that the greater number and severity of complications increased the time to recovery in elderly patients undergoing abdominal surgery. Using the short physical performance battery, an objective measure of functional capacity, the deterioration curve was deeper for those with complications as compared to those without. 58% and 74% of patients who did not suffer postoperative complications had recovered at 1 and 6 months, respectively, compared to 34% and 58% of patients who had experienced complications [39]. In patients above the age of 80 undergoing colorectal procedures, one study found that elective surgeries were associated with a return to premorbid functional status in 83% of patients, whereas this number was as low in 53% of patients undergoing emergency colorectal surgery. This difference was mainly attributable to the higher number of complications in the emergency group. Finally, in a multivariate analysis, the development of postoperative complications was associated with an odd ratio of 24.5 of not returning to premorbid function, far surpassing in importance every other factor included in the analysis [40].

Malnutrition has been shown to be related to poorer traditional outcomes, but there is also good data to suggest that it has a significant impact on recovery of longer-term functional outcomes. This is of particular importance in elderly patients who are at greater risk of malnutrition [41]. Six months after major abdominal surgery, increased dependency in daily activities was seen in 80% of malnourished patients as opposed to 30% of those who were well nourished. [25] In a study of elderly hip fracture patients, Goisser et al. measured the daily oral intake of patients during postoperative hospitalization. Regardless of their preoperative functional status, patients who ate smaller amounts had significantly lower ADL scores up to 6 months after surgery, and a greater percentage of them had long-term mobility loss [42]. Bastow et al. demonstrated the potential impact of preoperative tube feeding in a randomized controlled of 744 women with femoral neck fractures, stratified in 3 groups according to the level of nutrition: well nourished, thin, and very thin. Independent mobility was achieved at postoperative days 10, 12, and 23 days, respectively, and postoperative tube feeding in the thin and very thin patients reduced the time to full recovery to 10 and 16 days, respectively [43]. Despite these data and although nutritional screening is recommended for all hospitalized, medical or surgical, and elderly patients, there is still debate as to whether or not early optimization with parenteral or enteral nutrition improves postoperative recovery [44].

Frailty is a multidimensional syndrome that reflects a state of decreased physiologic reserves and vulnerability to stressors [45]. Currently available risk scores capture only a snapshot of a patient's health status at the time of the preoperative evaluation, which is heavily focused on comorbidities [46, 47]. They fail to capture the multitude of subclinical impairments that progressively accumulate with age and that ultimately determine the patient's physiologic reserve, which will be called upon at the time of major stress, such as the perioperative period [48]. These subclinical impairments may be responsible for the heterogeneity that is seen in older patients and may be better measured by the clinical frailty phenotype: slowness, weakness, weight loss, low physical activity, exhaustion, cognitive impairment, and mood disturbance [49, 50]. However, frailty may also be characterized by an accumulation of deficits that can encompass diverse signs, symptoms, comorbidities, as well as disabilities [51–53]. In a prospective study of almost 600 elderly patients undergoing elective surgery, Makary et al. demonstrated that frail patients were significantly more likely to have a prolonged hospital stay, more complications, and more often be discharged to skilled or assisted living facilities [54], findings corroborated by others [55]. Although these studies do not make a direct link between frailty and recovery, the higher incidence of complications and subsequent functional decline observed in this group serve as satisfying evidence that recovery is indeed impaired in frail individuals.

When the impact of poor baseline functional status is studied on its own, the data are more convincing and provide validation to the concept of pre-habilitation, which is discussed in the next section. Low preoperative physical function independently predicts slower recovery of ADL and IADL scores [22]. Finlayson et al. reported that in elderly patients undergoing surgery for colon cancer, preoperative functional decline was one of the most important predictors of postoperative functional decline [26]. A population-based study by Oresanya et al. paints a grim picture of the impact of baseline function. In a particularly functionally dependent population of over 10,000 nursing home patients with extensive vascular disease, 64% of patients experienced functional decline 1 year following lower extremity revascularization. At that time, among those that were ambulatory prior to surgery, 63% had become non-ambulatory or suffered a fatal event. Among those that were non-ambulatory at baseline, 89% had remained non-ambulatory or died. [56]

Strategies for Optimizing Recovery

Preoperative Care

Comprehensive Geriatric Assessment

The comprehensive geriatric assessment (CGA) is "a multidisciplinary diagnostic and treatment process that identifies medical, psychosocial, and functional capabilities of older adults to develop a coordinated plan to maximize overall health with aging." [57] In surgery, such a tool is useful for risk stratification, for preoperative optimization of modifiable risk factors, for informed decision-making, and for planning postoperative strategies and treatments to minimize age-specific complications. The domains that are evaluated by the CGA are summarized in Table 3 [58].

Table 3 Comprehensive geriatric assessment domains and tests [58]

Domain	Tests
Functional status	ADL and IADL Objective performance tests
Socioeconomic status	Income and housing Social support Transport
Comorbidities	Cumulative Index Rating Scale Revised Cardiac Risk Index
Cognitive Function	Mild cognitive impairment or dementia Depression and anxiety Risk of delirium
Nutritional Status	Mini nutritional assessment Nutritional global assessment Recent weight loss
Polypharmacy	Medication reconciliation
Geriatric syndromes	Frailty Incontinence Pressure ulcers Falls

There are few studies comparing CGA to regular care and even fewer looking at the long- to medium-term impact of this type of intervention. A recent systematic review by Partridge et al. showed that the use of the CGA in older persons scheduled to undergo elective surgery was associated with reductions in the number of cancelled surgeries and in length of hospital stay, with one study demonstrating fewer postoperative complications [59]. Despite there being no direct evidence of the CGA improving recovery, intuitively, identifying the factors that affect recovery, such as poor functional status, for example, and potentially modifying them to minimize their impact and avoiding complications, is a reasonable strategy to entertain in selected individuals.

Pre-habilitation

In the last decade, preoperative exercise therapy, or "pre-habilitation," has been investigated across several surgical fields, including general surgery, colorectal surgery, hepatobiliary surgery, orthopedic surgery, thoracic surgery, and gynecological surgery [60–71]. The goal is to maintain or possibly enhance the physical functioning and capacity of an individual to withstand the physiological stressors associated with a surgical intervention, thereby improving the baseline segment of the recovery trajectory [72]. A randomized controlled trial comparing pre-habilitation to rehabilitation in patients undergoing colorectal surgery showed that a greater percentage of patients in the pre-habilitation group had recovered to their baseline exercise capacity levels at 8 weeks (84% vs. 62%) [64]. Similarly, pre-habilitation programs for elderly patients undergoing colorectal surgery were reported to be associated with better postoperative performances on the 6-min walk test when compared to controls [66]. Although there remains many questions with respect to patient selection, exercise program design, and overall compliance and effectiveness, pre-habilitation seems to be a very promising strategy for optimization of recovery.

Hospitalization

Enhanced Recovery Pathways

Enhanced recovery pathways are multimodal evidence-based protocols, which span the entirety of the surgical experience, from preoperative patient preparation and nutrition, to intraoperative fluid and pain management, to early postoperative feeding and mobilization. Significant benefits have been demonstrated when enhanced recovery pathways are successfully implemented, such as shorter length of stay and fewer complications [73–76]. Many believe that these strategies are becoming the gold standard of care in many areas of abdominal surgery [77], although there has been uptake in other surgical disciplines as well. Contrary to what the term enhanced recovery would suggest, the great majority of the literature on the topic is quite limited when it comes to demonstrating or even studying the impact of these pathways on mid- to long-term outcomes or patient-centered outcomes, such as return to preoperative functional status [11, 78]. Nevertheless, a small number of studies in patients of all ages would suggest that enhanced recovery pathways are associated with improved quality of life and a quicker return to baseline function [79–81].

It seems intuitive that elderly patients, with their greater vulnerability to surgical stressors and decreased physiologic reserve, would have more to gain from the improved quality of surgical care that comes with these pathways [82]. In the context of enhanced recovery pathways, an early landmark study published in 1995 had demonstrated that enhanced recovery pathways provided effective postoperative pain relief, thus enabling earlier mobilization, reducing length of stay, and avoiding functional impairment in elderly surgical patients [83]. Following this, though, very little has been reported with regard to the impact on enhanced recovery pathways on functional recovery in this population. The few studies that exist are limited to short-term, traditional outcomes, such as length of stay and morbidity [84].

Multidisciplinary Intervention Team

The goal of multidisciplinary intervention teams is to ensure that care is delivered according to best known practices across a variety of complementary fields, in particular geriatrics, nursing, social work, physiotherapy, and occupational therapy. The key to the success of such teams is having (i) a shared, as opposed to competing vision; (ii) coordinated planning of interventions; (iii) effective communication; (iv) the ability of all team members to understand the purpose of the other members; and (v) proper completion and follow-through of tasks [85]. Unfortunately, most models of geriatric care that broadly implemented comprehensive groups of best practice processes did so in medical, rather than surgical patient populations. In fact, in a recent systematic review of geriatric co-management systems for in-hospital patients, only one high-level surgical study was included. There were conflicting results with respect to functional status improvement, with some studies showing mainly short-term improvement over standard care, while others showed no difference at all. [86] Several successful surgical programs are discussed below.

Hospital Elder Life Program (HELP)

The Hospital Elder Life Program consists of systematically putting into practice key processes to mitigate the effects of hospitalization in elderly patients, specifically functional decline, nutritional depletion, and delirium. Initially developed for a medical population, Chen et al. studied its impact on elderly patients undergoing a variety of abdominal surgical procedures. A single nurse carried out mobilization and rehabilitation, oral care and dietary education, and cognitive stimulation following surgery. The authors found that in the control group, 68% of patients who were pre-frail had transitioned to frailty, whereas in the HELP group, only 18% became frail, with another 18% actually becoming non-frail. Overall, at discharge, 19% of HELP group patients were frail as compared to 65% in the control group. This difference did not persist at 3 months, at which point 17–23% of patients were considered frail. [87] This intervention also reduces the rate of delirium from 15% to 7% and reduces length of hospital stay by 2 days [88]. The CareWell in Hospital program, based on HELP, reported more modest results in their mostly surgical patient population, in part because of the very variable adherence to the large number of processes that had been implemented during the study period [89].

Proactive Care of Older People Undergoing Surgery (POPS)

The POPS team consists of a geriatrician, a geriatric nurse, a physiotherapist, an occupational therapist, and a social worker. Eligible patients benefit from supervised care throughout the preoperative, hospitalization, and postoperative phases. This includes a CGA, planning of discharge needs; education on recovery, including counselling on physical activity, nutrition, and pain management; in-hospital assistance to the surgical team with mobilization; and prevention of population-specific complications, followed by postoperative ambulatory visits to address any outstanding or residual medical problems. POPS was studied in various surgical disciplines. In orthopedic surgery, the program demonstrated better pain control, less short-term dependency, and a shorter length of stay [90]. In elderly patients undergoing elective abdominal aortic aneurysm repair or limb revascularization, even when only the preoperative arm of the POPS program was implemented, a randomized clinical trial demonstrated a shorter length of stay, less delirium, and less dependency at discharge [91]. Finally, in urology, although reductions in length of stay and complications were observed, the impact on functional status was not examined. [92]

Acute Care for Elders (ACE)

ACE units have been studied almost exclusively in medical patients. Results have shown successful prevention of functional decline, reduced length of hospital stay, and reduced rates of delirium. A small pilot study in a surgical patient population admitted to a specific unit, where surgical and geriatric nurses carried out all interventions, showed only a modest improvement in ADLs when comparing the Katz score before surgery and at the time of discharge, as well as no documented falls and very minimal use of restraints [93].

Geriatric Surgery Service (GSS)

Tan et al. reported the benefits of a "dedicated collaborative transdisciplinary geriatric surgery service," which was involved in all aspects of the pre- and postoperative care of elderly surgical patients. This group consisted of a surgeon, a nurse clinician, an anesthetist, a geriatrician, a cardiologist, a physiotherapist, a dietician, a social worker, a pharmacist, and a "befriender" (an individual who would provide cognitive stimulation or "food for the soul" by conversing with the patient). 85% of elderly colorectal surgery patients in this program recovered to their baseline ADL level as early as 6 weeks [94, 95]. When pre-habilitation was added to the GSS, 100%

of patients (of which 26% were frail) had recovered to their preoperative functional levels by 6 weeks [96].

Post Hospital Care

Rehabilitation

Elderly patients are predisposed to a state of decreased physiologic reserves and stressor vulnerability [45]. The decreased physiologic reserves seen in geriatric patients are believed to be a result of predisposing molecular and disease-related triggers, compounded by the socioeconomic environment, immobilization, malnutrition, and numerous comorbidities, which in turn lead to multiple physiologic impairments. The impaired physiologic systems are centered around the dysregulation of the immune, hormonal, and endocrine systems, resulting in an upregulation of inflammatory cytokines and insulin resistance [97, 98]. This dysregulation leads to a catabolic milieu, which consequently results in a progressive decline in muscle mass and strength known as sarcopenia [99]. As skeletal muscle is the principal reservoir for amino acids [100], a decline in muscle mass impedes the body's capability to mobilize amino acids that are needed for protein synthesis [101], which are needed during periods of stress to promote immune function, wound healing, and acute phase reactants. The end result is a perpetual catabolic cycle that results in deconditioning, prolonged recovery, perioperative morbidity, and mortality [102, 103]. On the other hand, exercise has been shown to improve skeletal muscle blood flow, pulmonary gas exchange, and cardiopulmonary fitness and tolerance and have an upregulating effect on hundreds of genes that play a role in tissue maintenance and homeostasis [104, 105]. Counteracting the state of decreased physiologic reserve forms the rationale for surgical rehabilitation.

The goals of rehabilitation in the geriatric population are to (a) maintain and improve fitness, (b) assist and accelerate recovery, (c) improve range of motion, and (d) reduce pain after surgery. The rehabilitation process can be divided into several stages [106].

1. *Initial assessment*: An assessment focused mainly on physical function can be performed by a physiotherapist, or alternatively, information may be derived from a more global assessment performed by a geriatrician. This may be done prior to surgery by identifying the existing disabilities or after surgery by analyzing the physical impact that surgery has had on the patient (i.e., how far below baseline they now are).
2. *Planning*: In collaboration with the patient, goals of care are set, taking into account several facets, which may include, but are not limited to, physical disability. These facets include a positive goal (e.g., the ability to attend a future family event), a social goal (the ability to continue living independently at home), a functional goal (completing IADL without assistance), and a health-related goal (survival).
3. *Treatment*: Exercise-based interventions or therapies are implemented to reduce disability following surgery. Treatment is usually different for the deterioration (or hospitalization) and the rehabilitation (or at home) phases of recovery. In the former, the primary goal is to bring the patient from a state of physical dependency to one of physical autonomy, wherein the patient is able to leave the hospital safely. Traditionally, this was achieved somewhat passively through the use of incentive spirometry devices and breathing exercises to prevent cardiopulmonary complications. This has now progressed to a more proactive focus on early mobilization, facilitated by enhanced recovery pathways (early feeding, pain control, avoidance of tubes and drains, etc.). In this phase, rehabilitation protocols may be supervised by physiotherapists, nurses, or physicians. The goal of treatment in the rehabilitation phase (following discharge) becomes return to baseline physical function, or, if this is not deemed possible, return to a function which would allow the patient the greatest autonomy and quality of life possible. This is usually achieved through gradual

endurance and muscle building programs. These are less often supervised and may involve outpatient physiotherapy or personal training services, either in the home or at the gym. There exist several postoperative rehabilitation protocols that are tailored to the patient and specific surgery being performed, but there is little consensus on which are most effective at helping patients return to their preoperative state. Table 4 summarizes the Oxford University Hospitals rehabilitation program [107]. This structured program can be carried out throughout hospitalization and then at home, following discharge, does not require any special equipment or expertise, and is low-cost.

4. *Re-evaluation*: The effectiveness of the interventions is evaluated in the context of the goals which were established at the onset of the process. If needed, the program is modified to reorient the therapy toward the desired outcomes.
5. *Management of disability*: If permanent disability ensues, additional care and

Table 4 Oxford University Hospitals postoperative rehabilitation program [107]

A. Immediately postop
Breathing exercises (3–6 deep breaths and then rest. Repeat these exercises 3–4 times an hour) 1. While sitting upright, relax your shoulders and upper chest 2. Take a slow, deep breath in to fill your lungs as fully as you can 3. Hold this breath for 3 s 4. Breathe out slowly through your mouth
Sitting out of bed The nursing and physiotherapy staff will help you sit out of bed either on the first morning after your operation or on the same day. They will continue to help you until you are able to do this yourself. You should sit out of bed twice a day, at first for 1 h and then gradually increasing the time each day
Walking The nursing or physiotherapy staff will help you until you can walk safely on your own. Once you can do so, you will be responsible for walking regularly and increasing the distance that you can go. You should aim to walk once every hour if able. You may also be taken to try climbing stairs with nursing or physiotherapy staff or alone when comfortable
Exercises *1. Ankles*: Bend and stretch your ankles up and down firmly and quickly. Repeat 10 times *2. Knees*: Tighten your thigh by pushing the back of your knee down against the bed. Hold for 5 s. Repeat 5 times with each leg. Then, pull your toes/foot up, tighten your thigh muscle, and lift and straighten one leg. Hold for 5 s and slowly relax. Repeat 5 times with each leg *3. Buttocks*: Tighten your buttocks regularly to relieve pressure from your bottom *4. Abdomen*: Lie flat with back on bed, lying your head on a pillow and your knees bent and flat on bed. Gently place your hands on lower tummy or hips. Breathe in through your nose, and as you breathe out, gently pull your tummy down toward your spine. Feel muscles tighten. Hold for a count of 3 and then relax. Breathe in and out normally. Do 5 times, 3 times a day *5. Pelvis*: Lie flat with back on bed, lying your head on a pillow and your knees bent and flat on bed. Place your hands in the hollow of your back. Tighten your tummy, flatten your lower back onto your hands, and tilt your bottom up and back toward your chest. Breath normally and hold for 3 s and release gently. Do 5 times, 3 times a day *6. Knee Rolling*: Lie flat with back on bed, lying your head on a pillow and your knees bent and flat on bed. Tighten your tummy and gently lower both knees to one side as far as possible. Bring them back to the middle and relax. Repeat to the other side. Do 5 times, 3 times a day.
B. At home
Weeks 1–3: After being at home for a few days, you can build strength and stamina by having a short walk each day. Start with 5–10 min and gradually try to add to your distance each day. It is safe for you to go up and down stairs from the day you go home. By the second week, you can start to carry out light chores, such as cooking, wiping, and dusting. Increase your walking time and distance each week
Weeks 4–6: You can gradually do more household jobs such as ironing and cooking. Break tasks
down into smaller parts and ask other people to help. Aim to be walking between 30 and 45 min by 6 weeks. You must still avoid heaving lifting and standing for long periods of time
Weeks 6–12: You can begin more strenuous tasking such as vacuuming so that by week 12 you are back to normal

interventions may be needed to alleviate and reduce the consequences of the disability. Occupational therapists have expertise in person-environment interactions within the home and work environment and may provide recommendations for the integration of assistive technologies and environmental modifications. Assistive technology may include bathroom or self-care aids, prosthetics, or mobility aids, such as canes, crutches, walkers, or wheelchairs. Environmental modifications use methods to minimize the effects of one's environment in exacerbating disability and promote ease of access. Finally, social workers may be useful in introducing coping strategies for patients, family, and caregivers to address the psychosocial issues that may arise secondary to the disability.

In surgery, the benefits of postoperative rehabilitation are evident in specific fields, mainly cardiac and orthopedic surgery, in which it has been shown to improve physical function, to reduce pulmonary complications, to decrease length of stay, and to lower hospitalization costs [108–111]. Furthermore, postoperative physiotherapy has reduced postoperative pulmonary complications and reduced length of stay in hospital in other heterogeneous cohorts of hospitalized patients [112, 113]. Following hospitalization, postoperative rehabilitation may be delivered in a variety of facilities, including the home, outpatient physiotherapy services, and inpatient rehabilitation services. The optimal setting will depend on the individual needs of the patient and the resources available in their milieu, but it would seem that inpatient rehabilitation services may be superior in improving functional independence when compared to skilled nursing facilities delivering physiotherapy services [114, 115].

Evidence-based practices for postoperative rehabilitation in abdominal surgery are sparse. Houborg et al. showed that postoperative physical training had no effect on physical function in patients undergoing colorectal surgery; however, the study may not have been adequately powered for this endpoint. [23] The benefits of enhanced recovery programs and the focus on encouraging early mobilization and exercise-based physiotherapy are increasingly recognized and integrated into practice; however, it is unclear what the contribution of the exercise therapy is to the overall benefit seen in programs with several other simultaneous interventions. Given the paucity of evidence, it is difficult to make any strong recommendations, although most would agree that early mobilization following surgery, whether assisted or not, is important and should be carried out in most patients. In-hospital rehabilitation programs may have some value in achieving this goal, although this is a resource which may not be available in all centers and certainly not always at the intensity needed to make an impact. Although data is lacking on whether post-hospitalization rehabilitation centers improve recovery, they may nevertheless be useful in providing a bridge between the ward and the home, during which function can be optimized, and the support can be provided to the patients who would otherwise not have access to it at home.

Conclusion

Surgical recovery in the elderly is poorly defined and poorly studied. It seems to revolve mainly around the return to preoperative functional status, although other domains are sparingly reported, including cognition, fatigue, and quality of life. Depending on the measure that is used, recovery may take up to 6 months, and sometimes longer, in a significant number of elderly individuals. Major risk factors for prolonged recovery include frailty, or at least a poor baseline functional status, malnutrition, and the occurrence of surgical complications. To optimize recovery, several strategies have shown success. The preoperative identification of higher-risk individuals using the CGA may help better address modifiable patient characteristics, leading to fewer complications and a quicker return to functional independence. Pre-habilitation protocols are in their infancy, but show promise in improving preoperative functional status in order to better withstand the stressors of surgery. Several postoperative strategies, such as enhanced recovery pathways and multidisciplinary programs, share a common goal: to minimize the functional deterioration that is characteristic of hospitalization following surgery, by improving the adherence to best-practice processes, thereby promoting early mobilization and independence. Finally, following discharge, rehabilitation programs, which come in all shapes and sizes, should intuitively promote a faster return to the preoperative state, although the data are lacking. Overall, the fields of recovery and rehabilitation in elderly surgical patients suffer from a lack of knowledge. As the population continues to age, it is crucial to recognize the relevance of the surgical experience which occurs after discharge and to actively include elderly patients in surgical trials addressing the issues discussed in this chapter.

Available Government and Community Resources for the Care of Older Adults

29

Hadley K. Wesson

Contents

Abstract

In 2005, there were 37 million people who were aged 65 years or older in America, making up 12% of the population. By 2030, this is estimated to nearly double to 70 million. The fact that the elderly will make up more than 20% of the American population has inevitable implications to our health care system. We, as surgeons, receive little, if any, formal education regarding resources available to assist in our care of the elderly. This chapter outlines the availability and use of government resources, including Medicare and Medicaid, as well as community resources and providers as a context for their successful utilization.

Introduction

In 2005, there were 37 million aged 65 years or older in America, making up 12% of the population. By 2030, this is estimated to nearly double to 70 million or 20% of the population [1]. This increase in the elderly population has inevitable implications to our healthcare system that we begin to feel now. Advanced age is associated with an increase in chronic health conditions, healthcare needs, and medical expenses. As surgeons, we receive little, if any, formal education regarding resources available to assist in our care of our older patients.

Treating the older adult patient, whether in an outpatient or emergent setting, includes important components if longitudinal success in care is to be achieved. It is not only necessary to know how to medically and surgically tailor treatment towards the older adult, but also to understand the context in which these patients live. This chapter outlines the availability and use of government resources, including Medicare and Medicaid, as well as

R. A. Rosenthal et al. (eds.), *Principles and Practice of Geriatric Surgery*,
https://doi.org/10.1007/978-3-319-47771-8_31

community resources, while aiming to provide a context for their successful utilization. It is also important that we recognize the limitations of these programs and how we as surgeons can and must advocate for our patients.

Government Resources: Medicare and Medicaid

Medicare is the federal health insurance program for people 65 years old and older. Medicare was created in 1965 and expanded in 1972 to include people younger than 65 years old with permanent disabilities. Medicare currently serves 59 million Americans with a budget of $672.1 billion or 15% of the total federal spending [1, 2].

People 65 years and older can enroll in Medicare if they or their spouse are eligible for Social Security payments and paid payroll taxes for 10 years or more. Medicare covers basic health services including hospital stays, physician services, and prescription drugs. It is organized into four parts: Part A, Part B, Part C, and Part D.

Part A covers inpatient hospital stays, skilled nursing facility stays, some home health visits, and hospice. It is subject to a deductible which in 2018 was $1,340. In addition, beneficiaries must pay a coinsurance for extended inpatient hospital stays [1].

Part B covers physician visits, outpatient services, preventative services, and some home health visits. In 2018, there was a $183 deductible and a 20% coinsurance for most benefits [1]. Exceptions are preventative services and wellness visits to which there is neither a deductible nor a coinsurance payment.

Part C, also known as Medicare Advantage, allows beneficiaries to enroll in private health plans that contract Medicare to receive all Part A and Part B benefits and typically Part D benefits. In 2017, approximately 33% of Medicare beneficiaries were covered through Medicare Advantage [3]. The number of plans available to beneficiaries however varies by county: in 2018, beneficiaries living in 206 counties throughout the United States were able to choose from more than 30 different plans offered by six firms. In contrast, in 44 counties, beneficiaries only had one option to choose from [3].

Part D covers outpatient prescription medications using private health insurance plans to offset drug costs after a beneficiary's deducible is met. It also offers catastrophic coverage for very high drug costs. Part D has a coverage gap, often referred to as the "doughnut hole." What this means for the beneficiary is that in 2018, they would enter the doughnut hole after they paid $3,750 in drug costs for that year. Once in the doughnut hole, beneficiaries have to pay 35% for brand-name medications and 44% for generics. They continue to pay this until their out-of-pocket costs reach $5,000. After they reach this limit, they will be out of the doughnut hole and pay no more than 5% for their drug costs for the reminder of the year [1]. Under the Affordable Care Act, the coverage gap will close by 2019, when enrollees will pay 25% of the cost of their prescription drugs.

Medicare has relatively high deductibles and co-payments under Parts A and B. To help Medicare recipients with these costs, there are different types of supplemental coverage, including employer-sponsored retiree health plans, Medigap policies, and Medicaid. Approximately 19% of Medicare beneficiaries however remain without any supplemental coverage [1].

Supplemental health insurance coverage through employer-sponsored retiree health plans was once very common. Yet over the last four decades, employer-sponsored plans have decreased from 66% of Medicare beneficiaries in 1988 to 25% in 2017 as many employers have stopped offering this as an option to employees [1]. While this trend does not appear to have affected health outcomes, it is estimated that retirees' out-of-pocket healthcare costs increased [4]. In the highest 40% of out-of-pocket Medicare spenders, beneficiaries without an employer-sponsored plan spend on average 22% more than those enrolled in an plan [5].

Medigap, or Medicare Supplement Insurance, is supplemental coverage sold by private insurance companies to help cover the cost of Medicare

Part A and B deductibles, co-payments, and coinsurance. Approximately 23% of Medicare recipients have Medigap [1].

Medicaid is the federal program that provides health and long-term care to low-income people. It is a supplement to Medicare for approximately 11 million Americans or 22% of Medicare recipients. To be eligible for Medicaid, beneficiaries must have low incomes, limited assets, and a limited ability to work due to advanced age or a disability. Low income is defined as $733 per month per individual or $1,100 per month per couple which is approximately 75% of the federal poverty level [6]. Assets are limited to $2,000 per individual or $3,000 per couple [6]. To assist low-income Medicare recipients with the out-of-pocket costs of Medicare, state Medicaid programs must offer three Medicare savings programs: Qualified Medicare Beneficiaries, Specified Low-Income Medicare Beneficiaries, and Qualified Individuals.

Eligible Qualified Medicare Beneficiaries are Medicare recipients with incomes up to 100% of the federal poverty level. Once a recipient is enrolled in the program, Medicaid pays their premiums and coinsurance directly to Medicare. Specified Low-Income Medicare Beneficiaries have higher incomes from 100% to 120% of the federal poverty level and receive financial aid for Medicare premiums only [6]. Qualified individuals are those individuals who have incomes up to 135% of the federal poverty level and pay their Medicare Part B premiums through an expansion of the Specified Low-Income Medicare Beneficiaries program passed by Congress in 1997. However, there is a limited amount of funds allocated to each state by Congress each year for this plan. Once the state has spent that amount, beneficiaries who would have qualified for the Qualified Individual program do not receive financial assistance [6].

It is estimated that approximately one in three people over the age of 65 years will require nursing home or long-term care at some point in their life [7]. The average annual cost of nursing home care in 2016 was $82,000, or approximately three times the average annual income of older Americans [7]. Long-term care is not covered under Medicare but rather Medicaid. As such, 44 states allow Medicare recipients who need long-term nursing home care to qualify for Medicaid if they have incomes less than 300% of the Supplement Security Income level, or roughly 219% of the federal poverty level or $2,199 per month per individual [6]. In 2015, Medicaid paid $55 billion for long-term care covering 60% of the 1.4 million Americans living in nursing homes, making Medicaid the country's primary payer for long-term care [6, 7].

Community Resources

Key resources for older adults living in their communities are made available through the Older Americans Act. Passed by President Johnson in 1965 as part of his "Great Society" initiative, the Older Americans Act supports programs to help the older adults live independently in their communities for as long as possible [8]. It falls under the mandate of the Administration for Community Living within the Department of Health and Human Services.

A range of programs are available to eligible seniors through the Older Americans Act such as home health aids, nutritional programs, transportation, counseling, and legal aid. For example, through the Administration for Community Living, states can provide one, two or three meals a day five to seven times per week, of which each meal is required to provide at least one-third of the recommended dietary allowances [9]. A note of caution, however: the availability of these resources is state dependent and highly variable. A list of resources available by state is available through the Eldercare Directory (https://www.eldercaredirectory.org/state-resources.htm) [9]. Also note that receiving these resources does not correlate with improvements in health. In fact, the opposite has been shown: a recent retrospective review of over 2,000 adults found that those receiving Older Americans Act meals had poorer health and functional disabilities compared to adults who did not receive such benefits [10].

Two-thirds of Medicare beneficiaries have two or more chronic conditions. Fourteen percent have more than five chronic conditions which accounts for 55% of total Medicare spending and 63% of post-acute care, such as nursing homes [11]. Studies show income is related to chronic conditions and that older Americans who live in disadvantaged neighborhoods are more likely to have functional limitations [12, 13].

Medicare beneficiaries on average have two primary care physicians and five specialists [14]. In addition to offering community health programs, efforts are underway by the Institute of Medicine to develop care coordination programs for Medicare recipients. Ideally these programs would assess gaps in healthcare and develop individualized plans to collaborate with medical and community health providers [15]. Such programs have the potential to greatly contribute to current community resources.

There is some debate within the literature as to how surgeons can contribute to this concept of care coordination. One proposal is to identify high-cost patients in the preoperative setting, the so-called hot spotting, and develop preoperative cost reduction strategies such as prehabilition programs and readmission prevention initiatives [16]. This concept is currently in a trial phase but could prove to be a cost-effective approach in the future.

In its current state, the government spends more on Medicare than it accrues, and estimates predict that Medicare's funds will be depleted by 2030 [17]. Proposals to cut Medicare and Medicaid spending are ever present and hotly debated, especially within the political realm. It is however a "Catch 22": reductions in federal financing would limit the supply of Medicare and Medicaid services, while the demand will increase as America's baby boomers continue to age in an era aptly described as a "Silver Tsunami" [18].

Conclusion

Surgeons must be aware of these constraints and the out-of-pocket costs their older adult patients face despite coverage from federal insurance plans and available community resources. This adds a complexity to the practice of medicine in America. Not only must we as healthcare providers strive to provide excellence in care, but we much do so in a cost-effective manner, recognizing the investigations we order, medications we prescribe, and surgeries we perform are all at a cost borne ultimately by our patients.

Outcomes of Surgery in Older Adults

30

David A. Etzioni

Contents

Abstract

Older individuals represent a growing proportion of patients undergoing surgery. The outcomes of elderly patients are worse across a broad range of complication types, highlighting the importance of efforts to improve and maintain quality of care. Special consideration needs to be given to risk stratification and preoperative optimization in order to provide appropriate patient-centric care. Postoperative cognitive decline, loss of independence, and advanced directives are all areas where providers need to focus on the specific needs of this vulnerable population. This chapter reviews existing data supporting an approach that focuses on the elderly patient and surveys evidence-based methods to optimize care.

Introduction

Between 2012 and 2050, the US population aged 65 years and older is projected to nearly double, from about 42 million to more than 80 million individuals [1]. This unprecedented change in the demographics of the US population will significantly alter the landscape of surgical care and require increasing attention to the outcomes of surgery in older adults. Differences in physiology, metabolism, comorbidity, frailty, social support, and cognition can all affect the response of older adults to the stress of surgery. Thus, the clinical outcomes of operations and the strategies to optimize surgical care may differ for older adults.

Table 1 Ten most commonly performed inpatient operations in the United States (2012)

ICD 9 codes	Procedure description	# Performed	% in 65+ yo
81.54–81.55	Total knee replacement	613,290	56.5%
81.51–81.53	Hip replacement (partial, total, revision)	391,265	62.0%
51.21–51.24	Cholecystectomy	335,130	30.7%
47.01	Laparoscopic appendectomy	182,325	8.1%
45.71–45.83, 17.31–17.39	Colon resection	144,115	50.7%
8102	Other cervical fusion of the anterior column (anterior technique)	128,665	21.8%
6849	Other and unspecified total abdominal hysterectomy	119,585	10.9%
7935	Open reduction of fracture with internal fixation (femur)	117,570	73.8%
8107	Lumbar and lumbosacral fusion of the posterior column (posterior)	107,350	41.8%
7936	Open reduction of fracture with internal fixation (tibia and fibula)	105,335	27.7%
	TOTAL	2,244,631	43.7%

In general, older individuals use medical and surgical services at substantially higher rates than younger individuals. According to data from the US census, individuals over the age of 65 comprised approximately 14% of the US population in 2012 (Table 1) [1]. Yet, they account for [2]:

– 31% of cholecystectomies
– 49% of colon resections
– 62% of total hip replacements
– 57% of total knee replacements
– 53% of hospitalizations
– 67% of hospital days of care

Of the top ten most commonly performed inpatient operations in the United States, 4 are performed more often in patients 65 years old or older (Table 1).

The incidence of numerous operations increases with age, such that for many procedures, individuals in their eighth or ninth decade of life have the highest frequency of surgery, as shown in Fig. 1. As a result, the majority of major inpatient operations involve older adults.

Likewise, outpatient surgical procedures are also much more common in older individuals. The following graph (Fig. 2) examines rates of seven of the most frequently performed outpatient procedures based on data from the state of Florida. Two procedures – myringotomy tubes and tonsillectomy/adenoidectomy – are performed more commonly in younger patients and less so in older individuals. For the remaining 5 procedures, the age range with the highest rates of surgery is individuals aged 60 years and older. This is particularly true for cataract operations, which could not be included in the figure below for reasons of scale. The annual rate of cataract surgery among individuals aged 70–79 is 74 per 1,000 population, greater than the other 7 procedures combined.

In addition to generating an increased number of surgical procedures, older adults are more likely to require greater care and increased resource utilization around surgery. After major inpatient surgery, older patients have longer postoperative hospital length of stay and higher rates of readmission [3]. They are also significantly more likely to require postoperative inpatient skilled nursing care and prolonged utilization of health services. After major cancer surgery, for example, 24–44% of octogenarians used extended care facilities after hospital discharge [4], as do half of patients over 80 who undergo coronary artery bypass grafting [5]. Prolonged functional recovery is common in older adult surgical patients, with objective measures of disability often persisting as much as 6 months after major

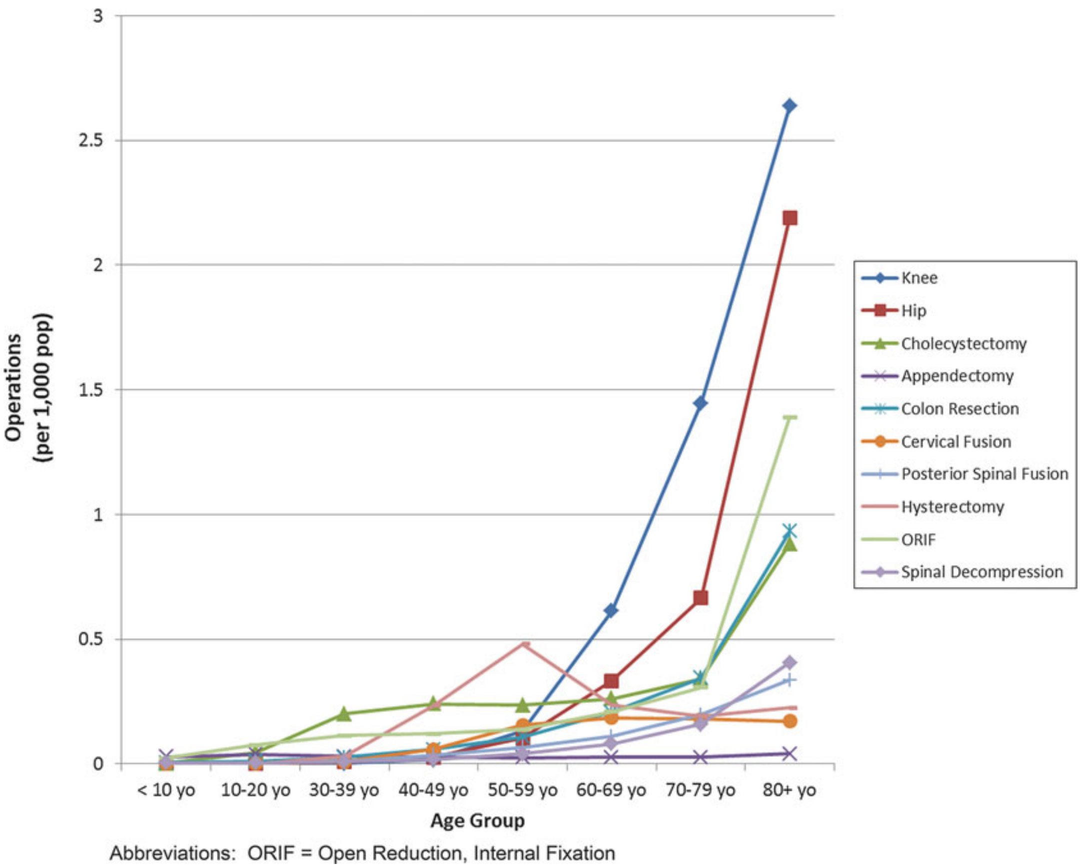

Fig. 1 Incidence rates for top 10 inpatient operations, by age group [2]. (Abbreviations: *ORIF* open reduction, internal fixation)

abdominal surgery [6]. During their hospitalization, older patients require greater medical services as well. In a recent analysis of Medicare claims data, Kuo et al. found a more than fivefold increase in the proportion of surgical admissions that involved care from a medical hospitalist [7].

Despite the increased care burden required by older surgical patients, there is a trend toward increasingly performing operations that were historically considered too risky to undertake in elderly patients [8–10]. The bias against aggressive surgical treatment for patients considered empirically "too old" appears to be diminishing, and the rates at which elderly individuals are undergoing several types of major surgical procedures are increasing [11]. These trends, as well as the demographic shift toward an increasingly older US population, will demand attention to research on clinical outcomes in elderly patients [12]. This chapter will address the evidence base informing our current understanding of the measurement of surgical outcomes in older adults.

Surgical Outcomes in the Elderly Population

Even after all other factors are considered, older/elderly patients incur a higher risk of complications after major operations. The challenge is to quantitatively consider this greater level of risk with the proposed benefit of a specific surgical intervention in a specific patient.

A large study by Hamel et al. used the National Surgical Quality Improvement Program (NSQIP) to evaluate 26,648 patients aged

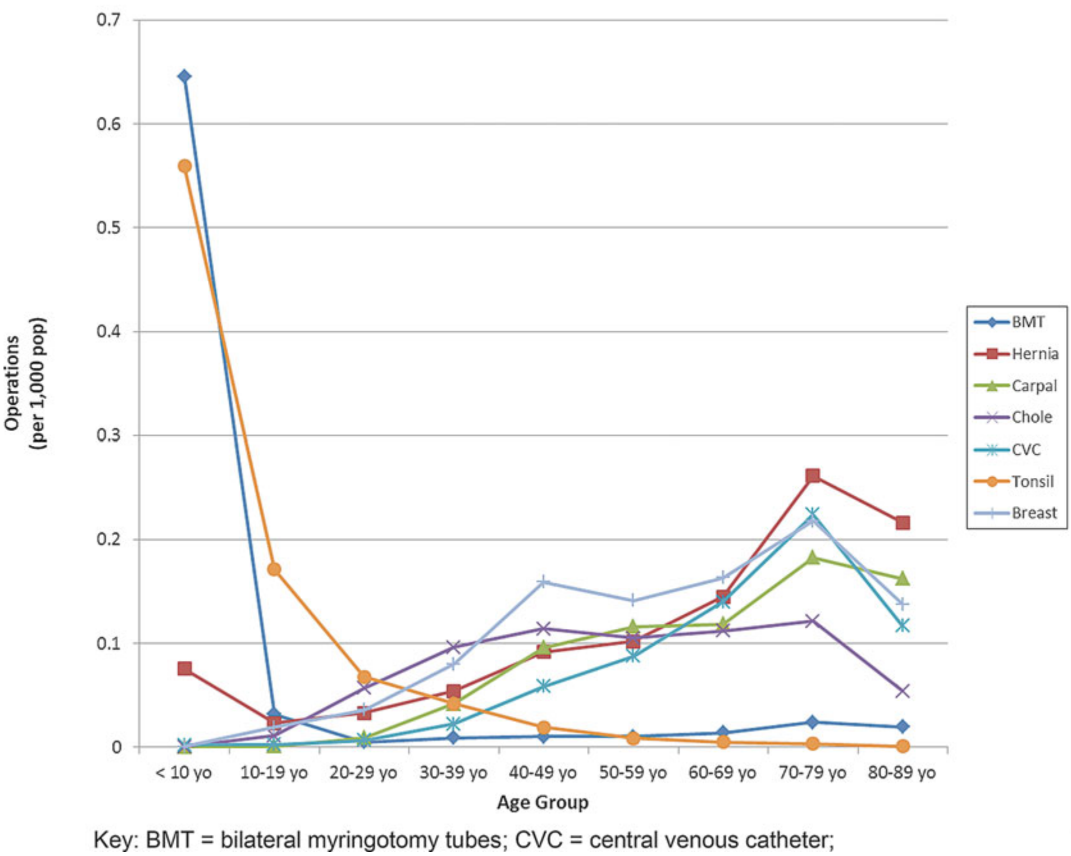

Fig. 2 Incidence rates for top 10 inpatient operations, by age group. (Key: *BMT* bilateral myringotomy tubes, *CVC* central venous catheter)

80 years or older undergoing major noncardiac surgery [13]. Patients >80 years of age had higher all-cause mortality rates than younger patients (8% vs. 3%, $P < 0.001$). Furthermore, of the patients >80 years, 20% had one or more of 21 identified potential postoperative complications (i.e., pneumonia, myocardial infarction). Postoperative complications are also distinct drivers of postoperative mortality. Of those with postoperative complications, a 30-day postoperative mortality was higher than for patients who did not have a postoperative complication (26% vs. 4%, $P < 0.001$). Interestingly, they also found that for patients >80 years, after adjusting for 33 baseline variables, there was a 5% increase in 30-day mortality risk for each year over the age of 80 (i.e., a 90-year-old has a 50% greater risk of 30-day mortality than an 80-year old). As might be expected, patients >80 had a higher 30-day mortality risk when undergoing emergent versus elective surgery (adjusted odds ratio 1.7) [13].

This study demonstrates that elderly patients have worse outcomes after surgery than younger patients, which is important to communicate when discussing expected outcomes after elective or emergent surgery.

Optimizing Surgical Outcomes for Elderly Patients: Best Practice Guidelines

With the goal of improving quality of care and optimizing the preoperative period for geriatric surgery patients, the ACS-NSQIP and American

Geriatric Society (AGS) collaborated to create best practice guidelines [14]. An expert panel was assembled to perform a systematic review of the literature and establish evidence-based recommendations for improving the preoperative assessment of geriatric patients (summarized in Table 2).

Special Considerations

Optimization of outcomes also includes understanding the concept of frailty, prehabilitation, postoperative cognitive decline, and how DNR orders may affect patients' postoperative course.

Assessment of Frailty

Preoperative assessments (e.g., American Society of Anesthesiologists (ASA) score) are commonly used to predict postoperative outcomes. However, these traditional scores account for organ function rather than physiologic reserve. Frailty is an emerging concept that takes an important step forward in conceptualizing and measuring physiologic reserve. Unfortunately, there is no gold standard for diagnosing frailty. Age and comorbidity alone do not define frailty since there is a spectrum of active versus debilitated elderly at each age. For now, frailty is defined as a syndrome characterized by a loss of biologic reserve causing increased vulnerability to minor stressors and risk for adverse outcomes, including disability, hospitalization, and death [15, 16].

Due to a relatively vague definition, multiple frailty assessment tools have been developed and validated for the identification of frail patients. Most tools have been developed around the conceptualization of physical frailty rather than cognitive assessment. The most commonly cited frailty screening tool is the physical frailty phenotype which defines frailty as meeting three or more of the following: weight loss of more the 5% of body weight in the last year, exhaustion, weakness, slow walking speed, or decreased physical activity [17]. A simpler, faster tool is the FRAIL scale that defines frailty if patients answer having three or more of the following: fatigue, resistance, ambulation, illnesses, and loss of weight [18, 19].

Makary et al. prospectively measured frailty in 594 patients age 65 years or older undergoing elective surgery to determine if frailty predicts surgical complications and enhances current perioperative risk models [20]. Frailty was defined as a score based on age-associated decline in five domains: shrinking, weakness, exhaustion, low physical activity, and slowed walking speed. Their main finding was that frailty is an important predictor of postoperative complications, increased length of stay, and discharge to a skilled or assisted-living facility. The group also found that frailty had considerable predictive capability above and beyond the known indices of ASA score, Lee's revised cardiac risk index, and Eagle score, underscoring the importance of physiologic reserve in the elderly population undergoing surgery.

More recent studies have investigated the association of frailty with postoperative mortality. McIsaac et al. used a population-based retrospective cohort to examine 1-year all-cause mortality among 6,289 frail patients, as defined by the Johns Hopkins Adjusted Clinical Groups (ACG) frailty-defining indicator [21]. The authors found frailty to be associated with a significantly increased risk of 1-year mortality. This association was especially important in the early postoperative period and after joint arthroplasty. Another study by Mosquera et al. analyzed 232,352 patients by using the NSQIP database to determine if frailty was associated with adverse postoperative events including mortality [22]. The study found frailty to be significantly associated with postoperative complications, prolonged duration of stay, and 30-day mortality on multivariate analysis. Colectomy and esophagectomy showed the greatest mortality in severely frail patients at a rate of 9.36 and 8.2%, respectively.

Prehabilitation

Given the importance of frailty as a risk factor for complications, the potential of frailty as a target for preoperative optimization is clear. Any intervention to strengthen (diminish frailty) patients before surgery has intuitive appeal, either because (1) patients are better able to recover from surgery or (2) patients have improved outcomes (fewer

Table 2 Domains of preoperative assessment in elderly surgical patients

Area of preoperative assessment	Instrument	Additional evaluation	Relevance
Cognitive impairment and dementia	Mini-Cog	If evidence of cognitive impairment based on the Mini-Cog, consider further evaluation	Dementia is common and the prevalence increases with age
Decision-making capacity	Use 4 legally relevant criterion		Critical to determine patient's ability to provide informed consent
Depression	Patient Health Questionnaire-2	If answers YES to either question, then evaluate further	Depression is common in elderly and can be associated with higher analgesic use
Risk factors for postoperative delirium	Potential risk factors include cognitive or metabolic disorders, comorbidities, and functional impairment	Avoid medications such as benzodiazepines and antihistamines. Correct any modifiable risk factors such as sleep deprivation and immobilization due to urinary catheter	Postoperative delirium is associated with increased morbidity, mortality, length of stay, and need for institutionalization
Alcohol and substance abuse	Modified CAGE questionnaire	If yes to any question, consider perioperative withdrawal prophylaxis	Preoperative alcohol abuse and dependence are associated with increased rates of postoperative morbidity and mortality
Cardiac	ACC/AHA algorithm	Important to effectively communicate operative risk	Older patients are more vulnerable to perioperative cardiac events
Pulmonary	Identify patient-related and surgery-related risk factors	Consider preoperative strategies to reduce risk such as smoking cessation, optimization in uncontrolled COPD, or asthma	Pulmonary complications are common and predict long-term mortality in the elderly
Functional status	Assess ability to perform daily activities; deficits in vision, hearing, or swallowing; history of falls. Perform timed up and go test	Consider formal assessment of ADLs/IADLs and referral to physical therapy if abnormal timed up and go	Poor functional status is an independent predictor of mortality
Frailty	Criteria include shrinkage, weakness, exhaustion, low physical activity, and slowness		Frailty independently predicts higher rates of postoperative adverse events, increased length of stay, and higher likelihood of discharge to a skilled or assisted-living facility
Nutritional status	Screen using BMI, albumin, and unintentional weight loss	If any of these items are abnormal, perform full nutritional assessment	Poor nutritional status is associated with infectious and wound complications
Medication management	Review and document patients' complete medication list	Identify medications that should be started, continued, or stopped before surgery, adjust doses for renal function, monitor for polypharmacy	Polypharmacy is associated with poor medication compliance, increased adverse events, cognitive impairment, morbidity, and mortality

(continued)

Table 2 (continued)

Area of preoperative assessment	Instrument	Additional evaluation	Relevance
Patient counseling	Discuss advanced directive, treatment goals, postoperative course and potential complications, family/social support	If concern for poor family/ social support, consider preoperative referral to social worker	Patient expectations and preferences influence treatment preferences
Preoperative testing	Hemoglobin, renal function, and albumin for all geriatric surgery patients	Other labs, ECG, CXR, PFTs, and noninvasive cardiac tests are for selected geriatric surgery patients	Many studies have highlighted the low yield and high cost of routine preoperative screening

Abbreviations: *ACC/AHA* American College of Cardiology/the American Heart Association, *ADLs/IADLs* activities of daily living/instrumental activities of daily living, *BMI* body mass index, *CAGE* questionnaire for alcoholism, *COPD* chronic obstructive pulmonary disease, *CXR* chest X-ray, *ECG* electrocardiogram, *PFTs* pulmonary function tests

complications). This concept – "prehabilitation" – is an emerging focus of research, and several studies have examined the extent to which these types of interventions are associated with improved patient outcomes.

A recent systematic review found 5 studies including 353 patients who prospectively received prehabilitation before elective colorectal surgery [23]. Overall, this body of research suffered from small sample sizes, poor compliance with interventions, and heterogeneity of intervention. The accumulated findings were that the interventions were not effective in significantly reducing rates of complications or length of hospitalization. These findings were similar to those seen in a systematic review of the effect of prehabilitation in joint replacement surgery [24]. In an examination of 22 studies including 1492 patients, Wang et al. found only nominal improvements in pain and level of function but no impact on length of stay and costs.

These initial findings are discouraging, but it is worth observing that this field is still in a very early stage. Because there was no consensus among colorectal surgeons as to whether preoperative exercise was beneficial, a Delphi survey was performed across a group of colorectal surgeons in an attempt to form a consensus opinion on prehabilitation in the elderly colorectal cancer patients [25]. Twenty two statements were included, and more than 80% agreement was defined as consensus. After three rounds, it was agreed upon that exercise training should form part of the preoperative care and would be supported by surgeons and that suitable programs posing significant risk to patients were rejected. There was no agreement on the strength of the current literature. Future study will better inform the community of the efficacy of preoperative rehabilitation.

Postoperative Cognitive Decline

Elderly patients are at significant risk for developing short-term, long-term, or permanent decline in the level of cognitive function. This phenomenon was first recognized after cardiopulmonary bypass (CPB) but is now increasingly well recognized as a complication after any operation under general anesthesia. A recent review found the incidence of postoperative delirium to range from 10% to 65% and that up to 40% of these patients never return to their baseline level of function [26]. For surgeons, an understanding of the likelihood and severity of postoperative cognitive decline is important.

The likelihood of long-term or permanent cognitive decline is an important element of informed consent for patients undergoing elective surgery. This consideration is a challenging one for surgeons, patients, and surrogate decision-makers as it is inherently difficult to quantify. Despite this challenge, it is critical that all parties to the consent process be aware of the potential for short-term and long-term decline.

Preexisting Do Not Resuscitate (DNR) and Failure to Rescue

As the patient population ages, the number of patients with DNR orders undergoing surgery has risen, and the question has been raised whether or not a DNR order should affect surgical management. The presence of a DNR order as a surrogate marker of illness or impending death is not well documented in the surgical literature. Recently, Speicher et al. used the NSQIP database to evaluate DNR and non-DNR patients undergoing emergent surgical management of intestinal obstruction in order to understand the expected postoperative complication and mortality rate in patients with a DNR order [27]. The main finding was that a DNR order status was an independent predictor of postoperative mortality even after adjusting for comorbidities and overall complication rate.

An important question that remained unanswered by Spiecher's study was *why* the DNR order was an independent risk factor for mortality. A subsequent study by Scarborough et al. also used data from the NSQIP to evaluate 25,558 patients over the age of 65 undergoing emergency surgery for common general surgery procedures such as appendectomy, cholecystectomy, and colon resections [28]. Patients with a DNR order had a significantly higher postoperative mortality rate than non-DNR patients but not a significant difference in the incidence of major postoperative complications. Interestingly, among those patients who did sustain one or more complications, subsequent mortality (i.e., failure-to-rescue) was significantly higher in the DNR group than in the non-DNR group (57% vs. 41%) despite the fact that the two groups had no detectable difference in their physiological ability to withstand such complications. The group concluded that the likely reason for higher mortality in the patients with a DNR order was the failure to pursue aggressive postoperative management, also called a "failure-to-pursue rescue." While patients with DNR orders may initially consent to surgical intervention to fix their acute problem, they may be less inclined to continue to pursue aggressive treatment after surgery.

Specific Patient Populations

The Nursing Home Patient

Nursing home residents may be the most vulnerable of elderly patients. While most of the published studies suggest that major surgery can be performed safely in older adults, they do not include nursing home patients in their analyses. This cohort makes up 5% of patients 65 years and older, and it is estimated that more than one third of people over 70 years will spend some time in a nursing home before they die [29]. Thus, a significant proportion of the elderly will reside in or be exposed to a nursing home.

In 1992, Keating et al. published a retrospective chart review of skilled-care nursing home residents who underwent major surgery. Of the 74 patients included, serious complications occurred in 43%, which the authors reported to be comparable to unselected geriatric populations [30]. A later study in 1996 by Zenilman et al. did a prospective study of nursing home patients who underwent major abdominal and vascular operations [31]. Overall survival was similar for nursing home residents who did versus did not undergo these operations. The authors concluded that the patients' overall survival was not affected by the need for surgery or the operation performed, and, therefore, surgery was not futile in this patient population and should be performed if of benefit to the patient in terms of patient dignity and a relief of suffering.

More recently, Finlayson et al. evaluated 70,719 nursing home patients by using national Medicare claims and the nursing home Minimum Data Set (1999–2006) to identify nursing home residents undergoing surgery [32]. These patients were compared to noninstitutionalized Medicare enrollees aged 65 years and older undergoing the same procedures. Operative mortality among nursing home residents was substantially higher than among noninstitutionalized Medicare enrollees for all procedures ($P < 0.001$), and invasive operations were more among common nursing home residents than controls ($P < 0.0001$). Through this well-designed study, the authors were therefore able to conclude that nursing home residents experienced substantially higher rates of mortality after major surgery even after correcting for age and comorbidities.

This population-based study, while limited by the use of administrative data, did raise some important points regarding the optimal management of surgical diseases in nursing home residents. For conditions that are truly life threatening, over half of nursing home residents over 85 years survived. Thus, surgery may not be futile for these patients who will die without surgery. However, for nonlife-threatening surgical diseases, less invasive treatment strategies such as antibiotics for appendicitis or percutaneous cholecystotomy tube for cholecystitis may be preferred in this population rather than undergoing elective surgery. Patients and their families should be appropriately counseled that surgery in this cohort results in much higher mortality regardless of age.

Elderly Patients with Dementia

Dementia is one of the most common cerebral disorders in older adults and is significantly associated with advancing age. The incidence of dementia rises rapidly at older age, from 5% of those 71–79 to greater than 37% of individuals over 90 years of age [33], and these patients are particularly vulnerable in the postoperative period for complications and worsening cognitive decline [34, 35].

Special attention is needed for older surgical patients with dementia, as perioperative complications, including acute renal failure, sepsis, stroke, and urinary tract infection, are far more common than in similar aged controls [36]. Further, functional recovery may be impaired in these patients. For example, lower extremity joint replacement among patients with Alzheimer's disease is associated with prolonged hospitalization and more frequent need for revision, even in the absence of perioperative complications [37]. Surgery for rectal cancer in patients with dementia incurs increased risk of postoperative incontinence [38]. It is also patients with preoperative dementia who are at greatest risk of long-term cognitive decline after surgery [26]. Unfortunately, alterations in anesthetic approaches have not altered perioperative outcomes for patients with dementia, as the incidence of perioperative complications and delirium is no different with the use of general versus regional anesthesia [39].

Both short- and long-term mortality rates after surgery are also significantly higher among older patients with dementia [40]. For example, death after hip fracture repair among nonagenarians was doubled among those with dementia, with mortality rates of 6% at 90 days and 62% at 1 year after surgery [41]. Although these worse outcomes have been attributed by some to inability to complete rehabilitation, efforts to redesign postoperative rehabilitation approaches to meet the needs of patients with dementia have not consistently demonstrated benefit [42].

Postoperative Care

The Use of Enhanced Recovery Pathways in the Elderly

Over the last decade, enhanced recovery programs (ERPs) have redesigned the approach to perioperative care of surgery patients in some settings. The multidisciplinary set of interventions in the perioperative and postoperative phases was initially proposed by Professor Henrik Kehlet from Denmark and focused on noncardiac surgery [43]. Among the main interventions, restrictive intravenous fluid therapy, the use of laparoscopy in combination with appropriate anesthesia, early enteral feeding, and early postoperative mobilization seem to be the most important to the pathway's success. There is now extensive literature documenting that adherence to ERPs can minimize morbidity and mortality while decreasing hospital length of stay and overall cost [44–48].

In order to achieve these improved outcomes with enhanced recovery, there need to be implementation and compliance to multiple interventions. This can be difficult to achieve, especially in certain patient populations. Therefore, elderly patients have been excluded from ERPs in some institutions due to the perceived impediments of physical impairments or medical comorbidities [49]. However, recognizing that frail older patients may have the most to gain from efforts to improve and hasten postoperative recovery, it is important to know whether similar care principles should be adopted.

Recently, three studies have demonstrated successful introduction of ERPs for elderly patients with outcomes suggesting they are safe and feasible. Despite greater comorbidities, older patients experience equivalent adherence to enhanced recovery pathways, fewer complications, and shorter length of hospital stay with enhanced recovery, which may further improve outcomes in this patient population [50–52].

Prevention of Postoperative Complications in the Elderly

The ERAS movement has clearly identified ways in which perioperative care can be improved to minimize metabolic derangement and lower risk of complications. A best practice guideline was recently published by the American College of Surgeons in conjunction with the American Geriatrics Society – this guideline is a highly recommended resource for all surgeons [53]. Many of the domains that are highlighted in these guidelines are inherent in the emerging ERAS guidelines discussed earlier in this chapter. These interventions are sensible for all patients, but there may be a subset of interventions that is specific to the needs of elderly patients.

As mentioned earlier, elderly patients are at risk for postoperative cognitive decline. This decline can be mitigated with some level of effectiveness. Widely recognized risk factors for cognitive decline include CPB, hypoxemia, hypotension, metabolic stress, neurotoxic anesthesia, analgesics, sleep disruption, and fasting [54]. Intuitively, minimizing patient exposure to these risk factors is sensible, but not always possible due to clinical factors [26]. With some focused attention, sleep protection, increased daytime activity, and minimization of opioids can be achieved without undue burden.

Older patients may be at greater risk for issues related to mobility and independence. Highly frail patients need a constant level of vigilance to prevent the occurrence of pressure ulcers. Physical therapy and early mobilization are needed to prevent rapid loss of physical function that can lead to loss of the ability of patients to complete activities of daily living. An important aspect of preoperative counseling is a discussion regarding expectations of where the patient will stay/live after discharge and what the level of help (friends, family, healthcare professionals) will be available. If a postoperative transfer to a rehabilitation facility or skilled nursing facility is planned, then this discussion should be initiated preoperatively.

Conclusion

With the fastest-growing segment of the population aged ≥65 years, the number of operations performed on elderly patients is increasing. It is imperative that physicians understand surgical outcomes specific to the elderly, best practice guidelines for improving and optimizing care prior to undergoing surgery, as well as the impact of both frailty and DNR orders on postoperative outcomes. There are several other areas specific to the elderly that also warrant further investigation including avoiding inappropriate medication use, prehabilitation, accurate assessment of preoperative cognitive function, and prevention of postoperative delirium. Further work is needed to better understand this vulnerable population in order to provide high-quality care and optimize postoperative outcomes.
