Surgery in the Frail Elderly: Nursing Home Patients

31

Emily Finlayson and Michael E. Zenilman

Contents

Abstract

Throughout our careers, each of us – the co-authors of this chapter and the editors of the textbook – have published about the role of general surgery in the nursing home population. The topic has retained its timeliness over the past 30 years, as the term “nursing home” evolved from a place of last resort for patients on their destination to death to a place where the frail, vulnerable elderly may go to for both short-term rehabilitation and long-term stay.

We will all encounter such high-risk patients in our practice. To aid the surgeon in assessing and caring for this group of people with very little reserve, in this chapter we review how to establish a consult service for academic and community-based nursing homes, and describe the types of surgical illnesses encountered. We then show data for 70,000 Medicare patients who underwent surgery in nursing homes using the powerful tool of population-based analysis. The studies

delineate the type of patients and procedures we will face, the resource utilization, and expected outcomes. This information is critical to help manage the expectations for physicians, patients, and family members.

Introduction

As a result of medical advances, healthier life styles, and decreased health risk, the aging population of the United States and other Western societies will approach the limit of aging, or the life-span. A comparative study performed on life expectancy of 80-year-old persons in Western countries showed that American octogenarian men and women are expected to live 7.0 and 9.1 more years, respectively. In England, the survival of octogenarians was 6.2 and 8.1 years, respectively; in France 6.7 and 8.6 years, respectively; in Sweden 6.5 and 8.3 years, respectively; and in Japan, 6.5 and 8.9 years, respectively [1].

As the limit of life expectancy is reached, a significant percentage of elderly persons become debilitated and become increasingly dependent on others for care. We already known that at age 65 about 10–20% of persons become dependent on others for one or more basic activities of daily living (ADLs). This proportion has been shown to increase to 25% at age 75 and to 50% at age 85 [2]. It is predicted that the overall average life expectancy in the United States will increase to 83 by the year 2050 [3], and by 2030 there will be 8.8 million persons over the age of 85 [3].

Many of these patients will, no doubt, need chronic nursing care.

A population with increased disability must have care, which is typically undertaken in nursing homes. One study forecast that of the 2.2 million persons who turned 65 in 1990, 43% (900,000) will enter a nursing home before they die: 32% are expected to spend more than 3 months under such care, 24% more than 1 year, and 9% more than 5 years [4]. The implications for medical management of these patients is obvious, and there is a definite need for good surgical care, as delineated below.

Focusing Surgical Care on the Frail Elderly: Development of a Dedicated Consult Service for Nursing Home Patients

A number of studies have addressed the utility of focused medical care for frail elderly patients in the inpatient setting. The establishment of an aggressive medical geriatric assessment service for frail elderly populations has been shown to increase patient survival, quality of life, and ability to return to independence [5–7]. In these studies, rehabilitation, independence in self-care, detailed discharge planning, and avoidance of iatrogenic illness were stressed. The interventions resulted in 10% improvement in function on discharge (34% vs. 24%) and decreased need for long-term care (14% vs. 22%) [7].

One study, however, found no real benefit of focused geriatric assessment in the hospital [8], but in this study, the geriatrician was used only as a consultant, not the coordinator of care. There is little argument about the fact that the only person capable of dealing with the complicated elderly patient is one who coordinates the medical, social, rehabilitative, and surgical care.

Little has been reported about the surgical care of nursing home patients. There are a fair number of reports on the treatment and outcomes of care for decubiti [9–11] but little else. Most studies on this population have been limited to addressing risk factors for death and survival. As a result, little is known about the utility of aggressive surgical care for the hospitalized or nursing home frail elderly patient. Moreover, some surgeons are reluctant to deal with common surgical illnesses in nursing homes because the patients are usually chronically sick, there is a question about its utility, and some patients have active “do not resuscitate” (DNR) orders.

It is reasonable to assume that a service devoted to the surgical care of chronically ill elderly patients would have a positive impact on their survival and quality of life. Therefore a geriatric surgery consult service was developed at the Johns Hopkins Bayview Medical Center, whose goal was to improve surgical care of the frail elderly resident at home, in the hospital, and in the nursing home.

The consult service was established on August 1, 1991. The Johns Hopkins Bayview Medical Center campus had an active general surgery service and geriatric medicine service. The Geriatric Medicine Department has an active acute medical care facility in the hospital, and they control the Johns Hopkins Geriatric Center as well, a 240-bed chronic care facility/nursing home on campus for patients who require both simple and complex chronic nursing home care. The consult service therefore established a close association with the geriatric division, giving exclusive surgical care for the patients residing in this nursing home facility. Using this service, with subsequent expansion to care for patients in other nursing homes affiliated with the institution, the primary questions were.

1. What is the typical makeup of the patient population referred to this service?
2. What is the incidence and severity of specific general and vascular surgical problems in this patient population?
3. What are the risks of surgical intervention, specifically the complication and morbidity rates?

Patients needing elective surgical consultation were consecutively referred to this service. All patients evaluated and treated by the service were enrolled, along with specific demographic data, into a computer database. All patients were followed in a prospective manner until June 1, 1994. We subsequently reported the results elsewhere [12].

Altogether 153 patients were enrolled, and 117 of them required intervention. The admission diagnoses to the nursing home and reasons for the surgical consultation are shown in Table 1. While maintenance care (decubitus, stoma, and enteral tube care) made up a substantial percentage of referrals, common surgical diseases of the abdomen, breast, and vascular systems were routinely encountered (55%). The actuarial 18-month survival of all patients referred was 35% (Table 2).

A total of 117 patients underwent 168 surgical procedures. The distribution of cases is shown in

Table 1 Diagnoses for geriatric surgery consult service

Diagnosis	%
At admission	
Dementia	20.9
Stroke	19.4
ADL	14.2
Peripheral vascular disease	9.0
Infection	7.5
Abdominal	6.7
Cancer	6.7
Chronic renal failure	6.0
Coronary artery disease	4.5
Chronic obstructive pulmonary disease	3.7
Diabetes	1.5

Table 3 Goals of Medical and Surgical Care for Individuals with Limited Life-Expectancy

Maximize or maintain potential life-span
Maintain dignity of life, maximize self-esteem
Maximize independent function, minimize dependence
Relieve suffering, with particular attention to pain
Cure might not be possible; palliation and comfort are just as important

Table 3. In patients subjected to surgery, the 30-day mortality rate was 8.5% and complication rate 9.4%. Interestingly, the 30-day mortality of the 36 patients not undergoing any intervention was 11.4%; this translated into *absolutely no difference* in overall survival for patients who underwent surgery compared to those who did not.

Although those undergoing major abdominal and vascular procedures had a higher complication rate (17.6%) than those undergoing lesser procedures (6.3%, $p = 0.05$), there was no difference in 30-day mortality (9.8% vs. 6.3%, respectively) or 18-month actuarial survival (33% vs. 32%, respectively). Multivariate analysis of survival using the Cox regression model showed that survival was adversely affected by the presence of the comorbid conditions of coronary artery disease [relative risk (RR) 3.27, $p = 0.01$] and dementia (documented by a Mini-Mental Score less than 24) (RR 2.39, $p = 0.04$), and age greater than 70 (RR 2.03, $p = 0.06$). It is interesting that the significance value of age was low compared to that of the other variables. Although univariate analysis showed age to be significant, multivariate analysis put it right on the edge of significance when compared to the comorbid conditions of cardiac disease and dementia. Overall survival was unaffected by the need of surgery, the magnitude of the procedure performed, sex, number of comorbid conditions or medications, and whether a preoperative DNR order was present.

This study concluded that general surgical disease is routinely found in the geriatric population, and, therefore, proper surgical care by a general surgeon is necessary. It also showed that routine surgical procedures can be performed safely in residents of nursing homes. Unfortunately, the overall survival of residents of nursing homes referred for surgical intervention is poor, even worse than the published survival of patients in geriatric inpatient units, which is approximately 77.2% (1-year survival) [13].

Analysis of Data from the Geriatric Surgery Consult Service: Role of Dementia, Age, and Coronary Artery Disease in the Nursing Home Patient

In this population of patients, the relative risk of death was increased by the presence of cardiac disease and dementia (determined by a Mini-Mental Score less than 24). Age, as described above, only approached statistical significance. Studies have shown that the presence of dementia adversely affects survival rates of nursing home patients [14–16]. The reported survival of nursing home patients with dementia is 68% at 1 year, 55% at 2 years, and 28% at 3 years [16]. The diagnosis alone increases the relative risk of mortality in these patients by a factor of 2.7 [17, 18].

Dementia is prevalent among not only the nursing home patient [14, 16–19] but also the "healthy elderly." Skoog et al. [20] showed that in a cohort of 494 nonhospitalized or institutionalized subjects aged 85 and older the prevalence of dementia was 29.8%. The dementia was mild in 8.3%, moderate in 10.3%, and severe in 11.1%. Interestingly 43.5% of the dementia was Alzheimer's type, 46.9% was vascular (multiinfarct)-related, and 9.5% was due to other causes. As in our study and others, the presence of dementia was a risk factor for death: The 3-year mortality was 23.1% in normal persons, 42.2% in those with Alzheimer's dementia, and 66.7% in those with vascular dementia.

Dementia can be assessed rapidly by the Mini-Mental examination [14, 19]. Although in our study we used only the Mini-Mental Score obtained on admission to the nursing home, in the future it might be useful to obtain a score at the time of the surgical consult to see if it can be an accurate predictor of short-term survival.

Contrary to what others have shown, survival in our nursing home population was also not dependent on the absolute number of concomitant medical diseases. This result is in contrast to those of other studies, which showed that in the general hospitalized elderly patient co-morbid illness significantly increased the relative risk of death [14–16].

The absence of difference in survival in nursing home patients who required surgical intervention compared to those who did not is interesting. Although one might infer that surgery in this population had no effect on survival because most of the procedures performed were lifesaving (e.g., amputation for infected or gangrenous limbs, gallbladder removal for acute cholecystitis) or life-maintaining (e.g., long-term intravenous access for nutrition or antibiotics, wound débridement to prevent systemic infection, mastectomy for local control of breast cancer), surgery in these patients actually improved their chances and brought their survival curve back to the downward sloping baseline.

Case Examples

Three cases highlight the utility of a geriatric-oriented surgical service and the need for surgical leadership in this arena.

Case 1

We were consulted to evaluate a 92-year-old arthritic woman who had had symptomatic gallstones for more than a year. She was maintained on chronic antibiotics and pain medications after eating. Her only other medications were nonsteroidal antiinflammatory drugs (NSAIDs) for the arthritis. After evaluation by our service, elective removal of the gallbladder was recommended. It was performed laparoscopically without incident. Postoperatively, she remained intubated overnight but was discharged back to the nursing home on postoperative day 2. Almost immediately after discharge, she noted only minimal symptoms after eating, her appetite improved, and she gained weight. She expired from unrelated illness 3 months later. She, her family, her geriatrician, and the nurses caring for her thought that she was much more comfortable after removal of the inflamed gallbladder.

Prior to our evaluation, all thought she was too old and frail for even elective surgery. She was a good surgical candidate; furthermore, because of the significant complication of the biliary system that had developed from the gallstones, I believe she would have expired rapidly. This patient was clearly helped by seemingly aggressive, but appropriate, surgical management. The patient, her family, and her health care providers had to be educated about the benefit of elective surgery, as all were basically uninformed prior to the surgical consult. Her DNR order, in effect during her nursing home stay, was rescinded during her procedure and her short stay in the intensive care unit (ICU).

Case 2

We were consulted to evaluate a malfunctioning percutaneously placed gastrostomy in an 85-year-old man. An endoscopic photograph of the stomach showed that the tube had migrated out of the stomach and into the prefascial space. Under local anesthesia with intravenous sedation, the tube was removed, the stomach was identified, and a new gastrostomy was placed. This procedure was performed as an outpatient operation, and the feeding tube was used the next day.

Case 3

A 78-year-old woman was a nursing home resident for 8 months after emergency subtotal colectomy due to septic colitis complicated by respiratory and cardiac problems. After a remarkable but prolonged recovery, she began to tolerate oral food well. Over a 2-week period she developed right upper quadrant pain, nausea and vomiting, anorexia, and fevers. Her white blood cell (WBC) count was 15,000 cells/mm^3; alkaline phosphatase was 400 IU/L; and other liver function tests and amylase were normal. Ultrasonography revealed a large gallstone and normal common bile duct. To convert this urgent situation to an elective one, a percutaneous cholecystostomy tube was placed, 250 cc of pus was removed, and the patient was placed on intravenous antibiotics. The WBC count normalized, and a diet was started the next day. Cholangiography was performed through the cholecystostomy 3 days later due to persistently elevated alkaline phosphatase, and a stone was noted in the common bile duct. Endoscopic retrograde cholangiopancreatography was performed 3 days later, and the stone was removed successfully. The patient did well and underwent elective cholecystectomy 1 month later.

Comment

These three cases illustrate the need for surgical involvement in the care of nursing home patients. We must educate the patient, family, and even primary physician about the utility of an invasive procedure for palliation of the patient's illness. We also must coordinate the multidisciplinary care these patients frequently need.

Development of a Second Geriatric Surgery Consult Service: Decubitus Care

An issue raised by the aforementioned study [12] is that the nursing home studied was situated near a tertiary care center and hence may have had a different population of patients from the "community nursing home." Furthermore, it dealt with a multitude of surgical illnesses, and conclusions about individual types of illness cannot be drawn from such studies.

To evaluate factors determining survival in residents of community nursing homes suffering from a single disease, we retrospectively studied 105 patients consecutively referred for surgical débridement of decubiti in a nursing home in the Bronx, New York.[27] The mean (±SD) age of the patients was 75 ± 1.3 years, and 70% were women. Patients were followed for 10.9 ± 1.0 months. The 1- and 2-year actuarial survivals were 60% and 42.7%, respectively, somewhat higher than what we previously observed. This survival is similar to that of the general nursing home population. It is probable that persons with decubiti are not as ill as others who develop surgically treatable illness.

Univariate analysis showed that the patient's sex and the diagnosis of coronary artery disease had a statistically significant effect on survival, whereas the diagnosis of dementia appeared not to matter, neither dementia nor age factored into survival in this study. Interestingly, these two factors were identified as significant in the previous study. There were differences between the two studies. The first was a prospective analysis in a nursing home associated with a tertiary care center and dealt with all surgical problems. The second (present) study is retrospective, in a community nursing home, and dealt only with surgically managed decubitus ulcers.

Cox regression analysis revealed the relative risk of death for male patients was 2.56 ($p = 0.004$) and for patients with coronary artery disease, 2.2 ($p = 0.008$). We concluded that survival of nursing home patients referred for surgical intervention for decubiti is similar to that of the overall nursing home population. The presence of decubiti in these patients does not adversely affect outcome, and their treatment should be aggressive. Obviously, a dedicated decubitus service in this setting may even improve patient quality of life.

A Dedicated Surgical Service for Community Nursing Home: The Einstein College of Medicine Experience

A surgical consult service was established at Albert Einstein College of Medicine to serve patients residing in a community nursing home. These patients were prospectively studied and overall survival was analyzed as well as the effect of independent variables such as age, gender, presence of coronary artery disease, presence of dementia and location and severity of ulcer on survival [21].

There were 105 nursing home patients referred to the consult service, all for debridement of chronic decubitus ulcers. The mean age of this cohort was 75 +/− 1.3 year and 70% were female. These patients were followed from January 1995 to August 1997 for an mean +/− SEM of 10.9 +/−1.0 months (range 0–36 months). 34% suffered from coronary artery disease, 31% had diabetes, 21% respiratory disease, and 9% from renal disease. Most decubiti were debrided at the bedside in the nursing facility. 33% were extremity decubiti, 27% trunk, and 17% were on both the extremity and trunk, and 23% were not specified.

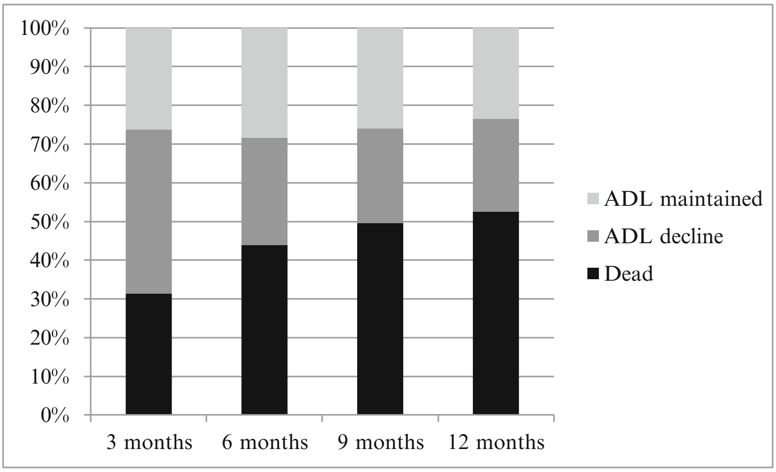

Fig. 1 Proportion of nursing home residents who experienced ADL decline, maintenance of ADL, and death after colon cancer surgery. (Source: Adapted from Finlayson et al. (ref))

Most procedures performed in this group were minor. We observed 1 and 2-year actuarial survival rates to be 60% and 42.7%, respectively. Multivariate analysis demonstrated that in this population, gender and the presence of coronary artery disease significantly affected overall survival, but older age, presence of dementia or comorbid illness did not.

Population-Based Outcomes After Major Surgery in Nursing Home Residents

In recent years, Medicare claims data and the Minimum Data Set for Nursing Homes, a national registry of nursing home residents, has been used to examine short- and long-term outcomes after major surgery in the nursing home population (refs). The Minimum Data Set for Nursing Homes is a standardized assessment administered quarterly for all residents of nursing homes participating in Medicare or Medicaid. It contains longitudinal information about medical, cognitive, and functional status [22–25].

In an analysis of over 70,000 nursing home residents who underwent surgery for common emergent abdominal operations (surgery for bleeding ulcer, cholecystectomy, appendectomy, and colectomy), operative mortality was two to threefold higher than among noninstitutionalized Medicare enrollees [23]. Furthermore, postoperative invasive life-sustaining interventions were significantly higher in the nursing home population than among noninstitutionalized Medicare enrollees – ranging from 18% versus 5%, respectively, after cholecystectomy to 55% versus 43%, respectively, after ulcer surgery.

Studies examining functional outcomes after surgery among nursing home residents have demonstrated that the majority of nursing home residents who undergo surgery experience substantial and sustained functional decline postoperatively [22, 24, 25]. Among residents who underwent colectomy for cancer, 53% were dead after 1 year and over half of 1-year survivors experienced functional decline [22] (Fig. 1). For residents who undergo lower extremity bypass, half die within a year of surgery [24]. At 1 year, 13% of the initial cohort was ambulatory and 18% had maintained or improved their baseline functional status – calling into question the efficacy of this procedure in the nursing home.

Hip fracture is mordid and not infrequent event in the nursing home population. Neuman et al. used the Minimun Data Set for Nursing Homes and Medicare Claims to examine functional outcomes after hip fracture in the United States Nursing Home Population [25]. They found that over a third of residents died and over half of residents had dies or experienced functional decline within 180 after fracture. Residents with multiple comorbidities and advanced cognitive impairment and those who did not undergo surgical correction of the fracture experienced the worst outcomes.

Conclusions

The population of nursing homes is going to increase over the next few decades, resulting from the increased population of elderly patients and the increased disability that accompanies the normal aging process. Common surgical illnesses are encountered in nursing home patients, and careful consideration is needed to guide the care of such patients. In this patient population, quality of life, patient dignity, and relief of suffering take often precedence over curative therapy and prolongation of life. Surgical decision-making must be informed by realistic prognostic information. The goals delineated in Table 3 should be followed to allow our elders dignity and comfort in their final days.

Abstract

Neurologic illnesses are a leading cause of death and disability in the elderly population. Many of these diseases require surgical evaluation. The US Census Bureau estimates that by 2030, 52 million Americans will be over 70 years of age [1]. The presentation, management, and outcomes of neurosurgical emergencies can be quite different in the geriatric population. It is imperative that practitioners are aware of the unique challenges that exist when caring for geriatric patients with neurosurgical emergencies.

Introduction

Neurologic illnesses are a leading cause of death and disability in the elderly population. Many of these diseases require surgical evaluation. The US Census Bureau estimates that by 2030, 52 million Americans will be over 70 years of age [1]. The presentation, management, and outcomes of neurosurgical emergencies can be quite different in the geriatric population. It is imperative that practitioners are aware of the unique challenges that exist when caring for geriatric patients with neurosurgical emergencies.

Traumatic Brain Injury

Recent studies report that approximately 1.1 million new cases of traumatic brain injury (TBI) are diagnosed and treated in US hospitals each year, approximately 450 cases per 100,000 people. Subgroup analyses demonstrate that the elderly have a significantly higher rate of TBI. In persons over 85 years of age, there were approximately 1,000 cases per 100,000 people [2, 3]. The majority of these injuries are caused by falls [4]. Multiple studies have demonstrated that despite similar injury severity, older patients have worse outcomes than younger patients [5, 6]. Morbidity and mortality from TBI start to increase in the fifth decade of life, but rise sharply after age 70 [7]. It is postulated that elderly patients have worse outcomes due to diminished cardiovascular reserve and fundamental differences in the aging central nervous system (CNS) and its response to injury [6, 7]. Because of this disparity, the literature suggests that age >70 years should be a criterion for full trauma team activation and that those patients should also be considered for transfer to a certified trauma center, regardless of the severity of the actual event [8, 9].

Extra-Axial Hematomas

Extra-axial hematomas are defind as hemorrhages within the intracranial space, but outside of the brain parenchyma. They occur almost exclusively in the setting of trauma and can be either acute or chronic in nature. Extra-axial hematomas that form under the dura mater are termed subdural hematomas (SDH), while those that form above the dura mater are termed epidural hematomas (EDH).

SDH may be caused by a variety of conditions, but they most commonly occur as a result of trauma. In the elderly population, SDHs occur in 46% of TBIs, while in younger patients, they occur in only 28% of TBIs [7]. This is thought to be due to the increased adherence of the dura mater to the inner surface of the elderly skull, which in concert with general cerebral atrophy, results in continuous stretching of the bridging veins that connect the cerebral cortex to the dural sinuses. With the added insult of a trauma, these stretched veins are easily injured, resulting in hemorrhage between the dura and brain, otherwise known as a SDH. The clinical manifestations of SDHs are the result of focal or diffuse pressure on the brain, or chemical irritation of the underlying cortex. Signs and symptoms include headache, nausea/vomiting, diplopia, altered mental status, pupillary dilatation, seizures, dysphasia, and hemiparesis/hemiplegia. Acute SDHs can become rapidly symptomatic as blood accumulates in the subdural space and presses on the underlying brain. Chronic SDHs can accrue over time as the result of multiple episodes of bleeding from repeated small traumas. Often times, they are larger than acute SDHs, however, their signs and symptoms are usually milder because the chronology of their development allows the brain to accommodate the mass effect. On CT scan, all SDHs appear as crescent-shaped extra-axial collections, which may cross suture lines but do not cross midline. Acute SDHs appear hyperdense to adjacent brain tissue on CT scan, while chronic SDHs are hypodense (Fig. 1a, b). Chronic SDHs may also have internal septations visible on the CT scan caused by the formation of membranes. Imaging appearance and symptoms are used to determine the need for surgical evacuation. Any symptomatic acute or chronic SDH needs to be evacuated promptly. In addition, acute SDHs >10 mm in maximal thickness or with >5 mm of midline shift are typically removed, regardless of symptoms [10]. The need for surgical

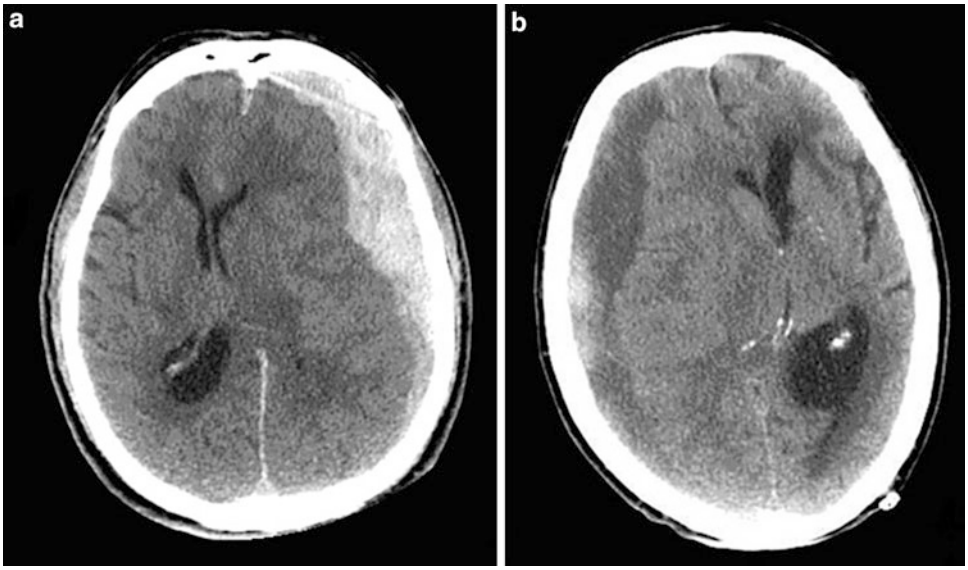

Fig. 1 Noncontrast axial head CTs demonstrate (**a**) acute subdural hematoma – a hyperdense crescent-shaped extra-axial collection and (**b**) chronic subdural hematoma – a hypodense crescent-shaped extra-axial collection. Both of these lesions are causing significant mass effect and resultant shift of midline brain structures

evacuation of large asymptomatic chronic SDHs is less clear. Operative intervention for an acute SDH usually requires a generous craniotomy, evacuation of the hematoma, and control of bleeding. Depending on the degree of underlying parenchymal injury and edema, expansion duroplasty and bone flap removal may be necessary to accommodate swelling of the underlying brain and minimize dangerous increases in intracranial pressure (ICP). Operative intervention for a chronic SDH usually involves burr holes and removal of chronic liquefied hematoma via suction and irrigation, often followed by the placement of temporary postoperative subdural drains. A special consideration in the elderly population is the degree of underlying cerebral atrophy. Because the atrophic brain is often unable to expand and fill the subdural space even after the mass effect has been removed, bridging veins remain under tension and at risk for future traumatic injury, and recurrent chronic SDHs often form. Occasionally, craniotomies are performed for chronic SDHs if there is concern for significant membrane formation and therefore inadequate drainage of the loculated subdural hematoma through one or two burr holes.

EDHs also occur as a result of trauma, but are much less common than SDHs, with an estimated incidence of 2.7–4.1% in TBI patients [10]. The increased adherence of the dura mater to the skull in the elderly serves to tamponade bleeding into the epidural space, thus EDHs are unusual in the geriatric population. When present, EDHs are often associated with skull fractures. Traditionally thought to be of primarily arterial origin, recent studies have indicated that EDHs from venous injuries are quite common as well [10]. Clinically, patients with significant EDHs present with focal and diffuse brain pressure findings similar to those with SDHs. Signs and symptoms include headache, nausea/vomiting, diplopia, altered mental status, pupillary dilatation, seizures, dysphasia, and hemiparesis/hemiplegia. Additionally, some patients present with the classic "lucid interval," an asymptomatic time period immediately following trauma before the onset of symptoms, attributed to the expansion of the hematoma as it slowly dissects between the skull and adherent dura, gradually increasing pressure on the underlying brain. On CT scan, EDHs appear as hyperdense biconvex extra-axial collections, which do not cross suture lines (Fig. 2a, b). Surgical evacuation of the

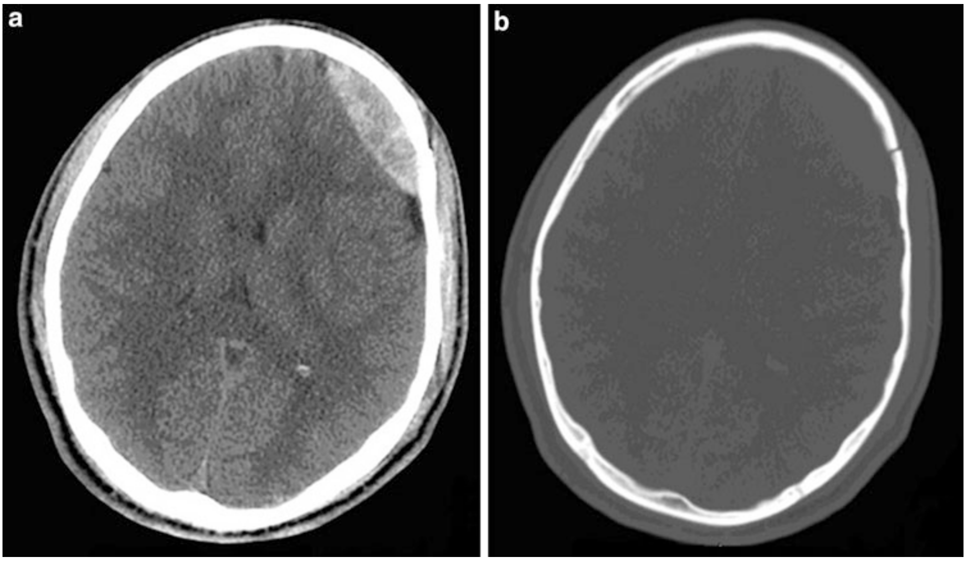

Fig. 2 Noncontrast axial head CTs demonstrate (**a**) acute epidural hematoma – a hyperdense biconvex extra-axial collection and (**b**) in the same patient, a minimally displaced left frontal skull fracture adjacent to the epidural hematoma, the likely cause of the vascular injury producing the hematoma

hematoma is indicated for symptomatic lesions. EDH evacuation usually requires a craniotomy, with or without expansion duroplasty and bone flap removal, based on the extent of the underlying parenchymal injury and edema.

Intracerebral/Subarachnoid Hemorrhage

In addition to extra-axial hematomas, patients with traumatic brain injuries often have intra-axial hemorrhages, either within the parenchyma of the brain or in the subarachnoid space. The management of traumatic intracerebral hemorrhages is similar to that of nontraumatic intracerebral hemorrhages. These lesions appear as hyperdense intra-axial collections on CT, which can vary in diameter from under a millimeter to several centimeters. Initial treatment should focus on blood pressure control, to prevent rebleeding, and management of ICPs. Frequent neurologic examinations should be performed to assess for acute decompensation and serial imaging studies should be performed to evaluate for rebleeding. In the event of elevated ICPs, medical management should be initiated, and in some cases, surgical decompression is required due to the degree of mass effect (Fig. 3) [10, 11].

Subarachnoid hemorrhages are also common sequelae of TBI. Although these hemorrhages seldom require surgical evacuation, they are often associated with seizures, altered mental status, and diffuse axonal injury, all of which can lead to significant morbidity and mortality. On CT, traumatic subarachnoid hemorrhages appear as layered, hyperdense lesions within the subarachnoid spaces, most commonly along the cortical surfaces. Patients with traumatic subarachnoid hemorrhages should be given prophylactic anticonvulsant medications for 7 days posttrauma [12]. Care should be taken in the administration of these medications to the elderly population, as they often have significant side effects including hypotension, cardiac arrhythmias, and confusion. Additionally, for those patients with traumatic subarachnoid hemorrhage and poor neurologic exam in the absence of a focal compressive lesion, placement of an ICP monitor is often required to measure ICPs, which require further management if elevated (Fig. 3) [10, 11].

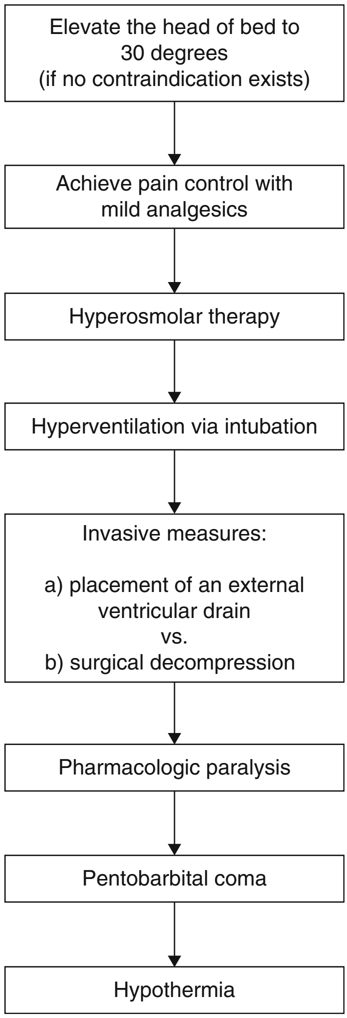

Fig. 3 General schematic for the management of elevated intracranial pressures

Fractures

The skull is a protective layer meant to absorb high-energy forces and to prevent direct intracranial parenchymal injury. In doing so, the skull is also placed at risk for fracture in the event of a significant trauma. Skull fractures can be loosely categorized into four groups: linear, depressed, skull base, and open, each of which has unique management strategies.

Linear fractures are the most common type of skull fracture and are usually the result of low-energy trauma over a large surface area. These fractures are nondisplaced, seldom require surgical intervention and are treated with observation and expectant management [13].

Depressed skull fractures are usually the result of high-energy trauma over a small surface area. Clinically, depressed skull fractures often manifest with seizures, due to an underlying cortical injury, or as an epidural hematoma, due to laceration of a meningeal artery adherent to the skull. Those fractures that are depressed below the inner table of the adjacent normal bone typically require surgical elevation [13].

Skull base fractures occur in the context of severe trauma and can manifest with a variety of neurologic symptoms [13]. Often, skull base fractures are associated with additional intracranial injuries due to the magnitude of the causative trauma. Most significantly, skull base fractures can cause vascular injuries, commonly to the internal carotid arteries, as well as cerebrospinal fluid (CSF) leaks [14–16]. Therefore, all patients with skull base fractures should undergo computerized tomographic angiography (CTA) to rule out vascular injury [14, 15]. Additionally, they should be monitored closely for the evidence of CSF otorrhea or rhinorrhea. Management of vascular injuries should be deferred to an experienced neurovascular team, which includes both neurosurgeons and neurointerventionalists. Management of CSF leaks includes initial conservative treatment with bed rest and head of bed elevation to reduce the hydrostatic pressure gradient and CSF flow across the dural defect, allowing for the body to seal the breach. If the CSF leak persists despite these conservative measures, CSF diversion using a lumbar drain and/or surgical repair are needed to eliminate the leak to prevent bacterial ingress and subsequent meningitis [16].

Open skull fractures are defined as those lesions with an overlying skin laceration, such that there is a communication between the external environment and the intracranial space. These lesions are at particularly high risk for infection [17]. Open skull fractures often demonstrate significant pneumocephalus on imaging due to the abnormal communication with the external environment. Open skull fractures may be classified as either clean or contaminated. All patients with open skull fractures should receive tetanus toxoid, and those with contaminated fractures should also receive prophylactic antibiotics [17]. In most cases, these injuries require operative exploration for wound cleansing, debridement, and closure [13, 17].

Penetrating Trauma

Penetrating brain injury (PBI) refers primarily to gunshot wounds to the head, although all foreign bodies that invade the cranial vault may be included in this group. The management of PBI has undergone fundamental changes since initial descriptions in the early twentieth century, which were based primarily on military injuries. The current literature includes accounts of both civilian and military experiences. The former contains mostly reports of low-velocity injuries and self-inflicted wounds, while the later includes a higher percentage of high-velocity and shrapnel injuries [18]. Regardless of injury etiology, studies of both groups have derived similar conclusions, and current management recommendations are based on Class III evidence from both civilian and military case series [18].

The primary goals in the treatment of PBIs are infection prevention and ICP management. World War I trauma surgeons advocated extensive exploration and debridement of PBIs, with removal of all foreign bodies and bone fragments to decrease the risk of infections and seizures. Subsequent military and civilian studies have indicated that extensive exploration and debridement of PBIs is unnecessary and leads to higher rates of morbidity and mortality [18, 19]. Modern studies have demonstrated that the primary cause of PBI-related infections is a persistent CSF leak [18–20]. As such, during the initial management of a PBI, care should be taken to achieve good local debridement, followed by a watertight dural and scalp closure. Extensive brain debridement should be avoided to prevent injury to normal tissues. Additionally, prophylactic anticonvulsant medications should be given to prevent seizures [18]. Surgical evacuation of large intracranial hematomas may be necessary to manage elevated ICPs, and earlier surgery is associated with better outcomes [18, 21]. Additionally, intraparenchymal or intraventricular ICP monitors are often needed to follow the response to treatment.

Increasing age is associated with poorer outcomes in patients with PBIs [22]. However, given that PBIs are relatively uncommon occurrences, and even more uncommon in the geriatric population, analyses of this association have been somewhat limited [22]. Of the studies which have examined the role of age in outcome from PBIs, two have demonstrated that increasing age is associated with higher mortality [21, 23]. It is likely that many of the same mechanisms which contribute to poor outcomes in the elderly from general TBIs play a role in PBIs.

Nontraumatic Vascular Lesions

Neurovascular lesions constitute a broad spectrum of pathologies, yet common to each of these disease processes is precipitous neurologic decline from disruption of vital bloodflow to brain tissue. Population studies indicate that neurovascular diseases are more prevalent among the elderly [24]. Moreover, the geriatric population appears to fare worse from neurovascular diseases than their younger counterparts [3]. This finding has significantly affected the treatment strategies for the elderly.

Aneurysms

The accepted prevalence of intracranial aneurysms is 5% of the total population, although the prevalence in autopsy series has ranged from 0.2% to 7.9% [25–27]. It is postulated that most intracranial aneurysms develop as a result of combined hypertension, atherosclerosis, cigarette smoking, and congenital predisposition [27]. Most commonly, these lesions develop in the intracranial anterior circulation arterial blood vessels – carotid, anterior cerebral, middle cerebral, anterior communicating, and posterior communicating arteries – although posterior circulation aneurysms of the vertebrobasilar and posterior cerebral arteries account for approximately 15% of all lesions [25]. Ruptured intracranial aneurysms are one of the most devastating and challenging neurosurgical emergencies.

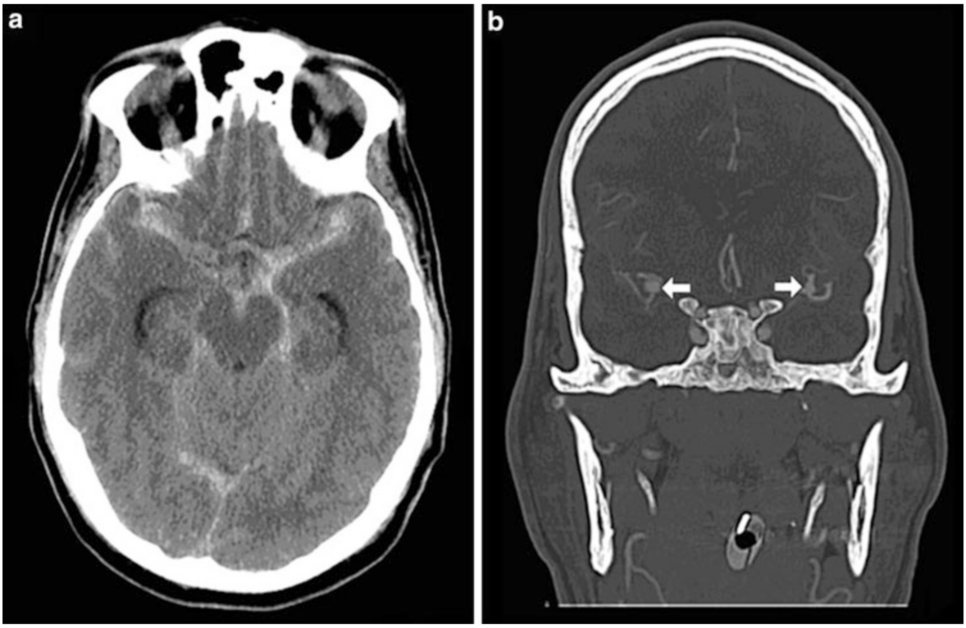

Fig. 4 (**a**) Noncontrast head CT demonstrates diffuse subarachnoid hemorrhage throughout the basal cisterns and bilateral Sylvian fissures, from a ruptured intracranial aneurysm and (**b**) contrast-enhanced cerebral CT angiogram reveals bilateral middle cerebral artery aneurysms (single arrows)

The majority of ruptured intracranial aneurysms cause sudden-onset of worst headache of life, focal neurologic deficits, and symptoms of increased ICPs (nausea, vomiting, headache, and decreased level of consciousness). Brain imaging shows acute subarachnoid hemorrhage (SAH), although intraventricular and intraparenchymal hemorrhages are not uncommon (Fig. 4a, b) [25]. The initial management of these patients focuses on the treatment of elevated ICPs and strict blood pressure control to prevent aneurysm rebleeding [28]. Additionally, the patient must be monitored closely for evidence of neurologic deterioration, which may be indicative of rebleeding, seizures, or hydrocephalus. Systolic blood pressures should be maintained <140 mmHg using short acting, titratable antihypertensive agents, such as labetalol, hydralazine, and nicardipine. However, hypotension must also be avoided as this may lower cerebral perfusion pressure and cause cerebral ischemia. Care should be taken to avoid antihypertensive agents which raise ICPs, such as nitroprusside. If there is clinical evidence for elevated ICPs, these should be treated as previously described (Fig. 3) [10, 11].

The incidence of aneurysmal SAH is 6–8 per 100,000 people in most western populations [25]. Approximately 10–15% of patients with aneurysmal SAH incur fatal brain damage and die before reaching medical care [25]. In the early survivors, the initial aneurysm bleeding stops; however, they have a 15–20% risk of rebleeding in the first 2 weeks post-SAH [28, 29]. The 30-day case fatality rate is approximately 50% [30, 31]. Following acute stabilization, decisions must be made regarding aneurysm repair to prevent future bleeding. Several studies regarding the timing of open surgical treatment have been published; however, no definitive conclusions have been drawn [32–34]. Following aneurysmal SAH, patients may develop cerebral vasospasm, during which blood vessels constrict and reduce blood flow to the brain, causing reversible neurologic deficits, stroke, or death. The prevalence of cerebral vasospasm is greatest between days 4 and 10 post-SAH, and patients who undergo aneurysm repair during this interval fare worse than those treated earlier or later [35]. The primary consideration in opting for early intervention within the first 96 h after aneurysm rupture is to repair the aneurysm and reduce the risk of rebleeding, an event that can cause stroke or death. Many patients are in poor medical and neurological condition after SAH, and may not be stable enough to tolerate aneurysm repair via open surgery or endovascular techniques. Later aneurysm treatment may allow for the improvement of medical and neurological issues, but exposes the patient to a greater risk of rebleeding from the unsecured aneurysm. Currently, the trend is toward early intervention for all patients with aneurysmal SAH, except for those in extremely poor neurological or medical condition.

Intracranial aneurysms may be treated with either open surgical or endovascular techniques [25]. Open surgical treatment involves craniotomy and placement of a small spring-loaded clip across the neck of the aneurysm, isolating the aneurysm from the parent blood vessel while maintaining vital blood flow to the brain. Endovascular treatment involves femoral artery catheterization and deposition of metal coils within the aneurysm, sealing it off from the parent blood vessel. In a randomized trail comparing endovascular treatment with open surgery for patients with aneurysms deemed treatable with either technique, there were 278 patients age 65 or older [36, 37]. Overall neither of the treatments produced better functional outcomes; however, subgroup analyses based on aneurysm location showed that open surgery was superior for middle cerebral artery (MCA) aneurysms and that endovascular treatment was better for internal carotid and posterior communicating artery aneurysms. The generalizability of these findings is limited, since many aneurysms are not equally treatable by open surgery or endovascular techniques. The durability of endovascular repairs has also been questioned [38, 39]. In current practice, the treatment plan is usually decided by a team of neurosurgeons and neurointerventionalists while considering patient condition, aneurysm location, and angioarchitecture. Despite treatment, only ~1/3 of those patients who survive their initial aneurysm rupture will regain a good functional status, while the remaining 2/3 will have significant deficits or die [25]. These outcomes are strongly associated with the patient's admission neurological exam [25, 40].

Historically, patients with aneurysmal SAH and advanced age (>70 years) have been deemed poor candidates for surgical or endovascular treatment [40–44], based on the worse neurological condition of older patients when compared with their younger counterparts [42]. Elderly patients were traditionally treated conservatively, with only medical management of their SAH symptoms. Not surprisingly, this led to very poor outcomes, with the vast majority (>75%) of elderly patients suffering severe morbidity and mortality [40, 43]. Evidence showing improved outcomes in elderly patients who receive surgical or endovascular treatment when compared with medical management [43] has spurred a recent trend toward offering geriatric patients with aneurysmal SAH definitive treatment for their aneurysm. However, it is clear that even with treatment, the geriatric population fares worse than their younger counterparts [42]. Using data from a multicenter randomized trial, it was found that with advancing age, patients have significantly worse admission neurological exams, thicker subarachnoid clots, and higher rates of intraventricular hemorrhage, hydrocephalus, and aneurysm rebleeding [42]. Additionally, older patients have higher incidences of preexisting medical comorbidities [42]. Interestingly, in this study, there were no age-related differences in time to presentation, timing of surgery, aneurysm size and location, or surgical complications. After controlling for the above factors, increasing age was still significantly associated with a poorer outcome [42]. This was thought to be related to the impaired ability of the aging brain to recover from acute stress, as well as the overall diminished cardiovascular reserve in older patients, which can lead to suboptimal cerebral perfusion [6, 42]. As endovascular technology evolves, it is likely that it will be used with increasing frequency in the elderly as a means to mitigate the risk of open surgery while still offering definitive therapy [41]. Regardless, it is clear that geriatric patients have better outcomes with definitive treatment than conservative treatment, although outcomes are worse than those in younger patients.

Vascular Malformations

CNS vascular malformations are congenital vascular lesions that fall into four categories: arteriovenous malformations (AVMs), capillary telangiectasias, venous angiomas, and cavernous malformations [25]. Of these, AVMs are most prone to hemorrhages requiring emergency neurosurgical care and will therefore be the focus of this discussion.

The prevalence of intracranial AVMs is not well known; hospital-based autopsy estimates range from 5 to 613 AVMs per 100,000 persons [45]. Anatomically, AVMs represent abnormal tangles of arteries and veins, with an absence of normal intervening capillary architecture, resulting in high-flow arterio-venous shunting [25, 45]. AVMs are congenital and occur throughout the CNS [45]. Although they may cause a variety of neurologic symptoms, the most common presentation is intracranial hemorrhage (ICH), which is a neurologic emergency (Fig. 5a–c) [25, 46].

The management of AVM-related ICHs begins with strict blood pressure control to prevent rebleeding. Subsequently, if there is evidence of increased ICPs, medical management should be initiated, as previously described (Fig. 3) [10, 11]. If significant mass effect and concern for herniation exists, surgical evacuation of AVM-related ICHs can be performed; however, the surgical approach is much different than that for typical ICHs and is beyond the scope of this discussion. If possible, it is preferable to stabilize the patient medically and treat the AVM in a nonacute setting. Treatment options include open surgical resection, radiosurgery, and endovascular embolization.

Most AVMs are diagnosed at an early age (~35 years), and patients who present with hemorrhage are even younger (~31 years) [45, 47]. Prospective data indicate that the patients at highest risk for future hemorrhages are those who have AVMs with deep locations, exclusively deep venous drainage, and a history of previous AVM-related ICH [48]. Additionally, the risk of future hemorrhages increases with age [48]. Given the rarity of this disease, there are no data on specific or different treatment strategies for the elderly population. However, it is likely elderly patients are more often treated with less invasive methods (i.e., radiosurgery and endovascular embolization) when possible, due to the perceived increased risks of open surgery with advanced age.

Stroke

Cerebrovascular accidents, or strokes, are a leading cause of morbidity and mortality, especially among the elderly [3]. Strokes can be either hemorrhagic or ischemic, both of which constitute

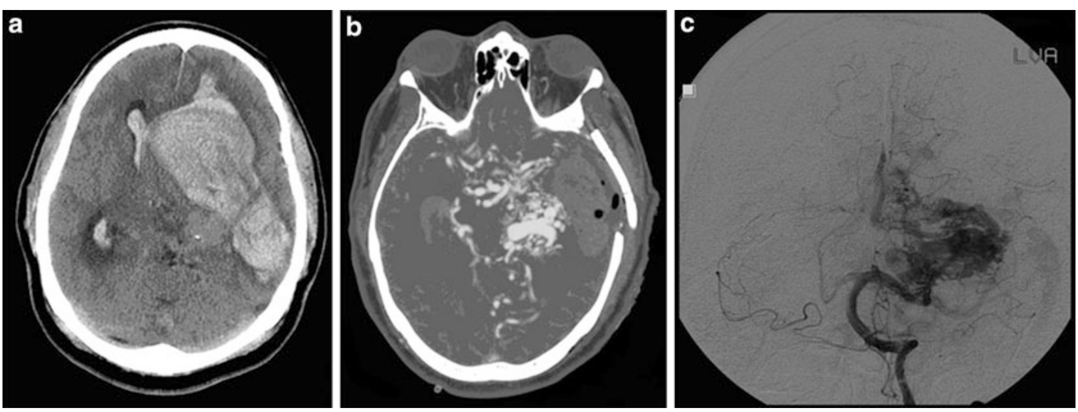

Fig. 5 (**a**) Noncontrast head CT demonstrates a large left fronto-temporo-parietal intracranial hemorrhage with associated intraventricular hemorrhage, mass effect, and midline shift, (**b**) contrast-enhanced cerebral CT angiogram reveals an underlying arterio-venous malformation, and (**c**) cerebral catheter angiogram confirms the presence of a large arterio-venous malformation

neurologic emergencies that may require surgical intervention.

Hemorrhagic strokes affect approximately 10–20 per 100,000 people each year [24, 49]. Although these events are less frequent than ischemic strokes, they have much higher rates of associated death and disability [3]. Specifically, the 1-year mortality rate following hemorrhagic stroke is approximately 62% [24]. The most common risk factor for hemorrhagic stroke is hypertension, which is the focus of this discussion [24]. Amyloid angiopathy is also a significant cause of hemorrhagic stroke and will be discussed in detail later in this chapter. Advancing age, male sex, and alcohol and tobacco use are known risk factors for hypertensive hemorrhagic stroke (HHS). Additionally, blacks have an incidence of HHS that is twice that of whites [24].

HHSs most commonly occur from the rupture of small intracranial perforator arteries in deep regions of the brain (e.g., basal ganglia and brainstem), although cortical and cerebellar hemorrhages occur as well (Fig. 6) [24, 25, 50]. The initial management of HHS patients focuses on strict blood pressure control and treatment of elevated ICPs (Fig. 3) [10, 11]. The INTERACT randomized controlled trial demonstrated that intensive blood pressure control reduces subsequent hematoma growth, although clinical outcome data are lacking [51]. The role of surgical evacuation in the treatment of HHS is controversial. A recent randomized controlled trial (STICH) evaluated the role of early surgical intervention in supratentorial ICHs and determined that there was no overall benefit from early surgery as compared to initial medical management [49]. Given the deep location of many of these hemorrhages and the need to traverse normal intervening brain to evacuate them, it is not surprising that there was no clear benefit with surgical intervention in this study. On the other hand, anecdotal evidence suggests that superficial supratentorial HHSs with significant mass effect may respond well to surgical decompression and therefore these patients should be evaluated on a case-by-case basis with the assistance of a neurosurgical team. Alternatively, HHSs in the cerebellum respond much more favorably to surgical evacuation. Cerebellar hemorrhages have a propensity for early hydrocephalus and brainstem compression [24]. Craniotomy and decompression is the definitive treatment for this process and studies have shown that those patients with large cerebellar hematomas (volume greater than 40 mL) have a clear benefit from surgical intervention [24, 52]. Of note, significant research has also been performed to ascertain the role of recombinant-activated factor VIIa (rFVIIa) in the treatment of acute ICHs, including HHSs. The final results of the phase 3 randomized controlled trial (FAST) demonstrated that although rFVIIa reduces the growth of the hematoma, it does not result in any significant improvements in survival or functional outcome, and therefore, the use of rFVIIa for acute ICHs has not become part of standard practice [53].

Fig. 6 Noncontrast head CT demonstrates an acute basal ganglia hemorrhage with mass effect and intraventricular extension

Ischemic strokes (IS) account for the vast majority of all strokes, with an incidence of 300–500 cases per 100,000 people each year [3]. In general, management of IS should be directed by a neurology team. On rare occasions, IS may require surgical intervention. The role of surgical intervention has been well examined in patients with a “malignant” MCA infarction, where swelling from the damaged brain can cause rapid neurological deterioration and 1-year mortality rates reach up to 80% [54–57]. Several randomized controlled trials (DESTINY, HAMLET, and DECIMAL) have been performed to evaluate the efficacy of early surgical decompression via hemicraniectomy and durotomy, to relieve the mass effect of the infracted and edematous brain [55–57]. The pooled analysis of these trials demonstrates a significant reduction in mortality; however, overall patient morbidity and functional outcomes remain unchanged despite surgical decompression [54]. It should be noted that these trials did not include patients greater than 60 years of age and therefore, surgical intervention in elderly patients should be considered on a case-by-case basis.

Amyloid Angiopathy

Cerebral amyloid angiopathy (CAA) is an important cause of nontraumatic ICH, comprising approximately 10% of all ICHs and 30% of all lobar ICHs [25, 58]. Moreover, this pathology has a predilection for the elderly population, making its review particularly germane to this discussion [25, 58]. CAA is characterized by the deposition of beta-amyloid, a fibrillar protein, in the media and adventitia of small- and medium-sized arteries [25, 58]. The exact prevalence of CAA is difficult to determine due to the lack of definitive histopathology in most cases; however, it is well known that the prevalence of CAA increases with age and it is rarely identified in those less than 55 years of age [58]. CAA has an equal predilection for both sexes. Approximately 1/3 of people greater than 60 years of age have evidence of CAA on autopsy, and in individuals over 90 years of age, the prevalence of CAA exceeds 60% [58]. Studies have also demonstrated that those individuals who possess the E2 and E4 alleles of the apolipoprotein E gene have a significantly increased risk of developing CAA [25, 58].

Although CAA can cause progressive dementia, transient ischemic attacks, seizures, and ischemic stroke, arguably the most concerning manifestation is ICH, caused by the rupture of amyloid-laden vasculature [25, 58]. These hemorrhages are most frequently lobar and can be multifocal [25, 58].

The management of ICHs due to CAA is not significantly different from the management of hypertensive ICHs. Most hemorrhages do not require surgical intervention; however, if significant mass effect and neurologic deficits exist, craniotomy for evacuation and decompression can be considered. Unlike cerebral aneurysms and AVMs, ICHs due to CAA do not require treatment of a discrete, underlying vascular abnormality. Although the vasculature is altered in patients with CAA, it does not require unique surgical maneuvers to control bleeding. In contrast with ICHs due to hypertension, CAA-associated ICHs are typically more superficial and therefore more amenable to surgical intervention [25, 58]. Although no specific pharmacotherapy exists for the treatment of CAA, there is ongoing research into the development of antiamyloid medications and vaccinations [58]. Additionally, as discussed above, the use of rFVIIa has not resulted in a significant clinical benefit in this patient population [53].

Adverse Drug Reactions

As the population ages, the use of antiplatelet and anticoagulant medications such as aspirin, clopidogrel, and warfarin, has increased dramatically. Protocols for managing patients with acute ischemic stroke using thrombolytic therapies, such as intravenous and intraarterial tissue plasminogen activator (tPA), have become more common [59]. Traditional guidelines recommend administration of tPA within 3 h of onset of stroke symptoms; however, many stroke centers now aim to administer tPA in an urgent fashion, within 60 min of onset of symptoms, for embolic stroke [59]. Given the potency of these medications, it is not surprising that some of their primary side effects include undesired bleeding, including ICHs [60, 61]. Patients who receive tPA and have early hypodensities on CT have significantly higher rates of ICH [62]. Patients who develop ICHs secondary to antiplatelet or anticoagulant therapies should have the offending medications discontinued immediately, followed by reversal of the platelet dysfunction and/or anticoagulation with the appropriate blood products and/or medications. The remainder of their management should follow that of other nontraumatic ICHs; strict blood pressure control should be employed and surgical decompression considered on a case-by-case basis for those patients with significant mass effect. In a study of surgical evacuation of ICH following administration of streptokinase for acute myocardial infarction, surgery was beneficial, although survival was dependent upon the time from the initiation of thrombolytic therapy to onset of stroke symptoms, initial Glasgow coma scale score, volume of ICH, and "baseline clinical characteristics" (defined as age, systolic blood pressure, Killip class, heart rate, infarct location, previous myocardial infarction, height, time to treatment, history of smoking, current smoking, diabetes, weight, history of coronary bypass surgery, type of thrombolytic agent, history of hypertension, and history of cerebrovascular disease) [63]. Importantly, all patients who are started on antiplatelet and anticoagulant medications should be counseled about the potential risk of ICH.

Sinus Thrombosis

Intracranial venous sinus thrombosis (VST) is a relatively rare condition that constitutes a neurologic emergency. There are several factors which predispose individuals to developing VSTs, including: a hypercoagulable state, dehydration, adjacent tumor or infection, pregnancy, vasculitis, systemic inflammatory disorders, and local trauma [25, 64]. Although most intracranial VSTs become evident through headache and other symptoms of increased ICPs, a significant portion of patients develop seizures, intracranial infarcts, ICHs, or focal motor deficits [25, 64]. VSTs cause venous outflow obstruction and subsequent parenchymal edema and infarction [25, 64]. The primary goal in the treatment of VSTs is the prevention of thrombus propagation while allowing for natural thrombolysis and recanalization of the affected vessel. This is achieved with anticoagulation and is typically managed by a neurology team [25, 64]. However, endovascular thrombolysis of the clot/affected vessel using pharmacologic and mechanical techniques is sometimes indicated, and in cases with large ICHs, surgical decompression and evacuation is occasionally performed [64]. As compared to intracranial arterial thromboses, VSTs have an overall better prognosis [64]. In the largest series to date of patients with VSTs, there was a 13% rate of death or dependence at 6 months after ictus [64]. Risk factors associated with poor outcome include advancing age, male sex, altered mental status on admission, deep cerebral venous system thrombosis, ICH, malignancy, and CNS infection [64].

Infection

Infections of the CNS are neurological emergencies, which must be treated in a timely fashion. Generally, CNS infections can be categorized by their location: meningeal, subdural, epidural, intraparenchymal, and intraventricular. Most CNS infections have bacterial, viral, or fungal etiologies; this discussion will focus on bacterial infections, as these most commonly require surgical intervention. Additionally, this discussion will be limited to intracranial CNS infections; a review of spinal CNS infections can be found in Chap. 87, "Benign and Malignant Tumors of the Brain".

Infections of the meninges, also known as meningitis, are the most common intracranial CNS infection [25]. Patients typically develop fever, headache, neck stiffness, photophobia, and malaise. Contrast-enhanced imaging studies often reveal diffuse meningeal enhancement, and CSF analysis demonstrates elevations in the nucleated white blood cell count. As meningitis is most often managed medically, without the need for surgical intervention, further discussion of its management is beyond the scope of this discussion.

Infections of the epidural space, also known as epidural abscesses (EA), comprise approximately 2% of intracranial CNS infections [65]. These infections present with fever, headache, neck stiffness, photophobia, periorbital swelling, scalp tenderness, ear pain, nausea, vomiting, and lethargy. Imaging studies reveal an extra-axial, biconvex lesion with peripheral enhancement. Imaging studies may also reveal evidence of underlying osteomyelitis, sinusitis, or mastoiditis. Cranial EAs typically occur via direct extension of an adjacent sinusitis, although they may also be the result of hematogeneous spread from infections located throughout the body. They most commonly occur in adolescent males, though all age groups may be affected [65]. Treatment of cranial EAs involves surgical evacuation, followed by prolonged antibiotic therapy. If the adjacent bone appears to be involved, it must also be debrided and/or removed [65]. The most commonly isolated organisms in cranial EAs are microaerophilic or hemolytic streptococci; however, staphylococci may also be involved in cases of postoperative or posttraumatic infections [65].

Subdural infections, also known as subdural empyemas (SE), occur in 12–25% of intracranial CNS infections [65]. These infections present similarly to cranial EAs; however, focal neurologic deficits are more common given the direct contact with the cortical surface [65, 66]. Imaging studies reveal extra-axial, crescent-shaped collections with peripheral enhancement. As with cranial EAs, there is often evidence of adjacent osteomyelitis, sinusitis, or mastoiditis. Intracranial SEs typically occur in the setting of sinusitis, via direct extension or hematogenous spread, but may also occur as a result of trauma or neurosurgical intervention [65, 66]. Treatment involves prompt surgical evacuation, followed by prolonged antibiotic therapy [65, 66]. The most commonly isolated organisms in intracranial SEs are aerobic and anaerobic streptococci species, as well as staphylococci species [65, 66].

Intraparenchymal intracranial CNS infections, also known as brain abscesses (BA), are occurring with increasing frequency as the prevalence of immunocompromised individuals rises [65]. These infections cause fevers, headache, meningismus, malaise, seizures, and focal neurologic deficits – and they most often have a rapid progression of symptoms. On contrasted imaging studies, BAs appear as intra-axial lesions with marked peripheral enhancement and restricted diffusion on MRI (Fig. 7a–c). They can occur in the setting of sinusitis and mastoiditis, but are also commonly the result of bacteremia in the setting of congenital heart defects, bacterial endocarditis, dental abscesses, pulmonary infections, and acute diverticulitis [65]. Treatment consists of abscess drainage, often with the use of intra-operative stereotactic navigation systems, followed by prolonged antibiotic therapy [65]. The most commonly isolated organisms include aerobic and anaerobic streptococci and bacteroides species, staphylococci species, and fungal organisms in the immunocompromised [65].

Intraventricular CNS infections are rare entities. They commonly cause signs and symptoms of obstructive hydrocephalus: headache, nausea, vomiting, lethargy, and coma [25, 65]. Most often, intraventricular infections are caused by parasites (i.e., neurocysticercosis) [25]. Imaging studies reveal an intraventricular mass with a variable enhancement pattern and evidence of obstructive hydrocephalus. Surgical management of these lesions is usually curative. Medical management using antihehninthics remains controversial and should be discussed with an infectious disease specialist [25]. Of note, bacterial ventriculitis may also develop in the setting of a prolonged intracranial bacterial infection. As with intraventricular parasitic infections, individuals with bacterial ventriculitis typically develop symptoms of hydrocephalus. Imaging studies reveal diffusely enhancing ventricular walls. Management includes CSF diversion for elevated ICPs and prolonged antibiotic therapy.

With the exception of meningitis, most CNS infections require neurosurgical intervention. Risks of prolonged, untreated CNS infections include VST, osteomyelitis, hydrocephalus, seizures, and catastrophic intraventricular BA rupture. Importantly, in the management and initial work- up of CNS infections, lumbar puncture is often considered. Although this can be performed safely in most patients with simple meningitis, for those patients with intracranial mass lesions,

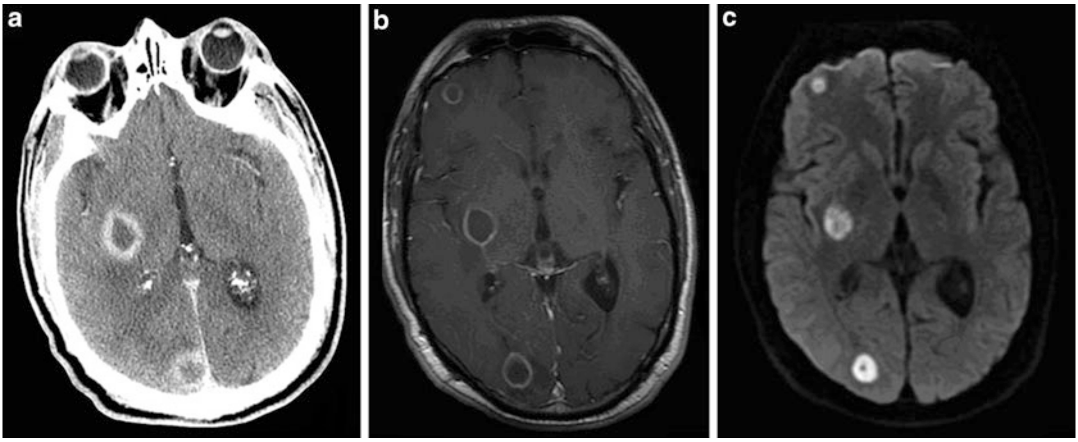

Fig. 7 (**a**) Contrast-enhanced head CT demonstrates multiple hypodense ring-enhancing lesions, (**b**) T1-weighted contrast-enhanced brain MRI demonstrates multiple hypodense ring-enhancing lesions with surrounding edema, and (**c**) diffusion-weighted brain MRI reveals restricted diffusion throughout the enhancing lesions, consistent with multiple brain abscesses

lumbar puncture should be deferred due to the risk of causing cerebral herniation [25]. Additionally, significant controversy exists regarding the use of steroids in the context of CNS infections [25]. This issue is best dealt with on a case-by-case basis, after careful review of the particular clinical scenario.

Most CNS infections tend to occur in the young; however, the elderly population deserves special consideration for several reasons. First, geriatric patients often have nonspecific signs and symptoms in the setting of infection [3, 67]. This increases the need for vigilant physical examination and CNS imaging studies in this population. Additionally, the elderly population has a relative immunosenescence, therefore, their clinical course and response to therapy may be worse than a younger counterpart with a similar illness [67]. Finally, the elderly tend to have more frequent and more severe adverse drug effects, especially from antibiotics, and this should be taken into account when choosing the appropriate drug regimen [67].

Peripheral Nerve Injury

Traumatic peripheral nerve injuries (PNIs) are relatively rare occurrences and are treated by a variety of specialists, including neurosurgeons, plastic surgeons, and orthopedic surgeons [68, 69]. Despite their rarity, PNIs can result in devastating functional loss and represent an important neurologic emergency. Clinically, they typically present in the setting of trauma with neurologic deficit confined to a single extremity [70]. PNIs often occur in tandem with bony fractures and peripheral vascular injuries [70]. Traumatic PNIs can be loosely categorized into three broad groups based on mechanism: stretch/avulsion injuries, lacerating injuries, and compressive injuries [71].

Stretch and avulsion injuries are the most common types of PNI [70, 71]. They are usually the result of motor vehicle accidents in which the torsional force of impact results in the movement of an extremity in one direction and the patient's trunk in another [70]. This results in a stretching of nerve roots, which, if severe enough, can cause complete nerve root avulsion from the spinal cord. Spinal imaging studies may reveal pseudomeningoceles indicative of dural nerve root sleeve disruption and adjacent soft tissue injury. Penetrating and lacerating PNIs typically occur as a result of gunshot and knife wounds. They are the second most common type of PNI and are often associated with injuries of adjacent vascular structures [70, 71]. These injuries are usually discovered on physical exam, as the external signs of trauma can be quite obvious. Compressive PNIs often occur as a result of local hematomas, soft tissue swelling, and bony hypertrophy. They cause indirect neural injury via external compression [71].

Operative interventions for PNIs vary widely based on the mechanism of injury, extent of neurologic deficit, presence of additional injuries, and surgeon preference [72, 73]. Surgical interventions may involve decompression, direct repair, removal of neuromas, and nerve grafting or transposition [72, 74]. Nearly all interventions employ the use of pre- and post-operative electromyography, and intraoperative nerve action potential and somatosensory evoked potential recordings [72]. Given the increased incidence of osteoporosis and bony fractures in the elderly, it is likely that they are at increased risk for PNIs in the setting of trauma. Therefore, since early identification of PNIs can maximize the potential for a functional recovery, it is imperative that elderly patients undergo complete neurologic examination as part of their trauma evaluation.

Tumors

Intracranial primary or metastatic tumors can cause medical emergencies via mass effect from tumor growth, edema in the surrounding brain, intratumoral hemorrhage, or seizures. Initial management should focus on the treatment of elevated ICP symptoms, blood pressure control, and seizure cessation. Further discussion of these lesions can be found in Chap. 87, "Benign and Malignant Tumors of the Brain".

Conclusions

Geriatric neurosurgical emergencies encompass a broad range of pathologies. Elderly patients have unique treatment challenges that must be accounted for by healthcare providers. The loss of cardiovascular reserve and the fundamental changes within the aging CNS appear to play a significant role in morbidity and mortality and should be carefully considered when treating and counseling geriatric patients with neurosurgical illnesses.

Case Study

History

An 82-year-old male, with multiple medical problems, seeks medical attention after the acute onset of worst headache of life. He also notes nausea, photophobia, and neck pain. He denies trauma, numbness, weakness, tingling, seizures, chest pain, and shortness of breath. A noncontrast head CT (Fig. 8a) is obtained and the patient is subsequently transferred to a tertiary care center. During transfer, the patient is noted to become progressively lethargic.

Past Medical History

1. Hypertension
2. Coronary artery disease
3. Chronic renal failure
4. Type II diabetes mellitus
5. Atrial fibrillation

Admission Neurologic Examination

Temp: 99.1 degrees Fahrenheit, HR: 70 beats per minute, BP: 160/70 mmHg, RR: 10 breaths per minute, O_2, Sat: 98% on 4 liters nasal cannula

Lethargic, nonverbal

Opens eyes to noxious stimuli

Pupils equally round and reactive to light, bilaterally

Moving all extremities symmetrically, not following commands

Localizes to noxious stimuli

Unable to assess sensory function

2+ deep tendon reflexes throughout

Toes downgoing, bilaterally

Relevant Admission Laboratory Values

Na: 138

Troponin-I: 0.40

WBC: 8.9 k

PLT: 228 k

INR: 2.8

(continued)

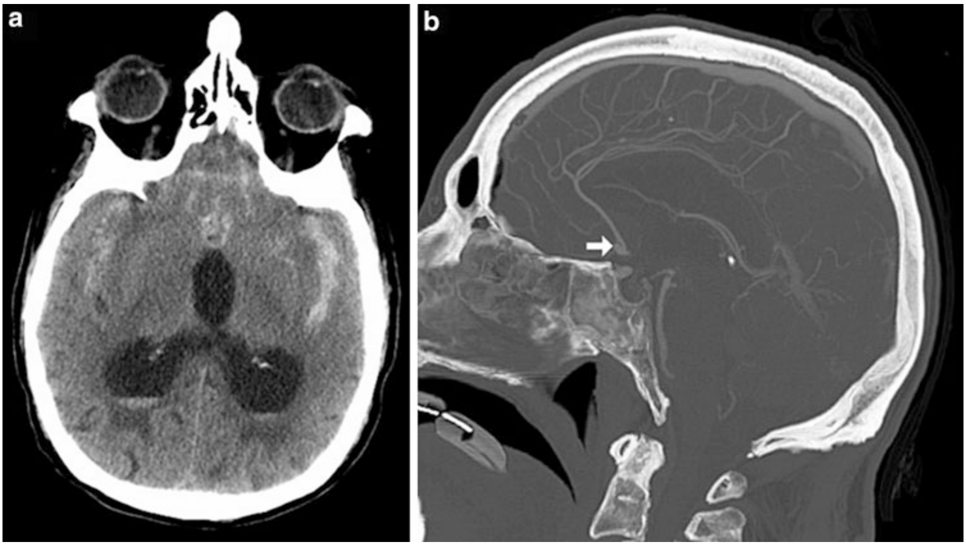

Fig. 8 (**a**) Noncontrast head CT demonstrates diffuse subarachnoid hemorrhage involving the bilateral Sylvian fissures as well as intraventricular hemorrhage and hydrocephalus and (**b**) contrast-enhanced cerebral CT angiogram reveals an anterior communicating artery aneurysm (single arrow)

Clinical Course

Upon arrival to the tertiary care center, the patient is intubated for airway protection. Subsequently, he is treated for hypertension and his systolic blood pressure is maintained below 140 mmHg. He is also given 1 g of IV phenytoin for seizure prophylaxis and 6 U of fresh frozen plasma to normalize coagulation. A cerebral CT angiogram is obtained (Fig. 8b), which demonstrates an anterior communicating artery aneurysm. The patient is transferred to the intensive care unit. His head of bed is elevated to 30°, he is sedated and hyperventilated, and a ventriculostomy catheter is placed to decompress hydrocephalus and manage elevated intracranial pressures. The patient's examination improves over the next 24 h; specifically, he begins to follow commands. An echocardiogram is obtained because of the abnormally elevated cardiac enzymes. The patient is found to have an ejection fraction of 35%. A family discussion is held regarding the risks and benefits of treatment and the decision is made to pursue endovascular therapy. The following day, the patient is taken to the angiography suite where he undergoes successful coil embolization of his intracranial aneurysm. Over the next 2 weeks, he is monitored carefully in the intensive care unit for evidence of vasospasm. His hydrocephalus resolves during this time and the ventriculostomy catheter is discontinued. His neurologic exam slowly improves, although his cognitive function appears somewhat diminished to his family members. He is extubated successfully. His ejection fraction also improves to 45% over this time period. He is later transferred to the floor and subsequently to a rehabilitation facility.

Discussion Questions

1. What are the most important initial measures that should be taken when caring for a patient with a ruptured intracranial aneurysm?

(continued)

2. What are the possible etiologies of the patient's change in mental status during transfer to the tertiary care facility?
3. What is the clinical and operative significance of the elevated cardiac enzymes on admission?
4. What is the current standard of care for treatment of ruptured intracranial aneurysms in the elderly?

Discussion Answers

1. The most important initial measures to be taken when caring for a patient with a ruptured intracranial aneurysm include: strict blood pressure control, administration of prophylactic anticonvulsant medications, and management of elevated intracranial pressures, if present.
2. Possible etiologies of the patient's change in mental status during transfer include: aneurysm rebleeding, hydrocephalus, and seizure.
3. Elevated cardiac enzymes in the setting of subarachnoid hemorrhage are associated with an increased risk of cardiogenic shock, pulmonary edema, and cerebral vasospasm. Elevated cardiac enzymes are also associated with higher rates of death and severe disability following aneurysmal subarachnoid hemorrhage. Therefore, when caring for patients with elevated cardiac enzymes, careful attention should be paid to optimizing their cardiopulmonary status. Moreover, in the setting of acutely elevated cardiac enzymes, it is often more judicious to treat patients with less invasive procedures (i.e., endovascular treatments) as opposed to maximally invasive procedures (i.e., open surgery), in order to minimize the degree of cardiac stress.
4. The current standard of care for treatment of ruptured intracranial aneurysms in the elderly is definitive surgical or endovascular repair in order to secure the aneurysm and prevent rebleeding. Aneurysm location, size, and configuration will often determine whether open surgery or endovascular techniques are the optimal approach to aneurysm repair. However, the patient's overall systemic health should be evaluated, and if significant comorbidities exist, strong consideration should be given to less invasive endovascular procedures, even if open surgery might provide a more definitive repair. Previously, elderly patients were treated with conservative, medical management without aneurysm repair. However, longterm studies have demonstrated that elderly patients have significantly better outcomes with definitive management and thus, this has become the standard of care. Nonetheless, elderly patients still fare worse than their younger counterparts, and as such, providers should have an open discourse with the patient and their family to discuss the potential need for longterm hospitalization, rehabilitation, and home care, so that treatment plans are made in accordance with the patient's wishes.

33 Anatomic and Physiologic Changes in the Ears, Nose, and Throat

Ara A. Chalian and Karthik Rajasekaran

Contents

Abstract

Physiological and anatomical changes with age in the ears, nose, and throat have long been the subject of clinical interest; increasingly, they are the subject of basic and clinical investigations [1–6]. Nonetheless, the role of alterations in cells and tissues and distinctions among genetic, pathological, environmental, and interactive effects on cellular, tissue, and organ functions are still emerging [3, 7–12]. Currently, presbycusis, presbystasis,

presbyosmia, presbylarynx, and presbyphonia are the terms used to denote the functionally and clinically apparent manifestations of aging changes in the ears, nose, and throat [1, 2, 13–15]. Presbyvertigo has also been proposed as a relevant term for matters of dizziness and falls in older adults though presbystasis is more commonly used [15, 16]. Notably, presbypharynx is, while being a parallel term to represent the manifestations of aging changes in the anatomy and physiology of the pharynx, not used in current literature. Instead, various uses of senescent swallowing and dysphagia predominate in the literature [17, 18].

Introduction

Research into conditions of the aging ears, nose, and throat offers a disparate and inconsistent body of evidence that connects aspects of the biology of aging, anatomy and histology, and functional changes. Related clinical literature has developed differentially, often relying on clinical observation and correlative science as well as treatment experience and case series reports. The magnitude of applicable science specific to the ears, nose, and throat varies by organ and senescent function. Similarly, the quality and quantity of translational science is inconsistent. Presbycusis is, for example, well studied with science that illuminates functional effects and clinical pearls [1, 19]. Conversely, presbyphonia and presbylarynx are only recently receiving significant attention in basic and clinical science [14]. Evenwith growing evidence ofmechanisms, processes, and effects, direct translation of this evidence to care of the older surgical patient remains limited. Application thus requires careful review and interpretation.

This chapter describes important known anatomical and physiological changes with aging in the ear, nose, and throat. Each organ is addressed separately with focus on relevant changes in organ anatomy and physiology, and the chapter highlights alterations in function that result in presbycusis, presbystasis, presbyosmia, presbylarynx and presbyphonia, and senescent oropharyngeal anatomy and physiology, respectively. The sections detailing functional conditions of aging conclude with a brief summary of clinical surgical considerations. The chapter concludes with a summary of highlights.

The Aging Ear

Auditory Anatomy and Physiology

Targeted review of the anatomy and physiology of the ear predicates understanding presbycusis and presbystasis and their impact on function and implications for surgical care [1, 2, 20]. This section reviews in sequence the anatomy of the ear and aspects of physiology relevant to understanding presbycusis and presbystasis.

External Ear

The external ear, from the pinna through ear canal to tympanic membrane, captures and intensifies sound in the 2–5 KHz range – frequencies in much of human speech – by acting as a resonator [13, 21] (see Fig. 1). These external structures change with advancing age. Importantly, cartilage collapses, resulting in somewhat deceptive appearance of larger ears for many elders. Further, the tympanic membrane and the ossicular chain in the middle ear stiffen, though the functional impact is minor. The conductive aspects of hearing promoted by these structures do not change appreciably with age [22] (see Fig. 2). Instead, concerns that are cosmetic and mildly distressing emerge, including larger pinna size, more apparent cerumen production, and growth of excessive hair in the pinna. Cerumen and hair growth often result in complaints of pruritus. While these matters may seem minor, they may influence acceptance and use of hearing aids as well as prove distressing to some older adults as they consider changes in appearance.

Middle Ear

Sound perception begins with vibration of the ossicular chain [23, 24] (see Figs. 2 and 3). The tympanic membrane and the ossicles (viz., malleus, incus, and stapes) are fairly resistant to aging

changes unlike larger skeletal bones. Thus, age-related considerations and functional impact here are minor if they are present at all [23, 24].

Cochlea

The cochlea is the anterior portion of the inner ear, called the bony labyrinth, which also contains the vestibule and the semicircular canals [13] (see Fig. 4). This hollow bone contains the neuro-epithelium for auditory perception (cochlea) and balance perception (vestibule and semicircular canals) [16]. This section addresses aging changes in the cochlea and the resultant condition of presbycusis. Alterations in the vestibule and semicircular canals are discussed in a following section to explicate presbystasis as a separate condition of aging in the ear.

A membranous canal, known as the cochlear duct, wraps around a central bony core, the modiolus, for two and a half to two and three-quarters turns through which the auditory nerve fibers penetrate [22] (see Figs. 5 and 6). The cochlear duct is divided into three compartments: the scala tympani, scala media, and scala vestibule (see Fig. 7). The scala media has a fluid composition (endolymph) different from that of the other two compartments (perilymph) and contains the organ of Corti, which is the sensory organ of hearing [22] (see Fig. 5). The organ of Corti rests on the basilar membrane, which separates the scala media from the scala tympani (see Fig. 6). The organ of Corti contains afferent nerve endings (about 3,500 inner hair cells), afferent/efferent nerve endings (approximately 12,000

outer hair cells), and a variety of other supporting cells. The hair cells communicate with the dendritic terminals of the bipolar cochlear neurons whose cell bodies are located within the modiolus. The hair cells serve as mechanoreceptors, converting the mechanical energy of basilar membrane displacement into an action potential to stimulate the ganglion cells. The cochlea's capacity to analyze periodicity, synchrony rate, phase, and spread of excitation of sound results in specific ganglion cell population stimulation and ultimately the perception of sound frequency patterns in the auditory cortex. The normal function of the cochlea occurs as sound energy in the form of vibrations reaches the oval window; the basilar membrane is set into motion and vibrates. The stereocilia of the hair cells on the basement membrane move and increase the permeability of the hair cell to potassium that depolarizes the hair cell (see Fig. 8).

A neurotransmitter is released by the hair cell onto the afferent ending of the cochlear nerve leading to a neurological signal [23]. Cochlear changes with advancing age result in presbycusis [13, 25]. Among the most significant alterations in anatomy and physiology include atrophy in the organ of Corti, vascular changes that affect the stria vascularis, and collapse of the cochlear duct [26,

27]. These changes lead to hair cell loss, neural fiber degeneration, and reduction in number of synapses at the base of the hair cells [25]. Accumulation of cochlear debris in the spiral bundles, abnormalities of the dendritic fibers and their sheaths in the osseous spiral lamina, and degenerative changes in the spiral ganglion cells and axons follow.

Auditory Nerve

The auditory nerve consists of about 30,000 afferent and 1,000 efferent bipolar neurons [22]. Ninety-five percent of the spiral ganglion is composed of myelinated (type 1) fibers that innervate only inner hair cells and nonmyelinated (type 2) fibers that innervate outer hair cells. The spiral ganglion is the densest at the mid and basal portions of the modiolus. The nerve fibers course in the nerve trunk in an orderly spatial arrangement (basal fibers located at the periphery and inferior portion of the nerve) through the temporal bone into the cerebellopontine angle into the pons to enter the cochlear nuclei [21].

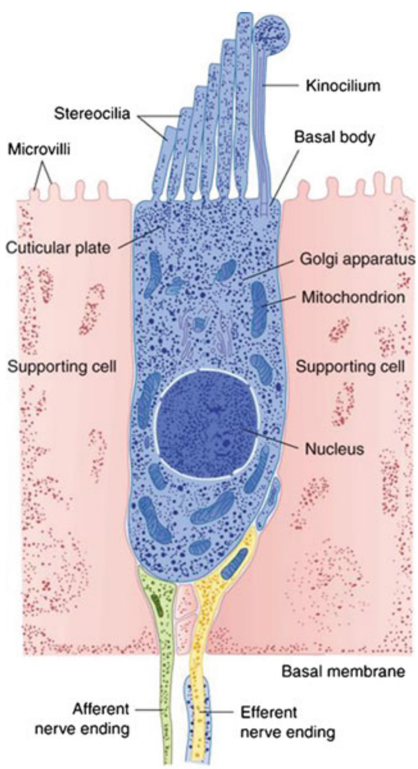

Fig. 8 A hair cell. (Reprinted from Waxman SG. Clinical neuroanatomy, 26th edn, with permission from McGraw Hill Companies)

Central Auditory Processing

Central auditory processing involves the cochlear nerve, the cochlear nuclei, and the auditory cerebral cortical regions [28]. Through this process, the neuronal signal is appreciated as sound and interpreted by the cognitive regions of the brain to recognize content [29]. The process is bilateral. Three morphologically distinct auditory nuclei are appreciated within the pons. Upon entering the pons, each fiber divides into an anterior branch, which terminates in the anterior part of the ventral cochlear nucleus, and a posterior branch, which again divides to terminate in the posterior part of the ventral cochlear nucleus and the dorsal cochlear nucleus.

Cells from these nuclei send axons in a complex pattern from the contralateral superior and accessory olive areas to the lateral lemniscus, the inferior colliculus, and through the medial geniculate body to the auditory cortex in the temporal lobe [21]. Aging results in decrease in neurons in the cochlear nuclei and auditory centers [29]. Neurons decrease in size as well, thus altering their physiology. Diseases and injuries that alter brain anatomy and physiology – such as cerebral atherosclerosis and stroke or mild cognitive impairment and dementia – may further alter central auditory processing [29]. Changes in central auditory processing account for complaints in hearing that exceed that anticipated by the audiogram [30]. These changes are manifest in limited auditory comprehension in noisy environments and in failure of simple amplification through hearing aids to remedy complaints of dysfunction [30]. The effects of normal brain aging on central auditory processing are a focus of dedicated current investigation [19, 31–33].

Auditory Function

Changes in auditory function resulting in hearing impairment associated with aging are termed presbycusis, a prevalent and disabling condition [13]. Presbycusis results largely from aging changes in the inner ear and is a form of sensorineural hearing loss. Subtypes, however, can be detected on audiogram though the differences are likely to be functionally undetectable. They are sensory, neural, strial, and cochlear conductive presbycuses [13]. Conductive hearing loss per se does not play a role in presbycusis. Early presbycusis affects high-frequency range, beyond the frequency characteristics of the human voice [13]. Thus, early alterations in function are often imperceptible to older adults. With advancing age, hearing loss encroaches on the speech frequencies. Impairment then becomes consequential in daily activities. Despite the expectation of presbycusis, hearing loss among older adults is often multifactorial. The contribution of central auditory processing changes, along with the influence of genetics and family history of congenital hearing loss, cumulative environmental damage through occupational or leisure exposure, and the use of ototoxic drugs should be considered [21, 34]. In fact, there are over 130 drugs and chemicals that have been reported to be potentially ototoxic [34]. Aminoglycosides and some chemotherapeutic agents are commonly identified as ototoxic medications. Additionally, other drug classes such as loop diuretics and beta-blockers may damage auditory function, albeit in a manner that may be reversible [21].

Clinical Implications

Presbycusis, while seemingly peripherally related to surgical care, has direct impact on all processes of care from decision-making through perioperative care to self-care after surgery. Gates and colleagues [35] suggest the simple screening question "Do you have a hearing problem now?" as the means to assess for impairment that results in disabling limitations in function. There are also screening tools that have been developed that provide a standardization of self-assessment for hearing screening of the elderly [36, 37]. In elective surgeries, opportunity to refer for otolaryngologic assessment and clinical audiometric testing should result in improved interdisciplinary care. Emergent surgical care, conversely, requires anticipation of problems that require compensation including decision-making, patient and family education, and postoperative care and the risk of reactions to the environment of care. Importantly, those older adults who wear hearing aids require additional support as their presbycusis may be inadequately corrected and central auditory processing problems unaddressed.

Vestibular Anatomy and Physiology

The vestibule is composed of three semicircular canals, the portions of the inner ear that are responsible for balance (see Fig. 5). The canals are posterior, superior, and horizontal, accounting for the dimensions in which the body is positioned in the physical environment of space [22]. The otolithic organs are the utricle and the saccule; they are structured to respond to linear acceleration of the body in space [21, 22]. The macula is the sensory portion of the utricle and the saccule. Type II hair cells are those that function in the vestibule (see Fig. 8). These cells are cylindrical with efferent and afferent synapses. Each type II hair cell contains approximately 50–100 stereocilia and 1 kinocilium. The kinocilium is located on one end of the hair cell, imparting anatomical polarization. Movement of the hair bundle toward the kinocilium causes an increase in the firing rate of the hair cell, while deflecting away causes a decrease in the firing rate. In the lateral semicircular canal, the kinocilium is located near the utricle [22, 26]. The opposite is true in the superior and posterior semicircular canals (see Fig. 5). Cilia extend from hair cells to touch the statoconial membrane. It has a gelatinous consistency with calcareous particles embedded in that gelatinous layer. The surrounding endolymph has a lower specific gravity, and hence when the body accelerates, the hair cells of the macula are triggered. The central section of the statoconial membrane is called the striola. In the utricle, the hair cells are toward the striola. In the saccule, they are oriented away from the striola, again accounting for spatial dimension and direction of movement.

The bipolar vestibular neurons create the inferior and superior vestibular neurons that merge when entering the brain stem [22, 26]. The vestibule is supplied by the labyrinthine artery.

The vestibular system senses linear and angular acceleration of the body. The semicircular canals sense angular acceleration, while the otoliths sense linear acceleration. This system also coordinates eye-head movement. The vestibulo-ocular reflex enables focus on an object (see Fig. 9). The vestibule-spinal reflex accounts for postural placement of the body. Together, these physiological functions contribute to a sense of the body in space [38]. Together with visual sensation and peripheral nervous system sensation in the feet, the vestibular reflexes create the complex sensory-perceptual system of proprioception [38]. Vestibular changes with age include alterations in the otoconia and in the hair cells [8, 15, 39, 40]. Atherosclerosis in the vascular supply and decline in the number of neurons in the vestibule further contribute to dysfunction and to altered vestibule-ocular and vestibule-spinal reflexes. Nevertheless, direct observation of the actual dysfunction is not possible given current assessment technology. Thus, clinical assessment relies on diagnosis by exclusion, employing means of inference including the caloric reflex test and other forms of electronystagmography [7, 15]. These tests attribute vestibular function through manipulation of the vestibulo-ocular and the vestibulo-spinal reflexes and may create acute discomfort for patients [41].

Vestibular Function

Presbystasis is the condition in which age-related changes in the vestibular system result in altered balance and symptoms of dizziness and vertigo [2, 15]. Vertigo and dizziness are common presenting complaints among older adults [7, 42, 43]. Nonetheless, presbystasis is a diagnosis of exclusion as vision and peripheral proprioception contribute to the sensation of dizziness and vertigo, which may culminate in a fall. Agrawal and colleagues [7] provide an elegant analysis of the prevalence of vestibular dysfunction among adults using a four-step test. The fourth step relies on standing on a foam-covered surface with an eye shield in place to isolate vestibular function. In their sample drawn of over 6,700 adults in the National Health and Nutrition Examination Survey, more than a third showed signs of vestibular dysfunction and could not remain standing without visual and proprioceptive cues. Prevalence was significantly associated with age. Almost half of those aged 60–69 and more than two-thirds of those aged 70–79, while the great majority of those over 80 years showed vestibular

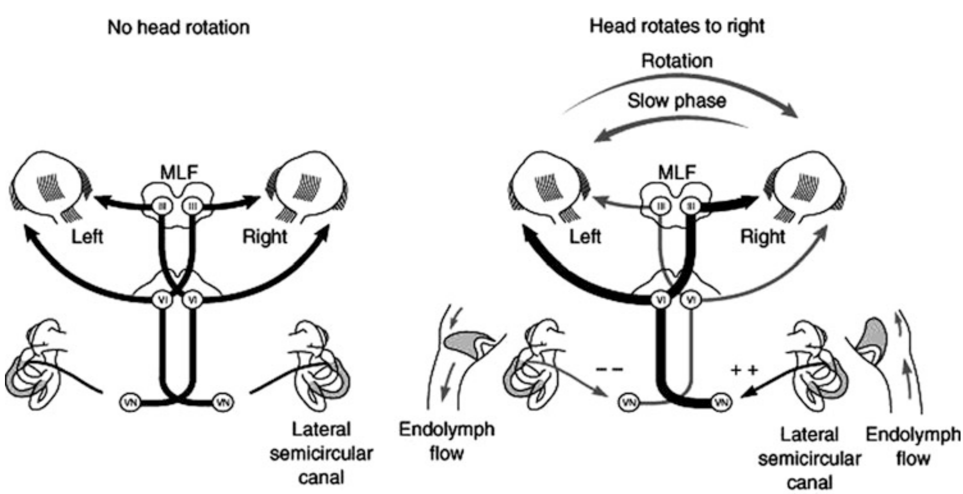

Fig. 9 The vestibulo–ocular reflex. (Reprinted from Lalwani AK. Current diagnosis and treatment of otolaryngology, head and neck surgery, with permission from McGraw Hill Companies)

dysfunction [7]. Thus, the functional state of dizziness is likely to be presbystasis among the very old. However, aligned conditions such as benign paroxysmal positional vertigo (BPPV) and Meniere's disease must not be excluded [42]. BPPV is, in particular, a competing diagnosis that may create great distress from the periodic nature of its presentation. The mechanism of BPPV is suspected to be otoconial debris – which results from aging changes – moving in the semicircular canals and creating hypersensitivity to bodily movement [42]. Despite aging-related elements, BPPV is considered a separate, narrower condition than the breadth denoted by presbystasis.

Clinical Implications

Presbystasis is extremely common and thus an important clinical consideration throughout the surgical trajectory [7, 16]. It creates risk of both minor and serious injuries as well as discomforting sensations throughout the process of surgical care. Individuals affected by presbystasis then carry a clinically important risk of falling at some time during surgical treatment. An estimated $10 to $20 billion dollar annual cost has been reported to be associated with fall-related injuries and a 20% mortality rate [16]. Individualized plans of care should include attention to preoperative condition and reconditioning efforts as possible, as well as modification of the hospital environment and promotion of visual and proprioceptive cues [44]. Aspects of surgical care, including pharmacotherapy such as anesthetics, analgesics, and diuretics, may interact with altered balance and promote the potential to fall. As with presbycusis, elective surgery affords the opportunity for screening through preoperative history and physical assessment to generate appropriate referrals to otolaryngology and physical therapy [44]. These referrals aim for specialized assessment and discrete diagnosis along with treatment designed to mitigate the effects of presbystasis and promote visual and proprioceptive cues with spectacles, well-fitting footwear, and similar interventions. In emergency surgery, efforts to modify the hospital environment, provide compensatory support and supervision, use visual and ambulation aids, and integrate rehabilitative interventions for overall physical condition as well as vestibular accommodation are paramount.

The Aging Nose

Anatomy and Physiology

The nasal vault lies behind the external structures of the nose, through which air passes during respiration [43]. Inspired air enters through the nares. The nasal septum divides the vault into two cavities, each of which contains three turbinates. Turbinates are rounded projections that extend the length of the cavity and labeled by position – superior, middle, and inferior. The space or valley below each turbinate is named for the turbinate above it. The paranasal sinuses drain into the meatuses. These sinuses, also labeled by location, are maxillary, frontal, ethmoid, and sphenoid. All the sinuses are lined with a specialized ciliated epithelium that secretes mucus and maintains mucosal flow with ciliary movement [45]. Together, the turbinates, mucus, and cilia insure humidification of inspired air and prevent gross and microscopic debris from entering the lower respiratory tract. The aging nose, like the external structures of the aging ear, is subject to cartilage collapse [43]. Few other changes in the nose are expressly linked to aging, though older adults may complain of more frequent rhinitis and sinusitis [46, 47]. Atrophic mucosa is a significant factor in these processes [45, 46]. The elderly may, as well, be more susceptible to nasal allergens and allergic rhinitis despite common clinical wisdom that allergen response declines with age [47].

The olfactory region is in the superior aspect of the nasal vault, a combination of olfactory and respiratory epithelial tissue [48, 49] (see Figs. 10 and 11). Olfactory epithelium is organized into pseudostratified columnar shape with four cell types constituting this epithelium (viz., ciliated olfactory receptor neurons, sustentacular cells, microvillar cells of unknown function, and basal

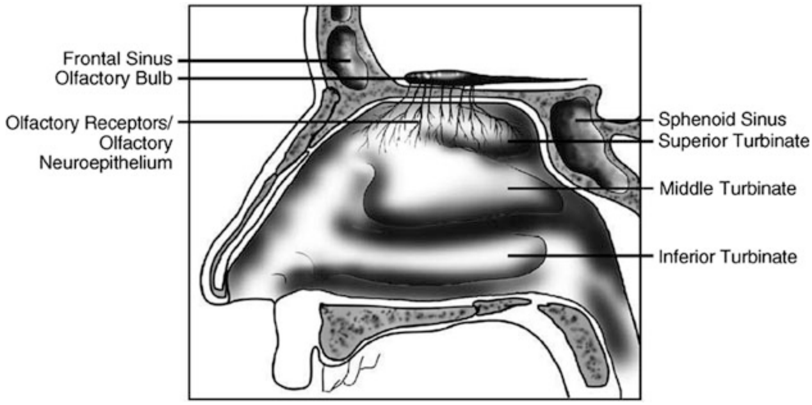

Fig. 10 Olfactory neuroepithelium – sagittal view. (Reprinted from Wrobel BB, Leopold DA (2004) Smell and taste disorders. Facial Plast Surg Clin North Am 12 (4):459–468, with permission from Elsevier)

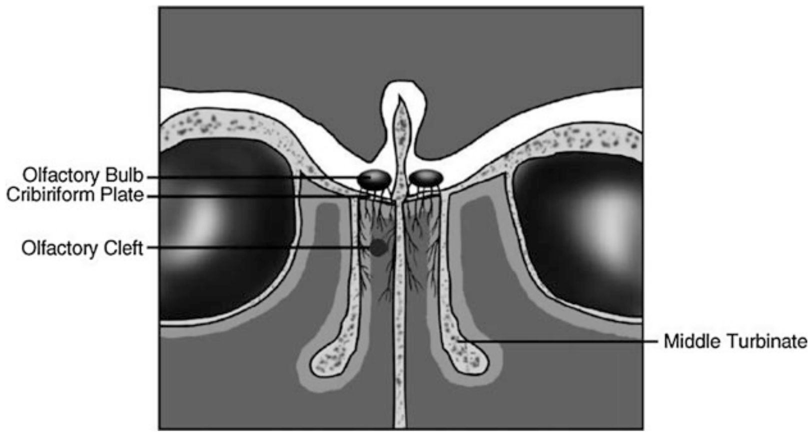

Fig. 11 Olfactory neuroepithelium – coronal view. (Reprinted from Wrobel BB, Leopold DA. Smell and taste disorders (2004) Facial Plast Surg Clin North Am 12(4):459–468, with permission from Elsevier)

cells). Basal cells are the stem cell population responsible for differentiating and replacing lost olfactory receptor neurons [48]. Olfactory respiratory neurons transmit the signal from the odorant molecules to the central nervous system. Early in life, there is a balance between neurogenesis and the lifespan of the olfactory respiratory neurons. With aging, this process of neurogenesis degenerates and is no longer one of equilibrium in terms of maintenance of the type of the epithelium [48, 49]. Additionally, there are increased patches of respiratory epithelium, representing a loss of the primary olfactory receptor neurons. The boundary between olfactory and respiratory epithelium becomes less well-defined with advancing age. Thus, age-related changes in olfactory function are multifactorial and encompass interactions among the composition of olfactory epithelium, decline in specialized cell populations, and decline in olfactory cilia [49].

Olfactory Function

Presbyosmia, loss of the sense of smell with aging, can significantly affect safety and quality of life [48]. Loss occurs on a continuum and is more correctly labeled by degree: anosmia (absent olfactory function), hyposmia (decline in olfactory function), and dysosmia (distorted olfactory function) [50]. Hyperosmia is less commonly noted in older adults. Well over half of adults aged 65–80 years of age have major olfactory disturbances [48, 49]. The potential implications of olfactory loss are significant and range from inability to perceive noxious odors that present threats to environmental or food safety to depression and anhedonia [48, 49]. Nonetheless, many patients are unaware of olfactory changes with age, will have no clinical response, and are unlikely to report changes to clinicians [48].

Clinical Implications

The aging nose presents few clinical ramifications for surgical treatment. Cartilage collapse in the very old may challenge the utility of nasal intubation (endotracheal and nasogastric) and should be considered by the anesthesiologist and the surgeon. Effects of presbyosmia in surgical treatment are also limited. Clearly, attention to patients' complaints with otolaryngologic and neurological referrals is critical. Abrupt or distinct anosmia, rather than being a manifestation of aging changes, may be a sign of Alzheimer's disease or Parkinson's disease, and, in mild cognitive impairment, olfactory decline may herald progression to dementia [51–53]. Additionally, given the intersections of the senses of smell and taste, presbyosmic patients may report disabling dysgeusia rather than altered olfaction specifically [54]. Further, these patients may be malnourished as a result of this complex of conditions with commensurate risk of immune dysfunction and impaired postoperative wound healing. Thus, preoperative assessment of nutritional status and referrals to an otolaryngologist and to a registered dietician optimize care of patients in elective surgery. The same consultations are warranted as soon as possible after emergent surgery if presbyosmia, dysgeusia, or consequent or multifactorial malnutrition is suspected. Patients who have respiratory allergies, including asthma and allergic rhinitis, may be candidates for allergen immunotherapy, which is the only disease-modifying treatment thus for patients with allergies [55].

The Aging Throat

Anatomy and Physiology

The anatomy of the larynx, the central anatomical component of the throat, comprises a cartilaginous skeleton, internal and external muscles, and a mucosal lining [56] (see Figs. 12 and 13). The larynx and pharynx sit below the nasopharynx and the oropharynx to form, with the oral cavity and the nasal structures, the upper aerodisgestive tract. The thyroid cartilage and the cricoid cartilage are visible anteriorly, with the cricoid forming the lower bound and the hyoid bone the upper bound of the organ (see Fig. 12). The two arytenoid cartilages are visible posterolaterally (see Fig. 12). These cartilaginous elements of the skeleton form two joints in the larynx. The cricoarytenoid joint is superior and the cricothyroid joint inferior at the posterior of the larynx. The vocal folds – or cords – attach to the arytenoids and form the glottis as their aperture (see Fig. 13). The cricothyroid muscles and the smaller vocalis muscle are responsible for tension and relaxation of the vocal folds. The posterior cricoarytenoid is the abductor of the vocal folds. The lateral cricoarytenoid, thyroarytenoid, and arytenoideus muscles adduct the vocal folds.

Branches of the inferior and superior thyroid arteries supply the larynx. Motor innervations arise from the cranial division of the accessory nerve, which travels with and therefore is clinically indistinguishable from the vagus nerve. The recurrent branch of the vagus nerve supplies almost all laryngeal muscles, save for the cricothyroid muscle that is innervated by the external laryngeal nerve. Sensory innervation is achieved through the internal laryngeal nerve above the vocal folds and the recurrent laryngeal nerve below them. These are branches of the vagus nerve that also supplies parasympathetic innervation.

The skeletal and muscular structures together create the form of the larynx [56]. In cross section, from the superior most aspect, the larynx begins with the aryepiglottic fold, the vestibule and the vestibular fold, the ventricle, the vocal fold, and the infraglottic cavity. The larynx is lined with mucosal tissue that maintains the humidity of inspired air during respiration and phonation, the central functions of the larynx. The mucosal lining also contributes to the pitch produced by the vibrating vocal folds when inspired air is drawn over them, creating phonation [56]. The epiglottis, which is critical to the laryngeal component in deglutition, sits behind the thyroid cartilage. The aryepiglotticus, thyroepiglotticus, and thyroarytenoid muscles close the larynx entirely, as during deglutition.

The pharynx begins behind the nasal structures, at the base of the skull, and extends to the cricoid

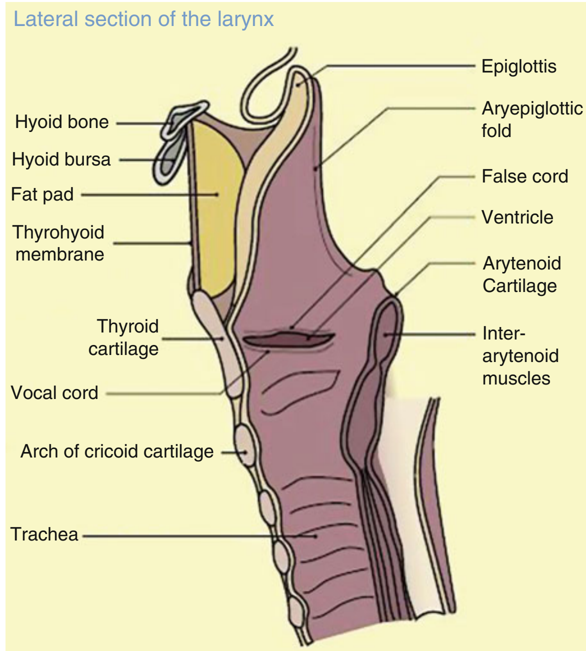

Fig. 12 The larynx – lateral view. (Reprinted from Marchant W (2005) Anatomy of the larynx, trachea and bronchi. Anaesth Intensive Care Med 6(8):253–255, with permission from Elsevier)

cartilage [57] (see Fig. 14). At this point, the pharynx becomes the cervical portion of the esophagus. Unlike the complex larynx, the pharynx is a muscular tube. The outer anatomy of the pharynx is composed of three circular, skeletal muscle constrictors – superior, middle, and inferior. The inner muscular layer of the pharynx is composed of the stylopharyngeus, palatopharyngeus, and salpingopharyngeus muscles. Together these muscles support the successive contraction necessary to move a food bolus to the esophagus. In addition, the inferior constrictor maintains tone to function as a sphincter to limit air entering the digestive tract. Like the larynx, most motor innervation is supplied by branches of the accessory nerve. The stylopharyngeus muscle is the sole exception as it is innervated for motor and sensory function by the glossopharyngeal nerve. The glossopharyngeal nerve is the sensory supply for the pharynx, while the parasympathetic supply arises from branches of the vagus nerve. The functions of the pharynx and larynx require neuromuscular coordination and feedback for functional respiration, phonation, and deglutition, including protection of the respiratory and digestive tracts [57, 58].

The oral cavity is delimited anteriorly by the oral labia [57] (see Fig. 15). The muscles that control the lips and thus the oral cavity aperture are levator labii superioris, depressor anguli oris, and risorius. The cavity is lined with mucosal epithelium that covers the buccal surfaces and the hard palate. The transition to the soft palate marks the transition to the pharynx. Several muscles form the palatal aponeurosis: tensor veli palatini, levator veli palatini, palatopharyngeus, uvulus, and palatoglossus. German and Palmer [57] note that these muscles coordinate to open or close the airway during swallowing and to contribute to deglutition itself by altering the shape of the pharynx. The oral tongue and 32 permanent teeth are contained within the oral cavity. The muscles of the oral tongue include the extrinsic muscles – genioglossus, hyoglossus, styloglossus, and palatoglossus – which are innervated by hypoglossal and the vagus or accessory nerves and the intrinsic fibers, vertical, transverse, and longitudinal, which are innervated by the hypoglossal nerve. The neuromuscular coordination of tongue movement is complex and involves the lingual nerve, branches of the glossopharyngeal nerve, and the internal laryngeal nerve in a minor capacity. The tongue, as well as aspects of adjacent structures like the soft palate, is covered with specialized papillae [58]. These papillae are found in fungiform, folliate, and vallate morphologies with a precise

distribution over the tongue, creating the peripheral taste anatomy [54, 58]. Taste sensation is innervated by a branch of the facial nerve, the glossopharyngeal nerve, and the internal laryngeal nerve [54]. The muscles of the oral floor form the inferior boundary of the oral cavity and include digastric, mylohyoid, and geniohyoid muscles. Dentition arises from the maxilla and mandible, elements of the oral skeleton. The functions of the oral cavity are supported by adjacent structures without which mastication and transit of food are not possible. These components of oral function are the salivary glands, including the parotid, submandibular, sublingual, and minor salivary glands; the nasal structures, most importantly the olfactory epithelium with its direct contribution to chemosensation; and the muscles of mastication, temporalis, masseter, medial pterygoid, and lateral pterygoid [57].

Aging Changes in Voice Function and Swallowing

Voice Function

Presbylarynx is the result of muscular atrophy and decreased elasticity in the muscular and skeletal components of the larynx [59, 60]. In fact, these changes begin early and are noted on examination as early as the fifth decade of life though functional effects are not noted by the individual potentially until the eighth or ninth decade of life if ever. Bowing of the vocal fold is the primary physical change. This bowing alters the aperture of the folds and results in incomplete closure causing a glottic gap. Other ligamentous and cartilaginous structures of the larynx are further altered with advancing age. The cartilaginous skeleton and joints ossify, and the joints may become arthritic and dysfunctional. Microscopically, fibroblasts in the lamina propria may senesce and lose elasticity [14]. The lamina propria becomes denser as it produces less hyaluronic acid and more collagen. These changes alter the vibratory characteristics of the vocal folds [14, 56]. The voice changes experienced by older adults with advancing age are termed presbyphonia [14, 56]. The alterations in the laryngeal skeleton and function of the vocal folds include poor projection, shorter duration of phonation, and vocal roughness or instability. Importantly, presbyphonia is a diagnosis of exclusion [56]. It is the least common cause of vocal disturbance among older adults, accounting for approximately ten percent of voice complaints. More commonly, in order of incidence, older adults will suffer benign polyps, malignant vocal cord lesions, vocal cord paralysis, or functional dysphonia [56]. Neurodegenerative conditions, such as Parkinson's disease, also frequently create significant vocal dysfunction [56].

Oropharyngeal Function

Oropharyngeal function in later life is less a matter of tissue senescence [57, 61, 62]. Dysfunction emerges more often as a product of "wear and tear" in the oral cavity with contributions of effects of local and systemic disease as well as treatment side effects of discrete functions like salivation [61]. Oropharyngeal dysphagia is a highly prevalent clinical condition, which affects up to 13% of patients aged 65 years and older and 51% of institutionalized older persons [63]. Taste sensation likely remains relatively robust in the absence of pathology or significant presbyosmia [54]. Notably, as many as a third of all older adults experience xerostomia [62]. Nevertheless, age-related changes in salivary production are often indistinguishable from primary salivary disease and the contributions of medications with antihistamininergic and anticholingeric effects. Percival [64] notes that microbial flora of the oral cavity remains stable with age, all other factors being equal. However, conditions like xerostomia; changes in dentition and oral hygiene; significant local disease, such as oral premalignant and malignant lesions; and systemic diseases including acute problems such as pneumonia and chronic concerns like Alzheimer's disease and Parkinson's disease may alter oral flora, salivary production, and functional capacity to perform hygiene [61–63]. As a result, oropharyngeal dysfunction among older adults is most often a complex and progressive cycle of direct and indirect functional changes [65]. Loss of muscle mass and function, a reduction of tissue elasticity, changes to the cervical spine, reduction of saliva production, impaired dental status, reduced oral and pharyngeal sensitivity, reduced olfactory and gustatory function, and decreased compensatory capacity of the aging brain increase the susceptibility to dysphagia [63]. Importantly, specific age-related alteration in taste is rarely noted, though Fukanaga and colleagues suggest that loss of taste perception may play a role in dysgeusia [66]. Dysgeusia is more likely the result of presbyosmia or the effects of disease or its treatment that impairs olfaction, tastes, or both or effects of contributory functions like salivation [62, 67]. Hall [67] notes that age-associated neuromuscular deconditioning or disease may result in oropharyngeal dyskinesia. There are resultant and often severe risks of dysphagia and aspiration, especially in stroke or with progressive neurodegenerative disease.

Clinical Implications

Presbylarynx and presbyphonia have circumscribed effects on surgical treatment. For patients who are distressed by presbyphonia, anxiety about being misunderstood or subjected to discrimination because of the "old" quality of their voices is likely real and thus a warranted concern. Attention to communication, discrete consideration of the basis for clinical decisions, and appropriate referrals to an otolaryngologist are important elements in addressing presbyphonia. Concerns about endotracheal intubation for surgery, given skeletal changes in the larynx, are probably theoretical and lack substantive evidence. However, rigidity in the cartilage and joints may offer some risk in the most affected elders, though the more clinical prominent issues of cervical spinal arthritis and kyphosis outweigh potential laryngeal rigidity. Skillful intubation with tacit recognition of laryngeal fragility is thus important in the absence of detailed and clinically relevant data. Nevertheless, post intubation voice changes may affect communication and comfort. Research into tissue engineering and electrical reanimation are some potential future options for treatment of presbyphonia [68]. Currently, a multidisciplinary approach offers the most complete improvement in the vocal quality of life.

Oropharyngeal dysfunction among older adults poses significant risk and threats to surgical treatment. Such dysfunction may arise from aging changes in the anatomy and physiology of swallowing, dental pathology, comorbid disease that affects neuromuscular coordination, or any combination of these factors [17, 65]. Side effects of intubation and anesthesia as well as postoperative healing, as it creates fatigue and saps functional reserves, may breach thresholds of functional compensation for dysphagia and aspiration. Elective surgery affords opportunity for integration of an interdisciplinary plan of care to assess and address for age-related and, more importantly, age-associated disease effects. Essential referrals include routine dental prophylaxis and treatment of dental caries and gingival disease that might affect tooth retention during the postoperative period as well as xerostomia; otolaryngologic and speech language assessment and intervention for diseases and dysfunction in deglutition, respiration, and phonation; and nutrition consultation and intervention to optimize visceral protein and overall nutritional status. These referrals are likely to be more successful given continuous collaboration with a particular patient's primary care provider. Comprehensive patient and family education further supports an effective plan of care and can be delivered by nurses on an outpatient basis before surgery, integrated into the inpatient care plan, and then reinforced during inpatient or outpatient rehabilitative postoperative follow-up. There is compelling evidence that active rehabilitation focusing on increasing strength of the head and neck improves swallowing in the elderly [17]. New treatments aiming at recovering the swallowing function are under research with promising results [69].

Conclusion

Aspects of aging anatomy and physiology in the ears, nose, and throat have manifold and often consequential implications for surgical treatment of older adults. In the ears, presbycusis affects communication that results in possible problems in decision-making and participation in perioperative care. Presbystasis is even more consequential as it is extremely common and results in significant risk of falls with the additive effects of anesthetics, analgesics, and diuretics, along with other postoperative interventions. Conversely, presbyosmia has little direct influence on surgical treatment save for implications of malnutrition when combined with the likelihood of dysgeusia and problems with food safety as a general concern. Presbyphonia conveys intermediate risk in surgical care for older adults. Older adults with noticeably affected voices may have difficulty in communication, both because of auditability and because of ageist discrimination for an "old" and infirm sounding voice. Finally, older adults with age-associated dental problems and acute or chronic disease that impinge upon neuromuscular coordination of the oropharynx are at significant risk for dysphagia and aspiration. The results of age-related functional changes in the anatomy and physiology of the ears, nose, and throat require thoughtfully integrated interdisciplinary surgical care. Knowledge of changes and functional implications is a rapidly evolving area of basic science and clinical investigation. Thus, surgeons can lead integration of a comprehensive plan of care that includes targeted referrals to specialists, preoperative preparation when possible, postoperative rehabilitation, and clear, consistent communication with patients, their family members, primary care providers, and other members of the interdisciplinary team. Modifications to the hospital environment that account for common sensory-perceptual and vocal changes, as well as ongoing patient and family education, further support successful care of the older surgical patient.

Abstract

The aim of this chapter is to identify and discuss characteristics of older adults that affect pre-, peri-, and postoperative decisions in the setting of cardiac surgery. There are unique physiologic considerations in this population that affect many aspect of cardiac surgery, from medication dosing to postoperative healing. To guide care providers who are treating elderly cardiac surgery patients, this chapter identifies epidemiological characteristics of the older adult, particular considerations for preoperative assessment, postoperative complications in this population, and a brief discussion of less invasive alternatives to cardiac surgery in older adults. In order to do this effectively, this chapter is structured such that characteristics of the older adult are discussed early on in the chapter as a bridge to explain strategies to maximize preoperative reserve and mortality and morbidity predictors and quality of life considerations in the older adult. The chapter goes on to consider both general and older adult-specific postoperative complications. The final sections briefly examine nonsurgical options for coronary artery and valvular disease and cardiac mechanical support. The chapter concludes with a pragmatic deliberation on longer-term postoperative follow-up strategies.

List of Abbreviations

ACE Inhibitors	Angiotensin-Converting Enzyme Inhibitor
ARB	Angiotensin II Receptor Blockers
AVR	Aortic Valve Replacement
CABG	Coronary Artery Bypass Graft
CAM-ICU	Confusion assessment method for the intensive care unit
CCB	Calcium Channel Blockers
CT	Computerized tomography
DSWI	Deep sternal wound infections
ECG	Electrocardiogram
FTR	Failure to rescue
GFR	Glomerular filtration rate
HRQoL	Health-related quality of life
ICDSC	Intensive care delirium screening checklist
ITA	Internal thoracic artery
LVAD	Left ventricular assist device
MI	Myocardial infarction
MRI	Magnetic resonance imaging
NYHA	New York Heart Association
OPCAB	Off-pump coronary artery bypass
PCI	Percutaneous coronary intervention
RAAS	Renin angiotensin aldosterone system
STS	Society of Thoracic Surgery
TAVI/TAVR	transcatheter aortic valvular implantation/replacement
TBW	Total body water
TSH	Thyroid-stimulating hormone

Introduction

Ancient physicians believed the living heart to be sacred and untouchable. They also observed that wounds and injuries to the heart were nearly always fatal. Over the past century, the art and science of cardiac surgery has expanded exponentially in both the number of cases performed and the complexity and sophistication of the surgical procedures. It is estimated that over 800,000 cardiac surgery procedures are performed worldwide each year. In the past 20 years, however, the increasing burden of heart disease in an aging population has resulted in cardiac surgery being offered to older and more *frail* patients, often with multiple comorbidities [1, 2]. In the current era of cardiac surgery, more than half of procedures are being performed in patients aged 75 years and older [3]. By extension, it is expected that increasing numbers of frail, older adult individuals will be offered cardiac surgery [4, 5]. Indeed, previous studies have demonstrated that despite an overall improvement in functional outcomes in recent years, older patients typically experience higher rates of postoperative morbidity, mortality and prolonged hospital length of stay, loss of independence, as well as associated increased costs to the health-care system [6–9]. As a result, it is becoming critically important for the health-care system to improve awareness and develop strategies to improve clinical outcomes in the contemporary, high-risk patient population undergoing cardiac procedures.

The purpose of this chapter is to provide an overview of the key issues pertaining to the preoperative evaluation, perioperative care, and postoperative recovery of the older adult (and by extension their caregivers) undergoing cardiac surgery in the current era.

Characteristics of the Older Adult Undergoing Cardiac Surgery

It is anticipated that from 2010 to 2040, the number of individuals in the United States (US) age 65 or older will double as a result of the aging baby boomer demographic and increased life expectancy [10]. Although death due to heart disease has been declining steadily since 1980, heart disease continues to be the leading cause of mortality in North America and remains the most common cause of mortality in the older adult population [11, 12].

Since coronary artery disease disproportionately affects older adults, the anticipated increase in the population of older adults is expected to result in considerable disease burden [10]. An estimated 25% of adults over age 75 experience symptoms of cardiovascular disease [13]. In patients with severe symptomatic cardiac disease, surgical procedures are often prescribed as a first-line treatment strategy. Although older adults account for half of the cardiac surgeries performed in North America, up to 78% of the major complications and deaths occur in this cohort [14]. Even so, randomized and observational studies continue to demonstrate that older adult patients can receive significant benefits from cardiac surgery, including improvement symptoms, quality of life, prevention of cardiovascular events, and survival [15–19].

The older adult with coronary artery disease poses many unique challenges for health-care providers, including physiologic changes of aging, which can lead to preoperative, perioperative, and postoperative challenges. Compared to younger cohorts, the older adult may have more numerous and advanced comorbid disease, in addition to heart disease, that compounds a reduction in physiologic reserve. Additionally, older patients may have more advanced coronary artery disease at the time of referral for cardiac surgery compared to younger cohorts [14, 20].

Over time, despite the increasing risk or negative periprocedural outcomes in older adults, there have been consistent reductions in mortality among octogenarians undergoing cardiac surgery [20]. Risk factors associated with increased mortality after CABG in younger patient groups are different than risk factors in the older adult population. Such risk factors include renal dysfunction and sternal wound infection. Furthermore, assessment of cognitive function and baseline functional status is crucial to establish prior to cardiac surgery. These measures may help assess for the risk of postoperative delirium and may help guide the clinician to optimize postoperative functional trajectory. It is estimated that one-third of individuals over the age of 80 have some degree of cognitive dysfunction. These patients are at higher risk of experiencing postoperative delirium and possible further deterioration in cognition. In addition to a comprehensive cognitive assessment prior to surgical intervention, assessing for baseline functional status and physiologic reserve is also becoming increasingly important. The concept of frailty has been well described in geriatric medicine literature as a "biological state characterized by increased vulnerability and decreased resistance to physiological stresses" [13, 21–23]. While frailty is not synonymous with age, it is more prevalent among older adults, more common in women and in patients undergoing cardiac procedures [22]. It is recognized that frailty in older adults with cardiovascular disease is an important condition that may help identify operative risk in these patients [13]. Preoperative assessment, including cognitive and frailty assessment, will be discussed in more detail in this chapter.

Pharmacokinetics and Pharmacodynamics in the Older Adult Undergoing Cardiac Surgery

This section focuses on common physiologic changes of the aging individual that may impact cardiac medication administration decisions.

Age-Related Changes in Pharmacokinetics and Pharmacodynamics

Pharmacokinetics refers to the relationship between a drug dose and the concentrations of that drug in the systemic circulation due to patient factors, or simply, pharmacokinetics is how an individual's body affects a drug [22]. There are several physiologic changes that occur with normal aging that can result in suboptimal drug handing of administered medications. These include changes in absorption, distribution, metabolism, and elimination [24]. Medication absorption can be decreased in older adults due to decreased gastrointestinal motility, decreased gastrointestinal blood flow, and increased in gastric pH. Generally, this does not result in clinically relevant changes for most medications. Medication distribution refers to the relative proportion of medication in patient tissue [25]. Distribution may decrease in older adults for a variety of reasons. As individuals age, there is generally a decrease in lean body mass, an increase in adipose tissue, and decrease in total body water (TBW). These changes result in a decreased volume of distribution for hydrophilic drugs and increased volume of distribution for lipid soluble drugs [25]. Hepatic metabolism of many medications decreases with age for a variety of reasons. Decreased hepatic blood flow can result in less effective first-pass metabolism. Decreased hepatic mass can impair phase I metabolism of some medications [26]. Therefore, medications that rely on hepatic metabolism will have decreased drug clearance, and for a given medication dose, there may be a higher concentration of the circulating drug. In the older adult patient, this may increase the risk of drug toxicity depending on the medication administered.

One of the most significant pharmacokinetic changes associated with aging is decreased renal elimination of medications. This results from decreased renal blood flow and decreased glomerular filtration rate (GFR) that occur with age. In older adults, medication doses may need to be reduced for drugs with a large reliance on renal elimination.

Pharmacodynamics refers to the relationship between concentrations of a drug in the systemic system and the body's pharmacologic response. More simply, pharmacodynamics refers to how a medication acts on an individual's body. Pharmacodynamics may be affected by drug-receptor interactions and homeostatic regulation. For example, in older adults the sensitivity of the cardiovascular system to beta adrenergic agonist and antagonists is decreased, and the incidence of orthostatic episodes due to drugs that lower blood pressure increases [27]. With increasing age, the central nervous system becomes more susceptible to drugs that affect brain function, including opioids, antipsychotics, and benzodiazepines [27].

Cardiac Medications and Aging

Due to the effects of pharmacokinetics and pharmacodynamics associated with aging, there are some important considerations when using cardiac medications in this population. We will briefly discuss some of these considerations as they apply to the following commonly used drugs in cardiac surgery patients: beta blockers, angiotensin converting enzyme inhibitors and angiotensin receptor blockers, neprilysin inhibitors, calcium channel blockers, and digoxin.

Beta Blockers. Increased age is associated with decreased baroreceptor reflex response, drops in blood pressure, downregulated Beta (β)-adrenoceptors, and increase in orthostasis [28, 29]. Overall there is a decreased response to β-adrenoceptor agonists and decreased antihypertensive effect of β-adrenoceptor blockers, the latter of which may be related to decreased renal levels in older adults. There have been several theories to explain the decreased effects of β-blockers in older adults, including variations in β-receptor conformation and receptor down-regulation due to increased serum noradrenaline [28, 29]. Regardless of the mechanism, aging is associated with decreased response to β-blockers, making these agents less effective than others at decreased blood pressure in older adults [29].

Angiotensin-Converting Enzyme Inhibitors (ACE Inhibitors) and Angiotensin II Receptor Blockers (ARB). The relationship between aging and vascular responsiveness to angiotensin II is unclear, but data indicate that there is no difference in vascular resistance responsiveness to angiotensin II with aging [29, 30]. In general, with age the circulating renin-angiotensin-aldosterone system (RAAS) becomes less active, renin activity is decreased, and aldosterone concentrations are decreased. These effects may become amplified with RAAS stimulation due to salt restriction, volume depletion, or upright posture. Increases in renin and aldosterone secretion with these stimuli are expressed as a percentage in baseline values, so the increases are similar in young and older normotensive individuals, suggesting that the RAAS is able to maintain its ability to respond to stress with age [31]. There does not appear to be a significant change in drug effect between younger and older adults, and it is not recommended to adjust initial dosing of ACE inhibitor or ARB in the older adult population. There was an age-related difference with the reporting of adverse drug reactions of ACE inhibitors; younger adults tended to report headaches while older adults displayed light-headedness and orthostasis.

Neprilysin Inhibitors. Neprilysin inhibitor sacubitril/valsartan (trade name Entresto) was approved for use by the US Food and Drug Administration in 2015 for patients with chronic heart failure with reduced ejection fraction. It provides simultaneous neprilysin and angiotensin II receptor blockage, causing increased effect of natriuretic peptides, and resulting in diuretic, vasodilation, decreased sympathetic tone, and suppression of the RAAS [32]. Available data suggest that there are no clinically relevant pharmacokinetic differences observed in older adults (age greater than 65) or very old adults (age greater than 75) compared with the overall population [32, 33]. Dose adjustment based on age is not necessary [32].

Calcium Channel Blockers (CCB). Dihydropyridine calcium channel blockers selectively block L-type calcium channels in cardiac and vascular smooth muscle to decrease arterial pressure and systemic vascular resistance. Studies suggest that in treatment-naïve older adults, dihydropyridines initially have a greater effect on blood pressure, but after prolonged exposure, the sensitivity of older adult patients approximates that of younger patients [29]. The mechanisms for this are unclear but may include decreased hepatic clearance, age-related decrease in baroreceptor response, and potentially higher baseline blood pressure in older cohorts. Initial doses of dihydropyridines may have to be adjusted to account for increased sensitivity in treatment naïve older adult patients, but this sensitivity may be transient [29]. Examples of dihydropyridine CCBs include amlodipine, nifedipine, and felodipine. Nondihydropyridine calcium channel blockers bind to L-type calcium channels in cardiac and vascular channels at a different site than dihydropyridines. Compared to dihydropyridines, nondihydropyridines have a greater suppressive action on AV node conduction, a greater negative inotropic effect, and decreased vasodilation. Examples of non-dihydropyridine CCBs include verapamil and diltiazem, which both have increased volume of distribution in the older adult [28]. Older people tend to have a greater drop in blood pressure and heart rate with verapamil, which is suspected to be due to decreased drug clearance with age [29].

Digoxin. In the older adult, the effect of digoxin is altered due to decreased volume of distribution caused by increased adipose tissue and decrease in TBW. Clearance may also be decreased due to decreased GFR, resulting in accumulation of the drug. As a result, the loading dose of digoxin should be decreased by approximately 20% in this population [27]. Drug monitoring is recommended, particularly in patients with impaired renal function. Generally, the therapeutic range for serum digoxin concentration is 0.5–2 ng/mL. Toxic effects may occur with a digoxin level greater than 3 ng/mL but are usually not experienced when the concentration is 1.4 ng/mL or less. However, in patients over the age of 70, clinical evidence of digoxin toxicity may occur even when digoxin level is within the therapeutic range. Animal studies with digoxin have shown that with increasing age there is increased sensitivity to the cardiotoxic effects of digoxin, likely related to a reduction in the sarcolemmal content of the enzyme Na,K-adenosine triphosphatase, which reduces digitalis-induced pump inhibition required before the onset of toxicity [27, 30].

Amiodarone. Amiodarone is often used in the postoperative setting due to atrial fibrillation or ventricular tachycardia after cardiac surgery. It is a class III antiarrhythmic agent that prolongs the cardiac action potential duration and repolarization time and may have a protective antioxidant effect on cardiac myocytes against oxidative stress [34]. It affects heart rate and rhythm by increasing the refractory period of SA and AV nodes, as well as the ventricles, bundle of His, and Purkinje fibers. Like digoxin, the effect of amiodarone is affected by decreased volume of distribution in older patients, and doses of amiodarone may need to be adjusted because of this. Amiodarone is highly bound to plasma proteins. The drug is poorly absorbed from the gastrointestinal tract, has slow elimination, and is very lipophilic. Due to its large volume of distribution, amiodarone requires a loading dose [34]. Additionally, it is a potent inhibitor of cytochrome P-450, which results in drug-drug interactions that potentiate the effects of lidocaine, digoxin, procainamide, quinidine, warfarin, lithium, and phenytoin. Although older adult patients may be more likely to develop arrhythmias postoperatively that may be treated with amiodarone, the lipophilic distribution and long half-life of amiodarone (25–100 days) may also put older adults at higher risk of developing drug-related toxicity.

Amiodarone has significant cardiovascular and non-cardiovascular side effects that can lead to end organ toxicity. Cardiovascular side effects due to its antiarrhythmic properties include bradycardia, atrioventricular block, QT interval prolongation, and hypotension [34]. Non-cardiovascular side effects include pulmonary fibrosis, hypothyroidism, hyperthyroidism, corneal micro depositions, peripheral neuropathy, ataxia, fatigue, skin discoloration, photosensitivity, abnormal liver enzymes, and hepatitis [34]. Amiodarone exposure at low maintenance doses for periods of 12 months or longer is associated with higher odds of developing thyroid, skin, neurologic, optical, and bradycardic adverse events [35]. Older adults with structural heart abnormalities may be more predisposed to bradycardic effects of amiodarone, and hypothyroidism may be more common than in younger adults using amiodarone [35, 36]. Due to the long elimination half-life of amiodarone (25–100 days), drug interactions or side effects caused because of amiodarone may exist long after the cessation of the drug. Due to the potential for toxicity amiodarone, this agent has been listed in the 2012 American Geriatrics Society Beers Criteria list of medications that require careful consideration due to the risk of potential inappropriate use [37]. This and the potential impact to multiple organs systems, a thorough medication history looking for amiodarone use in the older adult patient is crucial in individuals who present with new systemic symptoms. Surveillance with chest x-ray and electrocardiogram (ECG) is recommended annually, and thyroid-stimulating hormone (TSH) and hepatocellular liver enzymes should be checked every 6 months.

Preoperative Assessment of the Older Adult Undergoing Cardiac Surgery

Frailty in the Cardiac Surgery Patient

Frailty is a syndrome characterized by decreased physiologic reserve and is defined by an increased vulnerability to stressors, including cardiac surgery (Fig. 1) [22, 38].

The term is often used to describe a vulnerable subset of individuals that are at an elevated risk for poor health outcomes, including falls, admission to long-term care facilities, and mortality [38]. Currently, a universally accepted definition of frailty does not exist (Fig. 2). One common assessment of frailty was validated by Fried and colleagues using data from 5317 community-dwelling men and women enrolled in the Cardiovascular Health Study [22]. Demographically, participants were 65 years of age and older, and frailty was defined by the presence of three or more of the following characteristics: (1) unintentional weight loss (i.e., 10 pounds in past year); (2) exhaustion (i.e., self-reported); (3) weakness (i.e., grip strength in lowest 20% for gender and body mass index); (4) slow walking speed (i.e., slowest 20% on time to walk 15 ft); and (5) low physical activity (i.e., lowest quintile of kilocalories expended per week). Although this is a widely accepted definition of frailty, many other standard assessments and models exist, including the *Canadian Study of Health and Aging* accumulation of deficits model, the *Clinical Frailty Scale*, and singular measures such as gait speed or grip strength [39–41].

Due to an aging demographic and advances in surgical procedures, older and increasingly frail patients are being referred for cardiac surgery. In fact, the proportion of patients aged 75 years and older undergoing surgical procedures has increased from 16% in 1990 to over 25% in recent estimates made in 2012 [42]. While the prevalence of frailty in the general population of older adults ranges from 14% to 24% (i.e., depending on the definition of frailty used) [43], the prevalence of frailty in patients with cardiovascular disease, or in those requiring cardiac surgery, is estimated to be as high as 54% [44, 45]. Chronological age has been demonstrated to be associated with poor outcomes after surgery [46–48]; however, emerging evidence has also demonstrated that frailty, as a marker of physiologic reserve, may be an equally important prognostic indicator of surgical success (Table 1) [5–7, 9, 42, 44, 49]. One of the first studies to demonstrate an association between frailty and adverse postoperative outcomes was conducted by Lee and colleagues, which evaluated frailty in 3826 patients

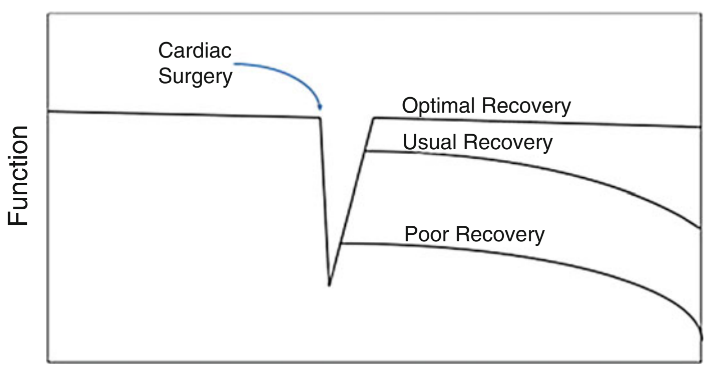

Fig. 1 Response to stressors. Following major stressor events such as cardiac surgery, a complete functional recovery (a return to the prior level of functioning) is anticipated. However, there is suboptimal recovery and patients attend a new "baseline" functional status. The patients with pre-existing vulnerability (i.e., frail) experience a disproportionate decline in their functional capacity and a poor recovery following cardiac surgery. (Reprinted from Experimental Gerontology, 87, Neupane, I., Arora, R.C., Rudolph, J.L., Cardiac surgery as a stressor and the response of the vulnerable older adult, 168–174, Copyright (2017), with permission from Elsevier)

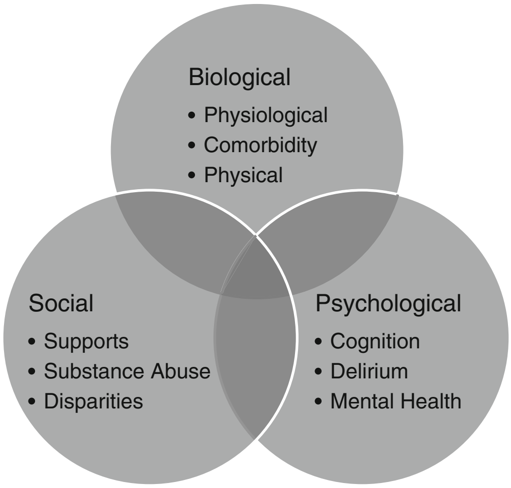

Fig. 2 Biopsychosocial Model for Frailty. (Reprinted from Experimental Gerontology, 87, Neupane, I., Arora, R.C., Rudolph, J.L., Cardiac surgery as a stressor and the response of the vulnerable older adult, 168–174, Copyright (2017), with permission from Elsevier)

requiring cardiac surgery [7]. This retrospective study reported that frail patients had a 1.5-fold increased risk of all-cause mortality, and frailty status (i.e., defined as an impairment in activities of daily living, ambulation, or documented history of dementia) was an independent predictor of in-hospital mortality (OR: 1.8, 95% CI: 1.1–3.0) and institutional discharge postoperatively (OR: 6.3, 95% CI: 4.2–9.4). The results of this retrospective analysis are supported by a recent systematic review conducted by Sepehri and colleagues, which suggests that frailty status, defined using multiple criteria, has a strong positive relationship with the risk of cardiac and cerebrovascular events following cardiac surgery (OR: 4.89, 95% CI: 1.64–14.60) [5]. The results of this systematic review are quite robust in that multiple definitions of frailty were assessed, including the multidimensional geriatric assessment, Fried phenotype criteria, and the comprehensive assessment of frailty [6, 9, 42, 50]. Another scoping review conducted by Beggs et al. reported similar associations between frailty and adverse perioperative outcomes in a variety of surgical populations, including cardiac, vascular, abdominal, and orthopedic procedures [49]. In addition to composite definitions of frailty, Afilalo and colleagues demonstrated the singular measure of gait speed to be an independent predictor of major morbidity and mortality (OR: 3.05, 95% CI: 1.23–7.54) and discharge to a health-care facility (OR: 3.19, 95% CI: 1.40–8.41) following coronary artery bypass graft or valve replacement surgery in patients over the age of 70 [3]. As part of this analysis, older patients were classified as having impaired gait speed if they required longer than 6 s to walk a distance of 5 m. This study is highly pragmatic in nature in that the simple gait speed assessment can be feasibly implemented in a clinical setting to support clinical decision-making during the preoperative period. The results of this initial prospective study have since been extended using the multicenter Society of Thoracic Surgeons Adult Cardiac Surgery Database in 15,171 patients over the age of 60 [20]. Compared to patients with a walking speed greater than 1.0 m/s, operative mortality is increased for those walking less than 0.83 m/s (OR: 3.16, 95% CI: 2.31–4.33). Even following adjustment, gait speed remained an independent predictor of operative mortality (OR: 1.11 per 0.1 m/s decrease in gait speed). Collectively, emerging evidence suggests that the frailty syndrome may be an important indicator of successful recovery following cardiac surgery. Strategies to optimize frailty status during the preoperative period may lead to improvements in postoperative outcomes.

Having a systematic approach to assessing and managing frailty is being examined in noncardiac surgery populations. Hall et al. published a large study in 2017 of a frailty screening initiative which included a screen of all patients undergoing elective major noncardiac surgery in a single center [51], in this case with the Risk Analysis Index tool [52]. The Risk Analysis tool combines many elements seen in other frailty tools and includes medical comorbidities, functional abilities, and cognition. Those identified as frail had their cases reviewed with interventions ranging from increasing awareness of the patient's frailty to changes in planned surgical and operative care approach to involvement of palliative care to clarify care goals. Researchers prospectively applied this approach over 54 months to 3878 patients

Abdullahi et al. [94], by permission of Oxford University Press

ADL, activity of daily living; CAF, comprehensive assessment of frailty; CI, confidence interval; FORECAST, frailty predicts death 1 year after elective cardiac surgery test; OARS, Older American Resources and Services; OR, odds ratio; STS, Society of Thoracic Surgeons; STS-PROM, STS predicted risk of mortality undergoing elective noncardiac major surgery. Only 6.8% of patients were identified as frail. Mortality increased with degree of frailty as identified by the Risk Analysis Index score. With intervention, mortality at 30 days improved in frail patients from 12.2% compared to 3.8% in a retrospective cohort ($p < 0.001$) and the benefit persisted to 365 days with improvement from 34.5% to 11.7% ($p < 0.001$) [51]. Interestingly, gains in mortality were observed in the non-frail population as well, attributed to the fact that care approaches were being measured and assessed more closely.

Strategies to Decrease Operative Risk

Improvements in surgical techniques and anesthesia have increased the confidence of cardiac surgeons performing operations in older adults with elevated perioperative risk. The two principal causes of stroke in older adult patients during cardiac surgery are embolization (air, atheroma, and calcific debris) and hypotension resulting in inadequate perfusion of the central nervous system. Preoperative evaluation of the ascending aorta and carotid arteries and intraoperative assessment of the proximal aorta using intraoperative transesophageal or epiaortic echocardiography may alter the conduct of the procedure, minimize surgical manipulation, and thereby significantly reduce the incidence of stroke [53–57]. Such information enables the surgeon to avoid cannulation or direct manipulation of heavily diseased portions of the aorta where atheromatous disease may dislodge or where plaque disruption may cause aortic dissection. The presence of extensive atheromatous or calcific disease, which precludes safe manipulation of the ascending aorta in patients with advanced coronary disease, leaves the surgeon with several choices:

1. Perform surgical revascularization on a beating heart (known as an off-pump coronary artery bypass (OPCAB)), using one or both internal thoracic arteries, radial artery, and/or non-aortic-based grafts [58–60].
2. Establish cardiopulmonary bypass via the femoral, axillary, or other systemic non-diseased artery and perform graft replacement or endarterectomy of the ascending aorta [53, 54]. The latter alternative is an aggressive, complex procedure, and in the older adult population, it should be reserved for the very good risk patient with no significant comorbidities.
3. Potential a "hybrid" procedure (i.e., a combination of coronary artery bypass graft to key target vessels and percutaneous coronary stents to other territories) [61–63].
4. Abandon the surgical procedure and consider nonoperative revascularization such as percutaneous coronary intervention (PCI) or transcatheter aortic valvular replacement (TAVR). This may require the acceptance of incomplete revascularization. If not suitable for PCI/TAVR, it may be necessary to ongoing medical management/palliative therapies.

Diffuse systemic atherosclerosis is more prevalent in the older adult than in younger patients; as such, special precautions should be taken to ensure adequate cerebral and renal perfusion both in the operating room and in the intensive care unit [64, 65]. Maintaining high perfusion pressures while on cardiopulmonary bypass can help decrease the incidence of ischemic stroke [66]. Managing blood pressure during the early perioperative period may also be beneficial in attenuating the incidence of postoperative delirium [67]. Control of atrial arrhythmias and avoidance of episodes of sustained arterial hypotension due to hypovolemia or medications are important during the immediate postoperative period, particularly in those patients with diastolic dysfunction who are increasingly reliant on the atrial contribution to cardiac output. Although there is still controversy regarding the management of asymptomatic carotid disease, it is believed that known carotid disease in the older adult population is a risk factor for postoperative stroke [53, 56, 68, 69]. Morris et al. recommended routine preoperative assessment of carotid artery disease in octogenarians and advocated carotid endarterectomy if significant disease is found; however this is still controversial and not the current standard of practice in most cardiac surgery centres [70, 71]. If symptomatic carotid artery disease is diagnosed prior to cardiac surgical intervention, consideration can be given to performing a staged or a combined cardiac/carotid procedure. If asymptomatic significant carotid disease is discovered by Doppler preoperatively (>75% stenosis bilaterally or lesser degrees of unilateral stenosis in the presence of an occluded contralateral artery), concomitant carotid endarterectomy may decrease the risk of perioperative stroke [72, 73].

Pre-habilitation

Older patients with multiple comorbid illnesses experience higher rates of in-hospital mortality after cardiac surgery when compared to younger patients [48]. Often surgery is required urgently, or the degree of cardiac compromise from valvular disease, angina, or heart failure precludes the ability to optimize preoperative status. However, in the setting of elective surgery, all possible measures must be taken to optimize the older adult patient preoperatively and in attempts to optimize their trajectory of recovery. Since the phenotype of frailty is characterized by reductions in muscle mass, strength, endurance, and activity level [22], cardiac rehabilitation programming is ideally suited to counteract impairments and improves frailty status among patients requiring cardiac surgery. Cardiac rehabilitation has previously been demonstrated to decrease morbidity and mortality in patients with established cardiac disease [74–78] and to be safe in older adults [79–82]. Furthermore, previous investigations conducted in nonsurgical populations of older adults suggest that the frailty syndrome is indeed modifiable through structured exercise interventions [83–86]. The concept of preoperative rehabilitation is well-established in many disciplines, including orthopedic, thoracic, and abdominal surgery [87–89]. Despite this, few clinical trials have evaluated preoperative exercise interventions in patients undergoing cardiac procedures. Herdy and colleagues conducted a randomized controlled trial in 56 patients undergoing coronary artery bypass graft (CABG) surgery, where participants randomized to a cardiopulmonary rehabilitation group received a minimum 5-day preoperative and 5-day postoperative progressive exercise program [90]. Notably, participants randomized to the intervention group presented with attenuations in atelectasis (RR: 0.15, 95% CI: 0.03–0.8) and atrial fibrillation (RR: 0.2, 95% CI: 0.05–0.8) and reduced their average postoperative hospital length of stay (5.9 ± 1.1 vs. 10.3 ± 4.6 days). Perhaps the strongest evidence supporting preoperative exercise interventions in patients undergoing cardiac surgery comes from a randomized trial conducted by Arthur et al., which investigated an 8-week supervised exercise program in 249 low-risk patients undergoing CABG [91]. The primary outcome of the study investigated postoperative hospital length of stay, while secondary outcomes examined exercise capacity, health-related quality of life, and anxiety levels. Notably, patients randomized to the intervention group reduced their hospital length of stay by a median of 1 day (95% CI: 0.0–1.0 day, $p = 0.002$) and spent an average of 2.1 less h (95% CI: 1.2–16 h, $p = 0.0001$) in the intensive care unit. Despite this evidence, routine clinical practice does not refer cardiac patients to cardiopulmonary rehabilitation programming until after their surgical procedure, leaving many patients to wait in fear [92] and experience further deconditioning. Currently, a multisite randomized controlled trial is being conducted in Canada to determine the efficacy of pre-habilitation among older adults undergoing elective CABG and/or valve procedures (NCT02219815) [93]. The pre-habilitation intervention will consist of twice-weekly exercise prescribed at 40–60% of heart rate reserve, for a period of 8 weeks. The primary outcome of the study will investigate the proportion of patients requiring a hospital length of stay greater than 7 days.

Predictors of Perioperative Morbidity and Mortality

A comprehensive preoperative assessment is essential to determine the relative risk and potential benefit of the surgical intervention in this patient population (Table 2). Current preoperative cardiac surgery risk scores, however, perform

Table 2 Key elements of preoperative evaluation

A meticulous history and physical examination	Documentation of acute and chronic (co-morbid) illnesses Baseline cognitive assessment Medication record including over the counter medications Baseline surgical risk score (i.e., STS-PROM or EuroSCORE II)
Routine laboratory tests	Cardiac workup: this typically included an electrocardiogram (ECG), chest radiograph, coronary angiography, and an echocardiogram Additional electrophysiology studies may be help define the patient's hemodynamic and physiologic profile The use of chest cardiac computerized tomography (CT) may be of benefit to determine degree of calcific atheromatous disease burden the ascending aorta and aortic arch Gated blood pool radionuclide studies or magnetic resonance imaging (MRI) may be necessary to define the coronary anatomy and myocardial viability Following evaluation of test results, the treatment format for surgical intervention is formulated
Frailty assessment	Frailty is highly prevalent in the older adult undergoing cardiac surgery. An optimal process of assessment in the cardiac surgery patients is still being determined; however the use of any frailty screening tool has been associated with improved prediction of outcome following cardiac surgery
Functional assessment	Identification of current living status and potential barriers to successful discharge and recovery should be identified in the preoperative setting to facilitate informed decision-making with patient-caregiver unit and to permit the health-care team to plan disposition arrangements

poorly in older adult patients [42, 94]. Cardiac surgery risk prediction tools, such as the Society of Thoracic Surgeons (STS) score [95] and the European System for Cardiac Operative Risk Evaluation (EuroSCORE II) [96], do not comprehensively account for preexisting frailty and disability, which is increasingly being recognized as critical determinants of health status with advanced age [42].

Frailty is a geriatric syndrome that reflects subclinical impairments in multiple organ systems impeding the body's ability to uphold physiological homeostasis in the face of stressors [97]. There are however >20 different frailty scales that have been developed, and new scales continue to emerge in the medical literature [94, 98]. Many scales are loosely based on Fried's core domains [22] and the Rockwood's frailty index [41]. The uncertainty regarding which frailty tool to use is compounded by uncertainty regarding which cutoff to use for each tool (e.g., gait speed [99]). As such, the choice of scale and cutoff can drastically modify the measured prevalence of frailty, which ranges from 6% to 44% in the same patients [100].

There is an unmet need to combine established cardiac surgery risk scores with measures of frailty and disability to provide a more complete model for risk prediction in older adult patients undergoing cardiac surgery. Despite this, there are some established risk factors for poor postoperative outcomes. Perhaps not surprisingly, in a prospective study of octogenarians undergoing cardiac surgery, the complexity and urgency of the surgery predicted poor outcome. The need to perform a CABG in addition to an (AVR) accorded surgical risk but is also a marker of the presence of extensive cardiovascular disease and more comorbidities. Independent of those factors, worsened creatinine clearance, previous MI, presence of atrial fibrillation, and chronic respiratory disease all independently predicted increased postoperative mortality [101].

Quality of Life Considerations

Although the short-term and intermediate survival for older adults undergoing cardiac surgery is less than younger cohorts, the long-term survival of octogenarians after open heart surgery compares favorably with survival for the general population of similar age. In a series of 600 consecutive patients 80 years of age or older undergoing various cardiac procedures, the 5-year actuarial survival, including hospital mortality, was 63 ± 2%. Survival in this group was identical to that for the comparable general US octogenarian population [68]. Excellent long-term results have been achieved by several groups in octogenarians after mitral valve surgery, aortic valve surgery, and coronary artery bypass surgery [102–104].

Another key determinant of "operative success" (and perhaps more importantly) is the consideration of post-discharge health-related quality of life (HRQoL) in older adults undergoing cardiac procedures. Several authors have shown that most (81–93%) of the octogenarians who survive open heart surgery "feel" as good and frequently better than before their operations [60, 68, 102, 104]. An equally high percentage (75–84%) of octogenarians believed in retrospect that having decided to have a cardiac surgical procedure after age 80 had been a good choice [68, 105]. Even so, the precise and objective measurements of quality of life may be difficult to quantify. Based on well-studied populations, it has been possible to construct instruments that reliably assess the various domains of daily living, thereby producing a meaningful, reproducible measurement of HRQoL [106]. A recent retrospective investigation of octogenarian patients undergoing cardiac procedures reported that 11.7% experience a prolonged stay greater than 5 days in the intensive care unit [107]. Of these patients experiencing prolonged stays in intensive care, 81.3% experienced functional survival (i.e., defined as alive at 1-year and living in their own home) as compared to 91.7% ($p < 0.01$) among those not experiencing a prolonged stay. A lack of physician visits in an outpatient setting within 30 days of discharge was associated with a fivefold increase in the risk of poor functional survival at 1 year (HR: 5.18, $p < 0.01$).

The Canadian Cardiovascular Society (CCS) and New York Heart Association (NYHA) angina scores and functional class and reflect symptom-free living with regard to chest pain and dyspnea [108, 109]. Octogenarians have consistently demonstrated substantial improvement in their NYHA functional class and cardiac failure functional class after cardiac surgery. In several reports, most (i.e., 68–92%) of the octogenarians who survived open heart surgery were in NYHA functional class I or II during long-term follow-up. When a well-validated HRQoL index, the SF-36, was employed to prospectively study a cohort of older adult and non-older adults, individuals over 75 years of age experienced identical long-term improvement in each of the seven domains of the SF-36. Indeed, many of the older adult patients had as low HRQoL SF-36 scores preoperatively as their younger cohorts; however while both age groups experienced improved SF-36 scores 6 months following surgery, the changes were even greater in the older adult population.

While most patients recovering from cardiac surgery will spend less than 48 h in the postoperative intensive care unit, some patients require a prolonged stay in the intensive care unit. Perhaps not surprisingly, patients with a prolonged postoperative intensive care unit stay experience increased rates of re-hospitalization and poorer HRQoL following their procedure. Many recent reports examining postoperative outcomes in the aging population undergoing cardiac surgery use hospital discharge as a metric to quantify surgical success. Even so, discharge from hospital may not necessarily translate to thriving in the community, particularly among older adults. There is an urgent need to consider patient-centered health outcomes, including functional capacity, quality of life, and activities of daily living, in addition to postoperative survival. Identifying patients at risk of poor functional survival would permit surgeons to improve the quality of informed consent and target modifiable risk factors in this vulnerable subset of the population both pre- and postoperatively.

Postoperative Complications

The vulnerable older adult patient, who is more susceptible to the complexity of surgical process, is at an elevated risk for complications of cardiac surgery and will be less likely to return to baseline function postoperatively [4]. In this section, perioperative complications that occur in all cardiac surgery patients will be addressed; however, a more detailed discussion of issue pertinent to the older adult will be undertaken later in the chapter.

With normal aging there is a reduction in both renal mass and glomerular filtration rate (GFR). In octogenarians this is more pronounced, with up to a 40% decrease in GFR and a 25% decrease in kidney mass [110]. Patients undergoing cardiac angiography should have pre- and post-angiography renal function assessed. Renal function may be made worse by transient hypotension that occurs during cardiopulmonary bypass, and in the older adult population, perioperative renal insufficiency is a strong positive predictor of postoperative mortality [110].

As individuals age, there is a decrease in adaptive immune function, primarily due to decreased production in naïve lymphocytes in the bone marrow [111]. This may be associated with increased susceptibility to infection in the geriatric population. This is particularly relevant in older adults undergoing cardiac surgery, where the use of monitoring lines, catheter, drainage lines, and central lines may provide further infection risk. Older age has been shown to be an independent risk factor for wound infection, including deep sternal wound infection [112]. Identification of postoperative infection can be delayed in the older adult population due to possible lack of leukocytosis and atypical presentation of infection, such as confusion or hypothermia [110].

General Postoperative Complications

Postoperative complications are associated with increased morbidity and mortality after cardiac operations [113]. The postoperative complications of cardiac surgery can be approached as complications that occur whenever one performs prolonged, complex surgery on a potentially vulnerable population and those complications that are very specific to cardiac surgery. The Society of Thoracic Surgeons (STS) is a large reporting body for more than 1800 international cardiac surgery programs (www.sts.org). The STS National Database is the largest and most representative data source in cardiothoracic surgery. The STS National Database currently identifies six major postoperative complications, including death, stroke, renal failure (defined as a threefold or greater rise in creatinine or new dialysis requirement), prolonged mechanical ventilation (>24 h), unplanned reoperation (for any reason), and deep sternal wound infection (DSWI). The STS National Database has further reported major morbidity or mortality outcome as a composite endpoint, defined as any of the outcomes listed in the six major complications.

With an increasingly complex population, there is an emphasis on ensuring there is an appropriate system of care in place, rather than focusing solely on developing the skills of a single clinician. When a complication occurs, how well it is assessed and managed is now a focus of attention. Failure to rescue (FTR) is increasingly recognized as an important quality indicator in cardiac surgery [113–116]. FTR refers to the prognosis of a patient cohort that has experienced a complication [117], and for the purposed of cardiothoracic surgery, FTR has been defined as the postoperative mortality rate after the occurrence of stroke, renal failure, reoperation, and prolonged ventilation [116]. For example, the STS National Database was used to develop FTR metrics and a predictive FTR model for CABG [116]. Recent work has shown that there is variation in FTR rates across cardiac surgery program in the United States [113]. This is an opportunity for improved systems for recognizing complications and improving team processes [113]. Postoperative care processes are evolving so that in many fields where the patient population is frail and complex, there is comanagement of care with a hospitalist. In vascular surgery, this process of care has been shown to decrease mortality and complications [118].

Major Bleeding, Transfusion, and Anemia

Postoperative bleeding is a relatively common complication after cardiac surgery. There are many factors that contribute to the development of major postoperative bleeding, including preoperative drug use and the effects of cardiopulmonary bypass [119]. Major postoperative bleeding, with associated allogenic blood product transfusion and perioperative anemia (the "deadly triad" of cardiac surgery [119]), is commonly experienced complications associated with poor postoperative outcomes [120–125]. In a retrospective study of 16,154 patients undergoing cardiac surgery, major bleeding, red blood cell transfusion, and anemia were all independent predictors of operative mortality. More specifically, patients with either major bleeding (OR: 3.453, 95% CI: 2.785–4.282) or red blood cell transfusion (OR: 2.916, 95% CI: 2.239–3.796) have an operative risk almost three times greater than patients without major bleeding or transfusion, even after adjustment for other covariates. Anemia is also associated with adverse outcomes after cardiac surgery, demonstrating an odds ratio of 2.0 (95% CI: 1.4–2.8) for a composite outcome of in-hospital mortality, stroke, or acute kidney injury [65]. As such, strategies to reduce postoperative major bleeds, anemia, and transfusion must be considered.

Complications Germane to the Older Adult Undergoing Cardiac Surgery

In 2016 the American College of Surgeons NSQIP and American Geriatrics Society coauthored the "Optimal Peri-operative of the Geriatric Patient: a Best Practice Guideline" which provides a practical and evidence-based foundation for approaching postoperative care [126]. In the postoperative period, the guideline focuses on delirium assessment and prevention, perioperative pain management, assessment of pulmonary complications, fall risk assessment, maintaining nutrition, urinary tract infection prevention, assessment and prevention of functional decline, and pressure ulcer prevention. General principles of having a structured approach to assessment, early mobilization, ensuring hearing and vision aides are available, early involvement of family and the multidisciplinary team, as well as avoiding inappropriate medications are all emphasized.

As preoperative comorbidities and frailty increase, so does the risk of complications, including delirium, acute kidney injury, and atrial fibrillation. Each of these complications has been determined to be an independent risk factor for both in-hospital morbidity and prolonged length of stay, but also poor long-term outcome [127–129]. Even with successful hospital discharge, in-hospital severity and duration predict increased long-term mortality.

Postoperative Atrial Fibrillation

New postoperative atrial fibrillation is a common complication that occurs in up to 33% of cardiac patients, with incidence increasing in combined procedures. It is often self-limited, with 80% of cases resolving within 7 days [130]. This is an area where there is still controversy over the optimal management approach, which includes either rhythm or rate control. A rhythm control approach results in accelerated resolution of the arrhythmia but has accompanying risks of toxicity from amiodarone. A rate control approach has less toxicity but slower resolution of the abnormal rhythm and a higher requirement for anticoagulation. Until recently, studies from nonsurgical settings have been used to direct practice in cardiac surgery. However, in 2016 Gillinov et al. published a trial specific to cardiac surgery. They prospectively followed 2109 patients undergoing a variety of surgeries; 33% developed atrial fibrillation, and 523 were randomized to either rhythm control or rate control as an initial management strategy. From a clinical effectiveness perspective, focusing on days in hospital, readmission rates, long-term atrial fibrillation, and need for cardioversion, the two approaches are equal [130]. Specific to the older adult, avoiding amiodarone because of the significant toxicity is a consideration. This consideration would favor a rate control approach, unless there is hemodynamic instability.

Stroke

Despite advances in surgical monitoring and management, stroke remains a devastating complication that typically occurs early in the patient course. As many as 30–40% of strokes occur intraoperatively, either from embolization (i.e., air, atheroma, and calcific debris) or hypotension, resulting in inadequate perfusion of the central nervous system. Postoperatively, they will occur in the first 1–2 days from a cardio-embolic source. LaPar et al. recently published a large retrospective study of all cardiac surgeries performed in Virginia over a 10-year period, who also had an STS score assessed at baseline (average age = 65 years). Of 57,837 patients undergoing surgery, 1.5% developed stroke as a complication [131]. In contrast, in a selected group of octogenarians undergoing elective surgery, the stroke rate was higher at 3.6% [101].

Stroke is more common after urgent and emergent surgeries, as well as isolated valve and combined CABG and valve procedures. Higher preoperative morbidity, as measured by the STS score, is a risk factor for stroke and reflects a higher burden of comorbidities, including peripheral arterial disease, diabetes, heart failure, and renal failure. Other independent predictors of postoperative stroke include prior cardiac surgery (OR: 1.33, $p = 0.05$), preoperative infection (OR: 2.39, $p < 0.0001$), and cardiopulmonary bypass time over 2 h (OR: 1.42, $p = 0.0004$) [132]. Being female is also an independent risk factor for postoperative stroke. In addition to immediate complications, having a stroke increases hospital mortality substantially. In a retrospective study by LaPar et al., mortality increased from 2% in those without stroke to 18% among those suffering a stroke. For those that survive, there is increased morbidity and often prolonged hospitalization as a result. A particular focus of LaPar's study was comparing stroke rates and FTR rates after stroke between institutions. As a clinical entity that can be readily diagnosed with a well-established management approach, it is expected that mortality rate would have little variability. It is concerning that institutional factors impacted both stroke rate and stroke mortality even after controlling for patient and procedure factors [131]. The next step is understanding variations in practice and sharing best practices between centers.

Delirium

Delirium is an acute change in cognitive function that negatively impacts outcomes in the cardiac patient. Delirium is a complication that remains frightening for the patient and equally upsetting for their caregivers. Delirium is the most common neurological complication in the cardiac patient [133, 134]. It is a marker of an injured or injury prone brain [135–137] that likely occurs secondary to alterations in cerebral blood flow [138, 139]. The existence of atherosclerotic vascular disease places the cardiac patient at an increased risk of delirium [140], with rates of delirium following cardiac procedures being reported as high as 78% [141], nearly twice the rate observed in other elective procedures [142–145]. Importantly, patients with heart failure [146] and valvular disease [147, 148] experience equal, if not higher, rates of delirium. Furthermore, while still commonly perceived as a transient syndrome with minimal adverse long-term impact, delirium in patients with acute cardiac illness and following cardiac procedures has been shown to be associated with higher probability of death, morbidity, falls, cognitive decline, and loss of functional independence [139, 149–155]. The burden of atherosclerosis is highly correlated with cognitive function [156]. Multiple studies have demonstrated decreased cognitive performance in patients undergoing cardiac surgery [157–159].

At present, a specific pathophysiology of delirium has yet to be identified and a single cause seems unlikely [160]. In a recent review, delirium has been characterized in three key determinants (also known as the "3-Strike Model"): an increased baseline vulnerability, suffering an acute cardiac event, and post-admission processes of care (Fig. 3) [161].

An important step in the prevention of delirium is the establishment of baseline risk. An advantage afforded to the cardiac surgery team is that they are often presented with the opportunity to obtain information on patients at baseline, prior to their procedure. While it is not clear what is "necessary" in the preoperative work up phase, there is value to the perioperative team to have an understanding of the baseline cognition using the Montreal Cognitive Assessment [162], Mini-Cog [163], or the Short Portable Mental Status Questionnaire [164]. Similarly, testing for frailty [44, 165], abnormal albumin [166, 167], anxiety, depression, and preprocedure pain [168–170] may also provide important information.

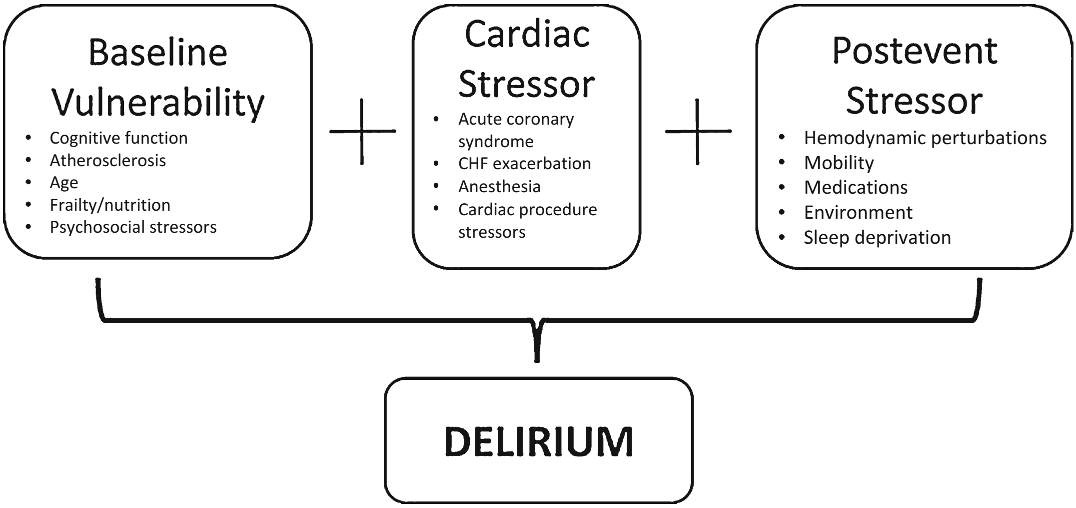

Fig. 3 The Cardiac "3-strike" paradigm- key factors leading to delirium. (Reprinted from Canadian Journal of Cardiology, 33, 1, Arora, R.C., Djaiani, G., Rudolph, J.L., Detection, Prevention, and Management of Delirium in Critically Ill Cardiac Patient and Patients Who Undergo Cardiac Procedures, 80–87, Copyright (2017), with permission from Elsevier)

Despite an increasing clinician awareness of the occurrence of postoperative delirium, under recognition continues to persist, particularly with hypoactive delirium [171, 172]. A system of daily assessment, specifically for delirium, should be in place. The ACS/AGS guidelines provide an excellent framework for approaching delirium [173]. In the postoperative ICU setting, two main screening tools for delirium have been developed and validated. The confusion assessment method adapted for the ICU (CAM-ICU) is a brief operationalized instrument that utilizes three assessments: the Richmond Agitation and Sedation Scale, the Attention Screening Exam, and five yes-no questions [174, 175]. The CAM-ICU has been validated in multiple studies and has been implemented in many ICUs. The Intensive Care Delirium Screening Checklist (ICDSC) consists of an eight-item checklist [176, 177]. Using the principles incorporated in the CAM-ICU screening tool, the ICDSC includes additional domains of perceptual differences, psychomotor agitation, sleep disturbances, and inappropriate speech. Both the CAM-ICU and ICDSC should be completed every nursing shift to potentially capture the fluctuations associated with delirium.

On the postoperative ward, there are several tools that have been developed for use of preoperative screening for postoperative delirium [167, 178, 179]. A rigorous study by Rudolph et al. [167] used the widely accepted confusion assessment method (CAM) [180] and included both a derivation and validation patient cohort as part of their analysis. This study, however, included the use of the Mini-Mental State Examination (MMSE) (which takes 15–20 min to administer), which may limit its clinical feasibility. This study serves to further highlight the urgent need for multicenter trials validating the current tools, which effectively screen for risk of delirium in cardiology and cardiac surgery environments.

A process for identifying individuals at high risk for delirium and counseling families preemptively is important. Principles of optimal perioperative care such as pain control, early mobilization, and fluid management are all relevant for prevention of delirium. If delirium emerges, in addition to considering surgical complications, infections, and electrolytes as precipitants, it is also relevant to reexamine pain control, review medications, and assess for urinary retention and fecal impaction. Once present, care includes meticulous attention to fluid balance to avoid dehydration and renal failure and close attention to pain control as the delirious patient may struggle to communicate needs. If delirium is hyperactive, then addition of an antipsychotic is indicated and should be used as a low-dose, scheduled drug rather than waiting for escalation. The ACS/AGS guidelines reference using haloperidol IM/IV initially which is appropriate in the ICU or if there is immediate risk to critical equipment. However more typically an oral agent can be used and risperidone or olanzapine can be used [97].

Deep Sternal Wound Infection

Deep sternal wound infections (DSWI) are infrequent but cause prolonged morbidity and hospital stays following cardiac surgery. Reports of occurrence are generally in the 0.5–2% range. One center publishing a large retrospective analysis of 13 years of cardiac surgery reported a DSWI rate of 0.77% [181]. The diagnosis is often made 2–3 weeks after the initial surgery with presenting symptoms consisting of wound dehiscence, wound discharge, or sternal instability; in one institutions review of all confirmed cases fever was present in only 29% [182].The formal definition follows the CDC classification for surgical site infections. There are also classifications systems for severity. On physical examination, local findings and fever are the main findings. The diagnosis requires a positive culture from the wound, mediastinum, or blood. Chest x-rays are not always helpful but can show damaged or misplaced sternal wires. Computerized tomography of the chest is useful for showing the extent of disease [181].

Preoperatively, risk factors for DSWI include male gender, obesity, diabetes, smoking, peripheral vascular disease, and advanced age. Intraoperative risk factors include prolonged surgery and bilateral internal thoracic artery grafting. The combination of diabetes and ITA grafting is considered particularly high risk for developing DSWI [181].

Traditionally, prevention of DSWI has included preoperative antibiotics and a short course of postoperative antibiotics. If infection is confirmed, treatment consists of wound debridement, primary sternal closure, and mediastinal irrigation, either with an antiseptic or antibiotic solution. Alternative approaches, such as secondary closure from granulation tissues, muscle flap reconstruction, secondary closure with omental flap transfer, and vacuum-assisted closure dressings, are also being used in some institutions. There is currently no consensus on the best practice approach to managing DSWI [181, 182]. Systemic antibiotics are continued for at least 6 weeks after the last positive culture.

Nonsurgical Alternatives

During the current era of health-care reform, there is considerable interest in providing the most appropriate care for patients more than 80 years of age at an “acceptable” cost [183]. As coronary bypass surgery is the most common major operation performed in the USA (more than 300,000 done annually), the use of coronary bypass in the very old adult is an important issue in the present cost-conscious environment. Medicare data from 1987 to 1990 indicated that the use of this operation in patients more than 80 years of age increased by 67% during that time period [184]. The projected rise in the number of coronary bypass procedures to be done in these patients and associated costs is impressive.

Several studies have attempted to compare the treatment results of less expensive and less invasive alternatives to coronary bypass surgery, particularly among older adults. In older adults, percutaneous coronary intervention (PCI) has the potential advantages of shorter hospital stay, less immobilization, and lower cost compared with coronary artery bypass; however, coronary bypass confers greater and more durable freedom from angina, less need for future repeat interventional measures, and overall improved health-related quality of life [185]. Although Mick et al. reported that the procedural complication rates in matched groups of patients undergoing coronary bypass versus PCI were similar, de Jaegere et al. identified that the extend of vessel disease is predictive of event-free survival [186, 187]. As mentioned above, compared with medical noninterventional therapy, coronary artery bypass provides a significant survival advantage and improved quality of life. Ko et al. compared 36 octogenarians who underwent coronary artery bypass with 29 octogenarians who continued medical noninterventional therapy and found that the functional class did not change in the latter group but improved significantly in the former group (NYHA functional class decreased from 3.4 to 1.2, $p < 0.01$) [185]. The 3-year survival rate of 77% for the surgical group was similar to the survival of octogenarians in the general US population and was significantly better than that of 55% for the medical group. In summary, coronary bypass surgery provides improved long-term survival and functional benefit compared with medical therapy and improved the quality of life compared with PCI.

Some high-risk patients diagnosed with severe symptomatic aortic stenosis may be suitable candidates for transcatheter aortic valve replacement (TAVR; also known as transcatheter aortic valve implantation (TAVI)) procedures. These TAVR procedures are conducted less invasively, via a small anterolateral thoracotomy, or more commonly now via the femoral vessels using a percutaneous technique. While the procedure is not without risk, it is generally hypothesized that high-risk patients undergoing TAVR will require a shorter hospital length of stay and experience an accelerated recovery period. Results from the prospective Placement of Aortic Transcatheter Valves (PARTNER) trial, which compared TAVR to standard therapy, identified that TAVR significantly reduced the rate of death at 1 year (30.7% vs. 50.7%, HR: 0.55, 95% CI: 0.40–0.74) among high-risk patients previously deemed inoperable by standard procedures [188]. The risk of all-cause mortality at 5 years is also significantly reduced among high-risk patients undergoing TAVR, compared to standard therapy (HR: 0.50, 95% CI: 0.39–0.65), with 86% of survivors having NYHA class I or II symptoms [189]. Collectively, the results of the PARTNER trail indicate that TAVR is more beneficial than standard therapy for the treatment of inoperable aortic stenosis. Even when compared to traditional surgical aortic valve replacement in high-risk patients, TAVR remains a comparable alternative with respect to 5-year survival rates (67.8% TAVR, 62.4% SAVR, $p = 0.76$) [190]. The results of the initial PARTNER trial have since been extended to intermediate-risk patients, reporting comparable 2-year outcome rates (i.e., death or disabling stroke) among patients undergoing TAVR and traditional surgical aortic valve replacement [191, 192]. Favorable 1–5-year survival rates for TAVR have also been reported among older adults (mean age 83 years), ranging from 83%, 74%, 53%, 42%, and 35% at 1, 2, 3, 4, and 5 years, respectively (Fig. 4) [193].

Transplantation and Mechanical Circulatory Support

In the mid-1980s, implantable mechanical circulatory assist devices were introduced in FDA clinical trials for patients with severe left ventricular dysfunction who were awaiting transplant and would otherwise not survive. The most popular device in this early era, the HeartMate pneumatic left ventricular assist device (LVAD), enabled patients to ambulate and exercise on treadmills while in-hospital. The advantages of LVAD therapy for the often debilitated, deconditioned patients were significant and resulted in improved outcomes for heart transplant recipients who were able to optimize their physical and physiologic conditions prior to transplant. Since then, LVADs have become smaller (e.g., HeartWare (HeartWare) and HeartMate II (thoratec)), more durable, and associated with increased survival rates when compared with the earlier models [194]. The oldest patients with these smaller LVADs are octogenarians who, like their younger counterparts, are leading productive lives outside the hospital. For a selective group of older adults that are physically active who suffer hemodynamic compromise due to severe cardiac dysfunction, a temporary mechanical assist device can be implanted if there is hope of cardiac recovery, such as after a large myocardial infarction.

The seminal Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial demonstrated that implantation of LVAD's can provide survival advantages superior to optimal medical management in end-stage heart failure patients otherwise considered ineligible for transplant. Survival among patients receiving LVAD treatment at 1 year was 52% and 23% at 2 years, compared to 25% and 8% among patients randomized to optimal medical management ($p = 0.008$) [195]. There was a 48% reduction in the risk of all-cause mortality (RR: 0.52, 95% CI: 1.34–0.78, $p = 0.001$) in the group receiving LVAD as compared to patients receiving medical therapy [196]. The REMATCH trial also demonstrated significant improvements in functional status among patients receiving LVAD therapy, as assessed by the Minnesota Living with Heart Failure scores. Collectively, the results of the REMATCH trial demonstrated that the use of LVAD in patients with advanced stages of heart failure results in enhanced survival and clinically meaningful improvements in quality of life.

As the population ages, the number of older adults suffering from heart failure and associated pathologies is increasing. As a result, there is an increasing number of patients that are becoming candidates for heart transplantation procedures. Several studies have demonstrated encouraging survival rates among older adults (i.e., 60 years and older) requiring transplant procedures, although survival rates remain lower when compared to younger transplant recipients [197]. Even so, recent studies indicate the 1-, 5-, and 10-year survival rates among transplant recipients over 60 years to be 87.3%, 80.4%, and 68.0%, respectively [198]. Stringent patient selection and consistent follow-up is essential to ensure optimal outcomes are achieved. Predictors of survival among older heart transplant recipients include ischaemic cardiomyopathy (HR: 4.1) and postoperative complications, such as dialysis treatment (HR: 9.5) and mechanical circulatory support (HR: 4.2).

Strategies for Postoperative Follow-Up

In older adults, there are several considerations when transitioning from hospital back to the community after cardiac surgery. Although there are well-documented acute postoperative risks and considerations, there is less data and evidence for the best models of outpatient postoperative care. Similarly, postoperative mortality after cardiac surgery has been well studied; however, postoperative changes in functional status are less well documented in older adults after cardiac surgery.

Supportive follow-up that emphasizes collaborative and coordinated discharge planning among multidisciplinary team members (e.g., physiotherapy, nursing, occupational therapy, home care, pharmacy, dietician) is beneficial, particularly in frail and at-risk older adult patients [199]. Detailed discharge planning for older patients with medical conditions may help decrease readmission rates within 3 months of discharge from hospital, though fewer data are available to validate this model in cardiac surgery patients [200, 201]. Often detailed discharge planning is organized by an interdisciplinary team and executed by nurse specialists in the community. Successful discharge and community transition models use an individualized approach to the older adult patient. Aspects of these plans may include (1) recurring comprehensive functional assessments to include any changing needs of the patient while in hospital; (2) collaboration between patients, family members, cardiac surgery, cardiology, and primary care teams, including specific follow-up dates with surgical and primary care teams; (3) interdisciplinary discussion of patient's discharge plan and anticipated challenges; (4) clear and validated patient and caregiver education; (5) frequent reassessment of the discharge plan based on patient progress in hospital; and (6) post-discharge follow-up via visits or telephone calls to monitor whether patient's need further support or intervention once back in the community.

Despite the increasing proportion of older adults undergoing cardiac surgery, older survivors of critical care often have a decline in their functional status throughout their time in hospital. Delirium in the intensive care unit, intravenous narcotics, surgical complications, and device self-removal are all associated with functional decline and new institutionalization in critically ill older patients. This places more emphasis on continuous reassessment of discharge planning based on patient's changes in hospital [202].

Upon discharge and at all subsequent follow-up appointments, a thorough medication reconciliation is recommended to identify and prevent adverse drug errors. The immediate post-hospitalization period is a high-risk time for older adults due to in-hospital medication changes. In general, it is estimated that 12–17% of individuals have adverse drug interactions after hospital discharge, many of which are preventable [203]. Factors that contribute to medication management mistakes post discharge include poor patient-patient communication, poor education regarding medication use, poor or unclear therapeutic monitoring, incomplete or inaccurate transfer of information between health-care providers, and lack of prompt follow-up after discharge. Anticipating these difficulties during organized discharge planning is crucial to identify patients and families who may need more information, ensure discharge summaries are sent to appropriate primary care and specialist who will be following the patient, and identify patients who may need to be scheduled more urgent follow-up appointments.

Similarly, post-cardiac surgery clinic visits should include a medication review to ensure patients are taking their medications as prescribed and identify any side effects that may be preventing appropriate medication administration. Medications should be assessed for being stopped. Many older patients may leave hospital with prescriptions for benzodiazepines, antipsychotics, or aggressive bowel regimens that may have been needed acutely postoperatively but should be identified and stopped if there are no strong indications to have them prescribed. Finally, as the older cardiac patient transitions back to community, during follow-up visits, screen for caregiver burnout, acute changes in memory or mobility, and other clinical changes that may warrant a comprehensive geriatric assessment.

Conclusions

Within the last few decades, cardiovascular surgery in older patients, particularly in those older than age 80, has evolved from a relative rarity to a commonplace intervention. Throughout this course, it has been shown that older adults can not only tolerate, but have tremendous benefit from cardiac surgery, including improved symptoms, quality of life, and potentially increased survival. As nonoperative and less invasive interventions for coronary artery and valvular diseases continue to expand and the proportion of older adults in North America increases, it is expected that the number of older adults with cardiac disease that are candidates for procedures will continue to increase.

Due to the rising number of older adults that are undergoing cardiac surgery, there has been increasing attention to and consideration of this population's unique pre- and postoperative risks. Particularly since the 1900s, more attention has been focused on the identification and treatment of delirium in the postoperative cardiac surgery patient, preoperative cognitive assessment, detailed functional assessment, and the impact of preexisting frailty on surgical outcomes. Within the last decade this focus has been further expanded, and in some cases extrapolated to assessments of patients undergoing non operative cardiac interventions.

Further development of risk assessment tools in the older adult population undergoing cardiac surgery has emerged as a significant area of research. On a go forward basis, it will be crucial to continue to devise models to assess and risk stratify older adults undergoing cardiac surgery to further improve surgical outcomes in these individuals to ensure that patient not only survive but thrive after hospital discharge.

This shift toward a comprehensive approach to the older cardiac surgery patient has helped this population continue to thrive postoperatively. Compared to younger cohorts, older adults are often followed by multi- and interdisciplinary teams that include cardiac surgeons, primary care physicians and geriatricians, pharmacists, physiotherapists, and occupational therapists. This widely accepted collective approach to the cardiac surgery patient pre- and postoperatively will continue to help optimize these patients' symptoms and quality of life.

Abstract

Cardiovascular diseases are the most common cause of morbidity and mortality in the world and account for 50% of deaths in people aged 65 and older. While there are many known modifiable risk factors, aging is as an independent and non-modifiable risk factor for worse outcomes in vascular diseases. The geriatric population is unique in their physiologic state, tolerance to stressors with serious risks to morbidity and mortality. Hence, it is essential for vascular surgeons and specialists in vascular interventions to consider the broader picture in older patients. This chapter delves into the geriatric-specific considerations for common vascular disease states. The first section studies the various preoperative risk factors and anesthesia considerations in older adults. Then, we dive into the various vascular maladies prevalent in the older population and their management approach including peripheral artery disease (PAD), carotid artery stenosis, and abdominal aortic aneurysms. Vascular atherosclerotic disease contributes to significantly high morbidity and economic burden in this cohort. Clinicians must carefully consider the decision to intervene, timing of intervention, as well as use of endovascular techniques for treatment of vascular disease. There is growing consensus to include frailty into the surgical workflow towards better planning for high risk patients. Preoperative frailty assessment using geriatric-specific tools could guide shared decision making and utilization of palliative services surrounding vascular care towards reducing morbidity and mortality.

Introduction

Cardiovascular diseases are the most common cause of morbidity and mortality in the world, and account for 50% of deaths in people aged 65 and older [1]. While there are many known modifiable risk factors, aging is as an independent and non-modifiable risk factor for worse outcomes in vascular diseases [1]. As the prevalence of atherosclerosis increases with advancing age, it comes as no surprise that the majority of vascular surgery patients are from the geriatric population [2]. In fact, increasing numbers of older people are undergoing emergency and elective arterial procedures [2]. Despite an overall improvement in the surgical outcomes of older adults, the combination of physiologic changes inherent to aging and the cumulative effect of comorbidities induces adverse postoperative outcomes in some of these patients [2, 3]. In addition to medical factors, the decision to intervene on these patients must also be weighed against several additional issues unique to the geriatric population including patient frailty, individual and family preferences, as well as quality of life. Because vascular disease primarily affects older adults, this is especially relevant to vascular surgeons and other practitioners who specialize in vascular interventions. As the population ages and life expectancy continues to increase, vascular surgery will play a key role in the treatment of geriatric patients. In this chapter, we will discuss perioperative factors, as well as some issues unique to each of the more common vascular maladies seen in contemporary geriatric populations (Table 1).

Perioperative Risk Factors and Anesthesia

Geriatric patients undergoing vascular interventions often have multiple perioperative risk factors, including diabetes mellitus (DM), coronary artery disease (CAD), chronic obstructive pulmonary disease (COPD), renal impairment, and cognitive decline. Preoperative assessment is extremely important in this population, and optimization of these factors will undoubtedly lead to improved

Table 1 Considerations in older adults with vascular diseases

1. Older adults are considered high risk for vascular surgery given their age, comorbidities, pathophysiology of occlusive/aneurysmal disease, poor functional status, muscle wasting, and risk for vascular dementia
2. Preoperative risk assessment using various risk-assessment measures and comprehensive geriatric assessments are associated with lower complication rates, shorter length of hospital stay, and decreased likelihood of being discharged to a facility with higher level of functional dependency
3. There is role for use of regional anesthetic techniques and multimodal opioid sparing analgesic pathways in vascular patients
4. Asymptomatic carotid disease should be carefully considered for medical management versus surgical intervention
5. Older adults often present late with PAD; have a high degree of suspicion for PAD with walking impairment and functional decline
6. Consider toe-brachial index (TBI) with suspected peripheral artery disease (PAD) given the high prevalence of medial calcific disease
7. Invasive diagnostic procedures with contrast should be approached with caution given incidence of contrast nephropathy
8. Consider high index of suspicion for abdominal aorta aneurysm (AAA) especially smokers, as they could present with chronic symptoms
9. Frail patients may be considered for watchful waiting for aneurysm repair if risk of surgery outweighs the risk of rupture
10. Decision to intervene should be patient and procedure specific with utilization of adjunctive medical therapies, palliative care, and shared decision-making

outcomes. To that end, observational and randomized studies have demonstrated that comprehensive preoperative geriatric assessment is associated with lower complication rates, shorter length of hospital stay, and decreased likelihood of being discharged to a facility with higher level of functional dependency [4].

Older adult patients with functional impairment are found to be at high risk for perioperative complications [4]. Efforts are often made to avoid general anesthesia in these patients, as it is considered to be riskier than other anesthetic options and may lead to higher rates of complications. However, this may not always be the case. A study by Moriera et al. [5] examined a geriatric cohort with functional impairment undergoing major lower extremity amputation and stratified outcomes by anesthetic type. The authors concluded that the mode of anesthesia did not have any significant effect on perioperative outcomes. On the contrary, several other studies have proved that regional anesthesia for lower extremity bypass in critical limb ischemia, as well as, for vascular access cases, improved cardiopulmonary outcomes and postoperative mortality when compared to general anesthesia [6, 7]. The decision regarding type of anesthesia should be individualized to the patient, associated comorbidities, and specific procedure. Communication between the surgical and anesthesia teams is of paramount importance in order to devise the safest anesthetic plan for each unique situation.

Peripheral Arterial Disease

The rate of peripheral arterial disease (PAD) is increasing, with a current prevalence of 10–14% in the Western world [8]. This is especially true of older adult patients: In a large database of over 3.6 million screened subjects, the prevalence of PAD increased with each decade of life [9] and nearly 25% of adults over the age of 80 years in the United States carry a diagnosis of PAD [10]. The economic burden related to this situation is significant. In 2001, 6.8% of U.S. Medicare recipients were treated for PAD, with an estimated cost of $4.3 billion [11]. Data from the REduction of Atherothrombosis for Continued Health (REACH) Registry estimated the total costs of vascular-related hospitalizations was $21 billion in the United States in 2008, with the majority of costs associated with revascularization procedures [12, 84]. A recent study found that annual costs attributed to chronic limb ischemia was ~$12 billion [85].

Symptomatic PAD can present either as intermittent claudication, ischemic rest pain, or tissue loss, with the latter two being grouped together as critical limb ischemia (CLI). As the median life expectancy has increased, the incidence of CLI has exponentially risen among the aging population [13]. Less invasive, endovascular procedures for CLI are attractive options for older patients since they can be performed without the need for general anesthesia. However, there is little objective evidence on the best management strategy for this cohort [13].

Currently, the US Preventive Services Task Force concludes that the current evidence is insufficient to assess the balance of benefits and harms of screening in asymptomatic patients [14, 15]. Interestingly, owing to a more sedentary lifestyle, older adult patients may not present with symptoms of claudication and often present only when PAD is more advanced. In addition, comorbidities of older adults, such as neuropathy, vertebral injuries, cardiopulmonary disease, or degenerative joint disease, can mask or mimic symptoms of PAD. For this reason, aortoiliac disease may go undetected. Patients often develop multilevel disease by the time of onset of CLI and may not undergo their first vascular intervention until later in life [16]. Hence, there should be a high degree of suspicion for PAD in the older adults and more research is needed regarding use of routine ABI screening in older adults.

Noninvasive Imaging

Noninvasive testing of older adult patients is well tolerated and should generally be the first imaging modality employed. Ankle-brachial index (ABI) is an excellent screening test for PAD, although intervention will generally still be driven by symptoms. ABI also provides an objective measure of perfusion to follow revascularization. Older patients have higher propensity develop medial calcification in their tibial vessels, which is known to falsely elevate the ABI [16]. This is especially true in older adults with diabetics [86]. In such cases, the toe-brachial index (TBI) may be more helpful, with values of <0.7 are consistent with small vessel disease [17]. Waveform analysis by pulse volume recording (PVR) can also be particularly helpful in determining the degree of vascular compromise in calcified vessels (Fig. 1). In patients with abnormal screening tests, further noninvasive testing can be performed with arterial duplex ultrasound to localize the lesion. For patients with absent femoral pulses or suspicion of supra-inguinal disease on duplex or PVR testing, CT- or MR-angiography may be of some use (Fig. 2). However, these modalities are limited in their ability to evaluate smaller blood vessels, especially calcified vessels below the knee. Moreover, higher rates of renal dysfunction in the older population may portend increased risk from contrast administration.

Invasive Imaging

Angiography is considered as the gold standard for evaluating occlusive vascular disease and will often confirm the findings noted on ultrasound. However, there is currently little use for this invasive procedure for diagnostic purposes, given the high precision of noninvasive testing. Elderly patients generally have lower creatinine clearance and should be considered high risk for kidney injury regardless of their baseline creatinine [18]. For this reason, angiography as a diagnostic tool should be avoided whenever possible. However, there is one exception when the benefits of angiography outweigh its concern for use. It is when patients are being considered for bypass surgery; in this case, angiography is helpful in identifying an appropriate distal target and may be considered for investigation.

Decision for Intervention

Maximizing medical therapy is important in the geriatric population, given the inherent risks of intervention. Optimal management consists of lifestyle changes such as smoking cessation and exercise, control of comorbid conditions including diabetes and hypertension, and optimizing medications to include low dose aspirin and statins [14]. Perhaps owing to increased complexity, medical management of older patients by vascular medicine specialists has been shown to improve outcomes when compared to the management provided by standard primary care physicians [19]. Elderly patients with atherosclerosis are often not on optimal medical therapy [20].

The decision to intervene on an older adult patient with PAD follows a slightly different algorithm than for their younger counterparts. For patients with intermittent claudication, the bias should be towards noninvasive management.

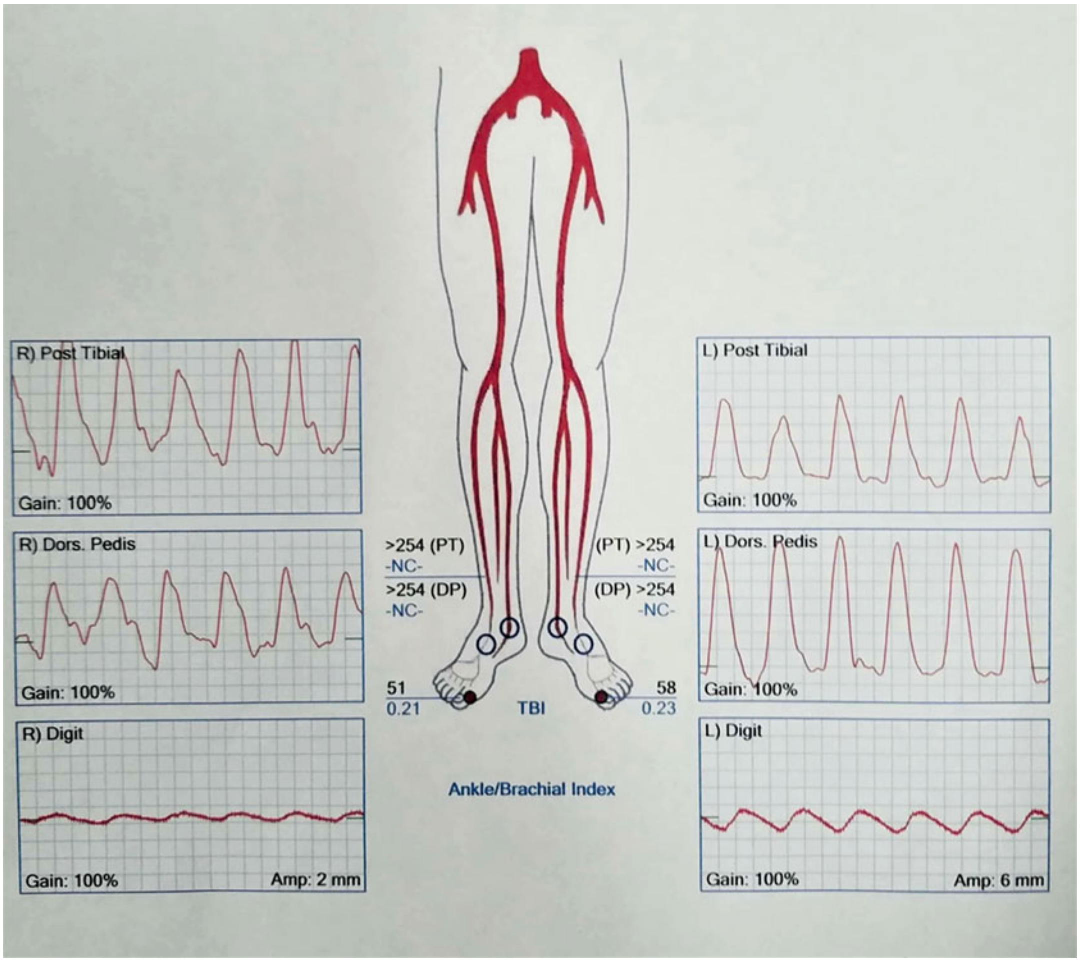

Fig. 1 Diagrammatic representation of a noninvasive methods of diagnosing peripheral artery disease (PAD) in the elderly population including the ankle-brachial index, toe-brachial index (TBI), and pulse volume recording (PVR) waveforms

Many studies have explained the benefits of supervised exercise programs with regard to disease stabilization and improvement in symptoms [21–23], and avoidance of invasive procedures in geriatric patients may be prudent. The use of oral agents such as cilostazol can also prove helpful in claudicants [21, 24]. For CLI, intervention should be undertaken in all but the sickest of patients due to the high risk of limb loss.

Endovascular Versus Open Surgical Revascularization

Although surgical bypass remains the gold standard for revascularization, more often than not a less invasive, endovascular approach is preferable [25]. Despite some positive institutional studies suggesting no increase in wound complications, amputations, or graft failures in octogenarians, many are reluctant to offer lower extremity bypass surgery to this cohort, attributed to the comorbidity burden in the older adults and risk of procedural complications such as wound complications, delirium, and high post-acute care needs [13, 26, 27].

When comparing octogenarians and nonagenarians with critical limb ischemia undergoing lower extremity bypass versus endovascular intervention, limb salvage at 1 and 2 years were similar between the two groups with a low associated mortality [13]. These and other authors have

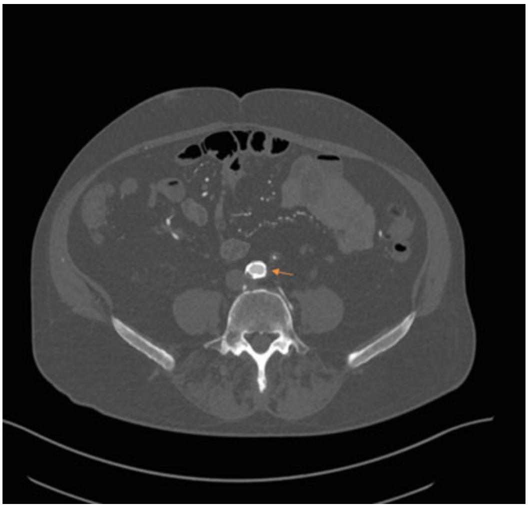

Fig. 2 Axial computed tomography showing vascular calcification present concentrically in the aorta (red arrow)

thus concluded that endovascular revascularization of this high-risk group is feasible and effective, with similar primary, assisted primary, and secondary patency rates [13, 27].

Geriatric patients for whom endovascular intervention is not an option should still be considered for bypass surgery and should not be excluded simply because of their age. For patients with intermittent claudication, the Society for Vascular Surgery (SVS) recommends that open surgery be offered if the patient will have reasonable likelihood of sustained benefit for at least 2 years [14]. Of course, this is particularly relevant to the older adult population. For elderly patients with multiple comorbidities though, less is often more. For example, geriatric patients with aortoiliac occlusive disease may be better served by a less invasive, extra-anatomic revascularization rather than inline reconstruction (e.g., axillo-bifemoral bypass versus aorto-bifemoral bypass). Additionally, for lower extremity disease, it may be appropriate to perform limb salvage procedures with non-autogenous conduits. This is often a more expedient approach to revascularization, and long-term patency rates are often overshadowed by the patient's short life expectancy. One institutional study looked specifically at outcomes in very elderly patients who underwent distal bypass for CLI. The authors found no difference in outcomes based on age alone, reporting similar data for patency, limb salvage, survival, and amputation-free survival. They recommended against using age alone as a determining factor for the decision to proceed with open surgery [27, 28].

Endovascular procedures can often be performed under local anesthesia, require less operative time, and have minimal blood loss [87]. However, endovascular therapy is not the panacea for geriatric patients, and they still must be optimized prior to these less-invasive interventions. Currently, there is a head-to-head trial underway in the United States, Best Endovascular versus Best Surgical Therapy in patients with Critical Limb Ischemia (BEST-CLI) to evaluate endovascular versus open first approach for patients with CLI that may provide contemporary data for treatment of older adults [29]. Overall survival and limb salvage rates are significantly reduced in older patients with poor nutritional status [30]. In addition, patients who are wheelchair bound, bedridden, or on dialysis all have increased risk of mortality following endovascular intervention for critical limb ischemia [30].

Amputation

Amputation has traditionally been reserved for patients without further revascularization options or for those with non-salvageable extremities due to extensive gangrene. However, amputation may also be considered first-line treatment in certain subsets of patients. Older adults who are non-ambulatory at baseline or whose functional status is so poor as to render revascularization senseless may benefit from primary amputation and faster discharge to home. Patients with comorbidities that prohibit extensive surgical revascularization should be considered for primary amputation, as well [31]. However, amputation is not without its own risks. A recent meta-analysis identified coronary disease, cerebrovascular disease, renal dysfunction, and dementia as independent predictors of increased mortality following major lower extremity amputation; these risk factors are more prevalent in the older adult population [32]. Even following successful amputation, rehabilitation programs can be challenging due to frailty and overall poor functional status. Geriatric patients also do poorly with amputation with regard to maintaining their independence [31]. Occasionally, patients will be deemed fit for neither an attempt at limb salvage nor an amputation, in which case terminal wound care is a potential alternative, with the goal to prevent infection and minimize pain and hospitalization time.

Acute Limb Ischemia

Acute arterial occlusion can also lead to significant morbidity in older adults, even in the absence of preexisting PAD. Patients may present with acute onset of unilateral pain, paralysis, and/or neurologic changes. Often, there will be a contrastingly normal vascular exam on the unaffected side. Atrial fibrillation, which is extremely prevalent in geriatric patients, is a significant cause of peripheral emboli [33]. In contrast to chronic PAD, and just as in younger patients, acute arterial occlusion is a surgical emergency and prompt restoration of blood flow is imperative to limb salvage. The age of the patient should not in itself be a factor in determining the strategy for revascularization in these instances: Limb salvage rates after surgical intervention for acute lower limb ischemia in the older adult population are comparable to those of the younger population [34]. However, thrombolysis has been associated with high risk of complications and should be undertaken with caution [20].

Extracranial Carotid Disease

Unsurprisingly, the overall increase in atherosclerotic diseases with age translates to an increased risk of carotid artery disease and ischemic cerebrovascular events [35]. However, finding the optimal treatment strategy for these patients is not always straightforward. In symptomatic patients, age was found to be an independent risk factor for stroke for patients treated with medical management alone, which would suggest that a more aggressive approach is warranted [36]. However, outcomes with carotid revascularization are poorer with advanced age as well. In the Carotid Revascularization Endarterectomy vs. Stenting Trial (CREST) trial, older patients undergoing carotid stenting had a higher periprocedural stroke risk than their younger counterparts [37]. Furthermore, geriatric patients undergoing endarterectomy have demonstrated higher risk of in-hospital stroke and mortality [38]. Unfortunately, though, level 1 data is lacking, as most prospective and randomized trials have excluded patients older than 80 years old. One large registry study of over 1900 patients undergoing endarterectomy examined the 80-plus cohort and aimed to identify specific outcomes and survival [39]. The authors found no difference in stroke rates between patients older or younger than 80 years. However, the older group did have significantly higher perioperative mortality (1.9% vs. 0.8%), as well as a higher combined stroke/death rate. Interestingly, this was primarily attributable to differences among symptomatic patients on subgroup analysis, with asymptomatic octogenarians having similar stroke/death rates to the younger cohort. Ultimately, the authors concluded that despite the higher combined stroke/death rate, the outcomes fell within acceptable national guidelines and that geriatric patients could still derive benefit from surgery when compared to best medical therapy alone [39]

Another study from the Carotid Artery Revascularization and Endarterectomy (CARE) registry looked retrospectively at over 4000 patients, both symptomatic and asymptomatic. In contrast to the previously discussed study, there was a significant increase in mortality seen among asymptomatic patients over 75 years old, but no such difference was noted in symptomatic patients [40].

Given these contradictory findings in multiple studies, it is important to base the decision for revascularization on each patient's "physiologic age" and known risk factors, rather than their chronological age alone [39, 41–43].

As with younger patients, management of carotid arterial disease begins with risk factor modification. This is true both for patients receiving medical therapy alone and those undergoing revascularization. Hypertension, cigarette smoking, diabetes mellitus, left ventricular hypertrophy, increased age, prior stroke, transient cerebral ischemic attack, extracranial arterial disease, obesity, and coronary heart disease have all been shown to be risk factors for stroke among geriatric patients specifically [44–46]. Optimization of these factors is of paramount importance, and patients should universally be on daily low-dose aspirin and statin therapy.

Management of the Symptomatic Patient

The major prospective, randomized clinical trial for determining treatment of patients with symptomatic carotid stenosis was the North American Symptomatic Carotid Endarterectomy Trial (NASCET) [47]. Unfortunately, NASCET included an age cutoff of 80 years, which limits its applicability to patients over 80. However, some of this level 1 data can be extrapolated to those patients. NASCET was terminated early because of the high stroke rate seen in the medical therapy arm for high-grade stenosis (i.e., >70%), and the significant stroke reduction provided with CEA at only 3 months follow-up [43–47]. NASCET also showed that there does not appear to be an increase in operative risks owing to age alone, with the caveat again that this only applies to patients under 80 years old. In general, the majority of practitioners treating patients over 80 years old still follow the guidelines stemming from this pivotal trial. The Society for Vascular Surgery (SVS) currently recommends carotid endarterectomy as the first-line treatment for most symptomatic patients with stenosis of 50–99%, without any exception made for age [48].

Management of Asymptomatic Patient

The Asymptomatic Carotid Atherosclerosis Study (ACAS) demonstrated a significant decrease in 5-year stroke risk among asymptomatic patients with >60% stenosis who underwent carotid endarterectomy versus those who were treated with best medical therapy (11% vs. 5%) [49]. Like the NASCET trial though, ACAS only included patients less than 80 years of age. Again, this data must be extrapolated to the elderly population. Unlike in symptomatic patients, asymptomatic patients do not derive significant benefit in stroke reduction from CEA until approximately 5 years of follow-up. Currently, SVS and AHA guidelines recommend consideration of CEA for asymptomatic patients with stenosis of 60–99% provided the patient has a life expectancy of 3–5 years and perioperative stroke/death rates are ≤3% [48]. However, these guidelines lack specificity and are do not consider medical therapy, which according to many contemporary studies, now carries an annual stroke risk of <1% [50–52]. The ongoing Carotid Revascularization and Medical Management for Asymptomatic Carotid Stenosis Trial (CREST-2) is a combination of two trial arms assessing treatment differences between intensive medical management alone compared to carotid endarterectomy (CEA) and carotid stenting (CAS) both with intensive medical management with no upper age limit to gather evidence for elderly carotid stenosis patients as well [53].

Endarterectomy Versus Stenting

Prior to the CREST trial, most assumed that stenting would be a better option for older patients given the less invasive nature of the procedure. However, overall outcomes in CREST were slightly better after carotid stenting in patients aged <70 years, and better after endarterectomy in the patients age >70 years [54]. Current SVS guidelines reflect this, recommending endarterectomy over carotid artery stenting in patients aged >70 years of age [48]. Additionally, a recent meta-analysis pooled data from four major randomized trials of stenting versus endarterectomy and found that older patients (≥65) had a significantly increased risk of periprocedural stroke and death with carotid stenting (HR = 2.16). The same was not true of CEA patients [55].

Although some smaller studies quote similar stroke rates between groups, the majority of carotid stent data has shown increased incidence of stroke in elderly patients compared to younger patients [43, 56–59]. However, carotid endarterectomy has been associated with increased mortality in older age groups [56, 58]. Data from CREST showed a higher myocardial infarction rate with CEA compared to stenting, which should disproportionally affect older patients with higher rates of underlying cardiac disease [60].

The most consistent data regarding safety and efficacy of carotid stenting remarks that the key to obtaining excellent results centers around high volume, experienced operators who exercise careful patient selection [57, 58]. According to the SVS guidelines, carotid artery stenting should be reserved for symptomatic patients with stenosis of 50–99% who are at high risk for carotid endarterectomy for anatomic or medical reasons [48]. Currently, carotid artery stenting is not recommended for asymptomatic patients. Again, without specific level 1 data, these guidelines should be applied to the geriatric population as well.

Aneurysm Disease

Epidemiology and Clinical Presentation

Abdominal aortic aneurysms (AAA) are a common disease of older adults with the greatest increase in incidence seen in men after the age of 55 and women after the age of 70 [61]. The epidemiology of abdominal aortic aneurysm is characterized by a large male predominance, and disproportionally affects Caucasian males [56, 61]. However, the incidence in women increases with age and approaches that of a male after the seventh decade of life [61]. The prevalence of AAA is five times higher in men than women and increases with age. AAA rates are reported as 1.3% in men and nearly 0% in women aged 45–54 years, and 12.5% in men and 5.2% in women aged 75–84 years [31].

The US Preventive Services Task Force recommends screening for AAA with abdominal duplex ultrasonography in all men aged 65–75 years old who have ever smoked and selectively in men who have never smoked [31]. Unless there is a family history of aneurysm, there is inconsistent evidence to support screening ultrasounds in women [31, 62].

While most often asymptomatic, presenting symptoms of AAA in older adults can be quite varied and include abdominal or back pain, failure to thrive due to mesenteric ischemia, acute renal failure, and distal thromboembolic disease (i.e., “blue toe syndrome”) [31, 63, 64]. A high index of suspicion is particularly important in the elderly population, as many older patients have chronic symptomatology, which can mask aneurysm-related findings. This may be one reason why octogenarians are more likely to present with ruptured aneurysms than are younger patients, in addition to the fact that octogenarians are more likely to have larger aneurysms [65].

Decision to Intervene

The Society for Vascular Surgery recently released updated guidelines on the management of abdominal aortic aneurysms [66]. Consistent with prior recommendations, there are no specific considerations for age as a determining factor for intervention. However, increasing age has been shown to correlate with poorer outcomes in a number of studies. A large, retrospective study of Medicare patients identified age as an independent predictor of mortality for both endovascular and open repair [67]. The Vascular Quality Initiative (VQI) now also includes age in its mortality risk prediction model for elective aneurysm repair, based on the results of a study from the Vascular Study Group of New England, which were subsequently validated against the VQI database [68]. The SVS guidelines include a recommendation to use this risk prediction model when determining overall fitness for aneurysm repair and therefore include age as an indirect factor to be considered. As such, the decision to intervene should be made on an individual, case-by-case basis. Age itself should be of secondary concern, with more emphasis placed on comorbid conditions and anatomic considerations. Frailty has been shown to be an independent risk factor for morbidity, mortality, and failure to rescue in abdominal aortic aneurysm repairs [69].

Open Versus Endovascular Repair

The consensus from the large, prospective, randomized trials of endovascular aneurysm repair (EVAR) versus open surgical repair of AAA indicate that there is an initial reduction in postoperative mortality with EVAR, with no difference in long-term mortality and increased rates of re-intervention. The mortality benefit may be more pronounced in older patients leading to an overwhelming majority of AAA repairs being done in the United States now being performed using an endovascular approach [70]. A recent analysis of over 45,000 propensity-score-matched Medicare demonstrated a lower mortality after EVAR than open surgical repair (1.2% vs. 4.8%), with the most pronounced and durable reduction in mortality seen in those of advanced age (80–84 years: 1.6% vs. 7.2%; $\geq$ 85 years: 2.7% vs. 11.2%) [71]. This difference among octogenarians is consistent with the anticipated benefits of a less invasive intervention, particularly among patients at high risk for perioperative morbidity and mortality.

Open abdominal aortic aneurysm repair in geriatric patients has largely been abandoned since the widespread adoption of EVAR, in part, owing to the perception that these patients are generally not fit for open surgery. In the United Kingdom Small Aneurysm Trial, increasing age was found to be an independent risk factor for perioperative mortality following open repair [72]. For octogenarians who have undergone open repair since the adoption of EVAR, the repair is often more complex: utilization of a retroperitoneal approach, suprarenal clamp position, ligation of the left renal vein, and longer operating room times have all become more common in the post-EVAR era [73]. This is presumably because more simple aneurysms are being preferentially treated with EVAR, with open repair relegated to those patients without a good endovascular option. However, open aortic surgery should not be totally dismissed based on age alone. Studies involving patients $\geq$80 years old undergoing elective open repair demonstrated an overall perioperative mortality rate of 5.6%, which was not statistically different from that of endovascular repair (4.5%) [65]. The authors do acknowledge a significant potential for selection bias though, and the EVAR mortality of 4.5% is much higher than one would anticipate. Nevertheless, in carefully selected patients with good perioperative risk profiles and good life expectancy, open AAA repair may provide a durable solution. A recent analysis of the national Vascular Quality Initiative (VQI) registry showed frail patients undergoing endovascular and open aneurysm having threefold higher long-term mortality with 1-year mortality rates being 15–20% for both open and EVAR repairs in frail patients, much higher than published randomized clinical trial data. Furthermore, 45.0% of patients underwent elective AAA repair at less than the recommended 5.5 cm diameter threshold. In frail patients, 35.6% underwent EVAR and 22.2% underwent open repair with aneurysms measuring <5.5 cm, suggesting a role for shared decision-making and possibly higher threshold for aneurysm repair in frail patients [74]. Ongoing studies show potential medical therapies for slowing progression of aneurysmal disease [75, 76].

Frailty

Frailty is defined as patient vulnerability to minor stressors due to physiological decline across multiple organ systems [2]. Predictably, many elderly patients undergoing vascular interventions meet this definition, especially given the multisystem effects of vascular disease in general [2]. Frailty is associated with several known atherosclerotic risk factors including hypertension, hypercholesterolemia, and smoking, and frailty itself is a known risk factor for adverse outcomes [2]. Frailty and sarcopenia are more prevalent in vascular surgery patients given the pathophysiology of vascular atherosclerotic and aneurysmal disease along with walking impairments, functional decline, and comorbid vascular dementia. Despite overlap of frailty and sarcopenia, diagnosis of frailty is an independent predictor of mortality and had the strongest prognostic significance in patients undergoing both surgical and nonoperative management [77].

Cognitive decline is an important factor in determining patient frailty. Eight percentage of critical limb ischemia patients 70 years old or greater suffer from dementia [78]; this frail group of older adults has high overall mortality rate of 52% within 1 year, and poorer limb salvage rates [78]. Even for those without overt cognitive issues preoperatively, postoperative delirium can often complicate the postoperative course. Delirium has been linked to higher mortality and longer institutionalization [79] and is most commonly seen following open aortic surgery, followed by peripheral arterial revascularization and amputation [79, 80]. Many factors have been associated with increased risk of delirium, including depression, smoking, alcohol use, visual and hearing impairment, ASA-score, biochemical abnormalities, and blood loss [79, 80]. The strongest risk factors for development of delirium are age and preexisting cognitive impairment [79, 80].

There are several frailty measures that can be employed during preoperative planning to ensure proper risk-stratification [81, 82]. One study, looking at preoperative risk factors for a nonhome discharge following elective vascular surgery procedures, concluded that frail patients are at a twofold increased risk of not returning home after surgery [83]. The authors therefore suggest that preoperative frailty assessments should be used to aid in counseling regarding postoperative disposition [83]. Preoperative assessment and optimization has also been shown to decrease hospital length of stay and increase chance of a home discharge [3]. Furthermore, preoperative risk stratification using geriatric specific tools can help shared decision-making and utilization of palliative care services in complex decisions surrounding vascular care of patients [84, 85].

Conclusion

The geriatric population has significant vascular disease prevalence. Clinicians specializing in vascular interventions should systematically consider geriatric-specific management pathways. The decision to intervene in older patients with vascular conditions should be carefully weighed in, and the type of intervention should be patient-specific. Further, preoperative risk assessment tools based on frailty have the potential of guide complex decisions surrounding vascular care of patients.

Abstract

The majority of pulmonary surgery is performed for lung cancer, which is a disease of older adults. The median age of diagnosis of lung cancer in the United States is 71 years and over 65% of patients are diagnosed after age 65. Importantly, the decision to treat this cancer surgically should not be based on chronologic age alone, but on physiologic factors and a patient's personal goals of care.

Physiologic changes of normal aging include decreased chest wall compliance and strength, increased residual volume and functional residual capacity, and an attenuated response to both hypoxemia and hypercapnia. Therefore, preoperative evaluation must include, in addition to routine assessment of cardiac and renal function, an evaluation of respiratory capacity; this can range from basic spirometry to full cardiopulmonary stress testing and quantitative ventilation/perfusion scanning. Geriatric assessments of cognition, frailty, function, and nutrition should be added.

Operative risk in the older adult is largely attributable to loss of functional lung tissue and pain/stress of the thoracic surgical approach. There is growing evidence that minimally invasive surgery is beneficial in the older adult. Limited resections such as segmentectomy or wedge resection, compared to formal lobectomy, should be considered a compromise treatment but are acceptable in the older adult with major morbidity or shorter expected life span. Resection should also be considered for pulmonary carcinoid and pulmonary metastases.

Specialized multidisciplinary postoperative care and attention to detail perioperatively holds great benefit for the older adult thoracic surgery patient.

Case Study

Ms. Jones is a 78-year-old female who recently fell in her kitchen, striking her rib cage against the counter. X-rays in the emergency department showed no rib fractures but did reveal an incidental unsuspected lung mass in the middle of the left lung. This led to a CT scan that showed a 2 cm spiculated nodule in the superior segment of the left lower lobe with no mediastinal adenopathy.

Ms. Jones had an appendectomy at the age of 16 and a cholecystectomy at the age of 48. She has had no other surgeries. Four years ago, she had an episode of severe chest pain after a large meal that slowly resolved over the next day or so. She chose not to go to the hospital at that time. Ever since then she has developed swelling of her ankles that generally resolves when she lifts her legs to a stool at night. Not infrequently she awakens at night feeling shortness of breath and has trouble falling back asleep.

On evaluation Ms. Jones is generally in good health except for mild osteoporosis and arthritis affecting her hand and legs. She has no other constitutional symptoms. She slowly walks with assistance from a cane. Ms. Jones frequently has a glass or three of wine for dinner but has quit smoking after her fall last week. Recently, she was fitted for a hearing aid because she reports difficulty participating in conversations when she goes out to crowded restaurants with her family. She has been taking insulin over the past 2 years but sometimes forgets a dose. It seems to her that she takes a lot of pills and has trouble keeping them straight.

Ms. Jones is a widow and has been living alone for the past 6 years. Her two sons and their families live nearby. She prepares her own meals, cleans her home, and meets twice a week with the ladies in her building to play cards. Her older son has recently provided for a housekeeper to clean the apartment and help with the laundry once a week. She does not have a regular exercise program. She sees her grandchildren regularly. Of late, she has been relying on family and friends for help with grocery shopping and carrying bags into the apartment. She is no longer comfortable driving at night or for long trips. The recent fall was the second in the last 6 months. What are the next steps in managing Ms. Jones lung nodule?

Introduction

With the aging of the baby boomer population, the number of people in the United States over 65 is expected to nearly double by 2060. Currently 14.88% of the US population is over the age of 65, and this percentage is projected to increase to 23.55% by the year 2060. The average life expectancy in the United States is 78.9 and projected to increase to 85.6 by 2060 [1–4]. Older patients increasingly present for consideration of thoracic surgery, and determining the best management for this group of patients will be a more frequent challenge in the future. While elderly patients present with a spectrum of thoracic disease, both benign and malignant, patients with cancer comprise the largest and most studied subset of this population.

Lung cancer is a disease of the elderly. The median age of diagnosis for lung cancer in the United States is 71 years, and over 65% of patients are diagnosed after age 65. National Cancer Institute statistics indicate that lung cancer is the leading cause of cancer mortality in men and women [5, 6]. Between 2010 and 2014, the US death rate for ages under 65 was 12.4 per 100,000, while the incidence for 65 years and older was 268.5 per 100,000 [7].

Non-small cell lung cancer (NSCLC) comprises 80–85% of primary lung tumors, small-cell lung cancer (SCLC) makes up 15–20%, and 1–2% are pulmonary carcinoid [8–10]. SCLC is usually widely metastatic at time of diagnosis, and rarely under the purview of the surgeon, however, the percentage of lung cancer patients with SCLC histology falls with age [10]. Surgical resection of NSCLC and pulmonary carcinoid offers the best chance for oncologic cure. Additionally, retrospective evidence suggests that resection of isolated metastases to the lung may improve survival.

The decision to undergo surgical resection for malignant disease should not be based on age alone. An understanding of the unique qualities of this patient population has led to improved surgical outcomes for the elderly over the last several decades.

Patient evaluation, selection, and perioperative management must all be adapted to provide best possible care for the increasing numbers of aged patients undergoing surgery for cancer. Management of an elderly lung cancer patient requires a global consideration of the characteristics of aging, differences in tumor presentation and histology, and comorbidities that tend to accumulate over time. The initial interview with a patient and family members is used to elucidate important variables that may impact operative risk and expectations of the recovery process. These questions should elucidate the current independent status of the patient, social supports, mood, and signs of reduced activity or physical limitations. After all, the elderly population is a heterogenous group of patients ranging in functional reserve from the surprisingly well-preserved to the wheelchair-bound invalid.

Physiologic Changes of Age

Physiologic changes of the respiratory system associated with aging include reduced chest wall compliance with stiffening of calcified costal cartilages and narrowing of the intervertebral disc space. A progressively restricted rib cage is sometimes accompanied by increased diaphragmatic excursion. Postoperative weakness of a hemidiaphragm in this group can lead to otherwise unexplained respiratory failure. There is also a reduction of lung elastic recoil with loss of alveolar architecture producing a decreased alveolar gas exchange surface. Progressive atrophy creates weakness of the respiratory musculature. Additionally, there is a decrease in central nervous system responsiveness. The loss of lung elastic recoil and decreased lung compliance diminishes negative intrapleural pressure, which then prevents reopening of the small airways, resulting in air trapping and inadequate ventilation. Functionally this manifests in a gradual decline of vital capacity and partial pressure of oxygen (P_{02}), with an increase in residual volume. Decline in motor power of the accessory muscles and a stiffening of the chest wall also result in a declining forced expiratory volume in 1 s (FEV1). Changes in lung compliance are not uniformly distributed. Higher respiratory rates therefore increase ventilation-perfusion mismatch. The elderly also exhibit a blunted ventilatory response to both hypoxic and hypercapneic insults [11, 12]. Physiologic changes in lung mechanics make elderly patients particularly sensitive to narcotics and muscle relaxants, as well as to supine positioning. Elderly patients are also at increased risk for respiratory tract infections, due to waning immune responses [13]. Smoking in particular has been shown to cause bronchial mucociliary dysfunction [14], which has been associated with increased susceptibility to infection [15]. Finally, elderly patients with marked kyphosis and accompanying paraesophageal diaphragmatic hernias are at particular risk for postoperative aspiration.

Increasing age is associated with declines in other organ systems as well. There is a decline in glomerular filtration rate, an increasing incidence of heart disease, and an increasing incidence of cognitive dysfunction. Changes in body composition decrease the volume of distribution of water-soluble drugs [16]. Additionally elderly patients take more medications than younger patients and are vulnerable to adverse drug effects such as altered mental status.

Preoperative Evaluation

Elderly patients are at increased risk for preoperative morbidity and mortality due to both comorbid conditions and decreased ability to recover physiologic homeostasis after surgical stress. Older patients represent a heterogeneous population and should be offered surgery based on physiologic rather than chronological age. A thorough preoperative assessment is imperative to determine whether a patient is an appropriate surgical candidate and to predict and avoid postoperative complications. Numerous risk assessment tools have been created to define preoperative variables that correlate with poor outcomes; however an easy to use, strongly predictive tool has been elusive. Geriatric assessment tools aimed at predicting outcomes in the specific elderly surgical population remain under study.

All patients in consideration for lung cancer resection surgery require a complete history and physical exam with particular attention to characterization of symptoms, smoking history, and weight loss. At a minimum, patients should undergo a chest X-ray, electrocardiogram, a room air arterial blood gas, pulmonary function tests for patients undergoing lung resection, and basic laboratory work. Further workup can be determined based on symptoms or the status of comorbid conditions.

Accurate diagnosis and staging is of utmost importance to ensure that patients are appropriately chosen for operative resection. Elderly patients should have radiographic and surgical staging of suspected lung cancers in the same manner as younger counterparts. Only after the exact stage is known can rational treatment decisions be made. Therefore, elderly patients should have chest CT scans to image suspected lung nodules, PET scans to look for metastatic disease, brain scans to look for occult metastases, and (if indicated) cervical mediastinoscopy to stage mediastinal nodes. Elderly patients with suspected lung nodules should not be denied this standard workup unless their functional status is so impaired that treatment is not possible.

Cardiac Risk Assessment

The American Heart Association (AHA) and American College of Cardiology (ACC) published a readily accessible consensus practice guideline for perioperative cardiovascular evaluation for non-cardiac surgery that provides a template for assessing patients of all ages [17]. The AHA/ACC guidelines describe a stepwise approach to preoperative surgery with risk stratification and further imaging determined by utilizing symptoms, clinical predictors, and functional capacity. Clinical history should focus on assessment for coronary risk factors and physical capacity including the ability to climb two flights of stairs or walk one block. In general patients with poor functional status or patients with a history of angina or claudication should undergo noninvasive testing. In thoracic surgery patients, it may be difficult to determine if symptom etiology is the result of cardiac or pulmonary pathology; thus it is appropriate to have a low threshold for additional cardiac imaging and assessment by a cardiologist to assist with risk stratification.

Supraventricular tachycardias are very common after thoracic surgery, with increased risk for older patients or those with a faster preoperative heart rate [18]. The risk of postoperative atrial fibrillation is 19% in patients undergoing lung resection for cancer [19]. Randomized trials of thoracic surgery patients have determined that calcium channel blockers or beta-blockers can reduce the incidence of postoperative atrial fibrillation by 50–60%; however beta-blockers were associated with an increased risk of pulmonary edema. Neither class of medication reduced mortality. Three trials showed that digitalis increased the risk of atrial arrhythmias [20]. Beta-blockers and calcium channel blockers will both reduce postoperative atrial fibrillation; however beta-blockers are preferred by some due to their broader benefits of cardiac risk reduction. On the other hand, up to half the doses of postoperative beta-blocker may have to be held due to transient hypotension or bradycardia, leading others to recommend the use of calcium channel blockers.

Pulmonary Risk Assessment

All patients considered for lung resection surgery should have pulmonary function tests performed. FEV1 by spirometry is the most common measured value used to determine a patient's suitability for surgery. Data obtained in the 1970s from over 2000 patients showed a $<5\%$ mortality rate for patients with an FEV1 > 1.5 L for lobectomy and >2 L for pneumonectomy [21, 22]. Absolute values for FEV1 may create a bias against older people; however a value of $>80\%$ of predicted has been quoted by some as sufficient for a patient to undergo pneumonectomy without further pulmonary testing [23]. In reviewing more recent spirometry studies performed from 1994 to 2000, Datta and Lahiri concluded that in NSCLC patients, increased postoperative morbidity and mortality were predicted by an FEV1 of <2 L or $<60\%$ for pneumonectomy, an FEV1 of <1.6 L for lobectomy, and FEV1 of 0.6 L for wedge or segmentectomy [24].

Lung resections have of course been undertaken in patients with much poorer lung function. In 2005 Linden et al. published data from a series of 100 consecutive patients with preoperative FEV1 of $<35\%$ predicted undergoing lung tumor resection. In this series there were 1% mortality rate (single case of perforated colonic diverticulum) and 36% complication rate. Morbidity was dominated by 22% of patients with prolonged air leaks. Eleven patients were discharged with a new oxygen requirement, and four patients developed pneumonia. Only one patient was discharged on a ventilator, and three other patients required intubation for >48 h [25].

Ferguson et al. found preoperative diffusion capacity for carbon monoxide (DLCO) to be more predictive of postoperative mortality than FEV1 in a study of 237 patients. In this study a DLCO of $<60\%$ predicted was associated with increased mortality, and a DLCO of $<80\%$ predicted was predictive of increased pulmonary complications [26]. Other studies, however, have not found this parameter to be a significant predictor of postoperative complications [27, 28]. DLCO and spirometry may be used as complimentary tests, particularly in patients with diffuse parenchymal disease or dyspnea that is out of proportion to the FEV1, with a low DLCO prompting further evaluation [22] (Fig. 1).

Formal and simple exercise testing evaluates the cardiopulmonary system under induced physiological stress and also has been found to be predictive of postoperative complications. Girish et al. prospectively studied symptom-limited stair climbing

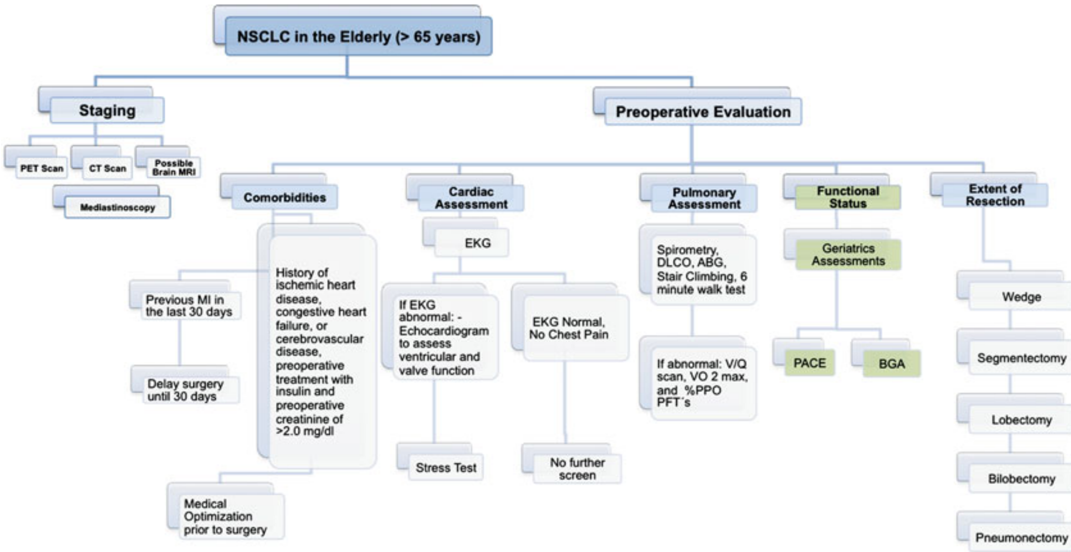

Fig. 1 Recommended pulmonary workup algorithm. *BGA* blood gas analysis, *CT* computed tomography, *EKG* electrocardiogram, *MI* myocardial infarction, *MRI* magnetic resonance imaging, *NSCLC* non-small cell lung cancer, *PACE* Preoperative Assessment of Cancer in the Elderly, *PET* positron emission tomography, *V/Q* ventilation/perfusion

in thoracic and upper abdominal surgery patients. No complications occurred in patients who could climb seven flights of stairs, while 89% of patients unable to climb one flight of stairs had complications. Inability to climb two flights of stairs had a positive predictive value of 80%. The ability of patients to climb stairs was found to be inversely related to the length of postoperative hospital stay [29]. The 6-min walk test (6MWT) measures the distance walked over a period of 6 min. In a qualitative review, Solway concluded that the 6MWT was easy to administer and more reflective of activities of daily living than other walk tests [30]. A normal patient should be able to cover 1400 ft in 6 min. While stair climbing and 6MWT are easy to perform, their use in elderly patients may be limited by orthopedic impairments, peripheral vascular insufficiency, or neurological impairments.

As published previously [31], a recommended preoperative pulmonary evaluation for an elderly patient should consist of spirometry, pulmonary diffusion capacity of the lung for carbon monoxide (DLCO), room air ABG, and exercise tolerance tests including stair climbing and 6-min walk. Patients with an FEV1 >1 L and no major abnormality of other tests (FEV1/FVC >50%, DLCO >50% predicted, ABG paO2 > 45 mm Hg, tolerance of exercise tests) may safely proceed with surgery, including pneumonectomy.

Further evaluations for patients who fall outside these criteria include VO2 max testing and ventilation/perfusion scans to calculate predicted postoperative (PPO) lung function. Measurement of maximal oxygen consumption (VO2 max) by formal cardiopulmonary exercise testing is helpful to further risk stratify patients with borderline lung function. A VO2 max value of <10 ml/kg/min had a very high operative morbidity (26% total in combined data) in several small case series. VO2 max values of 10–15 ml/kg/min had an intermediate perioperative morbidity (8.3% total), whereas patients with >15 mg/kg/min can proceed with lung resection surgery with an acceptable mortality rate [22].

A PPO FEV1 threshold of 0.8 L [32] or 0.7 L [33] has been suggested as a lower limit value for proceeding with lung resection. Absolute values of PPO FEV1 can underestimate postoperative lung function in people with small stature or the elderly and can thus be converted into percent-predicted postoperative (% PPO) lung function. Multiple studies have suggested that morbidity increases at a threshold % PPO FEV1 of <40% or a % PPO DLCO of <40% [26, 34–37].

Cognitive Assessment

One of the most important pieces of information for an elderly patient is the likelihood of returning to baseline physical and mental function after surgery. While patients and their families accept that there will be a postoperative recovery time in the hospital or rehabilitation setting, it is difficult to assess the magnitude of this functional decline and predict the risk of permanent loss of independence. There is a paucity of data assessing changes in quality of life after thoracic surgery in the elderly and few studies that assess whether surgery triggers postoperative loss of independence and change in need for assistance or living requirements. A study of 68 octogenarians undergoing pulmonary resections at Johns Hopkins Medical Institutions showed that 80% of patients were discharged directly home from the hospital rather than to rehab, offering some proxy information regarding immediate postoperative return to function [38]. Moller et al. published a study in 1998 that showed a 25% rate of cognitive dysfunction at 1-week postop from major non-cardiac surgery in elderly patients (average age 68), with continued dysfunction in 9% at 3 months [39]. Hshieh et al. found that elderly patients who experience postoperative delirium have a significantly worse trajectory of functional recovery [40]. Data from many studies verify a high incidence of postoperative cognitive dysfunction in the first week after surgery, and dysfunction does tend to increase with age. Only one other study has substantiated long-term declines over controls, and some have suggested that declines found in these studies may be due to random variation [41, 42]. Karneko et al. determined that preoperative dementia was a risk factor for postoperative delirium [43]. Furthermore, Fukuse et al. found that thoracic surgery patients with preoperative dementia, as estimated by the mini-mental status (MMS) exam, were fourfold more likely to have postoperative complications [44].

Geriatric Assessments

There are multiple assessment indices that have been applied to elderly patients to determine their risk for poor outcome. Functional status describes the ability to perform self-care, self-maintenance, and physical activities. Traditional measures used to assess functional status are activities of daily living (ADLs) and instrumental activities of daily living (IADLs). ADLs have six basic self-care skills, including the ability to bathe, dress, go to the toilet, transfer from a bed to chair, maintain continence, and feed one's self. IADLs include higher functioning skills that are used to maintain independence in the community. This scale assesses ability to use the telephone, go shopping, prepare food, perform housekeeping and laundry, use various modes of transportation, assume responsibility for medications, and handle finances. The need for assistance in these tasks has been predictive of prolonged hospital stay, nursing home placement, and home care requirements [45, 46]. Poor nutritional status, defined as a BMI <22 kg/meter squared, has been associated with increased need for assistance with ADLs and a decreased 1-year survival [47]. A lower ADL score is associated with postoperative complications [48]. The information source reporting a patient's functional status biases the results, with self-reported scores rating higher than scores reported by a significant other or nurse [49].

Performance status is a standardized scale designed to measure the ability of a cancer patient to perform ordinary tasks. There are two scales, the Karnofsky performance scale, which ranges from 0 (dead) to 100 (normal), and the ECOG scale that ranges from 0 (asymptomatic) to 5 (dead). Comparisons of the two scales have been validated with a large sample of patients [50]. Performance status has been used to select patients for entry into chemotherapy trials; however it is also well accepted to be associated with postoperative morbidity [51–53].

Postoperative Care

Postoperative management must be optimized specifically for the elderly population. Narcotic use should be minimized whenever possible to prevent delirium, and appropriate elderly patients should be assessed for preoperative placement of a thoracic epidural catheter for analgesia. Benzodiazepines and medications for sleep should also be minimized. Excellent pulmonary hygiene must

Oxygen tanks and ambulatory saturation monitors are stored along the sides. Pleural drainage systems can be suspended from the side rails. A cloth strap is used to secure the patient to the cart during ambulation

be maintained with frequent chest physiotherapy and early ambulation. At our institution, thoracic ambulation carts, as shown in Fig. 2, are used to facilitate walking patients who require oxygen and are otherwise tethered with multiple lines and catheters.

Non-small Cell Lung Cancer

Stage at Presentation

Elderly patients more frequently have early-stage disease, compared to younger patients with lung cancer. O'Rourke et al. used a database of 22,874 patients to demonstrate that percentage of patients with surgically resectable disease at diagnosis increases with age. The percent of lung cancer patients with local-stage NSCLC increased from 15.3% of those aged 54 years or younger to 19.2% of those aged 55 to 64 years, to 21.9% of those aged 65 to 74 years, and to 25.4% of those aged 75 years or older [54]. Data published from the Surveillance, Epidemiology, and End Results (SEER) database in 2005 analyzing a cohort of 14,555 patients with early-stage NSCLC showed that the frequency of stage I disease increased from 79% in patients <65 to 87% in patients age 75 or greater [55]. Thus, although the elderly are at higher risk of developing lung cancer, a higher proportion present with potentially curable disease.

Histology

Elderly patients are more likely to be diagnosed with squamous cell carcinoma (SCC) over other histology types [10, 56, 57]. Mery and colleagues' analysis of the SEER database showed that the frequency of SCC increased from 27% in patients less than 65 years old to 38% in patients 75 and older, with parallel decreases in frequency of adenocarcinoma from 61% to 50% in corresponding age groups, as depicted in Fig. 3 [55]. Squamous cell carcinomas are associated with a higher incidence of local disease [54], tend to have lower recurrence rates, and may have longer survival times than non-squamous cell cancers [58–60]. Squamous cell tumors are more likely to be centrally located however and thus are more likely to require pneumonectomy for curative resection.

Extent of Resection

Surgical resection for non-small cell lung cancer offers the best chance for cure. The extent of NSCLC resection in elderly patients has been extensively debated, with advocates for limited resections for the aged. Lobectomy, removal of one of the five lobes of the lung and associated lymph nodes within a single pleural membrane, is considered standard of care for surgical resection of early-stage NSCLC [61]. Unfortunately there are multiple studies that substantiate age as a risk factor for death after thoracotomy. Using data

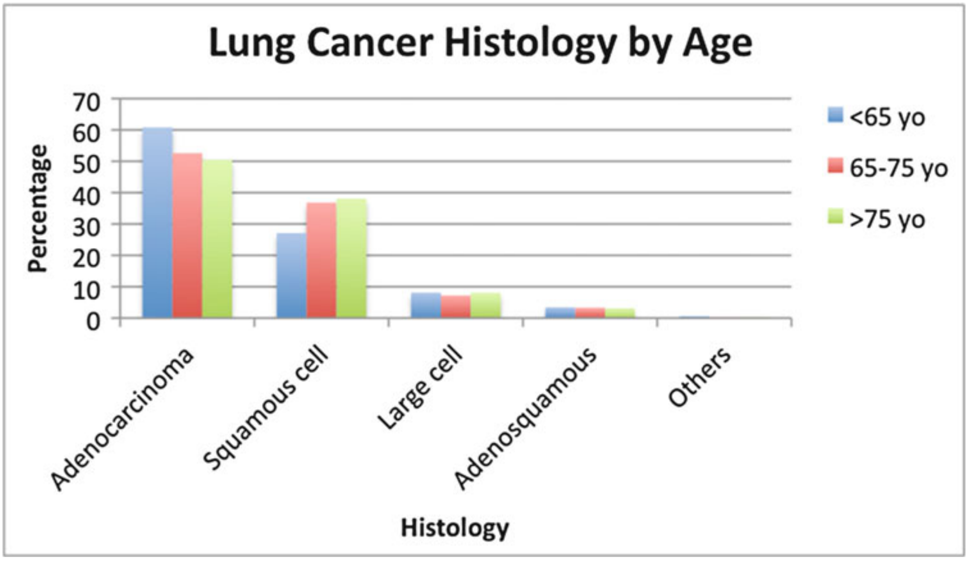

Fig. 3 Lung cancer histology by age. (Data from Mery et al. [55])

from the 1960s and 1970s, several small single-institution studies published operative mortality rates of 14 to 27% for the elderly depending on age and type of surgery [62–65]. These findings were confirmed by a multi-institution study by the Lung Cancer Study Group in 1983. Ginsberg et al. reviewed 2,200 cases of lung resection for cancer and found that operative mortality increased proportionally with age. Patients with age <60 had a 1.3% 30-day mortality rate, with increasing rates of 4.1, 7.0, and 8.1% mortality rates for the 60–69, 70–79, and 80 or greater age groups, respectively [66].

More recently Mery et al. determined a 30-day postoperative mortality rate of 14,555 patients who had undergone curative resections for treating stage I or II NSCLC over the period of 1992–1997. In an analysis of patients undergoing all types of surgery, there was a 0.45% mortality rate for those under age 65 years old, 0.6% for ages 65–74, and 1.2% for age 75 or older ($p = 0.001$). Mortality differences were found to be primarily due to differences in survival of patient undergoing lobectomy, with 0.3%, 0.5%, and 1.5% mortality, respectively, for these corresponding age groups ($p = 0.0001$). The difference in perioperative mortality was statistically similar for patients undergoing limited resection [67]. Prior published reports likewise did not identify a difference in expected operative mortality after thoracotomy if lung-sparing operations were performed [68–70].

The American College of Surgeons Oncology Group (ACOSOG) Z0030 Study published morbidity and mortality data in 2006 for 1023 clinically resectable T1 or T2, N0, or non-hilar N1 NSCLC patients randomized over a period from 1999 to 2004 to undergo lymph node sampling versus mediastinal lymph node dissection. Their age-stratified morbidity and mortality data is shown in Table 1. Notably, overall mortality was 1.4%, improved from Ginsberg's reported 3.8%, and was not statistically associated with age [71]. Ninety percent of patients in the ACOSOG Z0030 study underwent resection via a thoracotomy, with the remaining procedures performed as video-assisted thoracoscopic surgery (VATS) or VATS-assisted resections. Operative mortality reported by Ginsberg for pneumonectomy and lobectomy was 6.2% and 2.9%, respectively, compared with 0% and 1.3%, in the ACOSOG study. Notably the pneumonectomy rate of the earlier study was 25.6% versus 4% in ACOSOG, likely partially explaining the higher mortality rate of the earlier study. The complication rate did rise as age increased, with 49% of patients in

Table 1 ACOSOG Z0030 study age-stratified morbidity and mortality after resection for clinically resectable T1 or T2, N0, or non-hilar N1 NSCLC

Event	Age < 50 ($n = 35$)	50–59 ($n = 171$)	60–69 ($n = 386$)	70–79 ($n = 361$)	80+ ($n = 70$)
One or more complications	8 (23%)	50 (29%)	136 (35%)	162 (45%)	34 (49%)
Air leak > 7 days	1 (3%)	14 (8%)	24 (6%)	33 (9%)	6 (9%)
Chest tube drainage > 7 days	0	14 (8%)	42 (11%)	53 (15%)	9 (13%)

Respiratory	4 (12%)	8 (5%)	30 (8%)	29 (8%)	3 (4%)
Death	1 (2.6%)	0	3 (0.8%)	8 (2.2%)	2 (2.9%)

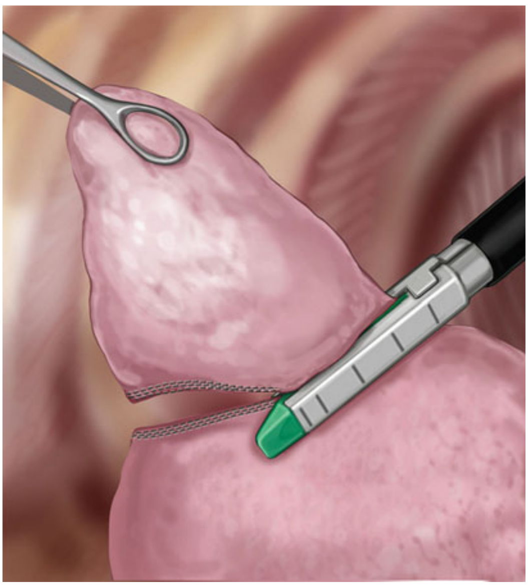

Fig. 4 Video-assisted thoracoscopic wedge resection surgery

the 80 and over age group experiencing one or more complications.

The operative risk of death after pulmonary resections is largely attributable to two anatomical disruptions. First there is the loss of functional lung tissue, and secondly there is the morbidity and mortality introduced by the access thoracotomy. Operative strategies particular to the elderly population have addressed both of these fronts, with use of video-assisted thoracoscopic surgery (VATS) to minimize the chest wall disruption of a thoracotomy and by consideration of limited resections for the most elderly. Figure 4 illustrates the difference in the disruption of chest wall musculature between thoracotomy and VATS approaches.

VATS is defined as surgery performed through two or three incisions that are 2 cm in length. A utility incision less than 10 cm long may be used, without spreading of the ribs. VATS procedures in the elderly have been shown to have lower morbidity, lower rates of postoperative delirium and result in earlier ambulation, a lower narcotic requirement, and a quicker recovery time [72–76].

Limited resections, consisting of either a segmentectomy or wedge resection, remove less lung tissue and are usually performed via VATS. These operations are associated with less perioperative morbidity and mortality but, however, do not completely remove draining lymphatics and may be associated with poorer oncologic outcomes. A randomized trial by the Lung Cancer Study Group of limited resection versus lobectomy for T1 N0 disease revealed a tripling of locoregional recurrence with limited resection and a trend toward improved survival in the lobectomy group [77]. Divergence of the survival curves between lobectomy and limited resection did not occur until 3 years after surgery, however, indicating a potential role for limited resection in patients with a shorter expected life span. Additional studies have concluded that limited resection remains a "compromise" treatment for elderly patients or those with limited cardiopulmonary reserve [78]. An age-stratified analysis of 14,555 patients in the SEER database showed no benefit for lobectomy over limited resection in patients over age 71 [55]. Figure 5 shows a schematic of

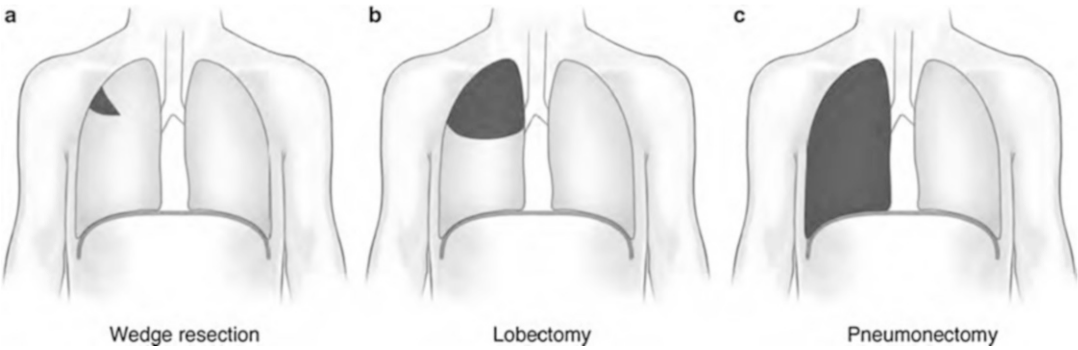

Fig. 5 Extent of resection: (**a**) wedge resection, (**b**) lobectomy, (**c**) pneumonectomy

the range of lung resections. The decision to perform a limited resection versus a lobectomy must take into account the patient's ability to tolerate a larger surgery and potential associated complications versus a smaller resection with less durable oncologic outcomes.

Pulmonary Carcinoid

Pulmonary carcinoids represent 1–2% of lung tumors. They consist of a spectrum of neuroendocrine tumors that are divided into those with typical (TC) or atypical (AC) histological features. While carcinoids tend to present in younger patients, atypical tumors are often diagnosed about 10 years later than typical carcinoid, occurring in the sixth decade. Atypical carcinoids tend to be larger, are usually localized to the peripheral lung fields, and are more aggressive than typical carcinoids. The 5-year survival is 40–60% versus 90% for indolent typical carcinoids [79]. Limited resection with wedge or segmentectomy is the preferred treatment for localized carcinoids. More extensive resection has been advocated for atypical carcinoids, with extent of resection mirroring recommendations for NSCLC [80, 81].

Surgical Resection for Pulmonary Metastases

Metastasis to the lungs is a common oncologic problem. Pulmonary metastases tend to be an indicator of widely metastatic disease; however in some patients metastases to the lungs may occur in isolation. Retrospective evidence suggests that highly selected patients may have improved survival after resection of pulmonary metastases. Indications for the procedure include (1) control of the primary site, (2) metastatic disease isolated to the thorax, (3) resectable disease, and (4) sufficient cardiopulmonary reserve for the operation [82]. Most studies have found that age does not have a prognostic influence on overall survival [83–87].

The largest evaluation of outcomes after lung metastasectomy comes from the International Registry of Lung Metastases. Established in 1990, the registry enrolls all patients who have undergone resection of lung metastases with curative intent. Of the 5206 patients enrolled between 1991 and 1995, 43% of lung metastases were epithelial in origin, 42% were sarcomas, 7% were germ cell tumors, 6% were melanomas, and 2% were other types. Single metastases accounted for 46% and multiple metastases 52%. Germ cell tumors had the best survival and melanoma the poorest survival at 5 and 10 years (68% at 5 years and 63% at 10 years vs. 21% and 14%, respectively). The survival rates for epithelial tumors and sarcomas did not differ significantly (37% at 5 years and 21% at 10 years vs. 31% and 26%, respectively). Rates of recurrence also varied by histology type, at 64% for sarcomas and melanoma, 46% for epithelial, and 26% for germ cell tumors with a median time to recurrence of 10 months. In a multivariate analysis, disease-free interval (DFI), number of metastases, and tumor type were highly prognostic of long-term survival.

Based on these findings, Pastorino et al. proposed four prognostic groupings to provide a framework for management. Group I consisted of patients with resectable metastases, a DFI $\geq$ 36 months, and a single metastasis. Group II patients had resectable metastases and a DFI of <36 months or multiple metastases. Group III again had resectable lesions and both a DFI of <36 months and multiple metastases. Patients with unresectable metastases made up group IV. Median survival for these four groups were 61 months, 34 months, 24 months, and 14 months for groups I thru IV, respectively [88].

The use of VATS over thoracotomy for lung metastasectomy is controversial, as the surgeon is not able to palpate the lung for additional lesions. In 1994, Collie et al. reported that conventional CT missed up to 50% of pulmonary metastases found at surgery [89]. Furthermore, McCormack et al. found additional malignant lesions at thoracotomy in 56% of patients after initial VATS exploration and thus concluded that thoracotomy with manual palpation was the gold standard for metastectomy [90]. Preoperative evaluation with PET has a reported sensitivity of up to 94% for lesions 1.1 to 1.9 cm; however it has limited ability to detect smaller lesions [91]. Other investigators, however, found no difference in rates of recurrence or survival between VATS and thoracotomy [92, 93]. As advances in imaging technology increase the ability to detect smaller lesions, it is likely that the use of VATS will become more commonplace, particularly in older patients. Elderly patients with isolated pulmonary metastases and adequate cardiopulmonary reserve should be considered for surgical resection.

Treatment Patterns of Elderly Cancer Patients

There are multiple studies that point to the undertreatment of cancer in the elderly, which is not limited to patients with lung cancer [94]. Published data from the SEER database showed that the frequency of limited resections increased with age, with a decline of pneumonectomies and lobectomies with age. Approximately 30% of the most elderly patients in the database were denied surgery or were offered only palliative surgery, in contrast with only 8% of the youngest patients [55]. Age is associated with declines in functional reserve and organ function, and optimal treatment is often affected by comorbid conditions. Adding to the complexity involved in treatment, the elderly have often not participated in clinical trials, often forcing clinicians to rely primarily on retrospective data for treatment decisions [95].

An analysis of the Brigham and Women's Division of Thoracic Surgery modern prospective database suggests a morbidity pattern in the elderly that is similar to that of younger patients. The database was designed to collect graded postoperative complications based on the Clavien-Dindo classification of surgical complications. When graded complications were compared based on age alone (<70 and $\geq$ 70), the elderly population had an increased number of complications. When comparing graded complications based on age (<70 and $\geq$ 70) and organ system, insignificant differences were found among complications of the pulmonary and gastrointestinal systems. Significant differences were found in the number of patients experiencing neurologic, cardiovascular, and genitourinary complications, which were mainly driven by an increased number of elderly patients experiencing delirium, atrial fibrillation, and urinary retention, in each of these categories, respectively. Preoperative evaluation of these systems may reduce morbidity and improve the postoperative course of elderly patients undergoing major thoracic surgical procedures.

Using 2004 data, the life expectancy of an 80-year-old in the United States is 9.1 years (8.2 years for males, 9.8 years for females), whereas the median survival for elderly patients with untreated early-stage lung cancer is only 14 months [96]. This suggests that life limitation for an 80-year-old with lung cancer is likely to be cancer related [97]. Table 2 [98] shows life table data from 2004 for patients older than 65.

Table 2 Life expectancy by age, United States, 2014 – Con

Age	Total	Male	Female

Case Reveal

Estimating prognosis, identifying comorbidities, and determining functional status are all essential in deciding the appropriate management of Ms. Jones' lung nodule. Ms. Jones' age and gender are good initial prognosticators. The size of the lesion and absences of mediastinal adenopathy will help determine T and N stages. Even without a tissue diagnosis, this nodule is highly suspicious for adenocarcinoma for which curative resection indicates the best possible survival [99].

Ms. Jones' comorbidities potentially include MI, PE, aortic dissection, esophageal reflux, or esophageal spasms due to her previous episodes of severe chest pain after large meals. Her swelling ankles may indicate MI, rheumatic disease, or pulmonary hypertension. Recent smoking cessation may lead to increased phlegm, slowing her recovery. Her polypharmacy, trouble keeping track of her medications, trouble sleeping, and frequent use of alcohol may indicate an altered mental status which could increase her risk for postoperative delirium and therefore affect her functional recovery.

Ms. Jones' functional status is multifactorial. It is encouraging to see that she prepares her own meals, cleans her home, and regularly spends time with family. Although she is widowed and has lived alone for 6 years, her sons are actively involved and she happily engages in social activities. Yet, the recent addition of a housekeeper and help from family with shopping and carrying bags shows a decline in functional status. Additionally, her trouble walking and multiple falls are concerning for poorer outcomes. Falling at age 65 or older is the 7th leading cause of death in the United States [100]. This leaves us to wonder how quickly Ms. Jones is declining.

Ms. Jones presents a difficult case given her declining cognition and functional status. It is recommended that she receive a geriatric assessment, EKG, stress test, echocardiogram, PET scan, bronchoscopy, possible brain MRI, PFTs, and a 6-min walk test. Additionally, it would be beneficial if her case was reviewed by a multispecialty tumor board that includes a geriatrician. If this workup results favorably, then Ms. Jones should be offered a segmentectomy to preserve lung function.

Conclusion

Resection of pulmonary malignancies has been shown to be safe in selected elderly patients, and age should not be a contraindication to a therapy that offers the best chance for cure for early-stage cancer patients. A targeted preoperative assessment can help individualize the morbidity and mortality risk of surgery for each patient and thus provide both surgeon and patient with the information needed for operative decision-making. Operative interventions in the elderly require coordinated attention to the specific requirements of the aged. Efforts must be made to balance complete oncologic resection with the elderly's limited tolerance for homeostatic insult. Specialized multidisciplinary care provided by primary care physicians, geriatric specialists, cardiologists, oncologists, surgeons, anesthesia, nursing, physical therapy and nutrition optimize care for the elderly thoracic surgery patient.

Abstract
A significant number of people will experience urologic disease with age. The breath of urology covers the entire urinary tract along with the retroperitoneum and male genital structures. Herein, we discuss diseases of the kidney, bladder, and prostate with a particular focus in malignancies of these organ systems.

Benign prostatic hyperplasia (BPH) and prostate cancer are two common disease processes that occur in elderly men. Both of these conditions are rare before the age of 50, but by age 80, more than 80% of men have pathologic evidence of benign hyperplasia and more than 50% have at least microscopic foci of prostate cancer [1]. While BPH-associated urinary symptoms will impact quality of life in most elderly men, the likelihood of prostate cancer resulting in significant morbidity remains low [2, 3]. This chapter reviews the incidence of these two diseases, the appropriate evaluation of elderly men, and surgical options available to the geriatric patient.

General Anatomical Considerations

The prostate is a glandular organ situated in the pelvis. The base of the prostate is in continuity with the bladder and the apex rests on the pelvic floor. The prostate gland surrounds the urethra immediately below the base of the urinary bladder and is located posterior to the inferior symphysis pubis, superior to the urogenital diaphragm, and anterior to the rectum. It is composed predominantly of glandular elements with an investing fibromuscular stroma. The outer capsule is a band of concentrically placed fibromuscular and vascular tissue that is inseparable form prostatic stroma and surrounding fascia. The urethra runs through the gland with anterior angulation at the verumontanum, representing the exit site of the ejaculatory ducts. The prostate can be defined by anatomical zones or surgical lobes which are subject to pathology at varying degrees. The transition zone consists of periurethral tissue situated proximal to the verumontanum. The central zone surrounds the ejaculatory ducts, extending posteriorly to the bladder base. The posterior zone encompasses the remainder of tissue posterior to these two areas adjacent to the rectal vault. The anterior fibromuscular stroma is devoid of glandular elements and runs from the anterior bladder neck to the pelvic floor. While BPH arises almost exclusively from the transition zone, 70% of prostate cancers originate in the peripheral zone, with approximately 25% and 5% of cases stemming from the transition and central zones, respectively. Surgical lobes have also been described in relation to BPH. Lateral lobes are typically seen on cystoscopy as bilaterally bulging elements impinging on the prostatic urethra. A middle or central lobe represents the hyperplastic component that protrudes superiorly into the floor of the bladder, sometimes creating a perceived ball valve effect on voiding. A true capsule does not separate the peripheral and transition zones, but the term “surgical capsule” has been used to delineate a plane of dissection when bluntly enucleating BPH nodules from the peripheral zone. The blood supply to the prostate is mainly from the inferior vesicle artery which arises from the anterior trunk of the internal iliac artery with venous drainage to the plexus of Santorini. The gland is innervated by the pelvic plexus with nerves seen in the periprostatic neurovascular bundle. Lymphatic drainage is mainly to the obturator and internal iliac nodes with secondary drainage to the external iliac nodes and to the presacral group.

Benign Prostatic Hyperplasia

In order to understand the diagnostic and treatment dilemmas facing practitioners caring for the older adult man with BPH, it is important to have working knowledge of the historical terminology used to describe the clinical symptoms. “BPH” represented an acronym for benign prostatic hypertrophy, as the majority of men with urinary symptoms were found to have enlarged prostates. However, from a histologic standpoint, the growth of the gland represents a hyperplastic process – with increase in both glandular and stromal elements. Two problems with this terminology were: (1) hyperplasia has been noted in prostates from men in their third decade of life who exhibit no urinary symptoms and (2) a linear correlation between prostate size and degree of urinary symptoms does not exist. Several other acronyms can be encountered that represent attempts to circumvent these issues. BPE (benign prostatic enlargement) and BOO (bladder outlet obstruction) represent such examples. Although BOO is pathophysiologically correct with regards to the underlying process, it remains a urodynamically defined element thus requiring a semi-invasive and costly test typically not viewed as necessary for treatment or diagnostic purposes. In order to get back to the clinical picture which leads patients to seek treatment, yet another acronym was coined being LUTS (lower urinary tract symptoms). This covered the constellation of symptoms (urgency, frequency, hesitancy, intermittency, straining, sense of incomplete emptying, and nocturia) that were associated with the original "BPH." However, LUTS may be resultant from a diverse list of diagnoses not limited to the obstructive processes of an enlarged prostate [4]. Today ICD-10 coding includes both BPH with and BPH without LUTS.

Epidemiology

The prostate is small at birth, enlarges rapidly at onset of puberty, and then remains at a constant size during the next several decades of life. The average weight of the prostate slowly increases after 50 years of age with an associated increase in the incidence of symptomatic BPH. Although the development of pathologic BPH is almost a universal phenomenon in aging men, the cause and pathogenesis of this disorder are poorly understood. While genetic susceptibility may play a role in younger patients, the relevance dramatically diminishes for those over the age of 60. Androgens are recognized as necessary for the development of pathologic BPH; however, they are not the cause of BPH. While individuals castrated prior to puberty do not develop pathologic BPH, prostate size can continue to increase with age when androgen levels typically decline, suggesting little correlation between the two [5]. Several other risk factors have been proposed, but today there is no evidence to suggest that BPH can be attributed to any specific factors. Series have investigated sociocultural variables including celibacy, specific blood groups, the use of alcohol or tobacco, and disease is commonly found among older adult men such as coronary artery disease, peripheral vascular disease, hypertension, and diabetes.

Pathophysiology

The pathophysiology of symptomatic BPH is complex involving both static and dynamic components. BPH is a true hyperplastic process with histologic studies demonstrating an increase in cell numbers throughout the gland. Hyperplasia occurs in the form of nodules that consist of stromal and epithelial elements. In addition, many nodules contain smooth muscle. Prostatic hyperplasia increases urethral resistance due to mechanical obstruction from tissue expansion. Presumably, the confinement created by the capsule transmits pressure to the urethra leading not only to increased resistance but also compensatory changes in bladder function. How the smooth muscle tissue contributes to symptomatic BPH is unknown, but the muscle fibers are regulated by the adrenergic nervous system. Receptor binding studies indicate that alpha receptors are the most abundant type of receptor in the human prostate and partially explain the ability of alpha-blocking medications to relieve BPH-associated LUTS. In addition, age-related functional changes in the bladder and nervous system have been reported to contribute to LUTS. At the ultrastructural level, normative aging and BOO both result in muscle loss and axonal degeneration with increased collagen deposition [6]. This can lead to both hyperactivity and impaired contractility, which manifest with clinical symptoms associated with symptomatic BPH. It is interesting to note that clinical LUTS are as common in age-matched women as they are in men.

Diagnosis and Evaluation of Prostate Disease

Physicians evaluating older adult men for obstructive urinary symptoms should begin with a detailed history that focuses on the urinary tract, previous surgical procedures, general health issues, and fitness for possible surgical procedures. Specific areas to discuss include a history of hematuria, urinary tract infection, diabetes, neurologic disorders such as Parkinson's disease or previous stroke, urethral stricture disease, urinary retention, and aggravation of symptoms by cold or sinus medications. Physicians should check all current prescription medications to determine whether the patient is taking any anticholinergic drugs (which impair bladder contractility) or a-sympathomimetics (which increase outflow resistance). A history of lower urinary tract surgery suggests the possibility of urethral or bladder neck stricture. The etiology of LUTS is multifactorial, and specific symptoms may be a poor indicator of underlying pathophysiology. This is particularly true in the elderly patient. While LUTS are most often attributed to prostatic obstruction, only two-thirds of men with LUTS meet the accepted diagnostic criteria for obstruction. Obstructive symptoms (hesitancy, weakened stream, intermittency, straining, and sense of incomplete emptying) do not reliably predict outlet obstruction. Researchers' have shown that many aspects of detrusor performance decline with aging and progress to detrusor underactivity (DU) in many older individuals [7–9]. DU can influence the clinical picture and may impede the therapy of many lower urinary tract disorders including BPH. Other contributing processes include detrusor overactivity, sensory urgency, sphincteric incontinence, polyuria, or nocturnal polyuria [10]. The use of certain drugs is also associated with increased risk for LUTS. A community-based cross-sectional study that included 2115 men between 40 and 79 years found that daily use of antidepressants or antihistamines was associated with an increase in symptoms [11]. A tool for symptom assessment has been established and permits objective data for evaluation that can be followed in a longitudinal manner. This is the AUA Symptom Score which should be obtained at initial consultation and routinely thereafter (Table 1). This instrument consists of a series of questions, correlating to common LUTS that have five-graded responses. Symptoms are considered mild, moderate, and severe with scores between 0 and 7, 8 and 19, and 20 and 35, respectively. The AUA symptom score should not be used to diagnose symptomatic BPH but rather to evaluate treatment response or disease progression. Symptom scores alone do not capture the morbidity of a prostate problem as perceived by the patient. The impact of symptoms on a patient's lifestyle must be considered as well. Intervening with medical or surgical therapy may make more sense in a patient with moderate symptoms he finds relatively troublesome compared with a patient with severe symptoms who is able to manage them fairly well. Thus, the critical question for all patients is how much bother these symptoms create and what are they willing to do to improve them. In addition, use of a voiding diary may help to identify patients with polyuria, nocturia, or other non-prostatic disorders. The physical examination should include a digital rectal examination (DRE) and a focused neurologic examination. The rectal examination establishes the approximate size of the gland and can help to guide which surgical approach is most appropriate should this be warranted. Because prostate size does not correlate with symptom severity or treatment outcomes, and DRE typically underestimates size by 50%, size by DRE should not be used to make a diagnosis and proceed with treatment. The DRE is helpful only for guiding management. A focused neurologic examination can be used to exclude neurologic problems that may cause the presenting symptoms and should include an assessment of rectal sphincter tone. A urinalysis should be obtained to screen for hematuria and urinary tract infection. Urinary cytology is no longer indicated in men with severe irritative symptoms, only those with gross hematuria, especially if they have a history of smoking [12]. Although localized prostate cancer typically does not

Table 1 AUA symptom score

Criterion	Not at all	Less than one time in five	Less than half the time	About half the time	More than half the time	Almost always	Your score
Incomplete emptying: Over the past month, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0	1	2	3	4	5	
Frequency: Over the past month, how often have you had to urinate again less than 2 h after you finished urinating?	0	1	2	3	4	5	
Intermittency: Over the past month, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5	
Urgency: Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5	
Weak stream: Over the past month, how often have you had a weak urinary stream?	0	1	2	3	4	5	
Straining: Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5	
Nocturia: Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	0	1	2	3	4	5	
Total score							

produce urethral obstruction, it can coexist with BPH. Consequently, physicians may wish to consider assessing the serum PSA level should a diagnosis of prostate cancer alter the proposed management, although current guidelines recommend against screening for prostate cancer in men over age 75 [13]. Many patients advised to undergo surgical treatment may have cystoscopy and or a transrectal ultrasound. These examinations are not recommended to determine the need for surgery, but rather to help the surgeon determine the most appropriate technical approach based on prostate size. Formal urodynamic evaluation should be considered in elderly gentlemen who maintain high postvoid residuals, have a known or suspected neurologic disease that may affect the urinary tract, or have persistent symptoms after an invasive procedure. Clinicians should also perform a postvoid residual prior to surgical intervention.

Treatment of Benign Prostatic Hyperplasia

Prior to surgical management for BPH, behavioral therapy and medical therapy should be utilized. Behavioral therapies include double voiding, timed voiding, avoidance of caffeine, alcohol, use of nighttime diuretics, and fluid restriction at night.

Alpha Blockers

Alpha-adrenergic antagonists relax smooth muscle at the bladder neck and prostate helping to relieve BOO. They represent the most common initial therapy for treating LUTS associated with BPH. Alpha 1a selective blockers such as tamsulosin, alfuzosin, and silodosin are used commonly and avoid the systemic side effects associated with nonselective alpha blockade.

Common side effects associated with alpha blockade include hypotension that can result in dizziness (5–15% with $\alpha 1_a$-selective agents), retrograde ejaculation (6%), and rhinitis (12%) [14]. The cardiovascular effects are particularly seen when less selective drugs and higher doses of α-blockade are used (tamsulosin 0.8 mg daily). Silodosin is felt less likely to cause orthostasis given its high $\alpha 1_a$-selectivity. In regards to ejaculatory dysfunction, alfuzosin is thought to pose a reduced risk when compared to other means of alpha blockade [15]. The use of alpha blockers, in particular tamsulosin, has been associated with intraoperative floppy iris syndrome [16]. This problem leads to higher rates of iris trauma and posterior capsule rupture during cataract surgery and is associated with prior or concomitant use. Dosing regimens that can be used include but are not limited to tamsulosin 0.4–0.8 mg daily, or alfuzosin 10 mg daily, or silodosin 8 mg daily.

5-Alpha Reductase Inhibitors (5ARIs)

5ARIs suppress androgen synthesis by blocking conversion of testosterone to dihydrotestosterone. This is associated with reduction in prostate volume and a decrease in BOO. These drugs have a much slower onset of action when compared to alpha blockers and may take up to 6 months to see a benefit. The most common side effects associated with the use of 5α-reductase inhibitors include decreased libido (6.4%), erectile dysfunction (8.1%), ejaculatory disorder (0.8%), gynecomastia (0.5%), breast tenderness (0.4%), and rash (0.5%) in the first year of treatment [17]. Regimens that can be employed include finasteride 5 mg daily and dutasteride 0.5 mg daily.

It should be mentioned that alpha blockers and 5ARIs may be used in combination to augment therapeutic effect. Current guidelines published by the American Urologic Association (AUA) and the European Association of Urology recommend combination therapy with alpha blockers and 5ARIs for patients with moderate-severe symptoms, prostates above 40 cc, and advanced age. Sample regimens include finasteride 5 mg + 5 mg alfuzosin twice daily, dutasteride 0.5 mg + tamsulosin 0.4 mg daily, and finasteride 5 mg + doxazosin 8 mg daily.

Surgical Management of BPH

Men failing medical treatments can be offered surgery. Absolute indications for surgery include refractory urinary retention, recurrent urinary infections, recurrent gross hematuria, bladder stones, renal insufficiency caused by obstruction, and the concomitant presence of a large bladder diverticulum. Urologists have developed several surgical procedures to manage BPH. Open surgical excision, known as a simple prostatectomy, was developed more than 100 years ago. Although surgeons still utilize this approach to remove large glands, most urologists favor minimally invasive techniques for appropriately selected patients. Transurethral resection of the prostate (TURP) has been considered the treatment of choice for patients with glands less than 100 g in size. The procedure is typically performed under a spinal or general anesthetic with the patient placed in the lithotomy position. The resection is normally conducted in a fluid medium. Nonhemolytic solutions such as 1.5% glycine, sorbitol, or mannitol are commonly employed when monopolar resectoscopes are utilized. Bipolar electrodes have allowed the use of normal saline which helps to prevent dilutional natremia that can be seen with the use of hypotonic irrigants. The resection technique varies according to the size and configuration of the prostate. Resection is carried out in a circumferential manner from the bladder neck to just proximal to the verumontanum. Resection beyond this point risks damage to the external urinary sphincter. The majority of hyperplastic tissue exists between the 3 and 9 o'clock position with less noted anteriorly. The amount of intraoperative bleeding depends on the size of the prostate, the length of time required to resect the hyperplastic tissue, and the skill of the surgeon. Arterial bleeding is controlled by electrocoagulation. Venous bleeding may be apparent at the end of the procedure, when on irrigating the catheter the returning fluid initially clears but then turns dark red. Venous bleeding can be controlled by inserting a catheter and placing it on traction. Extravasation occurs in approximately 2% of patients, usually following capsular penetration. The symptoms associated with extravasation and fluid absorption include nausea, vomiting, and abdominal pain. Although TURP is considered the standard surgical procedure for treatment of BPH, several alternative surgical procedures have been developed. The majority involve a form of thermal energy transfer to the tissue which causes necrosis and desiccation with time, terminating the procedure and placing a urethral catheter. There has been a significant expansion in non-TURP procedures to assist with management of bladder outlet obstruction. Patients who absorb large amounts of fluid during TURP can become severely hyponatremic and may require treatment with hypertonic saline and diuretics. Over the past 50 years, there has been a steady decline in postoperative complications and mortality associated with TURP. These improvements can be attributed to several factors, including better medical management, better anesthesia, and better surgical equipment including improvements in optics and light sources. Wasson et al. reported that 91% of men undergoing TURP in the Veterans Affairs health care system experienced no complication during the first 30 days after surgery [18]. The mortality rate due to surgery was less than 1%. The most frequent complications reported included the need for catheter exchange (4%), perforation of the prostatic capsule (2%), and hemorrhage requiring transfusion (1%). Long-term complications at 3 years associated with TURP include bladder neck contracture requiring endoscopic surgery (3%), urethral stricture requiring dilation (3%), and secondary transurethral resection (3%).

Simple Prostatectomy

Simple prostatectomy is usually considered when the prostate gland is approximately 100 g or larger. This procedure should also be considered when other concomitant bladder conditions are present, such as a large diverticulum or a large, hard bladder calculus. The advantage of simple prostatectomy is a complete removal of the adenomatous tissue under direct vision without the risk of dilutional hyponatremia, which is often associated with a prolonged transurethral resection. The disadvantages include the need for a lower abdominal incision, a longer hospitalization, and an extended convalescence period. In addition, there may be an increased potential for intraoperative hemorrhage from the prostate fossa. Contraindications to this operation include a small prostate gland, a previous prostatectomy, previous pelvic surgery, and prostate cancer. An open simple prostatectomy can be accomplished using one of two approaches: retropubic or suprapubic. With the retropubic approach, the anterior prostatic capsule is incised and the hyperplastic adenoma enucleated. Advantages to approach include excellent anatomic exposure of the adenoma, precise transection of the urethra distally, clear and immediate visualization of the prostate fossa to control hemorrhage, and minimal trauma to the urinary bladder. The disadvantages of this approach include the inability to access the bladder and difficulty dealing with a large median lobe. A suprapubic prostatectomy is accomplished through an extraperitoneal incision in the lower anterior bladder wall. The bladder neck and prostate capsule are scored under direct vision and the adenomatous tissue enucleated. The urethra at the apex of the adenoma is transected sharply under surgeon feel. The major advantage of this procedure over the retropubic approach is that it allows better visualization of the bladder neck and bladder including the ureteral orifices. As a result, this operation is ideally suited for patients with a large median lobe protruding into the bladder, a concomitant symptomatic bladder diverticulum, or a large bladder calculus. It also may be the preferred approach in obese men when it is difficult to gain direct access to the prostate capsule and the dorsal vein complex. The major disadvantage of this approach is the inability to visualize the apical portion of the prostate directly. Both laparoscopic and robotically assisted laparoscopic approaches have been utilized. The robotic-assisted laparoscopic approach has the advantage of small incisions and less venous bleeding due to the use of intra-abdominal insufflation.

Recent advances in endoscopic technology including laser techniques have reduced the need to perform open simple prostatectomy. Enucleation with laser energy has reliably been shown to effectively treat glands >100 cc [19]. Both robotic surgery and enucleation are specialized techniques and may not be as widely available as TURP or other minimally invasive BPH treatments.

Transurethral Incision of the Prostate (TUIP)
Transurethral incision of the prostate capsule results in significant alleviation of the outflow obstruction, despite the fact that the volume of the prostate remains the same. This involves either unilateral or bilateral incisions, at the 5 and 7 o'clock positions, starting distal to the ureteral orifice ending just proximal to the verumontanum. The depth of the incision is generally described as down to the prostatic capsule. This has been considered an alternative to formal resection in elderly patients who are not deemed medical candidates for more invasive procedures.

Multiple other minimally invasive therapies have been developed. The majority of these involve energy transfer to the prostate causing tissue heating. Treated areas are either vaporized due to high temperatures or develop coagulation necrosis and slough after several days to weeks. Heat-generating elements include lasers (green light, holmium, Nd-Yag, and interstitial), high-intensity focused ultrasound (HIFU), or transurethral microwave thermotherapy (TUMT). Most of these procedures involve delivery of energy through a catheter placed transurethrally or under direct vision cystoscopically. The treatment area can be as long as 40 mm, as wide as 10 mm, and as deep as 10 mm. Laser prostatectomy has demonstrated several advantages over TURP, including technical simplicity, a forgiving learning curve, and the absence or minimization of complications such as intraoperative fluid absorption, bleeding, erectile dysfunction (ED), and incontinence. Patients can be continued on anti-coagulation/antiplatelet medications due to decreased risk of bleeding. The holmium laser has also been used extensively in enucleation of the prostate, described as HoLEP. Multiple patient series have described how large glands have been successfully treated by HoLEP, though a difficult learning curve as well as the need for morcellation to enucleate large lobes have restricted its wide adoption.

Prostatic Urethral Lift (UroLift®)
The prostatic urethral lift (UroLift®) involves implantation of tissue retracting implants inserted under cystoscopic guidance using the UroLift® delivery system. Appropriate patient selection based on prostate anatomy is critical for the success of this operation. An obstructive middle lobe is a contraindication due to the inability to treat this portion of the gland. Typically, 4–6 implants are placed in an anterolateral position that avoids the dorsal venous complex and neurovascular bundles. This system is an option for patients with LUTS attributed to BPH provided the prostate volume is less than 80 cc. Patients should be informed that the symptom reduction and improvement in flow is less when compared to TURP. The UroLift can also be offered to those patients concerned with erectile function for the treatment of LUTS attributed to BPH.

Prostate Cancer

Epidemiology

Prostate cancer is the most commonly diagnosed cancer in men. Nearly 240,000 men are diagnosed with prostate cancer (PCa) annually, and just over 80% of those cases represent localized disease [20]. Approximately 1 out of 7 US men will be diagnosed with PCa during their lifetime and nearly 2.8% of men will die from the disease (nearly 30,000 men) [21]. The majority of prostate cancer deaths (53%) occur among men age 80 and over [21]. Prostate cancer occurs much more frequently among African American men than in white Americans. Although the incidence rates are parallel for Whites and African Americans, the mortality from this disease is almost twice as high for African American men as for white men. Despite the significant mortality from prostate cancer, many men never experience symptoms from their disease. Many prostate cancers are indolent. Autopsy data from several countries have confirmed a high incidence of prostate cancer histology, suggesting that less than 1% of men with histologically identifiable cancer die from this disease [22]. Numerous studies have demonstrated that as many as 50% of men over the age of 50 years dying of causes other than prostate cancer have microscopic evidence of disease. These studies also demonstrated that the presence of these cancers increases with age. By age 75 years, more than 80% of men have microscopic evidence of prostate cancer at autopsy. The etiology of prostate cancer is unknown. The similar prevalence of latent disease among racial and ethnic groups at autopsy and the vast difference in the incidence of clinically significant disease suggest that the initiation of prostate cancer occurs frequently, but only some groups are susceptible to prostate cancer promoters. Known risk factors include familial inheritance. Several families have been identified with an apparent Mendelian pattern of inheritance, and several prostate oncogenes have been isolated [23]. A man with one first-degree relative with prostate cancer has a two- to threefold risk of being diagnosed with prostate cancer compared with the general population. A man with a first-degree and a second-degree relative may have a sixfold risk of developing prostate cancer [24]. Screening for prostate cancer remains controversial especially among older men. A greater understanding of the natural history of screen-detected prostate cancer suggests that as many as half of the screen-detected prostate cancers found among men age 70 and older are not clinically significant [25]. These findings led the US Preventive services Task Force to recommend against routine PSA testing in 2012. In 2013, the AUA released the following guidelines for prostate-specific antigen (PSA) screening:

- PSA screening in men under age 40 years is not recommended.
- Routine screening in men between ages 40 and 54 years at average risk is not recommended.
- For men ages 55–69 years, the decision to undergo PSA screening involves weighing the benefits of preventing prostate cancer mortality in 1 man for every 1000 men screened over a decade against the known potential harms associated with screening and treatment. For this reason, shared decision-making is recommended for men age 55–69 years that are considering PSA screening and proceeding based on patients' values and preferences.
- To reduce the harms of screening, a routine screening interval of 2 years or more may be preferred over annual screening in those men who have participated in shared decision-making and decided on screening. As compared to annual screening, it is expected that screening intervals of 2 years preserve the majority of the benefits and reduce over diagnosis and false positives.
- Routine PSA screening is not recommended in men over age 70 or any man with less than a 10–15 year life expectancy.

Table 2 Prostate cancer biomarkers

Test	When used	Result
PCA3	Post-DRE	Identification of clinically significant PCa
PHI	Negative biopsy	Identification of clinically significant PCa
4K score	Negative biopsy	Identification of clinically significant PCa
Oncotype DX	Post-biopsy	Identifies pT3 or Gleason 4
Prolaris	Post-biopsy or RP	PCa-specific mortality, biochemical recurrence, metastasis, biochemical failure, and biochemical recurrence
Decipher	Post-biopsy or RP	Identifies PCa-specific mortality, metastasis, and biochemical failure

Determining when to biopsy a patient based on PSA alone can be challenging and a number of adjunct biomarkers have been developed to determine the risk of prostate cancer in the pre-biopsy and post-biopsy setting. These are listed in Table 2.

Pathophysiology

Adenocarcinoma of the prostate is frequently diagnosed as a result of an elevation in PSA. In many cases, tumors cannot be palpated on rectal examination. Among men with clinically localized prostate cancer, the tumor is often multifocal, and most of the tumor mass is usually located in a peripheral location near the posterior edge of the prostate [26]. As prostate cancer grows, cancer cells invade the soft tissue surrounding the prostate directly and along the perineural pathways. Penetration of the capsule usually occurs posteriorly and posterolaterally, which may lead to extension into the seminal vesicles. The most frequent sites of metastatic spread are the pelvic lymph nodes and bone, especially the pelvis and vertebral bodies. In general, the size of a prostate cancer correlates with its extent [27]. Tumors are assigned a grade from 1 to 5, with 1 representing the most well differentiated and 5 the most poorly differentiated. A Gleason score is determined by summing the primary and secondary patterns. Men with high-grade disease (Gleason score 8–10) generally have a poor prognosis, whereas men with low grade disease (Gleason score 6) have an excellent prognosis. Once a diagnosis of PCa is made, risk assessment becomes paramount in guiding treatment decisions and for counseling patients accurately about expected oncologic and functional outcomes. Using clinical variables, men are commonly characterized into low-, intermediate-, or high-risk PCa categories. The AUA and the National Comprehensive Cancer Network (NCCN) both have similar risk stratification systems that are primarily based on PSA level, Gleason score, and clinical stage (Table 3).

Table 3 AUA and NCCN risk stratification

	AUA risk category	NCCN risk category
Very low	–	PSA $\leq$10 ng/mL, Gleason score $\leq$6, clinical stageT1c, <3 positive biopsy cores, $\leq$50% in each core, and PSA density <0.15 ng/mL/g
Low	PSA $\leq$10 ng/mL, Gleason score $\leq$6, and clinical stageT1c or T2a	PSA <10 ng/mL, Gleason score $\leq$6, and clinical stageT1-T2a
Intermediate	PSA >10–20 ng/mL, or Gleason score 7, or clinical stage T2b	PSA 10–20 ng/mL, Gleason score 7, or clinical stageT2b-T2c
High	PSA >20 ng/mL, or Gleason score 8–10, or clinical stage $\geq$T2c	PSA >20 ng/mL, or Gleason score 8–10, or clinical stage T3a
Very high	–	Clinical stage T3b-T4

Diagnosis and Evaluation

Unlike BPH, prostate cancer rarely causes symptoms early in the course of the disease because most prostate cancers arise in the periphery of the gland distant from the urethra. Symptoms in men with prostate cancer suggest locally advanced or metastatic disease. Growth of prostate cancer into the urethra or bladder neck can result in obstructive or irritating voiding symptoms. Metastatic disease that involves the bones can cause pain and anemia. Aggressive screening efforts have reduced the proportion of men with prostate cancer detected because of symptoms suggestive of advanced disease [28]. Because of the significant risk of prostate cancer, transrectal ultrasonography and prostate biopsy are recommended for all men who have an abnormality on DRE regardless of the serum PSA level. Unfortunately, in both screened and nonscreened populations, DRE misses 23–45% of prostate cancers that are subsequently found following prostate biopsy because of elevated serum PSA [29]. Routine use of the serum PSA assay increases the detection of prostate cancer over that achieved by a DRE alone. The use of serum PSA testing increases the lead time for prostate cancer diagnosis and the likelihood of detecting prostate cancers confined to the prostate. Recognizing that PSA elevations are common in aging men because of the high prevalence of BPH, investigators have focused on methods of improving the ability of the PSA test to distinguish between men with BPH and men with cancer. Recommendations include adjusting serum PSA levels for patient age, prostate volume, and the rate of change of PSA values [30]. With the advent of specific assays quantifying PSA molecular forms, the measurement of free, unbound PSA has been evaluated as a method of distinguishing between BPH [31]. A prospective analysis of more than 3600 men demonstrated that imaging studies are positive in fewer than 10% of cases when the serum PSA level is less than 20 ng/ml or the Gleason score is less than 8 [32]. Only men with serum PSA levels higher than 50 ng/ml are likely to have evidence of metastatic disease that can be identified on bone scan, CT scan, or MRI. Unfortunately, more than half of the men with newly diagnosed prostate cancer who have a serum PSA level over 10 ng/ml already have disease extension beyond the confines of the prostate [31].

Prostate MRI

Prostate MRI has been an increasingly utilized method for detection of suspicious areas of the prostate in men undergoing prostate biopsy for the first time and for those men who have had negative prostate biopsies but continue to have a rising or elevated PSA [33, 34]. The use of MRI-ultrasound fusion software platforms have allowed for targeted biopsy which has been shown to improve detection of clinically significant prostate cancer. Multiparametric MRI is often used pre-biopsy and images are acquired with at least one more sequence in addition to the anatomical T2 weighted images, such as DWI, or dynamic contrast-enhanced images. Based on the MRI, a PIRADS score is given to suspicious lesions from a grade 1–5, with grade 5 lesions being most likely to harbor clinically significant prostate cancer, and 1 signifying a normal prostate [35, 36]. A number of software platforms have allowed for the "fusion" of MRI images to real-time ultrasound allowing the operator to take targeted biopsies of the prostate using the MRI as a map. The negative predictive value of prostate MRI/US fusion prostate biopsy for detection of clinically significant prostate cancer on subsequent biopsy has been estimated at 97% [37]. The Precision trial was a large randomized trial that demonstrated prostate MRI, with or without targeted biopsy, was superior to standard 12-core biopsy in first-time prostate biopsy patients [38]. It is plausible that MRI-targeted prostate biopsy may become the standard in the future as operators and trainees gain familiarity with it.

Active Surveillance

Active surveillance (AS) is defined as a treatment strategy wherein men with low-risk prostate cancer are serially monitored for disease progression and then treated definitively (if needed), thereby avoiding or delaying the risk of treatment-related morbidity [39]. AS differs from observation or watchful waiting in that watchful waiting indicates a decision to avoid/forgo definitive therapy and palliate only if there is progression to symptomatic disease. Entry criteria for AS protocols vary from institution to institution. Men with very-low-risk and low-risk PCa per AUA and NCCN guidelines are typically candidates for AS. Similar to entry criteria, the monitoring protocols vary among institutions but typically involve routine history and physical with digital rectal exam, PSA testing, and prostate biopsy. As with AS selection and monitoring, indicators of progression and need for definitive treatment vary between institutions and continue to evolve. An increase in Gleason grade, number of positive cores, or percent of core positive on surveillance biopsy are common triggers for physicians to recommend treatment. Increasing PSA and subsequent patient anxiety/fear of cancer or even repeat prostate biopsies are other common triggers for patients to electively choose definitive treatment. In some cases, biomarker testing with the use of genomic markers (Oncotype DX Prostate, Prolaris, Decipher Biopsy) may help reveal patient mortality risk, disease stage, risk of progression, or biochemical recurrence or failure. Ultimately, 30–50% of patients on active surveillance ultimately undergo delayed treatment, though the vast majority will remain free of metastasis with a low risk of dying from prostate cancer [39].

Treatment of Prostate Cancer

The appropriate treatment of prostate cancer among elderly men remains controversial. Studies concerning the long-term outcomes of men treated conservatively for their disease have documented the relatively modest disease-specific mortality among men with low and moderate grade tumors [40, 41]. Alternatives to surgery include external beam radiation therapy and brachytherapy. When choosing therapy for an individual patient with clinically localized prostate cancer, the age and general health of the patient remain critically important because of the indolent progression of many prostate cancers. Death from a localized cancer left untreated is not likely to occur for 8–10 years, yet the risk of death from prostate cancer continues to increase for at least 15 years. As life expectancy decreases with older age, the potential benefits of surgical intervention decrease in parallel. Chronologic age is only one factor that influences life expectancy. Prostate cancer occurs frequently in elderly men who have associated comorbid conditions. Conversely, some older men are in excellent physical condition and have a life expectancy longer than average for their age group. The impact of comorbid conditions on long-term outcomes among men with localized prostate cancer has been assessed [42]. Men with significant comorbid disease, measured using one of several instruments, have a much higher probability of dying from causes other than prostate cancer compared with those men with no or relatively few competing medical hazards. Elderly patients must carefully assess the risks and benefits of surgical management compared with those of conservative management before making a decision concerning which therapy is the appropriate management for their localized prostate cancer.

Radical Prostatectomy

Radical prostatectomy (RP) is a curative treatment option for men with localized PCa and remains the gold standard of definitive therapy in patients that are surgical candidates. In addition to being curative in most patients, it allows for accurate pathologic grading and staging, and makes treatment failures easy to identify with PSA rises. Various surgical approaches for RP have evolved over the years and include robotic, open retropubic, laparoscopic, and open perineal RP. Currently, robotic-assisted laparoscopic and open retropubic are the most commonly performed RP procedures in the USA. More recent observational studies show that robotic surgeries may have better oncologic outcomes, less blood loss, and quicker convalescence.

Regardless of surgical approach, RP involves resection of the entire prostate and seminal vesicles, an urethrovesical anastomosis, and a pelvic lymph node dissection. Radical retropubic prostatectomy done open is performed with the patient in the supine position and laparoscopic or robotic with relatively steep Trendelenburg position to increase exposure to the prevesical space. The procedure is usually performed under general anesthesia. The lymphadenectomy may not be therapeutic but does provide additional pathology to stage the cancer more accurately. The procedure is performed by entering the prevesical space either directly through a lower midline incision or transabdominally, when a laparoscope or robot is employed. The Retzius-sparing approach has also been described and shown to improve return to continence while preserving oncologic control. The robotic approach usually approaches the prostate from the posterior, developing the plane between the seminal vesicles and the rectum. The prostate is separated from the bladder neck prior to controlling the dorsal vein complex and dividing the urethra at the level of the prostate apex. In younger selected men, care is taken to preserve the neurovascular bundles that lie on either side of the prostate from the base to the apex. Once the prostate and seminal vesicles have been removed, the bladder neck is repaired and secured to the stump of the urethra. Careful dissection around the apex of the prostate to avoid injury to the pelvic floor musculature should minimize the chance of incontinence. All techniques for performing a radical prostatectomy are associated with complications, which increase with the patient's age. An analysis of more than 100,000 Medicare claims has demonstrated that approximately one in four patients suffers a major or minor complication associated with these procedures [43]. The radical retropubic approach had higher risks of respiratory complications and miscellaneous medical complications and a lower risk of miscellaneous surgical complications. The perineal approach resulted in a 1–2% incidence of rectal injury, but this appears to be offset by the medical complications of the gastrointestinal tract with the retropubic approach. Short-term mortality following radical prostatectomy is low; approximately 0.5% for men under age 70 and about 1.0% for men aged 75 and older. Long-term complications associated with radical prostatectomy include impotence and incontinence. Although modern surgical techniques have decreased the incidence of postsurgical incontinence, reported rates of this complication vary widely. Patient reports of incontinence have been as high as 31%, whereas reports from tertiary medical centers suggest rates under 10% [44–46]. The age of the patient and whether an anastomotic stricture develops influence the recovery of continence. Patients over age 65 have a greater risk of incontinence compared to men under age 65. Return of erectile function has also been correlated with patient age. Quinlan et al. evaluated 503 potent men between the ages of 34 and 72 who underwent radical retropubic prostatectomy [47]. Among men under the age of 50, about 90% were potent if one or both neurovascular bundles were preserved. Among men age 65–69, only 27% recovered sexual function. Recovery of sexual function is likely to be even lower among men 70 years and older. Bill-Axelson et al. published 11-year outcomes from a randomized trial comparing radical prostatectomy against surveillance for men with clinically localized prostate cancer [48]. They found that all-cause survival was not significantly different between the two arms of the study, although there was a modest decrease in prostate cancer mortality from 18% in the watchful waiting arm to 13% in the radical prostatectomy arm. Interestingly, this benefit was only seen in men less than 65 years at the time of diagnosis and was achieved primarily during the first 5 years following treatment. Surgery in the setting of high risk and locally advanced disease has seen a resurgence. With improved imaging techniques and understanding of surgical anatomy, this can be completed with acceptable oncologic and functional outcomes. Consideration of disease location and burden may require altering surgical approach or surgical extent of dissection. Postoperative radiotherapy should be considered in this population as improvements in progression-free survival have been demonstrated in prospective trials [49, 50].

Radiation Therapy

Radiation therapy can also be used in the primary management of prostate cancer. Radiation therapy is frequently utilized for elderly men who have significant medical comorbidities which impose a high surgical risk but want treatment. There are various types of radiation treatment including external beam radiation therapy (EBRT), intensity-modulated radiation therapy (IMRT), stereotactic body radiation therapy (SBRT), proton therapy, and brachytherapy. External beam radiation is the directed delivery of high energy photons produced in a linear accelerator to the prostate, seminal vesicles, and, depending upon the patient's risk classification, pelvic lymph nodes. A simulation is a CT scan done with the patient placed in a position that is subsequently reproduced on each day of treatment (usually supine in an immobilization device designed to keep the pelvis still). Information from the CT scan with the patient in a reproducible position allows for the creation of the radiation delivery plan. IMRT is a specific type of EBRT delivery technique in which multiple metal leaflets pass across the path of a radiation beam while the radiation is being delivered. Small metal markers (fiducial markers) are often placed into the prostate prior to the SIM to allow for improved accuracy; this is termed image-guided radiation therapy. SBRT is a form of IMRT with even more precision and typically utilizing higher doses of radiation over fewer treatments. Proton radiation therapy is a specific type of EBRT in which protons are used instead of photons, the theoretical advantage being less effective to off-field targets compared to photon EBRT. Brachytherapy is the ultrasound-guided insertion of permanent, low-dose rate or temporary, high-dose rate radioactive sources directly into the prostate. Depending on the risk stratification of a patient's prostate cancer, radiotherapy may be used with or without hormonal therapy. The dose of radiation plays a role in acute and chronic toxicities. Acutely, patients can develop irritative and obstructive voiding symptoms due to bladder and urethral inflammation though may respond to alpha blockers such as tamsulosin. Late toxicities that occur greater than 3 months following treatment include stricture formation, hematuria from vascular changes in the bladder/urethra, and rarely incontinence. In addition, rectal toxicity such as radiation proctitis with rectal bleeding, urgency, and fistula formation may occur. Erectile dysfunction is also a late sequelae of radiation therapy and occurs in 30–40% of previously potent patients [51]. Recently, the use of rectal spacers between the prostate and rectum have been associated with significantly decreased rectal dosing of radiation and rectal toxicity. When assessing overall survival for men with less than 10 year life expectancy and localized prostate cancer, there is no difference in outcome whether receiving surgery or radiation [52]. As such, in those patients unfit for surgery due to competing medical risks but who would like to receive treatment, radiation represents an excellent primary therapy.

Ablative Therapy for the Treatment of Localized Prostate Cancer

Multiple energy modalities have been tested for the ablative treatment of localized prostate cancer; these include high-intensity frequency ultrasound (HIFU), cryoablation, laser ablation, photodynamic therapy, focal brachytherapy, radiofrequency ablation, and irreversible electroporation. The development of ablative techniques has been driven by its significantly lower side-effect profile when compared to whole-gland surgery or radiation. In addition, it is minimally invasive and can be performed in the outpatient setting with many returning to normal activities within a few days rather than weeks during or after radical therapy.

Cryoablation

Cryosurgical techniques have been used prostate treatment since the 1970s [53]. Cryoablation involves placing cryoprobes into the prostate to cause apoptosis and tissue destruction through extraction of heat from tissues below critical temperatures (−20 °C to −40 °C) with rapid freezing and thawing to prevent resistance and adaption. Patients with low- or intermediate-risk prostate cancer who cannot undergo surgery or radiation may opt for cryoablation. Several series have shown efficacy with cryoablation as primary treatment for localized prostate cancer. Ten-year progression-free survival for low-, intermediate-, and high-risk prostate cancer treated with cryoablation monotherapy has been estimated to be 81%, 74%, and 46%, respectively [54]. Complications of total cryoablation include erectile dysfunction, urinary incontinence, and in some very rare instances rectal urethral fistula formation. Following cryoablation, a prostate biopsy is recommended within 3–6 months. Focal cryoablation has also been used for patients with unilateral disease. In these instances, treatment consists of probe placement limited to the side of biopsy-proven disease in order to eradicate the cancer and preserve the contralateral neurovascular bundle.

High-Intensity Focused Ultrasound (HIFU)

HIFU is a noninvasive approach that uses precisely delivered ultrasound energy to achieve tumor cell necrosis without radiation or surgical excision [55]. Indications for HIFU use include those with localized prostate cancer who are unfit for surgery or radiation. In addition, focal HIFU therapy may be employed for patients in unilateral low-volume, low-grade tumors. Furthermore, HIFU has also been used in the high-risk setting and for postradiation salvage. The efficacy of HIFU in locally confined prostate cancer is comparable to those of radiotherapy and prostatectomy, characterized by failure rates of 63% at a mean of 38 months posttreatment and 30% at a mean of 34 months posttreatment [56]. Side effects of primary HIFU therapy can include prolonged voiding dysfunction and retention caused by edema, necrosis, or bladder outlet obstruction, as well as erectile dysfunction. In the same way as focal cryoablation, the goal of focal HIFU therapy is to provide oncologic control with a good side-effect profile in patients with unilateral, localized prostate cancer. The efficacy of HIFU and other focal therapies along with wider utilization will depend on precise diagnostic technologies as well as on accurate, safe, and easy applicable technologies to localize and ablate tumor foci [55].

Prostate Summary

Prostate diseases cause significant morbidity and mortality among elderly men. Both BPH and prostate cancer are relatively rare before age 50 but become increasingly common as men age into their 60s and 70s. For many patients with mild or moderate symptoms of bladder outlet obstruction, various medical therapies may prove beneficial. As symptoms worsen, however, surgical treatment may offer the best chance of relieving symptoms of urinary frequency, hesitancy, and slow stream. Most patients with symptomatic BPH should be offered therapy with an a-blocker or a 5a-reductase inhibitor before proceeding to surgery. Only patients with large prostates should be considered for simple prostatectomy. Minimally invasive therapies are available, but data on long-term efficacy outcomes are still needed. Prostate cancer poses a much more difficult problem for elderly men, especially men with well or moderately differentiated tumors. Prostate cancer in these men is frequently a slow-growing tumor, and other competing medical risks may become the dominant medical problem long before the cancer metastasizes. Patients must carefully assess the relative risks and benefits of a surgery. Elderly men with high-grade prostate cancers (Gleason scores 8–10) face a significant risk of dying from their disease even when it is diagnosed as a localized disease. These men may want to consider definitive treatment with radiation therapy or radical prostatectomy. Focal or subtotal ablative treatments may also be a viable option for elderly men as they provide effective short-term treatment with fewer associated side effects. For men with low grade and low-risk prostate cancer, active surveillance remains a widely utilized option with excellent cancer specific survival.

Kidney Cancer

Kidney Cancer Epidemiology and Etiology

Solid neoplastic lesions of the kidney are comprised of both benign and malignant pathology. Most solid lesions derived from the renal parenchyma are malignant in nature and are predominantly renal cell carcinoma (RCC) (80–90%) [57]. The World Health Organization (WHO) has classified benign renal masses based upon cell type of origin and histopathology (Table 4). The most common benign solid lesions of the kidney include renal cortical adenoma, metanephric adenoma, oncocytoma, and angiomyolipoma. Angiomyolipoma is the only benign tumor that can be readily distinguished by radiographic imaging from its malignant counterparts. Angiomyolipomas (AMLs) are a rare benign clonal neoplasm consisting of adipose tissue, smooth muscle, and blood vessels [58]. The presence of even a small amount of fat on CT is diagnostic of this tumor and can exclude RCC. Epithelioid AMLs lack macroscopic fat and are indistinguishable from other solid renal masses. Classic AMLs can occur either sporadically or in association with the tuberous sclerosis complex (TSC). Size greater than 4 cm and presence of intralesional vascular aneurysms >5 mm are associated with AML hemorrhage [59].

Table 4 WHO classification of benign renal tumors

Classification	Types
Epithelial tumors	Oncocytoma
	Papillary adenoma
Mesenchymal tumors	Angiomyolipoma
	Leiomyoma
	Hemangioma
	Reninoma
	Schwannoma
	Lymphangioma
Mixed epithelial and mesenchymal tumors	Mixed epithelial and stromal tumor
	Cystic nephroma
Metanephric tumors	Metanephric adenoma
	Metanephric adenofibroma
	Metanephric stromal tumor

Since the majority of solid renal masses are malignant and very few benign lesions can be characterized as noncancerous on imaging, it is the clinical assumption that solid lesions of the kidney are malignant until proven otherwise. RCC accounts for 2–3% of all adult malignancies and is considered the most lethal of all urologic cancers [20]. The majority of RCCs are sporadic in origin with hereditary etiologies (von Hippel–Lindau (VHL), hereditary papillary renal carcinoma syndrome, etc.) accounting for a small portion of RCC though the exact estimate of hereditary influence is controversial. RCC is a malignant disease of the elderly, occurring most commonly in the sixth and seventh decades of life [21]. Unlike bladder cancer, there are very few accepted environmental risk factors for RCC. Tobacco exposure is the only accepted factor, with an associated risk as high as 2.5, as compared to controls [60]. In contrast, the hereditary forms of RCC have given us an understanding of the genetic basis of renal carcinogenesis. In many instances, the genes responsible for the hereditary renal cancer syndromes play a role in the more commonly seen sporadic counterparts in the elderly. The most common variant of RCC is clear cell carcinoma. Molecular investigations have identified the inactivation of the VHL tumor suppressor gene located on chromosome 3p25 as the genetic cause of renal tumorigenesis in this subtype [61].

A high percentage of sporadic clear cell renal cancer seen in the elderly also demonstrates allelic loss of the VHL locus [62]. In a similar fashion, other hereditary renal syndromes have revealed the genetic etiology of various subtypes of renal cancer (Table 5).

Table 5 Familial renal cell carcinoma syndromes

Syndrome	Mechanism	Clinical manifestations
Von-Hippel Lindau (VHL)	pVHL tumor suppressor gene (3p25-26)	Clear cell or cystic RCC Retinal angiomas CNS hemangioblastomas Pancreatic cysts and islet tumors Epididymal cystadenomas Pheochromocytomas
Hereditary papillary RCC (HPRCC)	cMET proto-oncogene (7q31)	Type I papillary RCC
Hereditary leiomyoma RCC (HLRCC)	Fumarate hydratase tumor suppressor gene (1q42-44)	Type II papillary RCC (aggressive) Cutaneous leiomyomas Uterine fibroids
Birt-Hogg-Dube (BHD)	Folliculin tumor suppressor gene (17p12q11.2)	Chromophobe RCC or oncocytomas Fibrofolliculomas of head and neck Pulmonary cysts and spontaneous pneumothorax

Adapted from American Urologic Association, Renal Neoplasms

Natural History

A thorough understanding of the available knowledge regarding RCC behavior is important for treatment decisions in the elderly population. This special group of patients may have numerous confounding factors such as comorbid disease, which can impact life expectancy not related to their diagnosis of RCC. Therefore, it is imperative to understand the natural history of this tumor in the geriatric population. Although most clinical observations of RCC have been in patients in their late decades of life, these investigations do not specifically relate biology of tumor to age [63]. Factors such as tumor stage and grade are important prognosticators for RCC and can give insight into its clinical behavior [64]. Despite these important clinical parameters, the natural history of RCC in a particular patient can be highly variable. The clinical presentation of RCC can vary from an incidentally found solid renal mass, seen on imaging only, to a large rapidly growing mass with systemic metastasis. Prior to the advent of imaging techniques such as ultrasonography (US), CT, or magnetic resonance imaging (MRI), most of these kidney cancers were detected by clinical symptoms associated with RCC due to local tumor growth, hemorrhage, paraneoplastic syndromes, or metastatic disease. One prominent symptom, flank pain, is usually due to tumor hemorrhage and obstruction of the collecting system from clot. But in advanced disease, the symptom of pain may be the hallmark of local invasion. The classic triad of hematuria, flank pain, and an abdominal mass on physical exam is rarely seen in the modern era of advanced imaging [65]. Patients with advanced disease also complained of constitutional symptoms, such as weight loss, fever, and night sweats. On physical exam, they were often found to have palpable adenopathy, a nonreducing varicocele, and bilateral lower extremity edema. These tumors were often very large, and up to 25% were associated with metastases. Additionally, half of the patients who appeared to have organ-confined RCC

Table 6 Risk of harboring RCC at presentation

Tumor size (cm)	% Benign pathology	% Metastatic
<1	35–45%	<1%
1–2	20–25%	<1%
2–3	15–20%	<1%
3–4	15–20%	2%
4–5	~10%	2–3%
5–6	~10%	5–10%
6–7	~5%	5–10%
>7	~5%	15–20%

manifest asynchronous metastatic spread following an attempt at curative surgical extirpation, though contemporary series report a much lower rate [66, 67]. This malignancy preferentially spreads to the lungs, lymph nodes, and bone, although metastatic lesions are also found in less common sites such as brain, gallbladder, epididymis, and skin.

The increasing use of noninvasive imaging has shifted the presentation of this disease from a symptomatic course to that of a disease found incidentally in the elderly. The incidence of RCC has steadily increased during the last three decades, mainly due to the use of routine cross-sectional imaging for renal-related and nonrenal-related indications [68]. Now, most RCCs are detected incidentally as small tumors in patients without symptoms. The natural history of these neoplasms has not been investigated adequately, especially that of an incidentally found small renal mass. The risk of metastases at presentation and risk of harboring RCC at presentation are strongly associated with tumor size (Table 6) [49, 69]. As such, the American Urologic Association recommends active surveillance for small renal masses (<4 cm) detected in the elderly and infirm patients.

Management

Management of kidney cancer in the elderly may be a very complex decision process. Treatments must incorporate concerns about efficacy, comorbid illnesses, and complications, as well as physiologic effects on renal function and competing causes for future mortality. Surgery remains the mainstay for curative management of localized RCC. Patients with localized kidney cancer typically do not die of kidney cancer thereby underscoring functional aspects of therapy and survivorship. Features predictive of outcome after surgical treatment of localized RCC include T stage, tumor size, nuclear grade, presence of histologic necrosis, and performance status [70]. The foundation of surgical therapy for renal cancer is complete excision of all neoplastic tissue with an adequate surgical margin. This objective may be obtained by either complete removal of the kidney (radical nephrectomy) or via a nephron-sparing surgical approach (partial nephrectomy). In addition, many minimally invasive techniques, such as cryotherapy or radiofrequency ablation (RFA) can be used. Thermal ablative techniques can be applied during standard open or laparoscopic surgery but are better suited to a percutaneous approach under radiologic guidance (CT or MRI). When performed via the latter technique, a potentially curative treatment can be applied to a completely different patient demographic. Those with significant comorbid illnesses that were previously deemed unsuitable for surgical management can now be given treatment with curative intent, under local anesthetic or minimal sedation. Additionally, active surveillance may be an option especially for those elderly individuals with significant competing risk factors for non-RCC-related mortality. Renal biopsy may help delineate the natural history of RCC in this nontreatment group, to help identify aggressive renal cancers from those with minimal growth and metastatic potential [71]. There are several nomograms described in the published literature to help with competing risk counseling, including a Fox Chase competing risk calculator that is available online.

Radiologic Evaluation

The current radiologic modalities used to diagnose and evaluate renal masses include intravenous pyelography (IVP), renal ultrasound (US), CT, and MRI. In the past, the standard IVP was a commonly used test for the evaluation of hematuria. However, due to the lack of sensitivity and specificity for the detection of renal parenchymal tumors, this technology has been supplanted by multidetector computed tomography urography (CTU), for the evaluation of hematuria [72]. More than 70% of asymptomatic renal masses are found to be simple cysts. The prevalence of benign renal cysts increases with age and are found in over 50% of patients older than 50 years of age, thus a significant finding in the elderly [73]. These lesions are easily characterized by US and CT, and the most common “simple” variety requires no further workup or surveillance [74]. A dedicated renal protocol CT, which entails thin-slice images through the kidney with and without administration of contrast, is the single most important radiologic test to evaluate for RCC. Any renal mass with enhancement characteristics of more than 15 Hounsfield units (HU) after administration of contrast material should be considered an RCC, until proven otherwise [75]. Gadolinium-enhanced MRI is also an excellent modality equal to contrast-enhanced CT that can be utilized for patients with renal insufficiency, a significant problem in the elderly population. The gadolinium-based contrast agent (GBCA) used in MRI lacks significant nephrotoxicity, though previous formulations were shown to have an association with nephrogenic systemic fibrosis, a debilitating and potentially life-threatening disease, with the use of GBCA in renal failure patients [76]. Due to this finding, widespread transition to contrast agents that do not cause nephrogenic systemic fibrosis has been underway. Current precautions involve informing the patients regarding the potential risks of gadolinium-enhanced MRI versus performing a standard CT with iodinated contrast media and understanding the risk of contrast medium nephropathy.

Treatment of Kidney Cancer

Radical Nephrectomy

The radical nephrectomy is the standard of care for localized tumors not amenable to nephron-sparing technique such as partial nephrectomy. While nephron-sparing surgery is recommended by national guideline committees, the only randomized trial to compare partial and radical nephrectomy did not demonstrate any survival benefit to partial nephrectomy [77]. Radical nephrectomy may be the preferred modality for higher risk kidney tumors if there is a high tumor complexity with risk of complication even in experienced hands, there is no existing kidney disease, and postoperative GFR is anticipated to be well preserved. When compared to a partial nephrectomy, radical nephrectomy poses less risk of urinoma and hemorrhage but can lead to a relatively higher risk of chronic kidney disease. Removal of the adrenal gland during RN is generally not indicated unless there is clinical suspicion for involvement based on preoperative imaging and or gross involvement visualized intraoperatively. Regional lymph node dissection does not improve cure rate or survival in patients with low stage, localized RCC based on the results of the EORTC 30881 phase III randomized trial [77]. However, a lymph node dissection improves staging, and may potentially improve survival, albeit with the potential for added complications, in patients with clinical suspicion of positive nodes [78]. Another variable to consider is the choice of surgical incision, which can affect morbidity in the elderly. The radical nephrectomy can be performed through a variety of surgical incisions. The surgical approach is determined by the size and location of the tumor, body habitus, history of previous abdominal surgeries, and morbidity of the patient, all important considerations in the elderly population. This operation is usually performed through a transabdominal approach, which allows abdominal exploration for metastatic disease and early visualization of the renal vasculature with minimal mobilization of the tumor. The principal disadvantage is a slightly longer postoperative ileus and possible long-term complications related to adhesions. Other approaches include the flank incision, most commonly at the eleventh and twelfth rib, and a thoracoabdominal incision. The flank incision is an extraperitoneal approach that may be beneficial in the elderly or in patients with poor surgical risk, but exposure of the renal vasculature is limited especially in large tumors. The thoracoabdominal incision extends from the flank anteriorly, involving an incision through the diaphragm. This approach allows excellent visualization of the tumor and vessels but often requires placement of a tube thoracostomy for management of the consequent pneumothorax. Although large RCCs may be removed from this incision, the postoperative morbidity is high and should be avoided in patients with poor pulmonary function, and is rarely indicated in the elderly. The cancer-specific survival following this procedure is dependent on a number of variables, with pathologic stage proving to be the single most important prognostic factor for RCC [64]. Approximately 70–90% of patients with organ-confined RCC (TNM stage T1–2) are alive without disease at 5 years [64]. Survival decreases significantly once the tumor is locally advanced or when lymphatic and systemic metastases are discovered.

Laparoscopic nephrectomy or robotic nephrectomy for both benign and malignant disease has become the standard of care at most centers. This minimally invasive surgery is associated with less postoperative discomfort and improved recovery, and costs compare favorably with the open approach [79]. A variety of approaches are utilized laparoscopically which include transperitoneal, retroperitoneal, and hand-assisted approaches, each dependent on the skill and comfort level of the surgeon. In the elderly population, this technique is attractive due to decreased convalescence and pain. These benefits have been shown to result in improved pulmonary function among patients treated by LRN as compared to the open counterpart, suggesting that that this procedure may be particularly useful in patients with poor pulmonary reserve [80]. One exception is the patient with severe chronic obstructive pulmonary disease with CO_2 retention. These patients may develop significant hypercarbia or acidosis and will require close monitoring.

Partial Nephrectomy

Postoperative morbidity of radical nephrectomy includes renal dysfunction in the both the short- and long-term setting. This occurrence has prompted surgeons to investigate alternatives to complete removal of the kidney, especially in the patient with a solitary kidney, impaired renal function, or those that present with bilateral renal masses. In the past, parenchymal-sparing partial nephrectomy was performed only for the above reasons due to concerns about incomplete resection and recurrence. In addition, the renal transplant literature concerning donor nephrectomy (patients with a normal contralateral kidneys) have shown that donors do not have a higher rate of kidney failure during their lifetime [81]. However, distinct differences exist between donors and RCC patients. Renal donors tend to be carefully selected for medical comorbidities and are generally young, whereas those patients with RCC tend to have more comorbidities. These changes are reflected in the renal function of RCC patients who choose complete nephrectomy. A landmark study by Huang et al. highlighted the impact of radical nephrectomy on future renal function. The incidence of chronic kidney disease (stage 3) was much higher in patients who underwent radical nephrectomy (65%) than after partial nephrectomy (20%) [82]. This highlights the importance of considering partial nephrectomy even with a normal contralateral kidney. The classic partial nephrectomy for RCC involves removing the tumor with an adjacent 1 cm margin. A margin this size is easily obtainable for exophytic tumors but is not technically feasible for neoplasms located intraparenchymally or near the renal sinus/vasculature. More contemporary data has shown that a histologic tumor-free margin is more important; the width of the resection margin has no biologic or prognostic significance [83]. In fact, enucleation of the tumor with negative macroscopic margins has similar recurrence rates to wider resection. Partial nephrectomy is now considered an acceptable therapeutic approach in patients with a single, small T1a (<4 cm) RCC and a normal contralateral kidney. In an elderly patient, the choice of a partial nephrectomy is an accepted practice to avoid chronic renal dialysis. However, in the setting of a normal contralateral kidney, one must weigh the additional risk of complications unique to this procedure. These include increased bleeding, urinary fistula, positive margins, local recurrence, arteriovenous fistula, and nonfunction of the remaining portion of the kidney. Though it should be mentioned that studies have shown no difference in 30-day mortality for elderly patients who undergo partial versus radical nephrectomy [84].

Thermal Ablative Therapies

Many elderly patients with RCC have significant comorbidities that make them poor surgical candidates. This group of patients is often treated conservatively with active surveillance and not given an option for curative treatment. It is assumed that the patient will most likely have a non-RCC mortality. With improvements in health care, these elderly patients are living longer which would allow a subset of these RCCs to grow and metastasize. In addition, many elderly patients are very anxious about not treating RCC in their kidney, especially for such a chemo-/radiation-resistant tumor. Thermal ablative therapies are a minimally invasive option for curative treatment of RCC. These modalities include renal cryotherapy and radiofrequency ablation (RFA); both are different forms of ablative energy focused on the renal lesion.

Thermal ablation is an option for cT1a renal masses <4 cm in diameter. A core tumor biopsy is recommended and counseling about ablation should include a discussion regarding potentially higher risk of local recurrence, potential need for reintervention, need for long-term abdominal imaging, lack of proven parameters for success, and potential for difficult surgical salvage. Both cryotherapy and RFA use needles to transmit their energy to the tumor and can be placed percutaneously or through laparoscopic exposure. The percutaneous approach can be performed with local anesthetic alone or with intravenous sedation which would allow most patients who are poor surgical risks a chance at curative treatment. These focused thermal ablative therapies allow RCC treatment with minimal morbidity while maximizing posttreatment renal function. Percutaneous thermal ablative therapies are performed with image guidance: CT, MRI, and ultrasound. The most important principle in all the described therapies is precise localization and treatment application of the energy. In this regard, cryotherapy has an advantage because the treatment area or "iceball" is easily visualized on imaging unlike RFA. Ablative therapies have a slightly higher risk of recurrence compared to surgical removal; however, retreatment is an option.

Adjuvant Therapies for Localized RCC

There have been a number of kidney cancer trials that have explored the benefit of systemic therapies following surgery for high risk localized RCC. Although demonstrating promise in the metastatic setting, most adjuvant localized studies thus far have failed to show a benefit.

Management of Advanced RCC

About one-third of patients diagnosed with kidney cancer present with metastatic disease. Patients with advanced RCC present with a wide spectrum of disease varying from indolent to rapidly progressing. The majority of these patients are candidates for systemic therapy. Elderly individuals with advanced RCC are unlikely to benefit from surgical therapy unless a radical nephrectomy is performed with palliative intent. Therefore, systemic agents offer the most rational treatment options for older patients with this disease. Although categorical recommendations for the therapy of cancers based on chronologic age are neither appropriate nor reasonable, many decisions for or against administration of systemic therapy are often based on the age of the individual. Variability among aging individuals with regard to physiologic senescence and comorbidities suggests that a more practical approach for the clinician is the use of guidelines and performance scores to assess the elderly patient's functional and physiologic tolerability for potentially toxic therapy. First, it is important to define those who are considered elderly. Without readily usable markers of a patient's physiologic age, Balducci recommended that the clinician consider those individuals over 70 years as elderly and should undergo some form of geriatric assessment [85]. These individuals have an increased occurrence of the following: decreased musculoskeletal mass, functional limitations, geriatric syndromes (dementia, malnutrition, polypharmacy, incontinence, delirium), and multiple comorbidities.

Minimizing the occurrence of side effects from chemotherapeutic drugs in the elderly requires careful clinical assessment for functional ability and preexisting neuropathy, cardiac/hepatic/renal function, bone-marrow reserve, nutrition, polypharmacy, and cognitive function. Interventions should include adjusted doses of renally excretable agents to GFR, use of support agents such as growth factors and cytoprotective agents when indicated, appropriate nutritional support, and the preferential use of safer agents when indicated. Traditional cytotoxic chemotherapeutic agents and hormonal therapies have been ineffective in the treatment of metastatic RCC. An improved understanding of the molecular biology underlying metastatic RCC has led to the development of targeted agents to treat this disease. Vascular endothelial growth factor (VEGF) overexpression in RCC is a result of inactivation of the VHL tumor suppressor gene, which occurs in the majority of clear cell RCC cases. Insufficient or inactive VHL leads to constitutive activation of HIF and overproduction of HIF-related proteins, including VEGF. VEGF overexpression drives angiogenesis in RCC. Strategies to target the VEGF pathway include small molecule tyrosine kinase inhibitors (sunitinib, sorafenib, pazopanib, and axitinib) that target VEGFRs and anti-VEGF directed antibodies (bevacizumab). Nivolumab is an anti-programmed death (PD)-1 monoclonal antibody. Nivolumab acts as an immunomodulator by blocking ligand activation of the PD-1 receptor on activated T cells. VEGF and mTOR-targeted therapies have improved patient outcomes and represent the mainstay of treatment for advanced untreated RCC. The use of immunotherapy for advanced RCC in the aged must be approached cautiously due to the significant toxicities associated with its use. Improved understanding of the biology of RCC, especially through the VHL pathway, has led to the many "targeted therapies" for treatment of metastatic kidney cancer. Since 2005, two broad-spectrum TKIs (sunitinib malate and sorafenib tosy-late), one mTOR inhibitor (temsirolimus), and one VEGF antibody (Bevacizumab) in combination with interferon have been approved for the treatment of advanced RCC. In addition, another mTOR inhibitor (everolimus) has received FDA approval for patients with advanced RCC after failure of treatment with sorafenib or sunitinib, i.e., second-line therapy [86]. Sunitinib is well tolerated when compared to interferon and has become standard first-line therapy for metastatic RCC. In addition, data from an expanded access trial has revealed that sunitinib is safe and efficacious in subgroups of patients including those with poor performance status [87]. In current practice, most patients with treatment-naïve good/intermediate risk clear cell RCC receive sunitinib or pazopanib, while those with poor risk disease receive nivolumab+ipilimumab. Following failure of first-line treatment for metastatic RCC, treatment recommendations for patients with relapsed or recurrent disease are primarily limited to targeted agents. Everolimus, an mTOR inhibitor, is approved for the treatment of advanced RCC following treatment failure with sunitinib and sorafenib. Nivolumab, an anti-PD1 antibody was recently approved for use in previously treated patients (one or two lines of antiangiogenic therapy). All targeted agents can be used in the elderly metastatic patient with consideration of the caveats mentioned earlier (careful evaluation, GFR dose adjustment, use of growth factors, etc.) to minimize the side effects and improve the tolerability of toxic systemic therapy.

Bladder Cancer

Tumors of the bladder are among the most common oncological issues managed by urologists. Few conditions illustrate the link between cancer and aging better than urothelial cell carcinoma of the bladder (UCC). There is a distinct increase in incidence with age such that men over 70 have a 3.7% probability of developing bladder cancer compared with 0.92% of men 60–69 and 0.38% for men 40–59 [88]. As one ages, the risk for higher stage and grade disease increases. This raises the probability of developing invasive cancer and therefore affecting survival [89]. The basis for this phenomenon has triggered molecular research aiming to explain the influence of biological changes associated with the aging processes on the development and/or progression of UCC.

Urothelial cell carcinoma represents a broad spectrum of pathologic processes, extending from indolent low-grade papillomas to invasive poorly differentiated tumors with rapid metastatic capability. Age and performance status play a major role in the election of therapy and outcomes. Therefore, successful management of UCC of the bladder in the elderly patient requires an understanding of the natural history of UCC and the quality-of-life implications of each therapeutic approach.

Diagnosis

Bladder cancer represents an important consideration in the differential diagnosis of voiding complaints in the elderly individual. The presence of a neoplastic lesion within the bladder may be heralded by irritative symptoms such as urinary urgency, frequency, or dysuria. Hematuria, microscopic or gross, may also announce the existence of malignant bladder lesions. It has been estimated that 5–15% of patients, predominantly men, with hematuria harbor unsuspected bladder cancer [90]. The 2008 US Preventive Services Task Force found no high quality evidence that screening would impact mortality from bladder cancer. Although screening for UCC specifically is not recommended, many patients do routinely have urinalysis for the above symptoms or by their primary care physician. Any asymptomatic hematuria (>3 red blood cells per high power field in the absence of a benign cause) requires urologic evaluation with cystoscopy as well as urothelial tract imaging, typically excretory urography or with the more contemporary computed tomography urography. The cost implications of this approach, given the incidence of voiding symptoms and hematuria, are obvious. In the absence of a clear etiology such as infection, it is difficult at the present time to identify a subpopulation of patients not requiring a cancer evaluation.

Natural History

Epidemiologic and experimental evidence favors a strong role for environmental exposure as an etiology of bladder cancer in the elderly. However, since many cases arise in patients with no obvious exposure, it is important to understand the molecular basis of this disease. Several inherited tumor syndromes are associated with bladder cancer development including Lynch syndrome and Li–Fraumeni syndrome. Patients that have a strong family history of cancer, that have a syndromic phenotype, or that have bladder cancers occurring at a young age and without known risk factors should be referred to a geneticist for consideration of genetic testing.

The most important epidemiologic risk factors associated with urothelial carcinoma are chemical carcinogens, which are derived from tobacco products or a spectrum of industrial and environmental agents. Urothelial cell carcinoma of the bladder represents a broad spectrum of pathologic processes, thus preventing a linear description of the natural history of this disease.

Table 7 TNM staging of bladder cancer

Stage	Characteristics
Tx	Unknown
T0	No carrier
Ta	Noninvasive
Tis	Carcinoma in situ
T1	Invades lamina propria
T2	T2a – invades detrusor muscle superficially
	T2b – invades detrusor muscle deeply
T3	T3a – invades perivesical fat microscopically
	T3b – invades perivesical fat macroscopically
T4	T4a – invades prostate stroma (i.e., direct invasion and not only prostatic ducts) or vagina/uterus
	T4b – invades pelvic side wall or abdominal wall
Nx	Unknown
N0	No cancer in nodes
N1	1 positive pelvic node in the true pelvis (internal iliac, obturator, external iliac, presacral, perivesical)
N2	$\geq$ 2 positive pelvic nodes in the true pelvis
N3	Positive common iliac nodes
Mx	Unknown
M0	No metastases
M1a	Nonregional nodal metastases
M1b	Other distant metastases

To better understand the development and progression of UCC, it is important to make a distinction between superficial or non-muscle invasive bladder cancer and invasive carcinoma. Superficial UCC exhibits an overall low risk of progression (to a life-threatening cancer), but recurrences are very frequent. A minority of these recurrences may eventually progress into high-grade disease, which can then be locally invasive. The management of high-grade/invasive disease in the elderly is costly and challenging. Treatment options for patients with muscle-invasive disease or recurrent high-grade superficial disease include cystectomy (with or without chemotherapy), radiation and chemotherapy (bladder-sparing therapy), and a palliative approach. It is important to understand the difference between a superficial and invasive lesion when considering treatment of a geriatric patient with bladder cancer. The staging system for a primary bladder UCC is shown in Table 7.

Non-muscle Invasive Bladder Cancer

Approximately 75–80% of all bladder UCCs are classified initially as non-muscle invasive or superficial. This group of lesions encompasses indolent papillary lesions confined to the urothelium with high recurrence frequency (stage Ta), a poorly differentiated flat cancer called carcinoma in situ (CIS) with higher invasive potential (Tis), and neoplasms invading the lamina propria of the bladder wall (stage T1). Information regarding the recurrence and possible progression of superficial UCC is available after a complete transurethral resection of the bladder tumor (TURBT) has been performed. The pathologic specimen allows incorporation of information regarding the depth of invasion, histologic grade, and presence or absence of multicentric disease. The remainder of this discussion refers to the biologic behavior of each of these lesions in elderly patients. Stage and histological grade are central determinants of the disease-specific outcome for superficial UCC [91]. In general terms, a stage Ta lesion exhibits a 50–90% recurrence rate at 5 years with a 2–25% rate of progression to muscle-invasive disease. Within this same category (Ta), pathologic grade-1 and 2 cancers exhibit a recurrence rate of approximately 30%, whereas grade-3 lesions recur in over 70% of cases, exemplifying the importance of histologic grade [92].

Muscle Invasive Bladder Cancer

The concept of muscle-invasive disease refers to lesions that have invaded beyond the lamina propria into the muscle wall of the bladder (stage T2). The literature suggests that approximately 50% of individuals who present with stage T2–T4 TCC will develop distant metastasis within 2 years [93]. Most patients who develop T2 lesions of the bladder present initially with this muscle-invasive disease de novo rather than from a previous superficial cancer (Ta-T1). It appears that the proportion of patients with muscle-invasive TCC increases with age. Approximately 18% of patients aged 40–44 years have locally advanced TCC at presentation, whereas 39% of patients over 84 years of age present with this stage disease [68]. As a result, the elderly patient more often faces a life-threatening cancer compared to their younger counterparts. Unfortunately, this elderly patient will have a higher surgical risk due to comorbidities. Data extracted from SEER database found that individuals of 75 years of age and older with muscle-invasive bladder cancer had a higher prevalence of cardiac disease, prior cancer diagnosis, chronic anemia, and poor American Society of Anesthesiologists Physical Status Classification (ASA) [89]. These factors have a direct impact on treatment choices, especially when surgical options may involve significant morbidity.

Radiologic Evaluation

Once the diagnosis of a stage T2 UCC has been established through transurethral biopsy or resection, the patient should be thoroughly examined for evidence of lymphatic or hematogenous spread, as well as invasion into adjacent tissues. The primary sites for the dissemination of UCC include the pelvic lymph nodes (within the obturator and hypogastric regions), lung, liver, and bone. Pertinent radiologic studies include a chest radiograph and an abdominal/pelvic CT or MRI scan. A bone evaluation with skeletal scintigraphy (bone scan) is indicated in individuals with complaints of musculoskeletal pain or an elevated alkaline phosphatase level [94]. Approximately

5–15% of patients with invasive UCC harbor metastatic bone lesions, which obviate an attempt at curative (surgical) therapy. Computed tomography is about 80% accurate in differentiating locally advanced tumors involving perivesical fat or surrounding structures from those with less invasive tumors. However, since CT is often performed after a transurethral resection, interpretation of perivesical fat invasion becomes involved. It may be difficult to distinguish inflammatory or postsurgical edematous changes from true extravesical tumor extension. Another important limitation of CT is that it may miss tumors <1 cm in size, particularly those in the bladder trigone or dome. Tumors located in these areas may be better evaluated by gadolinium-enhanced MRI. The use of positron emission tomography (PET) in the evaluation of patients with localized TCC remains investigational, largely due to confounding factors from urinary excretion of the glucose-labeled tracers. MRI may ultimately be the preferred study over CT in the older patients since they often present with a suboptimal creatinine clearance.

Treatment: Non-muscle Invasive Disease

The presence of any feature displayed on Table 8 is associated with an increased risk of recurrence or progression for non-muscle invasive bladder cancer.

This is encouraging for the geriatric patient with comorbidities who does not present with these risk factors, since they can be managed conservatively. Management would involve intermittent resection or even fulguration of recurrent lesions without any additional treatments. In this context, patients who do not develop another tumor within 3 months of the initial resection for UCC have an 80% probability of never demonstrating another tumor in the bladder [95]. However, patients who experience ten or more recurrences exhibit a high rate of progression and death from TCC [96]. Therefore, in this instance, the conservative algorithm for stage Ta UCC with endoscopic resection alone should be complemented by intravesical therapy. CIS presents as a flat formation of poorly differentiated UCC confined to the mucosal surface of the bladder. This CIS lesion (Tis) may appear as a solitary primary lesion or accompanied by another form of UCC. Tis may also display a diffuse involvement of the mucosa and extend into the distal ureters or prostatic ducts. This pattern of superficial spread is associated with particularly aggressive disease, with the majority progressing to invasive cancer. Common presenting manifestations of CIS include severe irritative voiding symptoms and hematuria. But, many of these patients may be relatively asymptomatic with only an abnormal finding on urine cytology. In addition to recurrence, the literature supports an especially high rate of progression to invasive disease after endoscopic resection [97]. Therefore, patients with primary or concomitant Tis cannot be treated with endoscopic resection alone, regardless of their age. Intravesical therapy should be used in conjunction with TURBT. If this combination therapy fails to control the disease, cystectomy should be considered in the elderly individual with a good performance status. The final type of superficial UCC is a lesion that invades the lamina propria of the bladder wall but not the muscularis propria. This stage T1 lesion exhibits a high rate of recurrence (67–81%) and progression (12–49%). Patients presenting with this stage disease have a cancer-specific mortality ranging from 17% to 71% [97]. Virtually, all of these tumors are of high grade and require therapy beyond standard endosurgical resection due to the risk of progression [98]. T1 tumors are often treated adjuvantly with instillation of chemotherapeutic or immunotherapeutic agents in addition to endoscopic ablation. The intravesical

Table 8 Features associated with an increased risk of recurrence or progression

Multiple papillary recurrences (two or more in a given year)
More than three lesions or any tumor >3 cm in diameter, sessile or with a thick stalk invasion of the lamina propria (T1 tumor) or poorly differentiated histology
Incomplete resection due to diffuse bladder involvement and/or unfavorable location
Diffuse Tis alone or in association with papillary tumor

instillation of Bacillus Calmette–Guérin (BCG) has been shown to be efficacious in reducing the recurrence rate by 30–40% and may also reduce progression of T1 tumors [99]. Elderly individuals with significant comorbidities and solitary T1 disease may comprise a subpopulation of patients for whom endoscopic resection may be adequate. Nevertheless, intravesical immunotherapy in addition to TURBT should be standard practice for T1 lesions in the geriatric population given the high risk for progression and recurrence. A second-look (repeat) TURBT is done within 2–6 weeks of the first TURBT for T1 tumors and if the first TURBT is incomplete, if the tumor is high grade, and larger than 3 cm or multifocal.

An aggressive approach of early cystectomy for de novo T1 disease has been advocated by some as immediate cystectomy at the time of initial diagnosis of a T1 cancer can improve survival [100]. The selection of an adequate therapeutic plan for an elderly patient with T1 TCC must involve performance status, comorbid illness, and impact of the treatment on their quality of life.

Intravesical Therapy

Intravesical therapy permits high local concentrations of a chemotherapeutic or immunotherapeutic agent within the bladder to eradicate residual tumor cells that remain viable after TURBT, thus preventing recurrence. Conceptually, this application is provided after complete resection as a specific strategy against recurrence or progression. Less commonly, intravesical therapy is instituted for residual tumor following incomplete TURBT. These instilled agents may cause symptoms of bladder irritation as a side effect. Furthermore, systemic absorption can occur if the bladder mucosa is damaged and results in systemic toxicity. Treatments, therefore, are generally initiated 2–4 weeks after tumor resection, allowing the re-epithelialization of the bladder mucosa. The most commonly used agent for intravesical therapy is Bacillus Calmette–Guerin (BCG). A number of other agents also have activity, including mitomycin, thiotepa, gemcitabine, and docetaxel. The intravesical administration of an antineoplastic agent within 24 h of TURBT has been shown to reduce the bladder cancer recurrence rate by about 35% [101]. Anthracyclines (epirubicin, doxorubicin, pirarubicin) and mitomycin C have been used. The AUA guidelines state that in a patient with suspected or known low- or intermediate-risk bladder cancer, a clinician should consider administration of a single postoperative instillation of intravesical chemotherapy within 24 h of TURBT. Patients with bladder perforations should not receive perioperative IVC since systemic toxicities and severe cystitis reactions may develop.

The AUA guidelines state that in a low-risk patient, a clinician should not administer induction intravesical therapy. In an intermediate-risk patient, a clinician should consider administration of a 6-week course of induction intravesical chemotherapy or immunotherapy. In a high-risk patient with newly diagnosed CIS, high-grade T1, or high-risk Ta urothelial carcinoma, a clinician should administer a 6-week induction course of BCG followed by maintenance therapy [102].

Bacillus Calmette–Guérin is a live attenuated Mycobacterium that has been found to incite an immune response within the bladder, which appears to be responsible for its therapeutic efficacy against UCC. The immune activation may persist for a number of months facilitating an ongoing antitumor response. BCG has also demonstrated effectiveness when administered as therapy for CIS of the bladder. At the author’s institution, BCG maintenance therapy is the standard intravesical regimen, and the majority of elderly patients complete the full protocol duration with reduction doses if necessary. Lowering the dose of BCG for this population of patients still maintains its efficacy and can be utilized during time of nationwide BCG shortages. Patients that recur despite BCG should be offered bladder removal, but clinical trials and salvage intravesical therapy with a chemotherapy agent are alternative options albeit at a higher risk of recurrence and progression.

In summary, non-muscle invasive bladder cancer presents frequently in the aged population often with a protracted natural history and a low risk of progression. Most stage Ta lesions may be managed with endoscopic resection with subsequent outpatient follow-up utilizing cystourethroscopy and urine cytology. Surveillance protocols for such patients often involve cystoscopy every 3 months for 2 years, every 6 months for 2 years, and then every year thereafter with variation based on risk of disease. The intensity of this approach may be reduced for individuals in ill health or with favorable lesions at low risk for recurrence and progression. Patients who present with Tis or T1 cancers will benefit from a course of intravesical immunotherapy with BCG, following surgical resection. Again, these patients should be carefully followed with an organized surveillance protocol. Individuals with recurrent or refractory Tis or T1 lesions should be considered for curative radical cystectomy.

Treatment: Muscle-Invasive Bladder Cancer

Therapeutic approaches to muscle-invasive UCC of the bladder are determined by the presence or absence of clinically detectable lymphatic or hematogenous metastases. Multimodality curative therapy should be applied only in individuals whose cancers are confined to the bladder wall or associated with minimal-volume regional lymphatic disease. Neoadjuvant chemotherapy prior to radical cystectomy is considered the current standard of care for muscle invasive bladder cancer.

Surgical Therapy

The perioperative morbidity associated with radical cystectomy and the substantial impact of urinary diversion on the quality of life has led to the use of less radical approaches for the management of muscle-invasive bladder cancer in the elderly. Alternatives to radical cystectomy include radical transurethral resection (TURBT), partial cystectomy, or chemotherapy/radiation, which combines radical TURBT followed by external-beam radiation therapy with concurrent chemotherapy (cisplatin used as a radiation-sensitizing agent). In general, bladder preservation approaches are considered by many to produce inferior oncologic outcomes compared to radical cystectomy. It appears that solitary tumors confined to the muscle wall are ideal candidates for these alternative treatments with intermediate and long-term cancer-specific survival rates approaching that of radical cystectomy. An attempt at complete endoscopic resection of a solid muscle-infiltrating lesion within the bladder represents the most conservative surgical treatment approach. However, radical TURBT is applicable only to a small minority of patients with muscle-invasive disease and demands intensive, long-term cystoscopic follow-up due to local recurrence. This follow-up may represent a challenge for the geriatric population. Another surgical option, the partial cystectomy, allows complete pathologic staging of the primary tumor with an extended pelvic lymph node dissection. This technique preserves urinary function and avoids the need for diversion, therefore minimizing the impact on the elderly patient's quality of life. As with the radical TURBT, only a few patients are optimal candidates for this partial resection, and the risk of recurrent tumor in the residual bladder remains. Complete surgical extirpation with radical cystectomy remains the treatment of choice for locally advanced UCC in patients of all age groups. The contemporary surgical approach includes thorough pelvic lymph node dissection followed by complete removal of the bladder, uterus, and anterior vaginal wall in women or bladder with the prostate and seminal vesicles in men. A urinary diversion with either an ileal conduit (non-continent) or a continent reservoir (orthotopic or nonorthotopic) is constructed following the cystectomy. Radiotherapy prior to surgery increases the risk of operative complications and makes the creation of an internal urinary reservoir using irradiated bowel more difficult. Therefore, radical cystectomy alone has become established as satisfactory monotherapy for most patients with locally advanced UCC of the bladder. The impact on survival from a radical cystectomy performed in a healthy surgical patient is clear. The benefit of this extensive surgery, as we age, depends largely on competing risks for death. In the elderly individual, who typically carries a high burden of comorbid diseases and disability, the benefit of radical cystectomy versus radiation therapy is less dramatic. The largest case series involving contemporary data evaluated the benefit of cystectomy in different age groups (<60, 60–69, 70–79, >79), without correlating outcomes to physiologic measures, such as performance status [103]. A total of 8034 patients underwent cystectomy, while 2077 had radiation therapy as their primary treatment for muscle-invasive UCC. They found that older patients were less likely to have a cystectomy and that a sizeable survival advantage was seen with cystectomy in all age groups except for the octogenarian (15 vs. 18 months). The small benefit of cystectomy was lost when the elderly patient had a limited or no pelvic node dissection, highlighting the importance of a full lymph node dissection in locally advanced UCC. Another multicenter trial evaluated 888 patients over a 19-year period [104]. Thirty percent of the patients were 70–80 years of age, but only 6% were over 80. Age was an independent predictor for adverse outcomes. Currently, only two small studies have utilized functional geriatric assessment as it relates to radical cystectomy outcomes. Weizer et al. correlated a Karnofsky Performance Status (KPS) score with cystectomy in 106 patients with muscle-invasive disease [105]. Patients with a KPS score below 80 had an overall 4-year survival of 14% versus 33% for those with a KPS score above 80. This functional assessment tool was validated as the only independent predictor of overall survival in a multivariable analysis that included age, marital status, treatment type, mobility, and stage. These findings demonstrate the importance of functional age of the patient in contrast to their chronologic age when dealing with muscle-invasive TCC. It is, therefore, not justified to withhold a potentially curative therapy such as radical cystectomy on the basis of age alone. Historically, many individuals are willing to undergo intensive therapy and endure significant morbidity if the likelihood of cure from a disease is high. As discussed earlier, the ability to eradicate bladder cancer is directly related to the stage at presentation, particularly the presence or absence of lymphatic metastasis. Most reports demonstrate that lymph node metastasis at the time of radical cystectomy is associated with a 6–23% 5-year survival [106]. For the elderly patient with an otherwise asymptomatic stage T2–T4 bladder cancer with borderline nodal enlargement on CT, an accurate identification of lymphatic disease could dissuade them from undergoing radical cystectomy and make more palliative approaches attractive. Finally, minimally invasive alternatives such as laparoscopic radical cystectomy or robotic-assisted radical laparoscopic cystectomy, with the potential for reduced morbidity and more rapid convalescence, are being adopted in many centers worldwide. Reports have demonstrated the technical reproducibility and safety of these techniques, although extensive experience with these procedures is required to achieve optimal results. Advantages include faster reactivation of gastrointestinal motility and shorter hospital length of stay. Although this appears as a promising alternative for the geriatric population, data regarding the long-term oncologic outcomes is lacking at the present time, especially with regard to the adequacy of the pelvic lymph node dissection by these techniques.

Multimodality Therapy for Muscle Invasive Bladder Cancer

A viable alternative to radical cystectomy is combination chemo/radiation. Chemotherapy is widely used for therapy in advanced or metastatic bladder cancer and remains an area of active research as an adjuvant or neoadjuvant treatment with definitive local therapy. The 2017 AUA guidelines recommend that for patients with muscle-invasive bladder cancer who have elected multimodal bladder preserving therapy, clinicians should offer maximal transurethral resection of bladder tumor, chemotherapy combined with external beam radiation therapy, and planned cystoscopic reevaluation. It is unclear what proportion of patients who, having initially chosen bladder preservation, ultimately require cystectomy in a non-study setting. The reported bladder preservation rates may be dependent upon the degree of initial patient evaluation and selection. Thus, currently the AUA guidelines panel proposed that multimodal bladder preserving therapy is the preferred treatment in only those patients who desire bladder preservation and understand the unique risks associated with this approach or those who are medically unfit for surgery.

Metastatic Bladder Cancer

Although prognosis is poor for patients with metastatic bladder cancer, metastatic bladder cancer is generally responsive to palliative chemotherapy. Since Sternberg et al.'s original report of a 72% response rate in metastatic bladder cancer patients using methotrexate/vinblastine/doxorubicin/cisplatin (M-VAC) [107], the incorporation of newer and highly active agents, such as gemcitabine and paclitaxel, has led to the development of new combination regimens. One combination, gemcitabine plus cisplatin (Gem-Cis) demonstrated comparable efficacy but was significantly less toxic than MVAC and has become a commonly prescribed regimen for bladder cancer [108]. However, elderly patients may not be fit for intensive cisplatin-based chemotherapy regimens. A retrospective review of 381 patients with advanced urothelial carcinoma who were treated with one of several platinum-based regimens identified 116 who were 70 years of age [109]. The elderly experienced more frequent neutropenia and renal toxicity compared to patients <70 years of age. However, toxic death rates were similar in both age groups, and median survival did not differ significantly. Immunotherapy is currently a hot top in advanced bladder cancer. Antibodies targeting PD-1 and PD-L1 are thought to generate anti-tumor immunity by inhibiting these negative T cell signaling in the PD-1/PD-L1 axis. PD-1/PD-L1 therapies are now a principal component in the management of metastatic bladder cancer and are expected to impact less advanced disease states as well. There are at least five immune checkpoint inhibitors currently approved for patients on second-line therapy for metastatic bladder cancer or for those who cannot tolerate cisplatin-based regimen, this includes atezolizumab, nivolumab, darvalumab, avelumab, and pembrolizumab. It is a consensus among the medical oncology community that all immune checkpoint inhibitor have comparable activity in bladder cancer. However, pembrolizumab is the only drug with data from phase III trial demonstrating overall survival benefit as compared to chemotherapy in second-line setting for metastatic bladder cancer. As many patients will still progress on immunotherapy, there are ongoing trials assessing the efficacy of radiation combined with chemo-immunotherapy, immunotherapy with chemotherapy, dual checkpoint inhibitor, and immunotherapy in combination with vascular endothelial receptor tyrosine kinase inhibitors.

Conclusions

Improvements in diagnostic imaging, surgical techniques, advanced instrumentation, and systemic chemotherapy/immunotherapy have been combined to offer older individuals a wide array of treatment options for renal, prostate, and bladder malignancies. However, the myriad issues confronting these people serve only to complicate the choice of therapy. The literature suggests that aging may affect negatively the treatment response of superficial disease and the outcomes of curative surgery. Comprehensive geriatric assessment tools that incorporate not only age but also physiologic and biologic considerations, such as comorbidities, functional status, renal function, and hemoglobin are necessary to help stratify the elderly into "fit" and "frail" populations, allowing tailoring of appropriate therapy. Clinicians must avoid the unconscious bias against curative treatment for an elderly individual and thoroughly address all potential options and the impact of these in the patient's context of quality of life. Age-specific investigations in conjunction with comprehensive assessment tools are needed before the best treatment options for geriatric patients are identified.

Abstract

Nonmalignant and malignant genital tract conditions as well as pelvic floor disorders including pelvic organ prolapse and incontinence are common gynecologic problems encountered by the older woman. With the rapidly increasing population of active older American women, physicians can expect to provide evaluation and treatment of these conditions with increasing frequency. These conditions are typically amenable to both medical and surgical therapies making individualization of treatment approaches important. An evidence-based review of evaluation and treatment approaches of benign and malignant gynecologic conditions of the lower and upper genital tract as well as of pelvic floor disorders common in the older woman is presented.

Benign Gynecologic Conditions

Introduction

Nonmalignant and malignant genital tract conditions as well as pelvic floor disorders including pelvic organ prolapse and incontinence are common gynecologic problems encountered by the older woman. With the rapidly increasing population of active older American women, physicians can expect to provide evaluation and treatment of these conditions with increasing frequency. These conditions are typically amenable to both medical and surgical therapies making individualization of treatment approaches important. An evidence-based review of evaluation and treatment approaches of benign and malignant gynecologic conditions of the lower and upper genital tract as well as of pelvic floor disorders common in the older woman is presented.

Menopause

Menopause is defined as 12 months of amenorrhea secondary to cessation of ovulation. It can also be induced by surgical oophorectomy, chemotherapy, or radiation [1]. The transition into menopause (perimenopause) typically begins 4 years prior to the last period [2] and starts with irregular cycle lengths during which estrogen levels can be normal or elevated. Ultimately, estrogen and progesterone levels decrease with subsequent increase in follicle-stimulating hormone (FSH) levels. Postmenopausal estradiol levels, the most potent estrogen, are typically <20 pg/mL, while FSH is most often >70 mU/mL. Testosterone production, however, is maintained by the ovaries and adrenal glands maintaining serum levels of testosterone at 2–40 mg/dL. Even though estrogen production declines dramatically with menopause, a small amount of production continues via peripheral conversion of androgens by aromatase in adipocytes [2]. The natural process of aging results in increased fat body mass and decreased lean body mass such that obese postmenopausal women can manifest conditions due to estrogen excess, such as endometrial hyperplasia and carcinoma. In the United States, the mean age of menopause is 51 years [2] with cigarette smoking and low socioeconomic status being risk factors for premature (<40 years old) menopause [1].

Symptoms attributed to menopause include vasomotor (hot flushes and night sweats), vaginal atrophy (itching, dryness, and painful intercourse), urinary incontinence, sleeping difficulty, depression, anxiety, mood changes, cognitive decline, and somatic complaints. However, only vasomotor symptoms, atrophy symptoms, and trouble sleeping are consistently related to menopause in longitudinal studies [1–3]. A hot flush is the sudden feeling of warmth of the chest, neck, and/or face. It lasts for approximately 4 min, usually no longer than 5 min, and may have concurrent perspiration followed by a chill [1, 2]. Hot flushes occur most commonly in the late perimenopause (~65% of women). Symptoms decrease in intensity over time with up to 90% of women having complete resolution in 5 years [1]. The physiology behind hot flashes is poorly understood, but theories center around hypothalamic control in relation to hormonal changes with the transition to menopause [1, 2]. Studies have demonstrated that menopausal symptoms vary by race and ethnicity. For example, African Americans tend to have an increased prevalence of vasomotor symptoms compared to Caucasians [4, 5] and also have a higher level of bother from these symptoms [6]. At the same time, African American women may be less inclined to bring these symptoms up in the medical encounter [7]. It is important for providers to appreciate these racial differences and screen every menopausal patient for symptoms so that appropriate treatment can be provided.

Estrogen therapy is the most effective treatment for vasomotor symptoms [8]. However, use of systemic estrogen has been complicated by results from the Women's Health Initiative (WHI), which found that systemic estrogen alone increased the risk of stroke (relative risk 1.39), while the addition of progestin increased the risk of coronary events (relative risk 1.28), breast cancer (relative risk 1.26), and pulmonary embolism (relative risk 2.13) [2]. The absolute increase in risk for these events is lower in the younger menopausal women [2]. A description of the criticisms and various organizational guidelines regarding hormone replacement therapy is beyond the scope of this chapter.

The American College of Obstetricians and Gynecologists and the North American Menopause Society recommend that the lowest effective dose of systemic estrogen (plus progestin if the uterus is present) should be used and estrogen replacement should not be used for disease prevention [1, 2, 8, 9]. Alternative medicines for the treatment of vasomotor symptoms, especially when estrogen is contraindicated, include paroxetine, clonidine, and gabapentin [1, 2].

Connective tissue, in general, is sex-hormone-sensitive. Therefore, menopause may also be associated with a loss of skin elasticity and strength of bone because of the estrogen-sensitive collagen of these structures. Postmenopausal women who are given a combination of estrogen and testosterone have been reported to have greater skin collagen content and greater skin thickness than do untreated women [10]. In untreated women, skin collagen content is inversely proportional to the amount of time since menopause. It also has been shown that oral or transdermal estrogen given together with medroxyprogesterone acetate significantly increases skin collagen content in postmenopausal women [10].

Lower Genital Tract

Vulva

The vulva includes the portions of the genitalia that are externally visible: the mons pubis, labia majora and minora, clitoris, and vestibule. Within the vestibule are the hymen, vaginal orifice, urethral meatus, and the openings of Skene's and Bartholin's ducts [11]. The vulva is covered by keratinized stratified squamous epithelium with the exception of the vestibule which, like the vagina, is not keratinized. Skin changes that occur with menopause and the accompanying decrease in ovarian estrogen production are evident on the vulva as they are on all skin surfaces. These changes include dryness, roughness, wrinkling, and loss of turgor. Structurally, there is flattening and decreased thickness of the epidermis and dermis, an overall decrease and change in distribution of subcutaneous fat, and loss as well as depigmentation of hair. These changes lead to functional loss of the skin's barrier function, elasticity, mechanical protection, and wound healing [12].

Lichen Sclerosus

Lichen sclerosus is a chronic, benign epithelial condition associated with characteristic skin changes as well as vulvar pain and pruritus. The vulva is the most common site at up to 96% of cases, but lesions can be seen on any skin surface [13]. The condition typically occurs in postmenopausal women, with a mean age of 52.6 years at time of diagnosis in one study, but can also be seen in children, premenopausal women, as well as men [14]. The etiology is unknown, but possible mechanisms include genetic and/or local vulvar factors as well as immunologic abnormalities [15, 16]. Patients typically complain of vulvar pruritus, the hallmark symptom of the condition, along with pain or irritation; however, some women are asymptomatic. Other common symptoms include dysuria and painful defecation if fissures are present and dyspareunia associated with introital stenosis. On physical examination, the classic features of the disease are thin, pale, wrinkled (often described as "parchment paper") skin on the labia (Fig. 1). Excoriations may be present secondary to scratching, and fissures can be seen perianally or between the labial folds and around the clitoris. More advanced disease can lead to the destruction of labial and clitoral architecture, with nearly complete midline fusion of the labia.

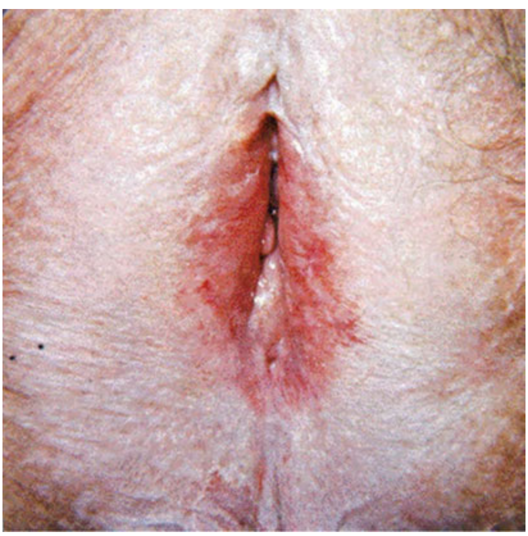

Fig. 1 Lichen sclerosus. Note the destruction of normal architecture and "parchment paper" skin

One important distinctive feature of lichen sclerosus is that the vagina and cervix are not involved [17]. Diagnosis is based on high-clinical suspicion and confirmatory 3 mm punch biopsy, as other vulvar dystrophies can have a similar appearance. Women with lichen sclerosis have a high prevalence of hypothyroidism (up to 30%) regardless of age, so we suggest screening for thyroid dysfunction in all women with biopsy-proven disease [18]. Women with lichen sclerosus are also at an increased risk of developing invasive squamous cell cancer of the vulva [19]. High-potency topical corticosteroids are the mainstay of therapy for lichen sclerosus, typically with clobetasol or halobetasol propionate 0.05% ointment nightly for at least 4 weeks followed by a slow taper when symptoms resolve. The ointment vehicle is preferred to the cream because the alcohol and preservatives in the creams irritate the skin [20]. Approximately 95% of patients will have complete or partial resolution of their symptoms with this regimen [21, 22].

Maintenance therapy with twice-weekly dosing may decrease flares or recurrent symptoms, though some experts recommend stopping therapy with resolution of symptoms and only retreating for recurrences [23]. It is unclear whether maintenance therapy reduces the chance of malignant evolution, so any recurrent or persistent lesions should be re-biopsied to rule out cancer [24]. Topical immunosuppressants have shown some promise in lichen sclerosus but are currently considered second-line therapy for disease that is unresponsive to high-potency corticosteroids [17].

Lichen Simplex Chronicus

Lichen simplex chronicus is an eczematoid disease of hyperkeratotic, scaling plaques of varying pigmentation that is associated with severe vulvar pruritus. It may commonly be seen in conjunction with a number of other vulvar skin disorders and is ultimately brought about by chronic scratching and irritation from both environmental and dermatologic processes [25]. Lichen simplex chronicus has been found to be associated with a history of atopic disease in up to 75% of patients and typically presents later in adult life though it can be seen in children. Initiating events range from chronic heat and excessive sweating to candidal infection or other dermatoses such as lichen sclerosus [17]. Diagnosis of lichen simplex chronicus is based on a history of vulvar irritation, pruritus, and typical hyperkeratotic lesions on examination. Ulcers and excoriations are sometimes seen due to chronic scratching. Biopsy may be done to identify the underlying disease (e.g., lichen sclerosus), and vaginal yeast cultures may also be helpful in this regard [17]. First-line therapy involves treatment of any underlying conditions, and topical corticosteroids may be used for symptomatic relief of inflammation and itching. Combination of steroid and antifungal ointments can be used as a convenient first-line therapy, if underlying yeast infection is suspected. Additionally, hygiene measures are important in controlling chronic vulvar wetness and avoiding potential irritants (strong soaps, perfumes, or detergents) that might exacerbate or prolong the condition.

Lichen Planus

Lichen planus is another inflammatory condition involving the genital mucosa that is thought to be caused by a cell-mediated autoimmune mechanism [26]. Unlike other vulvar dermatoses, lichen planus is more commonly found on non-vulvar skin or the mucosal membranes, especially the buccal mucosa [27]. Oral lichen planus is present in approximately 1% of the population, and up to one-fourth of women with oral disease will also have genital disease. The condition generally presents from 30 to 60 years, and the typical lesions seen are white reticulate striae on the buccal mucosal surface (Wickham's striae). Vulvar and skin lesions tend to consist of shiny, pruritic, violaceous papules; vulvar lesions can be less well demarcated and may even appear as white patches that are difficult to distinguish from lichen sclerosus [17]. The erosive form of lichen planus can lead to extremely painful erosions of the posterior vestibule and labia minora, with eventual architectural destruction and scarring and narrowing of the introitus; patients with such advanced disease complain of dyspareunia and difficulty voiding [17].

Diagnostic biopsy specimens are usually nonspecific, but classic findings in lichen planus include liquefactive degeneration of the basal cell layer and a band-like lymphocytic dermal infiltrate [28]. However, biopsy does help to rule out immunobullous diseases as well as cancer. There are a number of treatment options for lichen planus; unfortunately, though, response is typically poor, and therapy goals should focus on long-term maintenance of symptoms rather than complete control. Patient education, behavioral modification, and emotional support are all important components of any treatment plan. Medication options include topical and/or systemic high-potency corticosteroids, topical and oral cyclosporine, as well as a number of other immunemodulators [17]. In our experience, tacrolimus (Protopic) 0.1% ointment applied twice daily has been used with some success.

Bartholin's Cysts and Abscesses

Bartholin's glands, also called the greater vestibular glands, are pea-sized and located near the 4 and 8 o'clock positions on the posterolateral aspect of the vaginal opening. They function to provide vulvar and vaginal lubrication by way of mucous production [29]. The glands are connected to the vestibule of the vagina via ducts. The obstruction of the duct orifices can lead to Bartholin's cysts, which are typically asymptomatic unless they become large. These ducts and cysts may also become infected and evolve into polymicrobial abscesses, which generally present with exquisite pain and swelling. The treatment for symptomatic Bartholin's cysts or abscess is incision and drainage and placement of a word catheter, which allows for epithelialization and decreases the risk of recurrence. Other treatment options include marsupialization and CO_2 laser therapy [29]. The incidence of Bartholin's cysts or abscesses is up to 2% over a woman's lifetime but tends to be less common during the postmenopausal years [30]. Due to the possibility of underlying Bartholin's gland carcinoma, cysts and abscesses in women over the age of 40 should be drained and biopsied at the first occurrence, followed by complete excision of the gland for recurrent disease [31].

Vulvodynia

Vulvodynia is defined as chronic pain in the vulvar area lasting at least 3–6 months [32]. In 2003, the International Society for the Study of Vulvovaginal Disease classified vulvar pain into two categories: (1) vulvar pain related to an underlying disorder (infection, inflammation, neoplasm, or neurologic disease) and (2) vulvodynia, defined as vulvar burning or discomfort in the absence of any identifiable cause [33]. The true prevalence is unknown, but has been reported to be between 10% and 16% over a woman's lifetime, and tends to be more common in older patients [34, 35]. The etiology of vulvodynia is also unclear but is thought to have a neuropathic basis related to long-term tissue damage; it may also be related to changes in hormonal status, possibly explaining its temporal association with menopause [36].

While all patients present with complaints of pain, their descriptions may be widely variable with respect to location, timing, character, and provocations. Many patients believe that they have – and may have – been treated for chronic, recurrent yeast infections. Vulvodynia has been associated with coexisting conditions such as depression, interstitial cystitis, fibromyalgia, irritable bowel syndrome and frequent urinary tract, and yeast infections [35]. Incidence rates vary by demographic factors such as age, ethnicity, and marital status [37]. The diagnosis of vulvodynia is one of exclusion, and many times vulvar erythema, tenderness to palpation, and/or allodynia may be the only physical exam findings; vaginal pH, wet mounts, and yeast cultures may help to exclude other causes.

Vulvodynia can also be a frustrating treatment dilemma, as specific triggers for the pain patients experience are often difficult to identify. General measures should include education, emotional support, hygiene measures, and behavioral therapy; referral to a pain specialist may be helpful, and physical therapy involving pelvic floor muscle rehabilitation can be effective in patients with vaginismus and pelvic floor hypertonicity [38]. First-line pharmacologic therapy consists of tricyclic antidepressants (e.g., amitriptyline 10 mg nightly, increasing by 10 mg weekly until symptoms improve) with or without a topical anesthetic. Topical lidocaine gel may be used on a scheduled basis up to six times a day or on an as needed basis for intercourse. With the tricyclic antidepressants, care must be taken to watch for anticholinergic side effects as they may be more pronounced in the geriatric population. Other pharmacologic options include gabapentin, duloxetine, and the addition of topical estrogen if atrophy is present. For pain unresponsive to these therapies, local nerve block with a corticosteroid and lidocaine has been found to provide temporary relief, and referral to a pain management specialist may be appropriate in this case [39].

Cervix

In the geriatric patient, the appearance of the cervix changes in comparison to that of premenopausal patients as the transformation zone is usually found high within the endocervical canal. The cervix may also atrophy and become flush with the vaginal vault. While problems arising from the cervix are rare, two of the more common conditions in menopausal women are cervicitis and cervical stenosis.

Cervicitis in postmenopausal females is typically related to atrophic changes rather than an infectious process and can be a common cause of vaginal bleeding in this patient population. If there is no evidence of sexually transmitted or superimposed infection, treatment with vaginal estrogen should be started. A wet mount slide and/or cultures should be performed to evaluate any associated suspicious discharge and appropriate antibiotics prescribed for any infectious process.

In addition to cervicovaginal atrophy, the menopausal decrease in estrogen also induces changes in the endocervical canal that may lead to the agglutination of the cervix, ultimately resulting in complete stenosis. This can obstruct the outflow of secretions and debris from the atrophic endometrial cavity, leading to hematometria or hydrometria; pyometria can occur if this accumulation of debris becomes infected.

Urogenital Atrophy and Vaginitis

During menopause, the vagina, in particular, thins and loses elasticity. In addition, the vagina undergoes a decrease in blood flow and secretions. For one-third of women, this results in dryness, discomfort, itching, and/or painful intercourse early in menopause and is often referred to as atrophic vaginitis. On exam, an atrophic vagina appears pale and has decreased rugae. The vaginal introitus is often narrow, and the urethral meatus is prominent, simply because of the decreased bulk of the surrounding vulvar tissue. Unlike vasomotor symptoms, atrophy symptoms continue or worsen, and the prevalence increases to about one-half of women with aging. Additionally, lack of estrogen changes the vagina from an acidic to a more basic environment, which favors colonization with enteric potentially uropathic bacteria [1–3]. Low doses of transvaginal creams, pessaries, tablets, and rings are likely equally effective in treating symptoms of vaginal atrophy and are not associated with significant systemic absorption [3]. Vaginal estrogen therapy is usually prescribed in tapering doses: from nightly for the first 2 weeks of therapy to maintenance doses of twice weekly. Reversing vaginal atrophy before vaginal surgery is often performed (Fig. 2).

Other less common forms of vaginal irritation in the older women include bacterial vaginosis (BV) and candidiasis. In the atrophic vagina with a higher pH, lactobacilli and yeast are less commonly found likely explaining the decreased incidence of candidiasis [40]. Differentiation between these causes of vaginal irritation is important. Increased vaginal pH is found with both BV and atrophy. The discharge with BV is malodorous, thin, homogenous, grayish, and adherent to the vaginal walls. Candidiasis is odorless and "cottage cheese-like" in appearance; the labia can be erythematous and edematous with satellite lesions. BV also has a characteristic fishy odor with the application of potassium hydroxide. On saline wet mount, BV has clue cells (epithelial cells stippled with bacteria), while candidiasis has pseudohyphae [41]. With atrophy, the wet mount is predominantly intermediate and parabasal epithelial cells with few or no superficial cells [42]. Antibiotic treatment for BV and anti-candidal regimens is effective and routinely prescribed by practitioners caring for older women [41].

The lower urinary tract is also estrogen sensitive, as estrogen receptors are found in the bladder and urethra. Symptoms of dysuria, urethral discomfort, overactive bladder (OAB), hematuria, urinary tract infections (UTIs), and urinary incontinence (UI) are associated with aging. Estrogen had been a mainstay of treatment of urinary tract symptoms, generally based on small observational studies [43]. However, a 2003 Cochrane review called into question the routine use of systemic estrogen as a therapeutic agent for UI. Fifteen of the 28 trials in this review favored estrogen use to treat UI, but the results from the

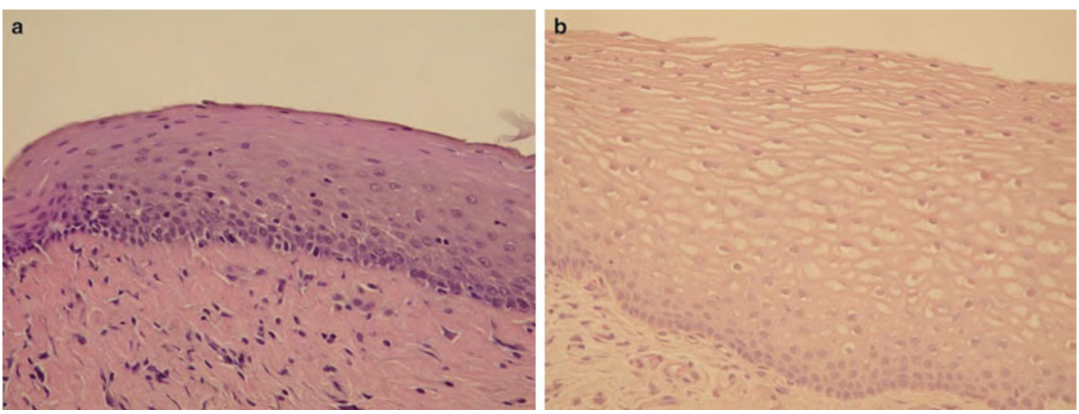

Fig. 2 Vaginal atrophy treated with estrogen cream. (**a**) A thin vaginal epithelium (0.075 mm) where the estrogen-sensitive superficial cell layer (flatter cells with smaller nuclei) composes a smaller proportion of the epithelium. (**b**) Epithelial changes after nightly treatment with 50 μg of estrogen cream. The thicker epithelium (0.4 mm) contains a larger proportion of superficial cells

Heart and Estrogen/Progestin Replacement Study (HERS) swayed the analysis toward estrogen worsening UI [44]. This review was followed by the negative findings in the Women's Health Initiative which showed increased or worsening of UI in women taking estrogen and progesterone or estrogen alone [43]. It is important to note that the influence of different estrogen formulations and route of delivery, in particular transvaginal estrogen, has yet to be elucidated. However, it is clear that systemic estrogen has not been shown to improve OAB or urinary incontinence and may actually worsen them [1, 43]. There is a role for transvaginal estrogen in preventing recurrent UTIs [45].

Genitourinary Syndrome of Menopause (GSM)

The previous section describes the effects of hypoestrogenism on the lower genital and urinary tract. In 2013, the Board of Directors of the International Society for the Study of Women's Sexual Health (ISSWSH) and the Board of Trustees of The North American Menopause Society (NAMS) convened to develop an all-encompassing and medically accurate nomenclature to describe these changes. From this meeting, the term "genitourinary syndrome of menopause" was born. GSM describes a collection of symptoms involving changes to the vulva, vagina, urethra, and bladder that occur solely because of menopause [46].

Upper Genital Tract

Uterus

Many of the changes evident in the postmenopausal uterus are a direct result of decreasing estrogen levels. There is an estimated 95% decline in blood estrogen concentration from the premenopausal to postmenopausal state [47]. The postmenopausal uterus undergoes involution and gradually becomes smaller with age. Benign abnormalities of the uterus, especially abnormalities of the uterine cavity, may result in postmenopausal bleeding, and endometrial cancer must be ruled out when it occurs in this age group. The primary causes of postmenopausal bleeding include vaginal atrophy with friability, endometrial atrophy, endometrial hyperplasia, endometrial and cervical polyps, and invasive cancer. The initial evaluation of postmenopausal bleeding should include either a transvaginal ultrasound or a biopsy of the endometrium. If the endometrial thickness is less than 4 mm on ultrasound, then a biopsy is not required. When a biopsy is attempted in the postmenopausal patient, either as the initial assessment of bleeding or as a follow-up assessment when the endometrium is >4 mm thick on ultrasound, providers often encounter cervical stenosis because of atrophic changes. In this case, endometrial sampling in combination with hysteroscopy in the operative setting may be beneficial [48].

Endometrial Atrophy

Endometrial atrophy is a frequent cause of postmenopausal uterine bleeding. The surface epithelium of the uterine cavity, otherwise known as the endometrial layer, is known to undergo cellular and glandular loss, likely as a result of lowered estrogen levels [49]. This ultimately thinned endometrial surface is subject to bleeding, especially as a result of trauma. The collapsed, atrophic endometrial surfaces contain little or no fluid to prevent intracavitary friction [50]. Microerosions of the surface epithelium then develop that are prone to light bleeding or spotting.

The diagnosis of endometrial atrophy is confirmed by endometrial biopsy or by ultrasound (double-layer thickness less than 4 mm). Adequate estrogen therapy is nearly always effective in relieving symptoms of both endometrial and vaginal atrophy. Although many oral preparations are available for the treatment of endometrial atrophy, local vaginal estrogen therapy has also been shown to be effective and well-tolerated in the treatment of endometrial atrophy but should be accompanied by a progestin for doses greater than 50 μg [3, 51].

Endometrial Polyps

Endometrial polyps, which are hyperplastic overgrowths of endometrial glands and stroma, develop from the endometrial basalis layer and are likely the result of estrogenic stimulation. The known association of large endometrial polyps with tamoxifen [52], a selective estrogen receptor modulator, strengthens this likelihood. The incidence peaks in the fifth decade of life; fortunately for most postmenopausal women, the incidence of endometrial polyps greatly decreases after menopause. They may be solitary or multiple and are usually pedunculated. Most are benign, with an estimated 1.5% being malignant [53]. In addition, while most are asymptomatic, they account for 12–25% of cases of postmenopausal bleeding [54, 55].

Endometrial polyps are diagnosed only by microscopic evaluation of the specimen post removal, although they can be further evaluated and characterized using sonohysterography (Fig. 3). Saline infusion sonography has been shown to be more accurate than ultrasound alone in diagnosis, with a sensitivity and specificity of 93% and 94%, respectively, compared to 65% and 76%, respectively, for ultrasound alone [56]. Treatment of symptomatic polyps is removal by dilatation and curettage (D&C) or hysteroscopic-guided polypectomy. Excision of symptomatic polyps is essential to rule out carcinoma because imaging characteristics cannot adequately distinguish between benign and malignant polyps [53].

Fig. 3 Saline infusion sonohysterogram of a perimenopausal patient with abnormal uterine bleeding. A polypoid lesion is seen extending near the anterior fundal region. This measures 10.2 × 6.7 mm (calipers). At the time of D&C with hysteroscopy, a polyp was identified and confirmed by pathology

The management of asymptomatic patients with incidentally found polyps remains controversial [57–59].

Leiomyomas (Fibroids)

Benign uterine leiomyomas, otherwise known as fibroids, are hormonally responsive and typically decrease in size after menopause [60]. Although leiomyomas tend to atrophy as the woman ages, their presence can cause concern during bimanual exams or with their appearance on imaging studies. Medical therapy to decrease fibroid size is generally not indicated in the older postmenopausal woman. Additionally, surgical interventions for simple uterine fibroids in the postmenopausal female usually are not indicated. However, while most uterine masses ultimately prove to be benign fibroids, a rapidly enlarging pelvic mass may represent a uterine leiomyosarcoma. These are relatively uncommon, accounting for only 1–2% of postmenopausal uterine masses [61]. With any enlarging or persistent uterine mass, evaluation in the form of ultrasonography, computed tomography, and referral to a gynecologic specialist is warranted to exclude sarcoma.

Endometrial Hyperplasia and Cancer

Endometrial hyperplasia, or excessive proliferation of the uterine endometrium, can occur from many conditions, almost all associated with long-term unopposed estrogen stimulation. Risk factors for endometrial hyperplasia, other than direct unopposed estrogen stimulation, include obesity, nulliparity, diabetes, early menarche, late menopause, polycystic ovarian syndrome, and tamoxifen therapy for greater than 2 years [62]. According to the World Health Organization (WHO), endometrial hyperplasia is classified as either atypical hyperplasia or hyperplasia without atypia. These classes are further subdivided into two categories: simple and complex, with complex and atypical classifications having higher risks for malignancy. Because of interobserver and intraobserver variability inherent in the WHO classification system, the Endometrial Intraepithelial Neoplasia (EIN) classification system was developed [63]. The EIN system uses molecular genetics to identify precancerous or cancerous endometrial lesions and to provide standardization [64]. Endometrial hyperplasia or EIN is made from direct tissue sampling in the form of an office endometrial biopsy sampling or dilation and curettage. Treatment strategies center around the use of progestins or hysterectomy, depending on the pathology. Hysterectomy is often the first management choice in patients with complex atypical hyperplasia or EIN given that the risk of concurrent malignancy is 26% and 24%, respectively [64].

Ovary

As women progress into menopause, there is a marked depletion of ovarian follicles resulting in decreased synthesis of circulating estrogen. The ovaries become atrophic becoming smaller in size than those of the premenopausal woman and are typically not palpable on bimanual examination. The risk of ovarian cancer increases with age, but unfortunately there is no validated way to screen for the disease. Educating patients on the signs and symptoms of ovarian cancer and encouraging them to present for evaluation should they develop those symptoms is paramount. Benign ovarian enlargement or benign cysts are rarely found in the postmenopausal female, as the ovary is inactive. Benign teratomas missed at an earlier age are sometimes found, but in general, most postmenopausal ovarian masses are suspect for malignancy.

Urogynecologic Conditions

Introduction

Pelvic floor disorders including pelvic organ prolapse and incontinence are common gynecologic problems encountered by the older woman. With the rapidly increasing population of active older women, physicians can expect to provide evaluation and treatment of these conditions with increasing frequency. These conditions are typically amenable to both medical and surgical therapies making individualization of treatment approaches important. Evidenced-based evaluation and treatment suggestions are provided.

Urethra

The female urethra is typically 4 cm in length and 6 mm in diameter. The proximal urethra is lined by urothelium, whereas the distal mucosa is lined by nonkeratinized stratified squamous epithelium which is continuous with the vulva externally. The urethra is composed of mucosa and submucosa, surrounded by smooth and striated muscles. The epithelium and submucosa are estrogen sensitive. The submucosa is highly vascular, and this vascular cushion helps the urethra to intrinsically remain sealed [65]. The periurethral glands are located in the distal two-thirds of the submucosa, and most of these glands drain into the distal one-third. Of the periurethral glands, the Skene's glands are most distally located, which drain outside and lateral to the external urethral meatus [66].

The urethral sphincters are composed of the urethral smooth muscle layers: an inner oblique and longitudinal layer and an outer circular layer; the outer skeletal muscle layer is most prominent in the middle third of the urethra. The urethra is supported by fibromuscular connective tissue which is suspended to the pelvic sidewall [66, 67].

Urethral Prolapse

Urethral prolapse is a circumferential eversion of the urethral mucosa at the external meatus, often appearing as a beefy red ring around the meatus. This condition is relatively rare and typically seen in postmenopausal women and prepubertal girls. The etiology has been linked to a lack of estrogen. Urethral prolapse can be asymptomatic. However, bleeding is the most common symptom, followed by voiding symptoms such as dysuria, urgency, frequency, and nocturia. If strangulated, suprapubic pain can occur. Concurrent infection can occur [67].

Since urethral prolapse is rare, careful examination is needed to confirm the diagnosis, as the more common urethral caruncles and rare malignancy are in the differential diagnosis. Urethral prolapse is distinguished by the circumferential prolapse with a central opening, which can be catheterized to confirm the presence of the urethra. Significant swelling can lead to anatomical distortion, strangulation, and potentially necrosis and may necessitate examination under anesthesia to confirm the diagnosis with possible surgical correction. Imaging studies are seldom necessary once the diagnosis has been confirmed with catheterization; otherwise, malignancy should be considered. Histologically, inflammatory infiltrates are seen in the underlying connective tissue.

Treatments include warm sitz baths, transvaginal estrogen cream, topical steroids to reduce inflammation, and antibiotics for infection [68, 69]. Estrogen has been reported to resolve the prolapse within 6 weeks [69]. If conservative management fails or if strangulated, surgical excision and short-term catheterization (less than a week) should be performed [70]. Surgical techniques include cauterization, ligation around a urethral catheter, and circumferential excision with reapproximation of the healthy urethral mucosa to the vagina. Complications include infection and urethral stenosis. Long-term transvaginal estrogen should be included in the postoperative care.

Urethral Caruncles

Urethral caruncles are benign, usually small, reddish exophytic lesion in the distal posterior urethra visible at the external meatus. These lesions are often asymptomatic and an incidental finding but can present with dysuria, tenderness, or bleeding especially if they enlarge to 1–2 cm (Fig. 4). Rarely, the large lesion can thrombose, which presents as a dark periurethral mass. The etiology likely starts with incomplete urethral prolapse, which becomes chronically irritated and takes a polypoid form. Like urethral prolapse, its origins are attributed to estrogen deficiency and more common in older women. Cystoscopy is generally unnecessary. Treatment of symptomatic urethral caruncles is conservative and consists of sitz baths, transvaginal estrogen therapy, and anti-inflammatories when necessary. When clinical differentiation from cancer is difficult, such as a large (1–2 cm) lesion, there is a failure of medical therapy, or in the presence of severe symptoms, surgical excision biopsy should be considered [71]. Intestinal metaplasia, melanoma, and lymphoma have all been reported to either coexist with or mimic urethral caruncles [72–74].

Fig. 4 Urethral caruncle. Note that it is a reddish, exophytic lesion off of the posterior urethra

Urethral Diverticulum

A urethral diverticulum is an outpouching of the urethra within the fibromuscular connective tissue protruding into the anterior vaginal wall. This defect often appears as cyst-like structure connected to the urethral lumen. In more complicated cases, the diverticulum can have a saddlebag shape or circumferentially around the entire urethra [66]. The prevalence of urethral diverticulum is difficult to estimate; however up to 1–6% has been reported [66, 75]. It is uncommon past 60 years of age. The diverticulum is thought to be the result of obstruction of periurethral glands and is most commonly found in the posterolateral distal one-third of the urethra. The classic symptoms include dysuria, dribbling, urgency, frequency, and dyspareunia. Other symptoms include hematuria, urinary incontinence, voiding dysfunction, hematuria, and pyuria. These women can have recurrent cystitis or urinary tract infections.

Up to 20% of patients with diverticulum may be completely asymptomatic. On examination, it feels like a suburethral mass expanding in the anterior vaginal wall; however, some may also expand laterally or even dorsally [66, 75]. It can be hard if a stone is present, mostly of calcium oxalate or phosphate, which can occur up to 10% [76]. Urine or purulence may be expressed from the meatus when massaged. The differential diagnosis includes vaginal wall cysts from an embryologic remnant or local gland and ectopic ureterocele. Malignancy has been reported in 6–9%. The most common type is adenocarcinoma [77]. Magnetic resonance imaging (MRI) is the diagnostic imaging modality of choice to confirm the diagnosis, location, and size. Three-dimensional ultrasound technique has been investigated as an alternative to MRI [78, 79]. Surgical excision is recommended treatment [76]

Pelvic Floor Disorders

Introduction

The national prevalence of symptomatic pelvic floor defects including pelvic organ prolapse (POP), urinary incontinence (UI), and fecal incontinence (FI) has been estimated to be 25%. Older women are far more affected, with rates up to 53% in women 80 years old and older [80]. The prevalence of anatomic stage II–IV POP using the Pelvic Organ Prolapse Quantification (POPQ) [81] (see Table 1 and Fig. 5) examination in the general population was reported to be 37%; prevalence in an older population of women with a mean age of 68 years was 64.8% [82].

Table 1 Stages of pelvic organ prolapse

Stage 0	No prolapse is demonstrated. Points Aa, Ap, Ba, and Bp are all at −3 cm, and point C is between total vaginal length (TVL) and −(TVL −2 cm)
Stage I	The most distal portion of the prolapse is >1 cm above the level of the hymen
Stage II	The most distal portion of the prolapse is <1 cm proximal or distal to the plane of the hymen
Stage III	The most distal portion of the prolapse is <1 cm below the plane of the hymen but no further than 2 cm less than the total vaginal length
Stage IV	Complete to nearly complete eversion of the vagina. The most distal portion of the prolapse protrudes to> + (TVL −2) cm

Clearly, these are highly prevalent conditions and contribute significantly to older women's overall quality of life. Despite the availability of effective evaluation and treatment methods, women continue to suffer needlessly, with nearly 50% of affected women neglecting to inform their healthcare providers about their symptoms [83].

Pelvic Organ Prolapse and Urinary Incontinence

The etiology of POP and incontinence is complex and multifactorial, involving potential injury to, or attenuation of, the many ligaments, muscles, connective tissue, and innervation of the pelvis. These conditions are associated with several risk factors including age, parity, forceps use at the time of vaginal delivery, abdominal circumference, and body mass index. Vaginal support defects as defined by DeLancey include Level I apical support defects (the cardinal-uterosacral ligament complex providing proximal support), Level II defects including cystocele, rectocele, or paravaginal defects (a defect in vaginal support at the level of the arcus tendineous fascia pelvis), or a Level III defect, detachment of the perineal body (Fig. 6) [84].

It is common for the older woman to be affected by more than one pelvic floor condition. POP can be associated with urinary as well as bowel dysfunction and fecal incontinence. Women with advanced POP may experience voiding dysfunction caused by urethral obstruction. Older women are at risk for coexisting urinary and fecal incontinence (accidental bowel leakage) or "dual incontinence." The reported prevalence of dual incontinence in community-dwelling adults ranges from 3% to 15% [85, 86]. A thorough history will elucidate these associated symptoms. An evaluation for occult urinary incontinence may be warranted in cases of advanced prolapse, as an incompetent urethra may be masked by the urethral kinking associated with advanced pelvic organ descent.

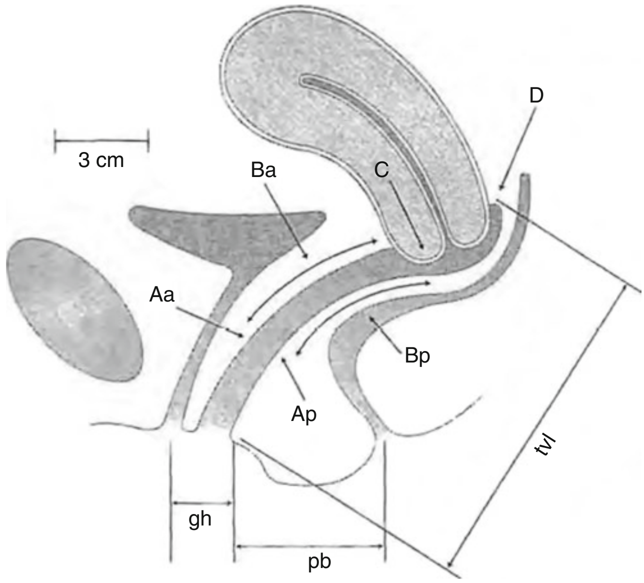

Fig. 5 Six sites (points Aa, Ba, C, D, Bp, and Ap), genital hiatus (gh), perineal body (pb), and total vaginal length (tvl) used for pelvic organ support quantifications. (From Bump et al. [81]. Reprinted with permission from Elsevier)

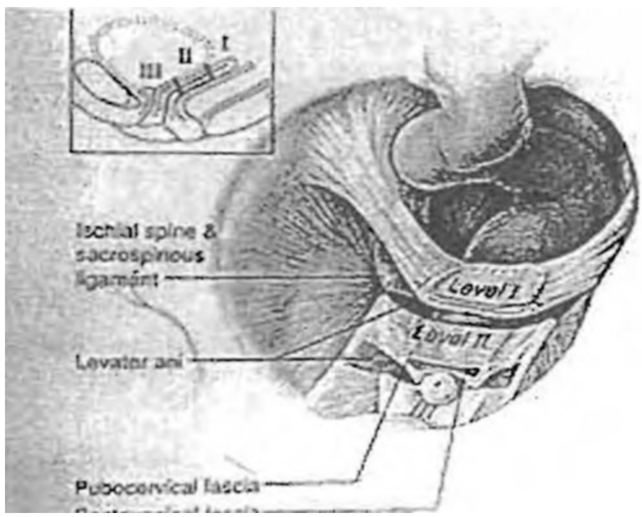

Fig. 6 Vaginal support defects as defined by DeLancey include Level I apical support defects (the cardinal-uterosacral ligament complex). Level II defects include cystocele, rectocele, or paravaginal defects (a defect in vaginal support at the level of the arcus tendineous fascia pelvis), or a Level III defect, detachment of the perineal body. (From De Lancey [84]. Reprinted with permission from Elsevier)

The diagnosis of POP is made during a pelvic examination. The full extent of the prolapse may not be appreciated unless the patient stands or uses a strong Valsalva force. Bladder and bowel dysfunction may require the use of further diagnostic testing such as urodynamics, anal manometry and ultrasound, or electromyography of the pelvic floor.

Urinary incontinence (UI) is defined as the complaint of any involuntary leakage of urine [87]. Diagnostic categories of UI include stress incontinence (leakage associated with episodes of increased intra-abdominal pressure), urgency urinary incontinence (leakage associated with urgency and involuntary detrusor muscle contractions), and overflow incontinence (seen when bladder emptying is insufficient).

Initial evaluation techniques center on the treatment of reversible causes of UI, for example, infection, inappropriate medication use, and mobility issues. After a thorough history, the examination focuses on pelvic/bladder anatomy and neurologic status. Bladder physiology and function may be further characterized using a stress test or urodynamic assessment, a diagnostic means of observing bladder neurologic and motor/muscle physiologic function. As overflow incontinence can mimic the symptoms of stress or urgency incontinence, it is important to check a post void residual volume with the use of a bladder scanner or in and out catheterization, as older women can have impaired bladder emptying.

Treatment of POP and UI

Management should be individualized based on the patient's health status, clinical setting, and preference. It is important to discuss the expectations and goals of therapy with the patient and her caregiver, when applicable. The first step is to determine if the patient has symptoms that are bothersome. Asymptomatic patients with pelvic floor disorders that are found incidentally on examination can be managed expectantly.

Nonsurgical Treatment of POP and UI

Nonsurgical treatment of POP and UI includes behavioral therapy (pelvic floor muscle exercises including stress and urgency incontinence strategies), medications, as well as the use of intravaginal supportive devices. A conservative treatment approach is usually considered in older women who do not desire a surgical intervention or where surgery may not be an ideal choice due to medical comorbidities causing increased surgical risk.

Pelvic floor muscle exercises may limit the progression of mild prolapse and related symptoms; however, less response has been noted with prolapse beyond the vaginal introitus [88]. This method of treatment is often employed to treat accompanying urinary and/or fecal incontinence. Results are generally dependent on patient motivation and adherence to the exercise program.

The use of an intravaginal device such as a pessary is an excellent option for nonsurgical treatment of POP and UI. Patient acceptance is relatively high with appropriate counseling. Pessaries are available in different shapes and sizes, the majority of which are made of silicone. Risk factors for failed fitting include a large genital hiatus and short vaginal length. Pessaries provide pelvic organ support within the vaginal vault. Two categories of pessaries exist for prolapse: support and space filling. The ring pessary (with diaphragm) is a commonly used support pessary, and the Gellhorn pessary is a commonly used space-filling pessary (Fig. 7). Most women with stage II and III prolapse were successfully fitted with ring pessaries, whereas women with stage IV prolapse usually required a Gellhorn pessary [89].

Possible complications associated with pessary use include vaginal discharge and odor. There may be failure to retain the pessary, or conversely the pessary may be too large, which could lead to excoriation or irritation. There may be de novo or increased stress incontinence [90] with the reduction of vaginal prolapse and in rare instances more severe complications such as fistula development.

Surgical Treatment of POP

The decision for surgical versus conservative intervention for the treatment of pelvic floor disorders should not be based on chronologic age alone. Prior to the selection of a specific treatment or procedure, all existing pelvic floor defects should be evaluated. The older woman can expect similar operative risks as well as subjective and objective anatomic and quality-of-life outcomes as that of younger women undergoing pelvic floor disorder treatment.

In the United States, 300,000 surgeries are performed annually for the treatment of POP [91]. Demand for the care of pelvic floor disorders has been projected to increase significantly in the coming years due to significant shifting of American age demographics. Women aged 80 years and older are the most rapidly growing segment of the older US population. A woman's lifetime risk of having surgery for either POP or UI by age 80 is 11.1% [92]. Women who have undergone a procedure for UI or POP are at risk for recurrence, with a reoperation rate of approximately 30% [92, 93].

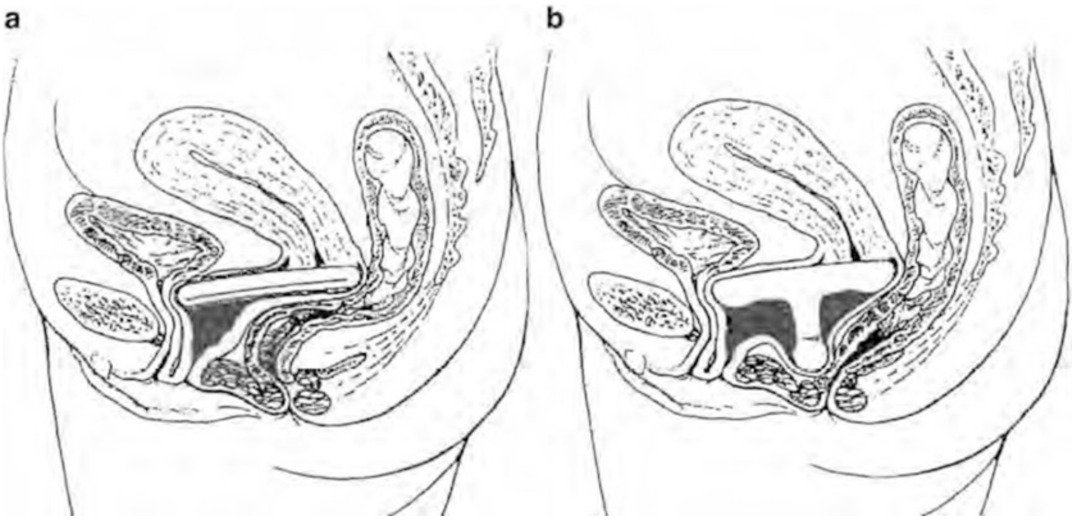

Fig. 7 (**a**) Ring pessary without support in place; patient with cervix and uterus. Note that the pessary rests at the level of the bladder neck anteriorly and behind the cervix posteriorly. (**b**) Gellhorn pessary in place; patient with cervix and uterus. Note that the disk of the Gellhorn pessary rests at the level of the bladder neck anteriorly and behind the cervix posteriorly similar to the position of a ring pessary and that the knob rests behind the perineal body. (From Weber and Richter [88]. Reprinted with permission from Lippincott Williams & Wilkins)

The ideal procedure in the older woman would robustly repair symptomatic pelvic floor defects, be performed efficiently, allow for rapid postoperative recovery including return to baseline or improved functional status, and conform with the sexual activity desires of the patient. Although many studies have included older women when examining outcomes after pelvic floor surgery, limited studies exist to specifically address POP surgery outcomes in older women. Older women undergoing elective pelvic floor surgery face risks similar to patients of all ages undergoing elective general surgery. Pelvic floor surgery is considered an intermediate risk procedure with a perioperative mortality rate <5%. A review of recent studies that examine outcomes of the older woman undergoing pelvic floor surgery shows mortality rates from 0.0% to 4.1% and complication rates from 15.5% to 33.0% [94]. Complication rates vary and may be due to the heterogeneous definitions of complications throughout the studies. However, the majority of complications were related to urinary tract infections, febrile morbidity, and blood loss requiring transfusion.

Presurgical preparation should include optimization of the urogenital epithelium. Topical estrogen improves the quality of vaginal tissue in postmenopausal women. The effects of vaginal estrogen on surgical outcomes in postmenopausal women undergoing transvaginal prolapse repair are currently being investigated in a multicenter placebo-controlled randomized trial (NCT02431897).

Surgery to correct POP and UI should address the specific pelvic floor defects that are present including the anterior vaginal wall (cystocele), posterior vaginal wall (rectocele), and apical vaginal support defects (enterocele) (Figs. 8 and 9). Surgical techniques to address anterior defects are the anterior colporrhaphy and paravaginal repair. Symptomatic anterior wall prolapse repair outcomes were compared at a 21-month average (12 months minimum) follow-up between 31 patients aged 80 years or more and 234 younger patients. They demonstrated similar rates of symptomatic failure between the groups, 6 versus 5%, respectively. Recurrence of any vaginal support defect in the older group was 10% [95].

The most efficacious technique to repair posterior defects is the traditional midline colporrhaphy [88]. Perineorrhaphy should be performed when there is separation of the perineal

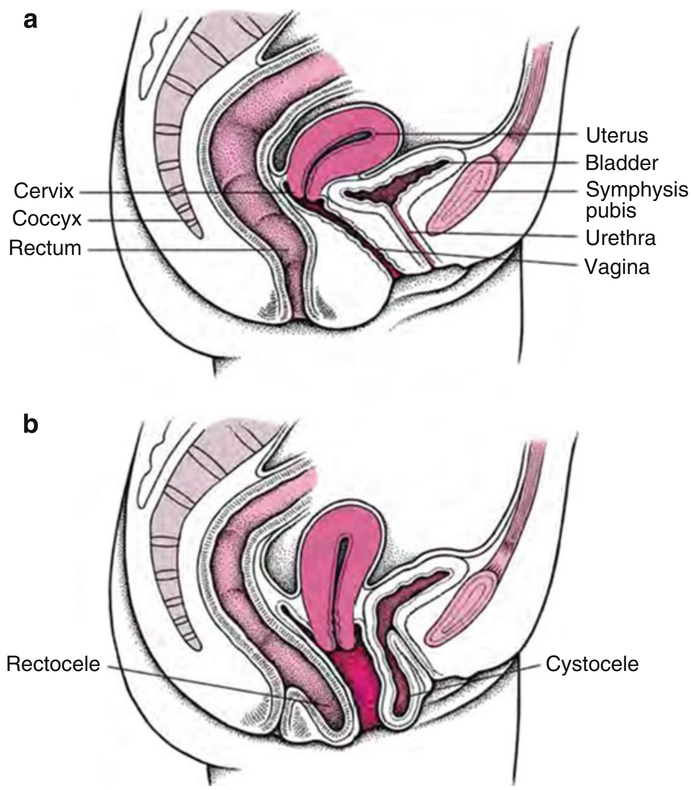

Fig. 8 Sagittal section showing normal anatomy (**a**); cystocele and rectocele (**b**). (Reprinted with permission from Beers and Berkow [12]. Copyright 2000 by Merck & Co, Inc., Whitehouse Station, NJ.)

muscles. The posterior rectovaginal connective tissue should be reattached to the perineal body if separated. However, careful attention should be paid to avoid excessive vaginal narrowing (unless desired) as postoperative dyspareunia is a common complication. Anatomic success is high with this procedure; however, functional success rates may be considerably lower regardless of age.

Surgical techniques to address apical vaginal defects include the abdominal sacrocolpopexy (ASC), uterosacral ligament suspension (ULS), iliococcygeus fixation, and sacrospinous fixation (SSLF). The ASC employs graft material to suspend the anterior and posterior walls of the vagina to the anterior longitudinal ligament of the sacrum. Published ASC apical cure rates range from 78% to 100% [88]. However, this surgery requires a laparotomy or laparoscopic surgery with or without the robot; has a longer operative time and, if performed by laparotomy, a longer recovery period; and has higher postoperative complications when compared with vaginal approach surgeries. A recent RCT demonstrated similar perioperative complication rates as well as subjective and objective outcomes in women aged 70 years and older compared to a younger group undergoing ASC [96]. ASC may be safely performed laparoscopically, even in the older woman.

The two most common vaginal native tissue apical suspension procedures are ULS and SSLF. ULS is an intraperitoneal technique that attaches the vaginal vault to the uterosacral ligaments at the level of the ischial spine bilaterally (Fig. 10). The SSLF is an extraperitoneal approach that attaches the vaginal vault to the sacrospinous ligament. A recent randomized controlled trial examined a direct comparison of outcomes from a ULS versus SSLF and demonstrated that there was no significant difference in success rates (ULS 59% vs. SSLF 61%, OR 0.9 [95% CI 0.6, 1.5]) or serious adverse event rates (ULS 17% vs. SSLF 17%, OR 0.9 [95% CI 0.5, 1.6]) [97].

Colpocleisis or colpectomy (narrowing or closure of the vaginal tissue and introitus) may be offered to the older woman who has no desire

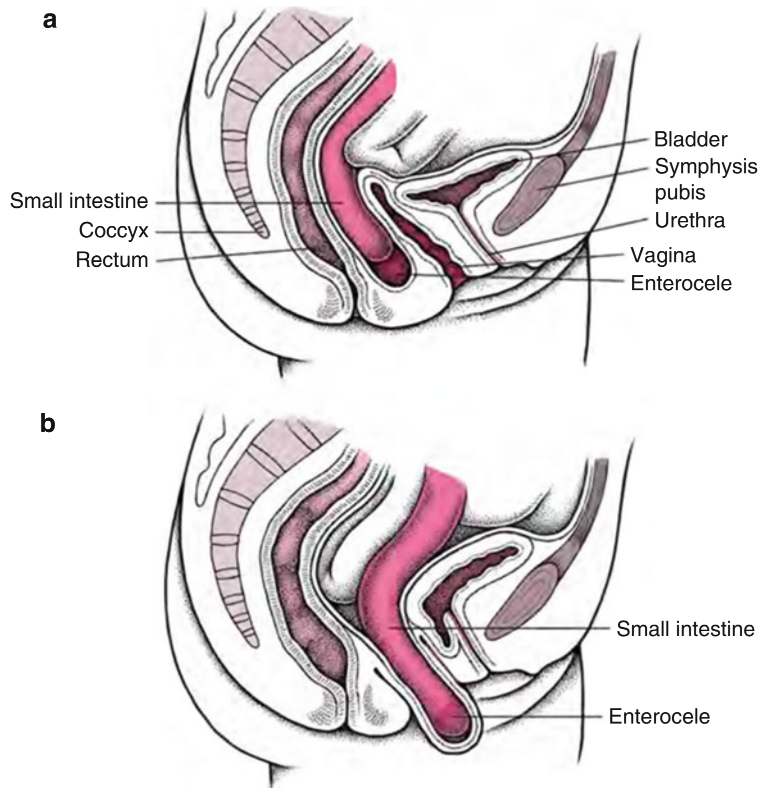

Fig. 9 Posterior enterocele without eversion (**a**); enterocele with eversion (**b**). (Reprinted with permission from Beers and Berkow [12]. Copyright 2000 by Merck & Co, Inc., Whitehouse Station, NJ.)

for vaginal function. These obliterative procedures have been shown to have shorter operative times and have fewer perioperative complications compared to reconstructive repair [98]. Patient satisfaction is high and prolapse recurrence is low [99]. Preoperative assessment and operative treatment for occult stress incontinence may help avoid this unwanted postoperative complication.

Transvaginal mesh augmentation is another approach for POP repair. The use of synthetic mesh to augment a repair addresses potentially and reduces the risk of recurrent prolapse; however, this approach is controversial. Mesh-related complications include erosion or exposure, infection, and de novo dyspareunia. A detailed discussion of the use of surgical mesh for prolapse repair is beyond the scope of this chapter.

Little information is available to guide us about which procedure should be considered in the older woman versus the younger woman. A multicenter three-arm randomized trial (NCT02676973) is currently undertaken to determine the efficacy and safety of three existing surgical approaches (native tissue vaginal repair with ULS or SSLF, sacrocolpopexy, and transvaginal mesh augmentation). The ultimate decision on which approach and which procedure to employ in the treatment of POP in older women should take into consideration the patient's overall health and physical activity status, her specific pelvic floor defects and her future sexual activity desires, as well as the surgeon's training, skills, and preference.

Surgical Treatment of Urinary Incontinence

Surgical management options for UI depend on the types of UI, which can be divided into two categories: stress or urgency urinary incontinence (SUI or UUI). Surgical approaches for the treatment of SUI include the midurethral sling (retropubic or transobturator), colposuspension, pubovaginal sling (autologous, synthetic, or allograft), and bulking agents.

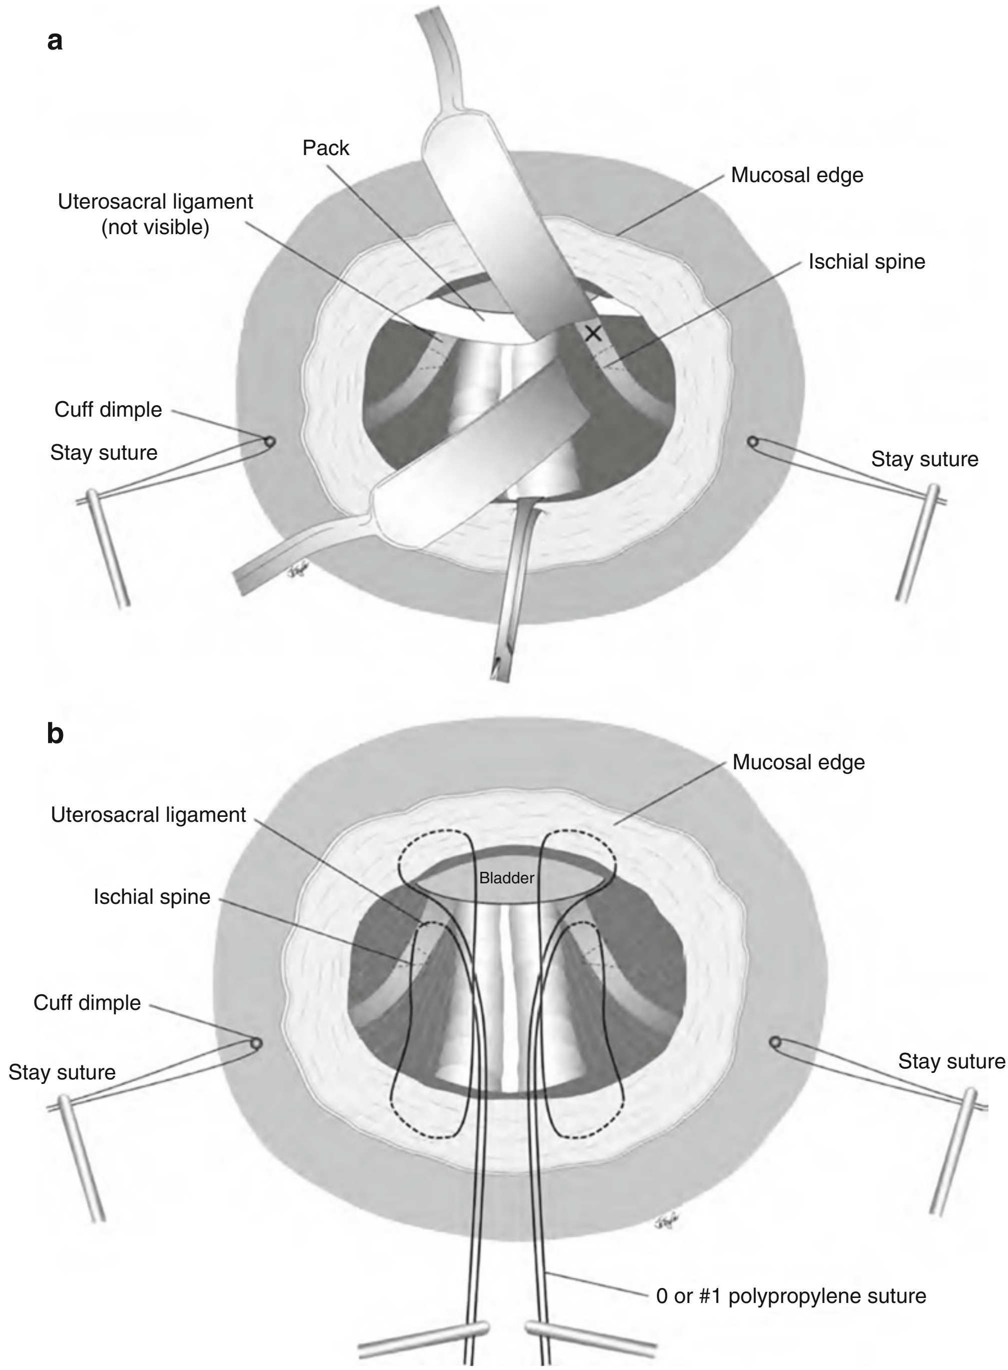

Fig. 10 Diagrams illustrating open vaginal apical area with (**a**) exposure of site for suture placement or lateral pelvic side wall and (**b**) suture placement through ligament and then through the posterior and anterior paravaginal tissue where they are locked to enable pulley action to the ligaments when tied. (From Berek JS (ed) [60]. Reprinted with permission from Lippincott Williams & Wilkins)

Older woman undergoing incontinence surgery can expect continence rates that in general compare favorably to those of younger women. The choice of incontinence surgery will depend upon patient history, physical examination, urethral and bladder function, and whether other concomitant procedures will be performed.

The midurethral sling (MUS) is a minimally invasive surgery and has become the gold standard for the treatment of SUI. Two main types of MUS are the retropubic and transobturator approaches. A recent randomized controlled trial directly compared the two approaches and demonstrated that the objectively assessed success for the treatment of SUI was equivalent between the two approaches (71% retropubic vs. 78% transobturator; 95% confidence interval [CI] −3.6 to 9.6). Subjective success rates were similar between the two and, however, did not meet the predefined equivalence criteria of 12% (62.2% retropubic vs. 55.8% transobturator; 95% CI −1.6 to 14.3) [100]. Existing data regarding the impact of aging on surgical outcomes are limited. A retrospective cohort study demonstrated no difference in treatment success of suburethral slings based on age groups (≤50 years, 51–69 years, ≥70 years of age) [101]. Another study using the British Society of Urogynaecology database including 7600 women undergoing a midurethral sling procedure (757 women ≥70 years and 119 women ≥80 years of age) reported that advanced age was associated with significantly lower subjective impression of improvement for the 70–79 year-old and 80–89 year-old groups (70%) compared to women younger than 50 (93%). Reassuringly, no difference was noted in the intraoperative and postoperative complication rates, except for short-term voiding dysfunction that was higher in the group of women older than 80 years of age [102].

Periurethral bulking injections may be offered in the treatment of SUI in older women. Regardless of the agent, cure and improvement rates are poor and appear to decline with time. The advantage of urethral bulking is that the injection can be performed in the office or operating room. Given the low risk of the procedure, this may be a reasonable option in the medically compromised patient or in the patient who has failed other approaches. Currently available bulking agents include carbon-coated zirconium oxide beads, cross-linked polydimethylsiloxane, and calcium hydroxylapatite. Existing data suggest insufficient evidence for one specific agent to be superior in treatment outcomes, long-term efficacy, and complication rates [103].

More invasive surgical approaches are available such as Burch colposuspension or pubovaginal sling procedure using autologous fascia. A secondary analysis of data from the Stress Incontinence Surgical Treatment Efficacy Trial (SISTEr), a randomized trial of Burch colposuspension versus autologous rectus fascial sling, addressed 2-year outcomes in older women (≥65 years of age) versus those younger [96]. Older women had a slightly longer time to normal activities (50 days compared with 42 days, $P=0.05$), but there was no difference in time to normal voiding (14 days compared with 11 days, $P=0.42$). Older women were more likely to have a positive stress test at follow-up (odds ratio [OR] 3.7, 95% confidence interval [CI] 1.70–7.97, $P=0.001$), less subjective improvement in stress urinary incontinence (eight-point lesser decrease, 95% CI 1.5–14.1, $P=0.02$), and urgency urinary incontinence (seven-point lesser decrease, 95% CI 1.5–12.2, $P=0.01$) as measured by the Medical and Epidemiologic Social Aspects of Aging questionnaire and were more likely to undergo surgical retreatment for SUI (OR 3.9, 95% CI 1.30–11.48). Perioperative adverse events and length of stay did not differ between groups.

The mainstay of treatment for overactive bladder (a condition including urinary frequency and urgency and nocturia with or without urinary urgency incontinence) includes a combination of pelvic floor muscle rehabilitation and medication. Patients refractory to these conservative therapies may be candidates for intravesical botulinum toxin A injections or neuromodulation techniques including posterior tibial nerve stimulation (PTNS) and sacral neuromodulation (SNM).

Fecal Incontinence

Treatment of fecal incontinence (FI) or accidental bowel leakage (ABL) in the older woman should include evaluation for possible functional, anatomic, and neurologic deficiencies in the lower gastrointestinal tract. Behavioral therapies that include diet modification with fiber supplementation and fluid rehabilitation should be considered. Fiber is a bulking agent and thus improves stool consistency, promotes complete evacuation of stool, and improves sensation of the need to defecate. It is beneficial for low-volume, loose-stool-associated FI. Severe constipation can lead to overflow FI; therefore, older women should avoid fecal impaction and have a good bowel regimen. Other conservative management includes pelvic floor muscle training with or without concurrent biofeedback and pharmacologic treatment with anti-diarrheal agents. Devices for the management of FI, such as anal and vaginal inserts, to provide temporary occlusion of the anal vault to prevent leakage have recently become available [104, 105].

Surgery is considered if conservative management is not tolerated or ineffective. Current data regarding surgical management of FI in older women are limited. Perianal bulking is a minimally invasive option. Bulking agents can be injected into the anal submucosa to increase the proximal anal sphincter volume to create a tighter seal. Currently, the most studied bulking agent is non-animal stabilized hyaluronic acid/dextranomer (NASHA/Dx). It is offered typically in the office with little morbidity. Long-term efficacy and safety of this agent is limited.

If an anatomic defect such as a sphincter disruption is identified, anal sphincter repair could be considered. Little studies address the efficacy of this approach in the older woman; however "good" short-term outcomes in all age ranges are achieved in approximately 70% of patients. Unfortunately, longer-term results may not be as robust, with one study reporting only 23% of patients with "good" results at 10-year follow-up [106]. Advanced age at the time of repair has been suggested as a risk factor for long-term surgical failure [107].

Other surgical approaches to consider for the treatment of refractory FI include sacral neurostimulation (SNS). The proposed mechanism of SNS is to reduce colonic activity, change rectal sensitivity via somato-visceral reflex pathway, to increase sphincter tone, and to improve rectal compliance. A recent analysis with a median follow-up of 44 months including patients with FI over 65 years of age demonstrated a significant reduction in FI episodes over 2 weeks, from 10 to 1 [108]. As the device often requires adjustment with the patient programmer, it may not be suitable for older women especially with cognitive or vision impairment or decreased dexterity.

Gynecologic Malignancies in the Older Woman

Introduction

Gynecologic malignancies are those that arise in the female reproductive tract including the uterus, ovaries, cervix, vulva, or vagina. The incidence of most of these cancers increases with age, and outcomes are worse for elderly women across all disease sites. This section outlines the presenting symptoms, diagnostic workup, and treatment for the most common gynecologic malignancies and reviews some of the unique challenges involved in diagnosis and treatment of these cancers in older patients.

Uterine Cancer

While cervical cancer is the most common gynecologic cancer worldwide, cancer of the uterine corpus is the most common malignancy of the female reproductive tract in developed countries. An estimated 61,380 new cases of uterine cancer are diagnosed annually in the United States, and 10,920 women die per year as a result of this disease [109]. Patients 65 and older account for 44.3% of new endometrial cancer diagnoses and 66.6% of endometrial cancer deaths [110].

Endometrial Adenocarcinomas

The most common type of uterine corpus cancers are the endometrial adenocarcinomas, which arise from the uterine lining. These have classically been divided into type 1 and type 2 endometrial adenocarcinoma. The more common type 1 endometrioid adenocarcinomas are endometrioid histology, associated with unopposed estrogen exposure, and generally have a good prognosis. Compared to type 2 adenocarcinomas, these tend to occur more commonly in younger, obese patients and arise in a background of endometrial hyperplasia [111].

In contrast, the type 2 adenocarcinomas are high-grade, non-estrogen dependent, more common in older patients, arise in a background of atrophy, and are associated with a poor prognosis [111]. Type 2 histologies include grade 3 endometrioid adenocarcinoma, uterine papillary serous carcinoma, clear cell carcinoma, and carcinosarcoma (previously malignant mixed mullerian tumor). These tumor types account for a small percentage of endometrial cancer cases but a disproportionate number of endometrial cancer deaths [112].

The majority of older patients with endometrial cancer present with postmenopausal vaginal bleeding. While endometrial cancer is not the most common cause of postmenopausal bleeding, any patient presenting with this complaint should have a diagnostic evaluation to rule out malignancy as a cause. A typical initial workup would include a pelvic exam and a transvaginal ultrasound and/or endometrial biopsy. In a postmenopausal patient, an endometrial stripe >4 mm or persistent or recurrent bleeding regardless of endometrial thickness warrants further evaluation with an endometrial biopsy [113]. Particularly in older patients, cervical stenosis may preclude office endometrial biopsy. If adequate tissue cannot be obtained in the clinic setting, a dilation and curettage is indicated.

Endometrial hyperplasia is the precursor lesion for type 1 endometrial cancer and is classified as simple or complex hyperplasia with or without atypia. While simple hyperplasia rarely progresses to invasive cancer and can be observed in elderly patients, 30% of patients with complex atypical hyperplasia (CAH) will ultimately progress to invasive cancer, and nearly 50% of patients with CAH on biopsy are found to have an invasive cancer on final pathology at the time of hysterectomy [114, 115]. Given the high likelihood of invasive cancer, the finding of CAH on endometrial biopsy should prompt referral to a gynecologic oncologist. Complex hyperplasia without atypia has a much lower risk of progression and can be treated with progestin therapy [115].

Endometrial cancer is surgically staged (Table 2), and primary treatment consists of a total abdominal hysterectomy, bilateral salpingo-oophorectomy, and pelvic and para-aortic lymphadenectomy. Because the majority of endometrial cancers are limited to the uterus, preoperative imaging to evaluate for metastatic disease is typically not indicated prior to surgery. Due to advances in minimally invasive surgical techniques, the majority of these cases can now be performed laparoscopically or robotically with substantially less postoperative morbidity than traditional laparotomy [116]. Lymphedema and other morbidity associated with lymph node dissections can be minimalized through use of sentinel lymph node biopsy, which has been shown to have a high sensitivity for detection of metastatic disease and a low false negative rate [117]. For older women with significant comorbidities or poor functional status that precludes surgical management, primary radiation therapy can be used [118, 119].

Table 2 Carcinoma of the endometrium [222]

Stage I	**Tumor confined to the uterine corpus**
IA	Less than ½ myometrial invasion
IB	Greater than ½ myometrial invasion
Stage II	**Cervical stromal involvement**
Stage III	**Regional metastases**
IIIA	Uterine serosa or adnexal involvement
IIIB	Vaginal and/or parametrial involvement
IIIC	Lymph node involvement
IIIC1	Pelvic lymph node involvement
IIIC2	Para-aortic lymph node involvement
Stage IV	**Distant metastases**
IVA	Invasion of bladder and/or bowel mucosa
IVB	Distant metastases

The need for adjuvant therapy is determined by final pathology results. Patients with low-grade, superficially invasive tumors confined to the uterus do not require adjuvant therapy and have an excellent prognosis (5-year survival >90%) [120]. High-intermediate risk has been defined as stage I endometrial cancers that are high-grade (grade 2 or 3), deeply invasive (outer third myometrial invasion), and/or have lymphovascular space invasion identified. Women >70 who have one of these risk factors, women 50–70 with two risk factors, and women of any age with all three risk factors have been shown to have decreased recurrence risk and improved progression-free survival with adjuvant brachytherapy [121, 122]. Adjuvant chemotherapy is indicated for patients with type II endometrial cancers, regardless of stage, and for patients with advanced-stage disease [123, 124].

Management of recurrent endometrial cancer is variable and depends on histologic subtype and site of recurrence. Isolated vaginal cuff recurrences can be successfully treated with salvage radiation therapy in a high percentage of patients [125]. Chemotherapy or hormonal therapies are options for treatment of more widespread disease. In older patients who are unable to tolerate chemotherapy, hormonal therapy may allow for disease stabilization and improved progression-free survival with minimal toxicity [126].

Uterine Sarcomas

The uterine sarcomas are a rare and aggressive group of soft-tissue sarcomas that typically occur in middle-aged to older women. These cancers account for <10% of all uterine malignancies and typically present as incidental findings at the time of surgery for presumed leiomyoma. Preoperatively, patients may present with vaginal bleeding or a rapidly enlarging pelvic mass [127, 128]. The two major pathologic subtypes are leiomyosarcoma and endometrial stromal sarcoma. Carcinosarcoma was previously thought to be a type of uterine sarcoma; however, it is now understood to be an aggressive, dedifferentiated carcinoma and as such is best grouped with the type II endometrial adenocarcinomas [129].

Uterine sarcoma is primarily a surgically treated disease, and complete surgical resection has been associated with improved survival [130]. Staging differs from that of the endometrial adenocarcinomas and is presented in Table 3. Unlike endometrial adenocarcinomas, sarcomas tend to metastasize hematogenously rather than via lymphatics; therefore, lymphadenectomy is not always required for surgical management of sarcomas [131]. There is limited data to guide adjuvant therapy of uterine sarcomas. Chemotherapy may confer some benefit for patients with leiomyosarcoma, while patients with endometrial stromal sarcomas may derive benefit from hormonal therapy [132, 133]. Radiation therapy does not appear to have a role in the treatment of uterine sarcomas [134].

Key Points in Uterine Cancer Affecting Older Women

- Any patient with postmenopausal bleeding should have a diagnostic evaluation to exclude uterine malignancy.
- Uterine cancers in older women are more likely to be the more aggressive type II histologies (papillary serous, clear cell, carcinosarcoma).
- Primary treatment for both endometrial adenocarcinoma and uterine sarcoma is surgical.

Table 3 Uterine sarcoma [222]

Stage I	**Tumor confined to the uterine corpus**
IA	Tumor <5 cm
IB	Tumor >5 cm
Stage II	**Pelvic extension**
IIA	Adnexal involvement
IIB	Extension to extrauterine pelvic structures
Stage III	**Abdominal metastases**
IIIA	One site
IIIB	More than one site
IIIC	Pelvic or para-aortic lymph node involvement
Stage IV	**Distant metastases**
IVA	Invasion of bladder and/or bowel mucosa
IVB	Distant metastases

Ovarian, Primary Peritoneal, and Fallopian Tube Cancers

With a 5-year survival of only 46.5%, ovarian cancer is the deadliest of the gynecologic cancers and is the fifth leading cause of cancer death in women in the United States [135]. Approximately 1 in 70 women will be diagnosed with ovarian cancer in their lifetime. In 2017, an estimated 22,440 women will be diagnosed with ovarian cancer in the United States, and 14,080 will die from this disease [109]. Forty-five percent ovarian cancer diagnoses and 65% of ovarian cancer deaths occur in women >65 years [135]. Ninety percent of ovarian cancers are epithelial in origin, and as epithelial ovarian, primary peritoneal, and fallopian tube cancers have similar pathogenesis, clinical behavior, and treatment, these are treated as a single clinical entity [136, 137]. As epithelial cancers are the most common malignancies of the ovary, they will be the focus of this chapter. Common histologic subtypes of epithelial ovarian cancer include serous, mucinous, endometrioid, and clear cell cancers.

It was previously thought that only 5% of ovarian cancer patients had a hereditary predisposition to develop the disease; however, we now know that as many as 15–20% of epithelial ovarian cancers are genetic. BRCA1 and BRCA2 are the most common – 40% of patients with a *BRCA1* mutation and nearly 20% of patients with a *BRCA2* mutation will develop ovarian cancer by age 70 [138]. Lynch syndrome is more commonly associated with colorectal and endometrial cancer but also carries a 10% lifetime risk of ovarian cancer. Other less common genes associated with hereditary ovarian cancer include *TP53*, *BRIP1*, *CHEK2*, and *RAD51C* [139]. As nearly one in five women with epithelial ovarian cancer may have a hereditary cancer syndrome, current guidelines recommend that all women diagnosed with epithelial ovarian cancer be referred for genetic counseling and offered genetic testing [140]. Other risk factors for ovarian cancer include nulliparity, early menarche or late menopause, and endometriosis [141]. Multiparity, oral contraceptive pills, tubal ligation, and breastfeeding have all been shown to be protective [142–145].

Because there is no effective screening test and ovarian cancer lacks early warning symptoms, approximately 70% of women have advanced disease (stage III or IV) at the time of their initial presentation [146]. The most common presenting symptoms are vague abdominal complaints, such as bloating, constipation, early satiety, and nausea. Diagnosis is often made by imaging obtained for evaluation of these complaints, which may show ascites, omental caking, and an adnexal mass. Physical exam may be notable for abdominal distension with visible fluid wave or a palpable abdominal or adnexal mass [147]. While not useful as a screening test, the tumor marker CA125 is often markedly elevated in patients with epithelial ovarian cancer and can be used both to support the diagnosis and to monitor response to treatment [148].

Ovarian cancer is surgically staged (Table 4), and survival is directly related to stage at diagnosis. Five-year survival for stage I patients is 81%, for stage II 57%, for stage III 30%, and for stage IV is 14% [149]. Treatment of ovarian cancer is typically a combination of cytoreductive surgery and chemotherapy, most often a platinum/taxane doublet [150]. Surgical staging of ovarian cancer includes total abdominal hysterectomy, bilateral salpingo-oophorectomy, omentectomy, pelvic and para-aortic lymphadenectomy, washings, and resection of any other visible disease. The goal of surgery is debulking to no gross residual disease (NRD) as this is associated with improved survival. If debulking to NRD is not feasible, the goal is to have no residual disease >1 cm [151]. Traditionally, patients were treated with surgery followed by adjuvant chemotherapy. As most patients present with advanced-stage disease, up-front cytoreductive surgery is often extensive and can be associated with high postoperative morbidity and mortality. More recently, there has been a shift toward use of neoadjuvant chemotherapy to decrease disease burden prior to proceeding with cytoreduction.

Patients typically have confirmation of diagnosis by either cytology or diagnostic laparoscopy with peritoneal biopsies, receive 3–4 cycles of chemotherapy, and then have an interval debulking surgery followed by an additional 3–4

Table 4 Carcinoma of the ovary [222]

Stage I	**Tumor confined to the ovaries**
IA	Limited to one ovary, capsule intact, no surface involvement, negative washings
IB	Both ovaries involved but capsules intact with no surface involvement, negative washings
IC	Limited to 1 or both ovaries, plus:
IC1	Surgical spill
IC2	Capsule rupture prior to surgery or surface involvement
IC3	Malignant cells in ascites or peritoneal washings
Stage II	**Pelvic extension below the pelvic brim or primary peritoneal cancer**
IIA	Extension to uterus and/or fallopian tubes
IIB	Extension to other pelvic intraperitoneal tissues
Stage III	**Extension to extrapelvic peritoneum and/or retroperitoneal lymph nodes**
IIIA	Positive retroperitoneal lymph nodes and/or microscopic extrapelvic disease
IIIA1	Positive retroperitoneal lymph nodes only
IIIA1(i)	Metastasis $\leq$10 mm
IIIA1(ii)	Metastasis >10 mm
IIIA2	Microscopic extrapelvic peritoneal involvement $\pm$ positive retroperitoneal lymph nodes
IIIB	Macroscopic extrapelvic peritoneal metastases $\leq$2 cm $\pm$ positive retroperitoneal lymph nodes. Includes extension to capsule of the liver or spleen
IIIC	Macroscopic extrapelvic peritoneal metastases >2 cm $\pm$ positive retroperitoneal lymph nodes. Includes extension to capsule of the liver or spleen
Stage IV	**Distant metastases excluding peritoneal metastases**
IVA	Pleural effusion with positive cytology
IVB	Hepatic and/or splenic parenchymal metastases or metastases to extra-abdominal organs

cycles of chemotherapy. For patients at high risk of suboptimal debulking, neoadjuvant chemotherapy is associated with less surgical morbidity and mortality, higher rates of interval NRD, and equivalent survival [152, 153]. Neoadjuvant chemotherapy can also be used to treat patients who are unable to tolerate extensive and lengthy surgery due to advanced age or significant medical comorbidities [154, 155].

With a combination of surgery and platinum-based chemotherapy, the majority of patients will achieve remission; however, recurrence rates are high with over 75% of patients eventually experiencing a relapse [156]. The majority of patients with recurrent ovarian cancer are treated with chemotherapy. There are numerous chemotherapy regimens that can be used for the treatment of recurrent ovarian cancer [157], and while survival can be prolonged, once ovarian cancer recurs, it ultimately leads to the patient's demise. Patients with an isolated recurrence following a long disease-free interval are candidates for surgical management of recurrence [158].

There are several important considerations in the management of ovarian cancer in the older woman. Age is an independent prognostic factor in ovarian cancer – older women are known to have a significantly worse prognosis than younger women [159, 160]. It is not clear whether this difference is due to old age and its associated comorbid conditions or to differences in treatment of elderly women. Elderly patients are more likely to receive primary chemotherapy, less likely to ever have surgery, and more likely to be treated with single-agent platinum rather than combination chemotherapy [161]. While some older patients may experience increased toxicity with chemotherapy, there is evidence that many elderly patients tolerate combination chemotherapy well. Assessing functional status with tools such as the Instrumental Activities of Daily Living (IADL) assessment may help differentiate between elderly patients who are likely to tolerate therapy well and those who are not [162].

Key Points in Ovarian Cancer Affecting Older Women

- Due to the lack of an effective screening test and nonspecific symptoms, the majority of patients present with advanced disease.
- Ovarian cancer is typically managed with a combination of surgery and chemotherapy.
- Resection to no gross residual disease confers the best prognosis.
- In patient with advanced disease, neoadjuvant chemotherapy increases rates of optimal debulking and decreases postoperative morbidity with affecting overall survival.

Cervical Cancer

Cervical cancer is the most common gynecologic cancer and the fourth most common cancer overall in women worldwide; however, the majority of diagnoses and 87% of cervical cancer-related deaths occur in less-developed countries due to the lack of access to appropriate screening and treatment of preinvasive disease [163]. In the United States, there are an estimated 12,820 cervical cancer diagnoses and 4,210 deaths annually [109]. Unlike the other gynecologic cancers discussed in this chapter, the incidence of cervical cancer is actually highest in women in their 30s and 40s and decreases with age [164]. While the incidence is lower in older women, survival also tends to be worse in this cohort [165, 166].

Persistent human papillomavirus (HPV) infection is the most important risk factor for the development of cervical cancer and causes >99% of these cancers worldwide [167]. The most common HPV subtypes implicated in the development of invasive carcinoma are HPV 16 and 18, which together are responsible for over 70% of cervical cancers [168]. The most common histology is squamous cell carcinoma (63.6%), followed by adenocarcinomas (25.1%) [169]. In addition to HPV infection, cigarette smoking, multiple sexual partners, young age at first intercourse, and immunosuppression have been established as risk factors for the development of invasive cervical cancer and its precursor lesion, cervical intraepithelial neoplasia (CIN) [170].

The incidence of cervical cancer in the United States has been steadily declining since the introduction of the Pap smear in the 1950s [169]. Current cervical cancer screening guidelines recommend cytology every 3 years from age 21 to 29. From age 30–65, both cytology and HPV co-testing are recommended at 5-year intervals. If all prior screening has been normal, continued routine screening is not recommended for patients >65. Abnormal cytology or the diagnosis of persistent HPV infection should prompt referral for colposcopy, a microscopic examination of the cervix and vagina, with directed biopsies [171]. The majority of CIN and cervical cancers originate in the transformation zone, where the squamous epithelium of the ectocervix meets the columnar epithelium of the endocervix. Careful evaluation of the transformation is critical for detection of CIN at time of colposcopy. If the entire transformation zone is not visible, endocervical curettage (ECC) is recommended. Of note, the transformation zone tends to recede into the endocervix after menopause; therefore, ECC is often required to exclude endocervical CIN in older women. High-grade CIN (CIN2 or CIN3) detected on biopsy can be treated in a variety of ways, including excision of the transformation zone with either cold knife cone (CKC) or loop electrosurgical excision procedure (LEEP), CO_2 laser ablation, or cryotherapy [171]. Large high-grade lesions or those with an appearance concerning for microinvasive disease should be treated surgically with either CKC or LEEP to allow for pathologic evaluation.

While most early cervical cancers are asymptomatic and detected via screening, patients may present with complaints of irregular or postcoital vaginal bleeding, pelvic pain, or malodorous vaginal discharge. Because cervical cancer typically spreads by direct extension, locally advanced disease may also cause bladder or bowel symptoms, including urinary hesitancy or frequency, constipation, or even vesicovaginal or rectovaginal fistulas. Any of these symptoms should prompt a pelvic exam with biopsy of any suspicious lesions. A screening Pap smear is not appropriate for evaluation of a visible mass.

Cervical cancer is clinically staged (Table 5), and treatment primarily involves surgery or chemoradiation, depending on the extent of disease. While advanced imaging modalities are not used to determine staging, CT, MRI, or 18-F FDG PET scans can be used to help guide treatment decisions.

Patients with stage I cervical cancer are primarily managed surgically, while stage II and higher are best served by primary chemoradiation therapy. Stage IA1 cervical cancer, which has ≤3 mm stromal invasion, can be adequately treated with an excisional procedure such as CKC or LEEP or with a simple hysterectomy given low risk of lymph node involvement (<0.5%) and low risk of recurrence (1.7%) [172]. Stage IA2 disease is typically treated with a type II (modified radical) hysterectomy and bilateral pelvic lymphadenectomy. Historically, stages IB1–IIA

Table 5 Carcinoma of the cervix [222]

Stage I	**Tumor confined to the cervix**
IA	Microscopic cancer with depth of invasion ≤5 mm and horizontal extension ≤7 mm
IA1	Stromal invasion ≤3 mm and horizontal extension ≤7 mm
IA2	Stromal invasion 3–5 mm and horizontal extension ≤7 mm
IB	Clinically visible or exceeds dimensions for stage IA disease
IB1	≤4 cm in diameter
IB2	>4 cm in diameter
Stage II	**Extension beyond the cervix but not to pelvic sidewall or lower 1/3 of vagina**
IIA	Extension to upper 2/3 of vagina
IIB	Parametrial involvement
Stage III	**Extension to pelvic sidewall, lower 1/3 of vagina, and/or causing hydronephrosis**
IIIA	Extension to lower 1/3 of vagina
IIIB	Extension to pelvic sidewall or hydronephrosis
Stage IV	**Extension beyond the pelvis or to mucosa of bladder or rectum**
IVA	Invasion of bladder and/or bowel mucosa
IVB	Distant metastases

were treated with a type III radical hysterectomy; however, patients who require adjuvant radiation due to positive margins or other pathologic risk factors have higher associated morbidity than those treated with either surgery or radiation alone [173, 174]. For this reason, patients with bulky IB2 or IIA tumors are often treated with primary chemoradiation. Advances in laparoscopic and robotic surgery and the increasing use of sentinel lymph node biopsy have resulted in decreased surgical morbidity for patients treated with radical hysterectomy [175–177].

For patients with locally advanced disease or who are not surgical candidates, the cornerstone of treatment is radiation therapy (external beam and brachytherapy) in combination with radiosensitizing chemotherapy. While both hydroxyurea and 5-fluorouracil have also been studied, cisplatin appears to confer a superior survival benefit and has become the chemotherapy of choice in this setting [178–180]. Patients with distant disease at time of diagnosis (stage IVB) have a poor prognosis and are typically treated with palliative chemotherapy. Radiation therapy can be used for palliation of bleeding and bulk symptoms in this population. Five-year survival for women with cervical cancer ranges from over 90% with women with early-stage disease to only 17% for women with stage IVB disease [169].

Treatment of recurrent disease depends on the site of recurrence and the primary treatment modality. In general, recurrent cervical cancer is difficult to treat and portends a poor prognosis. Patients with a pelvic recurrence who had surgery as their primary therapy can be treated with salvage chemoradiation. For patients who were treated with primary chemoradiation and develop a central pelvic recurrence, exenterative surgery is a potentially curative option; however, exenteration has high associated postoperative morbidity and mortality and can have significant detrimental effects on patients' quality of life. Patients with recurrent pelvic disease not amenable to exenteration or with distant disease can be offered palliative chemotherapy, although best response rates remain <50% [181]. Best supportive care is also a very reasonable option in this patient population.

There are significant differences in the management of cervical cancer in older patients compared to younger women. Older patients with early-stage cervical cancer are far less likely to undergo surgery as a primary treatment and less likely to have a lymphadenectomy if they do have surgery. Older women with locally advanced disease are far more likely to undergo no cancer-directed therapy at all compared to younger women. If treated with primary radiation, they are less likely to have concurrent brachytherapy, despite evidence that it is well-tolerated in older patients [111, 166].

Key Points in Cervical Cancer Affecting Older Women

- >99% of cervical cancers are related to human papillomavirus.
- Current guidelines recommend discontinuing routine cervical cancer screening at 65 in patients with a history of normal screening.
- Despite a lower incidence of cervical cancer in patients >65, survival is significantly worse in older women.
- Older women are less likely to receive standard of care treatment than younger women.

Vulvar Cancer

Vulvar carcinoma is a rare malignancy, representing less than 5% of all cancers of the female genital tract [182]. While vulvar carcinoma remains uncommon, the incidence is increasing [182, 183]. There were an estimated 6,020 new cases of vulvar carcinoma diagnosed in the United States in 2017 and an estimated 1,150 deaths from the disease [109]. The mean age at diagnosis is 68.7, and 70% of vulvar cancer diagnoses occur in women over the age of 60 [183].

Squamous cell carcinomas of the vulva are by far the most common histologic subtype, accounting for 90% of vulvar cancers [182]. There are two distinct pathways involved in the pathogenesis of squamous cell carcinoma of the vulva and its precursor lesion, vulvar intraepithelial neoplasia (VIN). Previously, VIN included grades 1–3; however, the nomenclature recently changed, and VIN now refers only to high-grade lesions of the vulva [184]. Human papillomavirus (HPV)-associated VIN, also referred to as usual-type VIN, occurs more frequently in younger women and is predominantly associated with the carcinogenic HPV genotypes, most commonly HPV 16 [185]. HPV-independent VIN, or differentiated VIN, occurs more frequently in older women and is associated with chronic inflammation often secondary to an underlying dermatologic condition such as lichen sclerosus or lichen planus [186, 187]. The clinical behavior of these two pathogenic subtypes is very different. HPV-associated VIN typically develops slowly and may spontaneously regress, while HPV-independent VIN is more likely to progress rapidly to invasive squamous cell carcinoma [185]. While 80% of VIN is associated with HPV infection, only 20–50% of vulvar squamous cell carcinoma can be attributed to HPV, indicating that most invasive squamous cell carcinomas of the vulvar actually arise independently of HPV infection [186].

Patients with VIN or vulvar carcinoma most often present with vulvar burning or pruritus and may report a visible lesion [188]. Diagnosis is made via careful inspection of the vulva with biopsy of any suspicious lesions. Usual-type VIN is multifocal in as many as 49% of cases, while differentiated VIN is more likely to be unifocal [185]. There are several options for treatment of usual-type VIN. Wide local excision, laser ablation, and topical treatment with imiquimod have all been shown to be effective [189]. Surgical management is recommended for patients with large lesions that have an appearance worrisome for invasive disease and for women with differentiated-type VIN given the higher likelihood of progression [184].

Vulvar cancer is surgically staged (Table 6). The presence or absence of lymph node metastasis is the most important prognostic factor for women with this disease. Five-year overall survival in the absence of nodal metastasis is 91% compared to only 57% for patients with node-positive disease [190]. Regardless of nodal status or stage at

Table 6 Carcinoma of the vulva [222]

Stage I	**Tumor confined to the vulva**
IA	≤2 cm in size with stromal invasion ≤1.0 mm
IB	>2 cm in size or with stromal invasion >1.0 mm
Stage II	**Tumor of any size with extension to adjacent perineal structures, including lower 1/3 of urethra or vagina and/or anus**
Stage III	**Positive inguinofemoral lymph nodes**
IIIA	1 lymph node metastasis ≥5 mm or 1–2 lymph node metastases <5 mm
IIIB	2+ lymph node metastases ≥5 mm or 3+ lymph node metastases <5 mm
IIIC	Positive lymph nodes with extracapsular spread
Stage IV	**Invasion of upper urethra or vagina or distant spread**
IVA	Tumor invading upper urethral, vaginal, bladder, or rectal mucosa, fixed to pelvic bone, or with fixed or ulcerated inguinofemoral lymph nodes
IVB	Any distant metastases, including pelvic lymph nodes

initial diagnosis, vulvar cancer-specific mortality increases with age. Women >65 years have a fourfold higher risk of death, and women >80 have a sevenfold higher risk of death compared to women <50 [191].

Historically, vulvar cancer was treated with en bloc radical vulvectomy with bilateral inguinofemoral lymphadenectomy; however, this approach was associated with substantial postoperative morbidity, including wound breakdown, lymphedema, and sexual dysfunction. Given these risks, there has been a trend toward less radical surgical management. Patients with tumors ≤2 cm with ≤1 mm depth of invasion can be treated with wide local excision to a 1 cm free margin alone as their risk of lymph node metastasis is exceedingly low [192]. Well-lateralized tumors <4 cm in size can be treated with wide local excision and ipsilateral groin node evaluation; however, midline or deeply invasive (>5 mm) lesions should have bilateral groin node assessment [193, 194]. Given the substantial infectious morbidity and lymphedema risk associated with inguinofemoral lymphadenectomy, sentinel lymph node biopsy using a combination of isosulfan blue and radiocolloid was investigated and found to have a high sensitivity for detection of metastatic disease and significantly less morbidity than full groin dissection [195, 196]. In many institutions, sentinel lymph node biopsy is now the standard method of groin node assessment for patients with early-stage vulvar cancer. For patients who are found to have positive groin nodes on final pathology, adjuvant radiation to the pelvis and groin with or without concurrent chemotherapy significantly decreases risk of recurrence and improves survival [197, 198].

Similar to changes in the management of early-stage disease, treatment of advanced vulvar cancer has also shifted to a less radical approach. Traditionally, patients with advanced disease were treated with pelvic exenteration; however, this procedure was associated with significant morbidity and high postoperative mortality. Neoadjuvant chemoradiation has been shown to eliminate the need for exenterative surgery for patients with locally advanced disease and to improve outcomes in patients with previously unresectable nodal metastases [199, 200]. Radiation with concurrently weekly cisplatin leads to high rates of complete pathologic response, and for these patients, subsequent surgical resection may be unnecessary [201]. Older women with vulvar cancer are much less likely than younger women to be treated surgically and are more likely to receive primary chemoradiation [191].

The prognosis and treatment of recurrent vulvar cancer depend on the site of recurrence. Isolated vulvar recurrence can be treated with surgical excision [202]; however, the optimal treatment for patients with nodal or distant recurrence is unclear. Prognosis for these patients is poor regardless of choice of therapy. Chemotherapy and palliative care are both reasonable options in this setting [203].

Other Vulvar Malignancies

Vulvar melanoma is the second most common malignancy of the vulva after squamous cell carcinoma and makes up 5–10% of vulvar malignancies. The majority of vulvar melanomas occur in elderly patients, and it is much more common in Caucasian women [204]. Compared to cutaneous melanoma and other mucosal melanomas, prognosis for patients with vulvar melanoma is poor with a 5-year overall survival rate of less than 50%. Forty percent of women with vulvar melanoma will have metastatic disease at the time of initial presentation [205]. Similar to cutaneous melanomas, wide local excision with sentinel lymph node biopsy has been adopted as the treatment of choice for these patients [206, 207].

Extramammary Paget's disease of the vulva is an intraepithelial adenocarcinoma that occurs most commonly in postmenopausal Caucasian women and may be associated with underlying adenocarcinoma of the vulva. Invasive Paget's disease of the vulva is rare, accounting for only 1–2% of vulvar malignancies [208]. Patients classically present with pruritus, and physical exam shows an erythematous plaque with white scaling. Ulceration may also be present [208, 209]. Diagnosis is typically made by biopsy, which shows intraepithelial mucin-producing cells known as Paget cells [208]. Treatment is typically wide local excision, which may be extensive given the propensity for multifocal disease. Positive margins are common, and re-excision is indicated to ensure complete resection [208].

Bartholin gland carcinomas are rare adenocarcinomas of the vulva that are frequently misdiagnosed as cysts or abscesses as these are common abnormalities of the Bartholin gland. Any suspected Bartholin cyst or abscess in a postmenopausal patients warrants biopsy [210].

Key Points in Vulvar Cancer Affecting Older Women

- Vulvar cancer in older women is more likely to be associated with vulvar dermatoses than with HPV infection.
- Ninety percent of vulvar cancers are squamous cell carcinomas.
- Older women have a worse prognosis than younger women regardless of stage at diagnosis.
- Lymph node status is the most important prognostic indicator.

Vaginal Cancer

Primary cancer of the vagina is rare, accounting for only about 2% of all gynecologic cancers. The incidence increases with age with 50% of patients presenting at age 70 or older [211]. By definition, vaginal tumors that involve the cervix or vulva are classified as primary cervical or vulvar malignancies; thus, the most common tumors involving the vagina are actually metastases. Over 50% of primary vaginal carcinoma occurs in women with a previous hysterectomy [212]. Similar to cervical cancers, the majority of primary vaginal cancers are squamous cell carcinomas (80%) and are related to HPV disease, especially HPV-16. Adenocarcinomas account for 15% of vaginal carcinomas, and the remaining 5% are made up of rare histologies including melanoma and sarcoma [211, 213].

The most common presenting complaints in women with vaginal cancer are vaginal bleeding and abnormal discharge; although, patients with more advanced disease may also present with pain and/or urinary or rectal symptoms [214]. These symptoms should prompt a careful pelvic examination with biopsy of any suspicious lesions. Patients who have had a hysterectomy for cervical intraepithelial neoplasia may present with abnormal findings on vaginal cytology. If no visible lesion is seen, colposcopy with Lugol's iodine solution can be used to identify areas of vaginal intraepithelial neoplasia (VAIN) or microinvasive disease.

The prognosis for vaginal carcinoma correlates with the stage of disease, which is determined according to the FIGO staging of vaginal cancer. Similar to cervical cancer, vaginal cancer is clinically staged rather than surgically staged (Table 7). Five-year overall survival ranges from near 80% for patients with stage I disease to less than 15% for patients with stage IVB disease [213].

Because vaginal carcinomas are such a rare disease, there are no large randomized trials to guide management. Choice of primary therapy depends largely on stage, tumor size and location in the vagina, and patient factors [214]. The majority of patients are treated with primary

Table 7 Carcinoma of the vagina [222]

Stage I	Limited to vaginal wall
Stage II	Involves subvaginal tissue but does not extend to pelvic wall
Stage III	Extension to pelvic sidewall
Stage IV	Extends beyond the pelvis or involves bladder or rectal mucosa
IVA	Invasion of bladder and/or bowel mucosa
IVB	Distant metastases

radiation or chemoradiation. Surgical management with a radical upper vaginectomy and pelvic lymph node dissection appears to be superior to radiation for patients with stage I or small stage II tumors that are limited to the upper third of the vagina [211, 215]. For patients with early-stage disease who are not surgical candidates, radiation therapy is an effective treatment option that results in excellent local control and long-term disease-free survival. The majority of patients are treated with a combination of external beam and either interstitial or intracavitary brachytherapy [216–218]. Patients with advanced disease are often treated with chemoradiation, which is extrapolated from data showing improved survival with the addition of chemotherapy in cervical cancer [180, 219]. Although there is no prospective data showing a benefit with chemoradiation, available retrospective data suggests a significant benefit over radiation therapy alone [220].

Management of recurrent vaginal cancer is similar to that of recurrent cervical cancer. Central recurrences can be managed surgically with a pelvic exenteration, while distant recurrences are managed with chemotherapy or best supportive care. Prognosis for recurrent disease is poor [221].

Key Points in Vaginal Cancer Affecting Older Women

- Primary vaginal carcinomas are rare. The majority of vaginal tumors originate from the cervix or vulva.
- The majority of vaginal cancers are squamous cell carcinomas and are related to HPV.
- Select patients with early-stage disease may be candidates for surgical management, but the majority are treated with radiation therapy or chemoradiation.

Research Involving Older Woman

Given the growing geriatric population along with the high prevalence of both benign and malignant gynecologic disorders, there is a pressing need for information on the nonsurgical and surgical treatment outcomes in older women. Understanding aging-related physiologic and anatomic changes as well as unique challenges such as cognitive and functional limitations in the geriatric population is critical in providing effective therapy. There is a relative paucity of literature that addresses the older woman. In fact, older women have been excluded from many of the trials that have examined outcomes. In the area of pelvic floor surgery, a systematic review found the median percentage of women aged 70 or older who participated in surgical trials for SUI was 3.8%, while the number of surgeries for SUI performed on this population of women is estimated at 16% [223]. Less invasive treatment options have recently become available, yet long-term data on efficacy and safety specifically in the geriatric population are still lacking.

Another unique challenge for research on aging-related conditions is that there is no discrete age to define “old.” Research has suggested the use of different age groups: young old (65–75), old-old (75–85), and the oldest old (>85). Among these groups, the oldest old is the most rapidly growing population. It is essential to consider not only the chronological age but also the functional status and “physiologic age” of the patient when discussing treatment with patients. Continued effort in research initiatives should be made to increase high-quality data to improve evidence-based management of all gynecologic issues in the older women.

Conclusion

This chapter summarized an evidence-based review of the evaluation and treatment of benign and malignant gynecologic and urogynecologic conditions. Optimization of gynecologic health in the older woman may involve the spectrum of gynecologic subspecialties. Evidence-based treatment approaches are important to appreciate and can result in marked improvement in quality of life. Increasingly, the older woman is seeking to continue to be active in the workforce as well as physically and socially. Being proactive in the care of our older female patients should be a priority for all providers of care to women.

Abstract

Elderly patients will constitute 20% of the population in the USA by 2030. This phenomenon has clear implications for healthcare including perioperative care. While this group consumes approximately 35% of the surgical services, their perioperative outcomes lag behind other age groups.

While traditional anesthetic management focused in the intraoperative portion, it is peremptory to provide comprehensive and coordinated care along the perioperative continuum. In the preoperative phase, a systematic review of systems and comorbidities remains most important. However, the concepts of frailty as a determinant of outcomes and pre-habilitation in order to further optimize those presenting for anesthesia and surgery provide new perspectives in the care of these patients. Intraoperative, assuring organ perfusion, proper ventilation, and minimizing the physiological responses to surgery are key aspects. In addition prevention of awareness and movement are also important goals. Postoperatively, assessing and treating pain properly; avoiding, recognizing, and treating postoperative delirium; preventing falls; and assuring proper hydration and nutrition are important aspects in the management of these patients.

The care of the surgical geriatric patient is complex and requires excellent coordination and communication across all healthcare providers involved in their care. The perioperative surgical home promotes such collaborative effort and has proven results in different surgical service lines. This approach might prove useful when caring for the older adult across all the phases of the perioperative continuum.

Introduction

In America, about 10,000 people turn 65 years of age every day. This phenomenon started in January 2011 and is estimated to last for 19 years. By the time it ends in 2030, 18% of the population will be older than 65 years of age, compared with only 13% in 2013 [1]. Combined with the fact that the fastest growing segment of the population encompasses those older than 85 years of age [2], it is clear that there is a socioeconomic impact of such demographic change at all levels. Healthcare, including perioperative care, is no exception. Older adults receive 35.3% of the inpatient surgical procedures and 32.2% of all outpatient procedures performed in the USA [3, 4]. In 2002, this age group consumed 36% of the healthcare expenditures [5]. It has been estimated in the USA that this group will have at least one procedure done before dying [5].

This increase on demand for perioperative service in this demographic group has not been paired by improvement in outcomes. A prospective observational study in patients undergoing noncardiac surgery found that the 1-year mortality of those over 65 years of age was 10.3%, almost twice of those below that age (5.5%) [6]. The authors reported that in this cohort of 1064 patients, being over 65 years of age implied a relative risk of 1-year postoperative mortality of 4.459, which was the highest risk factor after having three or more comorbidities or having an ASA classification of 3 or 4. Others identified age as one of nine independent predictors of a cardiac adverse event after general vascular and urological surgery in a cohort of 7740 patients of 68 years of age or older [7]. Similarly, a review of the National Surgical Quality Improvement Program database from February 24, 2002 through June 30, 2005, showed an overall 28% morbidity rate and 2.3% mortality rate among 7696 surgical patients. However, for those older than 80 years of age, the morbidity rate was 51% and the mortality 7% [8].

If we consider that the cost of care in the USA on those older than 65 years of age is significantly higher than other developed countries, it is not difficult to infer that there are opportunities to enhance the care we provide to our older adult patients [9]. In this chapter, we will cover current trends in the anesthesia care in the older adult. While we will follow a traditional format of preoperative, intraoperative, and postoperative care, we will also discuss the need of better coordination of care for these patients along the whole perioperative continuum.

Preoperative Evaluation

The need to improve outcomes in the older adult undergoing surgery and anesthesia is obvious. Although age seems to be related to these not-so-desirable outcomes, it is not the only cause. Physiological changes of aging, comorbidities, occurrence of complications and type of surgery also play a role. As perioperative evaluation, frailty, and rehabilitation are explored in detail in other chapters of this book, we will only highlight some of the important aspects.

The expected physiological changes of aging are noted in Table 1. In terms of the impact of existing comorbidities, Tiret et al. demonstrated that as patient ages, the presence of one or more comorbidities is correlated with a higher incidence of complications [10]. The importance of this data resides in the impact that complications have in these patients. In a publication looking at patients older than 80 years of age undergoing noncardiac surgery, 20% had one or more postoperative complications. Furthermore, in those who suffered complications, the 30-day mortality was higher than those who did not (26% vs. 4%, $P < 0.001$) [11]. Therefore, optimization of pre-existing comorbidities is most important when caring for the older adult in the perioperative period. Additionally, quality of life should not be forgotten as an important outcome measure. Postoperative complications in the elderly have been

Table 1 Physiological changes of aging

Organ system	Changes with aging
Central nervous system	Loss of neural tissue: 26% reduction of white matter 10–20% Reduction in cerebral blood flow Decreased number of serotonin, acetylcholine, and dopamine receptors Decline in memory, reasoning, perception Disturbed sleep/wake cycle Prone to delirium and cognitive dysfunction
Cardiovascular	Diastolic dysfunction and loss of compliance of vascular bed Less responsive to catecholamines Autonomic tissue is replaced by fat and connective tissue: Prone to arrhythmias – most commonly atrial fibrillation and AV block
Respiratory	Loss of pharyngeal reflexes Decrease in chest wall compliance Decline in lung elasticity Alteration in control of ventilation Decreased diaphragm strength Increased A-a gradient Increased closing capacity
Renal	Loss of renal tubular mass Decreased renal blood flow by 50% Decreased glomerular filtration rate (by 80 years old, decreased by 45%) Reduced ability to dilute and concentrate urine and conserve sodium Decreased drug clearance
Pharmacological	Decrease level of proteins Decreased protein binding Decreased lean and increased fat body mass Decreased circulating blood volume

correlated to with decreased independency on activities of daily living [12].

The type of surgery performed also impacts outcomes. Schwarze et al. reviewed two cohorts of patients from 2001 and 2007 and looked at procedures that had a mean crude inhospital mortality of at least 1% [13]. About 227 procedures were identified; most of them are in high-risk cardiac, vascular, gastrointestinal, neurosurgical, urological, and vascular case. The need for emergency interventions also seems to play a role in outcomes. A Canadian retrospective study looking at patients 80 years or older undergoing emergency surgery in a tertiary care institution found that the inhospital mortality was 14.7% and that over 60% of patients require additional services or an alternate level of care upon discharge [14]. Another report form this group reported an inhospital mortality of 12%, which not surprisingly correlated with higher ASA classification and inhospital complications [15].

When assessing a patient presenting for surgery and anesthesia, it is important to consider all the above aspects. The American College of Surgeons, in collaboration with the American Geriatric Society, has published comprehensives guidelines for the perioperative care of the geriatric patient [16, 17]. A chapter devoted to perioperative assessment can be found elsewhere in this book.

While a thorough assessment of all organ systems is of great importance during the preoperative evaluation, one of the most important factors in determining outcomes is the assessment of the patient's functional capacity. As we age – and even when in health – the capability to respond to stress is progressively lost. This process does not necessarily correlate well with chronological age [18]. Perioperative functional and performance status may be predictive of postoperative outcomes, including incidence of delirium, surgical site infections, discharge institutionalization, and 30-day and 6-month mortality [16]. Assessment of functional status is relatively easy and could be achieved with a short series of screening questions assessing a patient's ability to independently perform activities of daily living, e.g., the ability to get out of bed or chair, dress, bathe, prepare meals, and shop. Lack of capacity on any of these should prompt further evaluation, consider physical and/or occupational therapy referral, and start proactively planning the hospital discharge. Worsening self-reported mobility has been found to correlate with negative outcomes [19]. Other functional aspects to evaluate include hearing, vision, swallowing, gait or mobility deficits, as well as screening for falls or risk of falling [16–20].

More recently, the concept of frailty has emerged as a good indicator of the patient's functional capacity and has been shown to correlate well with increasing the risk for adverse postoperative outcomes. Frailty is a syndrome independent of disability and comorbidity that is highly prevalent in the geriatric population; some estimate that up to 50% of those over 85 years of age may be frail.[16] Multiple measures of frailty exist, but one widely recognized definition was put forth by Fried et al. [21]. This group suggested that a clinical syndrome is present when three or more of the following criteria were met: unintentional weight loss (10 pounds in the past year), self-reported exhaustion, weakness (grip strength), slow walking speed, and low physical activity.

Based on this definition, Malaky et al. reported their finding using these criteria scale in patients presenting for surgery [22]. They classified patients with a score of 2 or 3 as intermediately frail and those with a score of 4 or 5 as frail. They found that in this cohort of patients, preoperative frailty was associated with an increased risk for postoperative complications (intermediately frail: odds ratio [OR] 2.06, 95% CI 1.18–3.60; frail: OR 2.54, 95% CI 1.12–5.77), prolonged length of stay (intermediately frail: incidence rate ratio 1.49, 95% CI 1.24–1.80; frail: incidence rate ratio 1.69, 95% CI 1.28–2.23), and higher likelihood of discharge to a skilled nursing or assisted-living facility after previously living at home (intermediately frail: OR 3.16, 95% CI 1.0–9.99; frail: OR 20.48, 95% CI 5.54–75.68). Robinson and colleagues used a different frailty scale in patients undergoing cardiac or colorectal surgery [23]. They used seven criteria: Katz score less than or equal to 5, Timed Up and Go test greater than or equal to 15 s, Charlson index greater than or equal to 3, anemia less than 35%, Mini-Cog score less than or equal to 3, albumin less than 3.4 g/dL, and 1 or more falls within 6 months. Based on the number of positive traits, patients were classified as nonfrail, 0 to 1 traits; prefrail, 2 to 3 traits; and frail, 4 or more traits. Their findings were similar to the Malaky study as frailty was associated with increased postoperative complications after colorectal (nonfrail: 21%; prefrail, 40%; frail, 58%; $P = 0.016$) and cardiac operations (nonfrail: 17%; prefrail, 28%; frail, 56%; $P < 0.001$). It is important to mention that this finding was independent of advancing age. Additionally, frail individuals had longer hospital stays and higher 30-day readmission rates in both groups. A recent systematic review of the literature recently published suggests that there is strong evidence that frailty in the elderly patient undergoing surgery and anesthesia predicts outcomes such as mortality, complications, and extended length of stay [24]. It is pertinent to mention a recent study looking at the association of hospital volume of frail surgical patients presenting for elective major noncardiac surgery and outcomes. Survival among frail patients was better at institutions that care for larger number of frail surgical patients [25].

A remaining challenge is how to collate all this information in terms of age, comorbidities, type of surgery, frailty, and other factors and estimate the risk of postoperative complications. As a tool to help with this issue, the American College of Surgeons created a Surgical Risk Calculator that is accessible to the physicians and the public [26]. Physicians and patients can enter perioperative information about the patient to help estimate the risk of postoperative complications and make better informed decisions.

Associated to the concept that the presence of frailty or decrease functional status has been associated with worse outcomes, the notion of pre-habilitation as a way to optimize patients in preparation for surgery is an emerging concept. Currently, there are studies which suggest that an exercise program aimed to improve the functional status of patients before surgery might improve recovery and overall outcomes, including in the geriatric population [27–29]. Some studies also propose that there might be benefits in the cognitive domain as well [30]. This concept of pre-habilitation and perioperative optimization is not only a focus in the management of elderly patients: the State of Washington has a program entitled "Strong for Surgery," demonstrating the interest that those paying for healthcare (in this case a particular state) have identified pre- and perioperative care as an area of focus for improving surgical outcomes [31].

Intraoperative Management

Anesthetic Goals

Intraoperative management focuses on the immediate surgery, but consideration should also be given toward promoting postoperative recovery whenever possible. An adequate anesthetic prevents painful stimuli from being sensed by the brain, thereby preventing patient awareness of pain in attempt to minimize the body's physiologic responses to painful stimuli. The latter implies the goal of a stable blood pressure, maintained organ perfusion, appropriate ventilation, controlled body temperature, and, hopefully, a minimal hormonal response to the pain and trauma of surgery. Lastly, a relaxed, immobile patient is important.

Central Nervous System Management

In the operating room, one of the first goals to be considered is the desired state of consciousness. The goal will vary depending on the type of anesthetic employed. With a general anesthetic, the patient should remain unconscious and have no awareness of the surgery postoperatively. In contrast, when a regional block is used as the primary anesthetic, there should be no pain experienced by the patient. Sedation is therefore an optional component. How much sedation is used becomes heavily dependent on the patient's desires and expectations. World War II veterans rarely needed anything at all, whereas anxious patients often state that they do not want to be aware of anything. Such a request can be accommodated, but it requires levels of sedation that essentially constitute a general anesthetic and raises the question of why utilize a regional anesthetic unless it is provided for postoperative analgesia as well. Regional anesthetic techniques that can be used as the primary anesthetic include spinal or epidural anesthesia with high concentrations of local anesthetics to achieve complete neural blockade and peripheral nerve blocks that completely numb and paralyze an extremity. MAC, or monitored anesthesia care, cannot be considered as a primary anesthetic technique. In MAC cases, the surgeon is responsible for blocking painful stimuli, typically via injection of local anesthetics into the surgical field. Theoretically, with MAC, sedation, is optional, although most patients desire some degree of sedation. Anesthesia personnel often provide MAC not so much for the administration of sedation but to closely keep track of the patient's vital signs because of the patient's severe systemic disease.

Whenever an anesthetic does not involve a general, consideration must be given to what needs to be done if the regional block and/or the local anesthetic provides inadequate pain control. More sedation and opioid analgesia is typically administered, but increasingly deeper levels of sedation increase the risk of an obstructed airway. The older patient is at increased risk for obstruction due to changes in anatomy, muscle tone and control, and concurrent obesity. In short, as the "sedation" progresses to a largely unresponsive or even unconscious patient, at some point the airway may need to be secured. It is therefore important to recognize that if local anesthetic agents are unlikely to provide successful analgesia, it is likely riskier to the older patient to be essentially under a general anesthetic with an unsecured airway than to have proceeded with a general anesthetic that includes a laryngeal mask airway or endotracheal tube.

All drug administration is usually given to effect rather than a fixed dose. Nevertheless, the anesthesia caregiver will likely at least start with smaller drug doses in the elderly patients. A rough rule of thumb is that opiate and induction agent dosing should be approximately half that of a young adult, whereas benzodiazepine dosage may only require modest reductions until very old age at which point dosage should be markedly reduced.

Cardiovascular System Management

All anesthetics tend to lower blood pressure, primarily by reduction of sympathetic tone. Older patients typically have much higher sympathetic tone than in young adults, both at rest and in response to stimuli [32]. General anesthesia suppresses sympathetic outflow from the brain. Spinal or epidural anesthesia blocks the pain signals from reaching the spinal cord, although when low concentrations of local anesthetics are used for epidural analgesia that blockade is not complete. Local anesthetic action also blocks sympathetic outflow over a dermatomal range that may extend well above the level of sensory blockade, especially with spinal anesthesia. A given dose of local anesthetic is likely to spread to more dermatomes in older patients as well. However, blockade of a single extremity typically has a minimal effect on blood pressure, not only because of the limited area of sympathetic blockade but because the rest of the sympathetic nervous system is intact and can be involved in the baroreflex control of pressure. When sympathetic outflow is high, as is often the case in the elderly, central nervous system or direct nerve blockade of most the sympathetic nerves can result in quite extreme effects, and the resultant hypotension appears to be more from a decrease in vascular resistance than a decrease in cardiac output (Fig. 1) [33].

Although propofol and all of the potent volatile anesthetics possess some direct depression of the vascular smooth muscle and the myocardium, significant myocardial depression is highly unlikely, even when there is baseline myocardial dysfunction. It is important to recognize that even drugs with no direct hemodynamic effects can cause profound hypotension in an acutely ill patient who is surviving on intense vasoconstriction and tachycardia. Any drug affecting the brain will decrease sympathetic nervous system outflow and indirectly decrease vascular resistance and possibly cardiac output. In this sense, the older, frail patient is similar to a young, healthy trauma patient. Where the difference between these two classes of patients resides is typically in their volume status. The young trauma patient is most likely severely hypovolemic. At baseline, the elderly

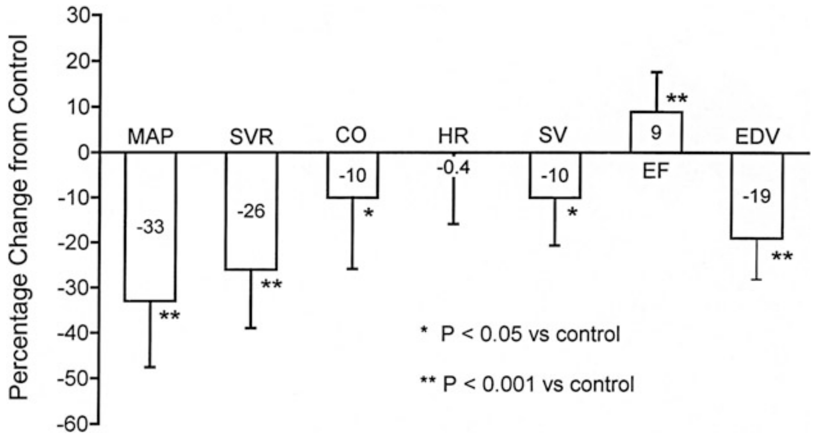

Fig. 1 The effect of total sympathectomy from spinal anesthesia is demonstrated in older men with varying degrees of cardiac disease. The large decrease in systemic vascular resistance (*SVR*) accounted for the majority of the decrease in mean arterial blood pressure (*MAP*). Although cardiac filling (*EDV*, end-diastolic volume) decreased significantly, the overall increase in the ejection fraction (*EF*) prevented an equal decrease in stroke volume (*SV*) and cardiac output (*CO*) (Reprinted from Rooke GA, Freund PR, Jacobson AF: Hemodynamic response and change in organ blood volume during spinal anesthesia in elderly men with cardiac disease. Anesth Analg 1997; 85: 99, with permission)

patient may be slightly hypovolemic but likely has a high degree of vascular tone that will disappear with an anesthetic. Management of hypotension should therefore be quite different for these two groups. Fluid administration for the trauma patient is a key aspect of resuscitation, but volume alone is not the primary therapy for the older patient: the improvement in cardiac output will be modest at best and is not capable of compensating for a large decrease in vascular resistance. The better therapy is a drug that causes vasoconstriction and will restore systemic vascular resistance, such as phenylephrine. Besides causing direct arteriolar vasoconstriction, venoconstriction will shift peripherally pooled blood back to the central circulation and improve ventricular preload and cardiac output, although the effect on vascular resistance likely accounts for most of the effect on blood pressure.

Not only is volume administration often poorly effective in older patients, but it may prove harmful in the long run. Venous stiffening leads to greater swings in cardiac filling for a given change in intravascular volume. This instability is made worse by the ventricular stiffening and diastolic dysfunction that occurs from both aging and chronic hypertension [34]. Although overt hypovolemia and inadequate ventricular filling must be avoided, fluid overload is dangerous. The amount of crystalloid that remains in the blood vessels is highly dependent on the volume status of the patient. Most of the fluid given to a hydrated patient ends up in the interstitium. The jury is still out as to how harmful tissue edema is, but where that fluid unequivocally can be deleterious is when the third-space fluid starts to mobilize. The stiffened cardiovascular system poorly buffers the increased intravascular volume and can lead to pulmonary congestion if not outright pulmonary edema and clinical heart failure. The best volume administration strategy in older patients may well be to give volume for preexistent hypovolemia, basic metabolic needs (minimal), and blood loss but not to make any guesses on third-space fluid requirements. Instead, administer volume challenges when there is physiologic evidence of hypovolemia.

Respiratory System Management

General anesthesia suppresses ventilatory drive and, along with the ciliary suppression of an endotracheal tube, suppresses elimination of secretions [35]. Controlled ventilation is common during general anesthesia and is particularly useful for preventing atelectasis. The decrease in lung tissue stiffness with age leads to an increase in closing capacity. With induction of general anesthesia, functional residual capacity (FRC) decreases and further increases the volume that must be given to the lungs to get from FRC to above the closing capacity. Therefore, either a large tidal volume must be used or positive end-expiratory pressure (PEEP) must be applied to raise FRC. Serious respiratory complications are reduced when a strategy is to employ a modest tidal volume and add PEEP as needed to prevent atelectasis [36].

Another risk factor for perioperative respiratory complications is residual neuromuscular blockade [37]. The phenomenon occurs more often than is commonly appreciated and the elderly are at increased risk [38]. The mechanism behind the increased risk with aging is not clear but may involve the poorer muscular control of swallowing and protection from aspiration that develops with age. Residual neuromuscular blockade certainly would not help. Avoidance of this phenomenon requires rigorous attention to the state of neuromuscular blockade present at the end of surgery. Complete reversal of neuromuscular blockade with neostigmine can only be achieved if the level of existing blockade is modest [39]. Administration of neostigmine too soon into the natural resolution of the blockade can actually make things worse and increase the duration of residual blockade. Concern over the ability to reverse the blockade is the likely basis for disagreements between the surgeon and anesthesiologist over the management of "tight" muscles toward the end of the surgery. Frequently, merely deepening the anesthetic can muscle relaxation without having to resort to more non-depolarizing muscle relaxant. Proper management of significant residual blockade at the end of the case requires waiting for neuromuscular blockade to wear off to a point where neostigmine can work effectively. This can take a long time, even an hour or more. Whether the use of sugammadex, at present a very expensive drug, will have a significant effect on avoiding residual neuromuscular blockade has yet to be determined.

Temperature Management

The operating room is a cold environment and presents a stress to all patients. Inhalational anesthetics, many intravenous agents, and even spinal anesthesia lower the temperature at which vasoconstriction and shivering commence. Aging further impairs these thresholds. In addition, the older patient has a lowered metabolism and therefore produces less heat. Hypothermia has been associated with adverse outcomes including myocardial ischemia, coagulopathy, and wound infections [40]. Shivering may place a significant stress on a patient with low pulmonary or cardiac reserve. Prevention of hypothermia has been greatly aided by the widespread use of active warming, not only in the operating room but also in the preoperative holding area and the recovery room.

Stress Response to Surgery

The physical response to trauma is complex and can be deleterious to the patient [41]. The adverse consequences may include the brain, though the evidence for that is weak. Reduction of the stress response to surgery should begin in the operating room [42]. It can be argued that improvements in surgical technique that limit trauma and improvements in analgesia are responsible for the ability to perform surgeries on increasingly frail patients with reasonable outcomes.

Regional anesthesia may limit the hormonal response more effectively than general anesthesia, but this advantage goes away postoperatively when the regional anesthetic wears off. At present, there are no good studies showing an overall improvement in outcomes with regional anesthesia over general anesthesia. Postoperative epidural analgesia has had some limited success in reducing complications in some situations, but the only definitive statement is that epidural analgesia has the potential to produce the best possible analgesia [43]. The methods available for analgesia and therefore stress reduction continue to evolve.

Controversies in Geriatric Anesthesia

There are always controversies over the "best" anesthetic management, but most of the current controversies in anesthesia principally affect the older patient. This discussion presents "pro" evidence only as this section is only meant to introduce the topics and not to present a comprehensive evaluation. No definitive conclusions are possible without additional studies, but it is likely that these topics will be studied and debated for some time to come.

Perhaps the most extensively examined concern is the contribution of anesthetic management to delirium and postoperative cognitive dysfunction (POCD). Certainly any drug that obtunds the brain can contribute to delirium. What is controversial is to what extent the depth of anesthesia contributes to delirium. One provocative study found that general anesthesia monitored with bispectral index was associated with approximately a 25% lower incidence of delirium than when bispectral index was not used [44]. Even with just propofol sedation, deep sedation levels were associated with more delirium than from low levels of intraoperative sedation [45]. The impact of anesthesia on POCD is discussed later and is far more confusing a picture than with the relationship to delirium.

Intraoperative hypotension as a risk factor for adverse outcome is another important topic. Risks include adverse cardiac events, acute kidney injury, stroke, and death) [46, 47]. In addition to hypotension alone, hypotension in combination with low levels of anesthetic gas administration and low bispectral index values constitutes a mortality risk [48]. What is less clear is the causal relationship beyond the seeming logic that hypotension is bad. It is entirely possible that intraoperative hypotension, especially in the elderly, is merely a marker of a patient with diminished reserve who is less able to withstand the stress of a surgical procedure.

Recent studies indicate that many older patients have postoperative troponin leaks [49], those that do demonstrate an increased risk of both short-term and long-term mortality. Most of the troponin elevations occur in the absence of symptoms, making the diagnosis of the damage after the fact. Furthermore, many patients present for elective surgery with recent troponin elevations, and they, too, are at increased risk of adverse outcomes [50]. Clearly more needs to be known about these phenomena and what can be done to ameliorate the subsequent increased risk.

Postoperative Care of the Surgical Geriatric Patient

The core competencies of anesthesiology include optimization of comorbidities and volume status, management of pain and sedation, as well as postoperative nausea and vomiting (PONV) prophylaxis. Consequently, given the growing and medically complex geriatric population, there is an increased emphasis on anesthesia care in the postoperative period [17, 51–54]. Geriatric care is quickly becoming an area where anesthesiologists can have an impact on postoperative outcomes. In addition to traditional outcomes such as ambulation, nutrition, cognition, and length of stay, anesthesiologists can directly affect the subjective patient experience, including their emotional well-being, overall translating into increased satisfaction with their care and the surgical team [54]. In short, the goal of postoperative anesthesia care should be to keep the elderly patient:

- Mentally and physically active (using multimodal pain control and avoiding sedation) to prevent complications (e.g., DVT, infections, functional deconditioning, or cognitive problems)
- Normothermic
- Well fed (PONV, ileus, and pain prevention) to facilitate their recovery and wound healing
- While being cognizant of reduced renal/hepatic function and the prevalent polypharmacy

A multidisciplinary approach is the way to do it [17, 51, 54]! To accomplish these goals, the healthcare provider needs to be familiar with the unique considerations in the elderly patient and the key concepts of pain management as well as understand the most prevalent issues and complications in this medically complex population [52]. The recently published best practice guidelines by the American College of Surgeons provide an excellent overview of managing the older adult in the perioperative period [17].

Anesthesia Considerations for Postoperative Care in the Elderly Patient

As mentioned earlier in the chapter, aging affects baseline physiological functions as well as the response to stressors and medications [54]. The key changes accompanying the normal aging process include [17, 51, 54, 55]:

- Pharmacokinetics and pharmacodynamics: The combination of increased adipose tissue mass accompanied by a loss of skeletal muscle mass, lean body mass, and total body water, together with the prevalent malnutrition (low albumin), leads to [54]:
  - Increased reservoir, protracted clearance, and an increased duration/effect of lipid-soluble medications, including inhalational anesthetics, opioids, and benzodiazepines [56]
  - Decreased volume of distribution and therefore higher plasma concentrations and greater clinical effects of water-soluble drugs [57, 58]
  - Decreased reservoir for albumin-bound drugs, like diazepam or propofol, potentially leading to high plasma concentration of the free drug [59]

Consequently, the elderly patient frequently requires a reduction in the dose of the postoperative medications. Additionally, polypharmacy is highly prevalent, with an estimated 40% of geriatric patients using ≥ 5 medications and up to 19% taking ≥ 10 medications per week [60].

Organ Anatomy and Physiology

- The aging brain can be associated with a decline in thinking and memory after surgery, including postoperative cognitive dysfunction and/or delirium. The clinician taking care of a geriatric patient should be particularly cognizant of the increased sensitivity to analgesics and sedatives [54, 61, 62], placing the elderly patient at risk for respiratory depression [62]. Furthermore, the geriatric patient was found to have a 40–50% reduction in response to hypoxia and hypercapnia [63]. The data on age-related changes in pain sensitivity are contradictory and inconclusive. While some groups suggested that pain perception decreases in old age, others showed an increase in the pain threshold with aging [64–67].
- Liver function is decreased due to the reduction in hepatic mass and blood flow, leading to an overall decline in metabolism and clearance of medications commonly used in the postoperative period [68].
- Kidney function decreases throughout life. In fact, the clinician should assume a 30–50% decrease in glomerular filtration rate (GFR) in a geriatric patient [57, 60–72]. The elderly surgical patient has a higher risk of electrolyte or fluid shifts, acid-base abnormalities, as well as of an acute renal failure after surgery [73–75]. Lastly, the elderly surgical patient has a decreased ability to correct for iatrogenic fluid overload or under-resuscitation [54, 71, 73, 76].
- GI tract is another organ that can undergo changes relevant for postoperative care. For one, the gastric drug absorption is commonly delayed, i.e., there is an inconsistent dose-time-response relationship [59]. Second, the elderly patient has a higher risk of aspiration, as swallowing dysfunction and the loss of the coughing reflex are commonly reported in this population; up to 30% carry the diagnosis of GERD [77]. Third, up to 50% of patients >60 years of age are seropositive for *Helicobacter pylori* [78]. Fourth, gastric atrophy is prevalent, thus increasing the risk of GI

bleed. Finally, up to 30% of the geriatric population takes laxatives preoperatively for chronic constipation [79, 80]. Consequently, the clinician needs to be familiar with the side effects and interactions of the commonly used medications to treat GI issues, including antacids (diarrhea, plasma levels of sodium and magnesium), sucralfate (constipation), misoprostol (diarrhea), antibiotics (changes in metabolism, absorption), proton pump inhibitors (risk of hip fractures in patients at risk, community-acquired pneumonia, C difficile infection, hypomagnesemia), histamine-2 receptor antagonists (changes in metabolism, absorption, tachyphylaxis, cognition) [54, 81–85].

- Other comorbid conditions, including COPD, CAD, heart failure, diabetes, etc., are prevalent and place the geriatric patient at higher risk for perioperative morbidity and mortality [55].

Postoperative Pain Management

Effective pain control is one of the essential interventions to reduce or even prevent postoperative complications in the elderly. Pain can negatively affect vital aspects of recovery, including time of ambulation, nutritional intake, respiratory and GI function, risk of venous thromboembolism, cognition, as well as the emotional well-being. However, effective postoperative pain control can be challenging in the geriatric population, given the age-related changes in physiology, the prevalent comorbidities, and polypharmacy, overall placing the elderly at a higher risk of drug-comorbidity and drug-drug interactions [56, 86–88]. Lastly, exposure to surgery has been reported to exacerbate chronic nonsurgical pain, like back pain.

The two principles of postoperative pain control in the elderly are (1) multimodal, "balanced" approach using different analgesics with additive or synergistic properties to minimize the use of opioids and (2) individualization of the medications and doses used, to account for the less predictable onset, delayed effect, and protracted clearance [86, 87, 89–91]. The multimodal approach is anchored in the observation that postoperative pain involves multiple different mechanistic pathways. Consequently, combining different types of analgesics while limiting the use of narcotics improves the quality of analgesia while reducing potential complications [86, 89–91].

Though the full scope of multimodal, "balanced" analgesia is beyond the scope of this chapter, here are a few clinically relevant pearls [17, 51, 54, 55, 86, 89–91]:

- Acetaminophen (PO or IV) is one of the safest analgesics in the elderly, typically needing no dose adjustments.
- NSAIDs, while effective, should be used with caution as they may increase the risk of GI bleed or renal failure. In this context, cyclooxygenase-2 (COX-II) inhibitors may represent an effective short-term alternative (long-term use is associated with cardiovascular complications) [92].
- There is a plethora of nontraditional drugs that have been found to effectively reduce postoperative pain and deserve consideration on individualized basis, including gabapentin, ketamine, clonidine, and dexmedetomidine.
- Opioids remain an important pillar in the postoperative pain management as part of a "balanced" anesthetic plan. In patients with kidney or liver dysfunction, opioids should be used cautiously since they can cause a variety of side effects and/or complications. As a general rule of thumb, the clinician should start with a lower dose at regular (or extended) intervals first and subsequently adjust the dose and interval based on the clinical picture and signs of drug accumulation [93].

In Patients with Renal Dysfunction

- Should not be used [94, 95]
  - Codeine and meperidine: accumulation of active metabolites with risk of cardiorespiratory depression as well as neuroexcitatory effects.
- Should be used cautiously, possibly requiring dose adjustment

  - Morphine: active metabolites accumulate in renal failure (risk of cardiorespiratory depression as well as neuroexcitatory effects).
  - Oxycodone: 10–20% excreted unchanged in the urine, 80% metabolized in the liver
  - Hydromorphone: metabolized in the liver, but hydromorphone-3-glucuronide metabolite can accumulate and produce neuroexcitatory effects (agitation, confusion, and hallucinations).
  - Hydrocodone: metabolized to hydromorphone. Parent drug and active metabolite can accumulate and produce neuroexcitatory effects.
- Considered safe
  - Remifentanil: metabolized by nonspecific plasma esterases. No active metabolites.
  - Fentanyl, sufentanil, and alfentanil: seem to be safe in renal impairment. Metabolized by the liver without clinically relevant active metabolites.
  - Methadone: mostly metabolized in the liver to an inactive metabolite. Considered by some as one of the opioids of choice in dialysis patients [96].

In Patients with Hepatic Dysfunction

- Should be avoided [93, 94, 97]
  - Codeine: prodrug with no analgesic activity that needs to be converted to morphine in the liver to exercise analgesic effect. Consequently, in patients with hepatic failure codeine may fail to produce analgesia.
  - Meperidine: reduced clearance in liver failure with risk of seizures.
- Should be used cautiously, possibly requiring dose adjustment
  - Morphine: while morphine is not a pre-drug, the conversion to active metabolites as well as hepatic excretion may be affected.
  - Hydromorphone: the half-life time may be increased.
  - Hydrocodone: pre-drug metabolized into hydromorphone and oxymorphone.
  - Oxycodone: plasma concentration may be increased.
  - Methadone: clearance is reduced with increased half-life.
- Considered safe
  - Remifentanil: metabolized by nonspecific tissue and plasma esterase; no hepatic metabolism.
  - Fentanyl: recommended by some as the opioid of choice in liver failure.

Peripheral nerve blocks using local anesthetics can provide effective postoperative analgesia and reduce narcotic use; rebound pain is, however, a possibility as is the documented higher risk of permanent nerve damage [54, 98–100]. The addition of a glucocorticoid steroid (dexamethasone) and/or alpha-2-agonist (clonidine, dexmedetomidine) may further improve the quality and extend the duration of the block [99, 100]. Finally, a continuous perineural infusion of local anesthetics using a catheter should be considered as it has been found to reduce postoperative pain and improve sleep quality and overall patient satisfaction [99]. On the other hand, it has been recently suggested that prolonged quadriceps femoris blockade may prevent early mobilization and increase the fall risk [101, 102]. In their article, entitled, "Femoral nerve block for total knee replacement – A word of caution," the authors noted, "The literature, which is largely in anesthetic journals, reflects the high quality of analgesia of femoral nerve block, but makes little or no mention of the delays or dangers in early mobilization. We believe that the potential risks to orthopedic patients are underestimated" [101]. Consequently, while quality of analgesia is important, every effort should be made not to negatively affect patient's ability to ambulate early.

Epidural anesthesia is another option to address postoperative pain, especially for thoracic and abdominal procedures [32, 103, 104]. The main advantage of this technique is the reduced narcotic effect, leading to less sedation and/or respiratory depression. In addition, given the typically excellent quality of analgesia, the epidural technique is associated with better respiratory mechanics. Despite the many advantages, epidural anesthesia should be used cautiously in the elderly patient since it can cause a pronounced sympathetic and muscular blockade, leading to a higher risk of hypotension, dizziness, delayed ambulance, and urinary retention postoperatively. The frequently required intravenous administration of fluids to correct for hypotension can lead to congestive heart failure, while the use of vasoactive agents, such as the alpha-agonist phenylephrine, can be detrimental in patients with reduced arterial perfusion or with vascular grafts. Epidural anesthesia using only opioids without local anesthetics in order to avoid sympathetic blockade can be associated with respiratory depression [104].

Postoperative Complications in the Elderly Patient

While the full scope of postoperative complications in the elderly patient is beyond the scope of this chapter, here is a brief and pragmatic overview of common postoperative complications in the geriatric patient from an anesthesiologist's perspective.

As was previously mentioned, postoperative cognitive decline (POCD) is of concern to physicians and patients alike. POCD is a common complication that can present as two separate entities; postoperative delirium and postoperative cognitive dysfunction.

Postoperative delirium (POD) is defined as an acute, early-onset, and transient disturbance of consciousness that is characterized by inattentiveness and cognitive impairment with a fluctuating course [105]. POD is one of the most common complications in the elderly surgical patient. The reported incidence of postoperative delirium ranges from 5% to 15%, with rates as high as 16% to 62% in high-risk groups, such as hip fracture patients [17, 106]. Clinically, POD can present in three different subtypes: hyperactive delirium (i.e., the "prototypical" combative and agitated delirious patient), hypoactive delirium (calm and quiet patient with decreased motor activity), and mixed subtype [17]. Typically, POD is diagnosed using the Confusion Assessment Method for the ICU (CAM-ICU) [for ICU patients] or Confusion Assessment Method (CAM) [for ward patients] [107]. The POD diagnosis requires an acute onset or fluctuating course, plus presence of inattention, and either altered level of consciousness (i.e., anything other than alert and calm) or presence of disorganized/incoherent thinking [17, 55, 107, 108]. Multiple risk factors for development of postoperative delirium have been identified, with preexisting cognitive impairment and advanced age being the strongest predictors of postoperative delirium [17, 109]. The development of delirium is associated with increased mortality,[109] increased risk of institutionalization [110], the development of dementia [110], increased length of stay [109], as well as increased risk of major complications [109]. The occurrence of delirium can predict long-term cognitive impairment [110].

It has been estimated that 30–40% of cases of delirium are preventable using multicomponent interventions, including individualized care, pain management, cognitive reorientation, daily mobilization/activity, attention to sensory deprivation, constipation prevention, facilitation of sleep, geriatric-focused training of staff, etc. [111–113]. In terms of treatment, it is recommended to start with the abovementioned multicomponent non-pharmacological interventions, followed by antipsychotic agent like haloperidol starting at 0.5–1 mg PO. However, the results for haloperidol have been mixed [113]. When used as prophylaxis in a randomized, double-blind, placebo-controlled study of 430 elderly patients (≥70 years of age) undergoing elective hip surgery, haloperidol failed to decrease the incidence of postoperative delirium [114]. Haloperidol prophylaxis did, however, significantly reduce the duration and severity of postoperative delirium [114]. In contrast to haloperidol, the atypical antipsychotic drug olanzapine significantly decreased the incidence of the postoperative delirium, while significantly increasing the duration and severity of postoperative delirium [115]. Collectively, the data on the role of antipsychotic drugs in prevention of postoperative delirium are too limited to draw any firm conclusion. Similarly, the cholinesterase inhibitors donepezil hydrochloride and rivastigmine failed to reduce the incidence of postoperative delirium [116, 117] or length of hospital stay [117]. Finally, there is no clear evidence that melatonin or melatonin agonists reduce delirium incidence compared to placebo [112].

Postoperative cognitive dysfunction (POCD) is defined as a longer-lasting decline in the level of cognitive performance after surgery as compared to preoperative baseline [118]. It includes acute (weeks), intermediate (months), and long-term (years) cognitive decline. Up to 50% of surgical patients suffer from POCD in the early weeks following a major noncardiac surgery [119, 120]. Although the majority of patients gradually recover over time, permanent cognitive decline has been described [121]. Advanced age, history of cerebral vascular accident, lower educational level, and alcohol abuse have been shown to be independent risk factors for POCD at 3 months [119–122]. POCD was found to be associated with poor short- and long-term outcomes including depression, decrease in daily functional ability, loss of independence, premature unemployment, and possible permanent dementia [120, 123]. Here are few clinically relevant pearls [124]: There is currently no strong evidence in humans that anesthetic agents or anesthetic techniques are a risk factor for POCD [125–130]. Two meta-analyses comparing general anesthesia (GA) vs. regional anesthesia (RA) failed to demonstrate that GA is a risk factor for POCD [126, 128]. In two recent clinical trials, the incidence of POCD in patients undergoing an intervention under RA or monitored anesthesia care was at least as high as in the GA group [125, 129]. Furthermore, while volatile anesthetics have been found to promote and accelerate AD-neuropathology in animal models, all human studies examining this subject have failed thus far to show such a relationship [131–133]. The mechanism underlying POCD is unknown. In terms of prevention and treatment, currently there no prophylactic/therapeutic interventions that consistently and predictably reduce the incidence of POCD.

Another issue affecting the older adult is immobility, and the risk of falling [17, 51, 54, 55]. It has been estimated that 1.5% of surgical inpatients suffer a fall after surgery [17]. Many elderly patients have preexisting conditions that place them at higher risk of immobility or falls, including baseline functional deconditioning, malnutrition, sarcopenia, arthritis, or poor sensory input (vision, hearing, etc.). In addition, surgery and anesthesia may add surgical pain, sedatives, analgesics, and/or muscle weakness due to peripheral nerve blocks that may make mobilization more challenging while increasing the risk of falls. Early ambulation, daily physical activity, and avoidance of falls are the key steps to prevent functional decline as well as prevent respiratory, thromboembolic, and cognitive complications after surgery [17, 51, 54, 134–136]. Multicomponent interventions are recommended, including early assessment, early involvement of physical therapy, supervised and assisted exercises, maintaining call light within reach, placing handrails in relevant areas, using nonslip footwear, and geriatric-focused training of staff. Obviously, early ambulation with a low risk of a fall is more likely in a patient with normal cognition who is not in pain – so effective pain control and prevention of delirium are a must.

Hydration in the postoperative period is also an important aspect of the care [17, 51, 54, 55]. As mentioned above, age-related physiological changes place geriatric patients at higher risk for decreased glomerular filtration rate (GFR), urinary concentration ability, and free water clearance. A reduced sense of thirst is a common problem in the elderly. Consequently, the elderly patient is at higher risk for electrolyte and acid-base abnormalities as well as fluid disorders. Finally, given the frequently impaired renal function already at baseline, the elderly patient is also at higher risk for acute postoperative renal impairment. Therefore, an early return to oral intake, balanced approach to fluid management, maintaining appropriate blood pressure, and avoiding nephrotoxic drugs are essential – especially in the context of the highly prevalent polypharmacy. When measuring electrolytes after surgery, the clinician should be aware that even normal creatinine plasma levels of in the elderly patient might indicate a decreased GFR due to the decreased skeletal muscle mass.

Postoperative problems with nutrition are notorious in the elderly [17, 51, 54, 55]. In fact, up to 40% of hospitalized patients are malnourished. Chronic constipation, poor appetite, and/or social isolation are additional factors that increase the risk for malnutrition in the elderly. Finally, exposure to surgery, sedatives, and analgesics further compounds this problem with the attendant risks of ileus, nausea/vomiting, and loss of appetite. Early return to oral intake plus nutritional supplementation in undernourished patients is key to reduce the risk of malnutrition [137]. In addition, early ambulation, opioid-sparing pain management, and normal fluid intake should be considered to prevent postoperative ileus. Whether early enteral feeding is warranted in patients in whom oral intake is not possible remains controversial. A recent multicenter, single-blind clinical trial that randomized 1372 ICU patients expected to remain in the ICU longer than 2 days with relative contraindications to early enteral nutrition to either standard care or early parenteral nutrition failed to demonstrate a difference in day-60 mortality, ICU, or hospital-stay duration [138]. According to the accompanying editorial, "This article joins several articles that suggest either benefit or harm from supplemental parenteral nutrition or whether 'trophic feeding' is 'just as good' in patients in the ICU during the first 7 days of their hospitalization" [139].

The older adult can also face issues with wound healing and the development of pressure ulcers. The prevalent comorbid conditions, such as poor nutritional state, sarcopenia, circulatory and oxygenation problems, and diabetes, can impair wound healing in the elderly. Thus, it is imperative to avoid fluid overload, hypotension, hypoxia, hypothermia, ileus, or hyperglycemia after surgery and provide appropriate antibiotics. Similarly, the elderly are at higher risk to develop postoperative pressure ulcer. Early involvement of physical therapy, turning patients regularly, oral/tube feeding, nutritional supplementation, and optimization of comorbidities can be instrumental.

Finally, cardiovascular and pulmonary complications are common in the geriatric patient during the perioperative period [17, 51, 54, 55]. The burden of cardiovascular and pulmonary disease increases as the body ages. In fact, cardiac pathology is the most common cause of death in the elderly surgical patient. In addition to the obvious maintenance of stable hemodynamics, oxygenation, and electrolytes, postoperative management should focus on early restarting of preoperative medications for preexisting comorbidities. The care should include vigilant management of fluids (especially avoiding fluid overload), prevention of atelectasis and pneumonia (incentive spirometer, upright position, pulmonary toilet, respiratory therapy), early mobilization, and oral intake of fluids and food.

Long-Term Outcome in the Elderly Patient

Some authors have argued that the long-term outcomes have been improving [17, 54, 140, [141], with a morbidity and mortality in the elderly undergoing elective surgery ranging from 7% to 20% and 0% to 5.4%, respectively, which is comparable with outcomes in younger patients [54, 141–145]. However, the outcomes of emergent surgeries in the elderly are markedly lower, with morbidity and mortality ranging from 30% to 68% and 13.6 to 31%, respectively [142, 145].

A key difference exists when assessing the long-term success between the non-geriatric and geriatric population. In the younger patient, the outcome is typically defined using standardized measures like morbidity (e.g., stroke, MI, creatinine, troponin, length of stay, etc.) and mortality, while in the elderly patient, the long-term success is defined using much more subjective criteria, like quality of life, cognitive function, the subjective perception of health, and the return to preoperative baseline level of functioning allowing the patient to live an independent and fulfilling life. Overall, the long-term postoperative outcome based on quality of life and independence, while increasingly important, is still a developing field with paucity of data. Disconcertingly, studies from the 1980s and 1990s examining this field reported that [54, 146–150] up to 75% of geriatric patients who were independent at hospital admission were not independent at hospital discharge, that 33% of patients sent to a nursing home after suffering a hip fracture remained there for ≥1 year, and that, of those who enter nursing home, 55% spend ≥1 year and 21% spend ≥5 year of total lifetime in the nursing home.

More research is required in this important area to help us guide the postoperative care in the elderly surgical patient.

Putting All Together: The Geriatric Perioperative Surgical Home

The Institute of Health (IHI) Triple Aim calls to improve the quality of care, reduce the healthcare expenses, and improve the overall health of the population [150]. Considering the characteristics of the older adult population, it seems that initiatives aimed to improve all those domains should be a priority. The American Society of Anesthesiology has introduced the concept of the perioperative surgical home (PSH) as a patient-centered, physician-led, team-based coordination of care along the perioperative continuum [151]. This initiative aligns well with goals of the Triple Aim. They both share common goals, namely, to improve the quality of care, reduce the global healthcare expense, and improve the overall health of the population. Most of the literature in PSH has been related to specific service lines [152]. However, a geriatric PSH has to be able to be embedded into PSH service lines and also be able to stand alone to care for the geriatric population regardless of the type of surgery [153].

Conclusions

The rapidly growing geriatric population imposes challenges to the healthcare system, and perioperative services are not the exception. The outcomes in the older adult presenting for surgery lag behind improvements in surgical and anesthesia. While age and the physiological changes of aging play a role, other factors such as comorbidities, type of surgery, and the occurrence of complications also weigh heavily in patient outcomes. Recently, the concept of frailty has emerged as a reliable marker for outcomes in this population. The concept of pre-habilitation to further optimize patients prior to surgery is also becoming more prevalent.

Meticulous intraoperative and postoperative care is fundamental to avoid complications and improve outcomes. However, it seems apparent that those efforts should occur in concert and should involve all the teams that participate in the care of the patient. The concept of a geriatric perioperative surgical home aimed to enhance the quality of care, decrease costs, and improve the overall health of this population is likely the future for care of geriatric patients embarking in the perioperative continuum.

Abstract

The skin is the body's largest organ and is the most conspicuous. It plays not only an integral role in self-perception and outward attractiveness but very often conveys the earliest diagnostic signs of internal disease. Attention to and care of the skin contribute not only to the elderly patient's health and physical comfort but also to their quality of life, psychological well-being, and dignity. In this chapter, we review age-related mechanical and functional changes in the skin. The prevalence of skin malignancies and pressure sores is increasing in the growing elderly population. These conditions are often curable, if not preventable, in their early stages. Therefore, caregivers and surgeons must be vigilant for the subtle skin changes inadvertently ignored or neglected by the elderly patient experiencing impaired vision, sensation, mobility, or cognition.

Common Benign and Malignant Skin Lesions

The elderly patient presents with a variety of benign and malignant skin lesions. The ability to differentiate various cutaneous neoplasms is especially important in the geriatric population because of the higher incidence of malignant skin tumors that arise in aging skin. The aim of this chapter is to acquaint the surgeon with normal skin anatomy, with changes in the skin anatomy during aging, and with the pathophysiology, diagnosis, and treatment of common benign and malignant skin tumors of the elderly.

In general, we recommend an annual total body skin examination for the elderly patient who has any of the following independent risk factors: fair skin color; history of blonde, red, or light-colored hair; green, gray, or blue eye color; a family or personal history of skin cancer; chronic occupational or recreational exposure to the sun; a history of sunburns; or anyone with numerous or atypical nevi. Patients with a personal history of skin cancer should be seen every 6–12 months.

Basic Skin Anatomy

The skin is composed of two layers: a stratified squamous epithelial layer, or epidermis, and an underlying connective tissue layer, or dermis. The cell types making up the epidermis provide skin protection and include keratinocytes, melanocytes, Langerhans cells, and Merkel cells. Keratinocytes are the predominant cell type of the epidermis and form a mechanical barrier. Melanocytes produce pigmentation important in UV protection. Langerhans cells function in antigen presentation and immunity. Merkel cells sense pressure and two-point discrimination [1].

Dermis

The mesoderm-derived dermis sits just below the avascular epidermis, supplying it with a rich neurovascular system. Histologically, the dermis can be divided into two layers. The superficial papillary dermis is composed of a loosely woven arrangement of connective tissue bundles. Beneath it lies the reticular dermis, so named for its denser, interwoven pattern of connective tissue fibers. The resident cells of the dermis are mostly fibroblasts, which secrete collagen, elastin, and ground substance. Collagen and elastin give the skin its tensile strength, distensibility, and flexibility. Ground substance, which is comprised of polysaccharides and proteins, provides a supportive matrix for the connective tissue fibers. The overall structure accommodates the network of vascular, lymphatic, and nerve plexi that supply the skin. Other cellular constituents of the dermis include mast cells, macrophages, lymphocytes, and other leukocytes.

The dermal–epidermal junction is characterized by downward folds of the epidermis into the dermis. These folds, called rete ridges, provide mechanical support against shearing forces. Beneath the dermis lies a fatty layer of subcutaneous tissue that serves to insulate and protect the underlying structures.

Epidermal Appendages

During embryologic development, epidermal cells invaginate and migrate into the dermis forming adnexal structures such as hair follicles, sebaceous glands, and eccrine and apocrine sweat glands collectively termed epidermal appendages. Hair follicles are composed of modified keratinocytes that form a tubular structure enclosed by a collagenous sheath. Each hair follicle is associated with one or more sebaceous glands, which secrete sebum, an oily viscous fluid composed of triglycerides, free fatty acids, wax monoesters, squalenes, and sterols. Sebum functions to help moisturize and waterproof skin and hair. Apocrine glands are modified sweat glands located in the axillae and groin. Like sebaceous glands, they secrete their product into the follicular lumen. With the exception of the groin and axillae, the remainder of the skin is covered by eccrine sweat glands. These glands are thermoregulatory in their capacity to secrete sweat and immunologic in their capacity to excrete active cytokines [2].

Skin Function

The basic functions of the epidermis, dermis, and epidermal appendages include that of a physical barrier as well as homeostasis, thermoregulation, immunologic defense, communication, and sensation. As a physical barrier, the skin protects the body from ultraviolet radiation-associated DNA damage, microorganisms, and toxic chemicals. Far more than simply a sheet of protective wrap, the skin continually regenerates itself by sloughing off damaged cells and providing a fresh interface for the ever-changing environment. Central to its barrier function is the maintenance of water balance and protection against dehydration. Not all water loss is damaging, however, and eccrine gland-mediated evaporative water loss is critical to thermoregulation. In the battle against microbial invaders, the skin provides the first line of defense. The skin hosts both adaptive and innate immune functions; in the skin itself, circulating lymphocytes and antibodies encounter foreign materials and activate antigen-presenting cells. Cathelicidins, neutrophil-derived polypeptides resident in the skin, also function in antimicrobial defense and cell–cell signaling [3]. Additionally, it is often a fundamental disruption in the immunologic function of the skin that facilitates the development of cutaneous malignancies. In social interaction, the communication and sensory functions of the skin are intertwined. The skin and hair are central to our mechanisms of physical attraction. Neural modulation of the cutaneous blood supply conveys information in interpersonal communication, and the skin is the organ through which touch, temperature, itch, pleasure, and pain are perceived.

Changes in the Skin Associated with Aging

The intrinsic changes that occur in aging skin are important for understanding the pathophysiology of benign and malignant lesions that affect senescent skin.

Epidermis

Between the third and seventh decades, the turnover rate of keratinocytes is reduced by 50% [4]. The slower epidermal turnover rate increases the duration of keratinocyte exposure to carcinogens such as ultraviolet radiation, making the epidermis more susceptible to the development of keratinocytic neoplasms. Decreased proliferative capacity of keratinocytes also prolongs wound healing.

The aging epidermis also undergoes structural alterations. The rete ridges at the dermal–epidermal junction retract, making elderly skin more susceptible to shearing forces. Keratinocytes in the basal layer of the epidermis become increasingly pleomorphic, displaying variations in size, shape, and staining pattern [5]. With age, the most superficial layer of the epidermis, the stratum corneum, increases in thickness due to a slower rate of desquamation. This thick stratum corneum has reduced intercellular lipid content and reduced water-binding capacity, predisposing aging skin to xerosis, or drying, with cracking, compromised mechanical barrier function, and subsequent irritation and inflammation [6, 7].

Melanocytes also undergo age-related decrease in number over time. After age 30, the surviving population of melanocytes drops by 8–20% each decade [8]. As a result, less melanin is produced which allows greater penetration of ultraviolet radiation and results in an increase in the risk of developing skin cancer. Like melanocytes, Langerhans cells decrease in number with age. Langerhans cells are especially sensitive to UV radiation and are further functionally impaired by the age-related decrease in protective melanin. This UV-induced immune suppression compromises the cell-mediated immune response in elderly skin, increasing its vulnerability to the development of tumors.

Dermis

As the skin ages, the dermis thins and becomes less vascular. Collagen fibers become thickened and less resilient, and the dermis becomes more susceptible to shearing injuries. Elastin fibers display structural degradative changes, resulting in skin laxity and wrinkle formation [5]. The amount of ground substance decreases, reducing the supportive dermal matrix, and so structures such as blood vessels become more susceptible to damage. This manifests clinically as easy bruising in the elderly. Thinning of vessel walls may also contribute to the increased susceptibility to ecchymoses. Other changes in cutaneous vasculature include a decrease in the density of vessels. Diminished cutaneous circulation can lead to impaired clearance of foreign material, delayed wound healing, and diminished thermoregulatory capacity. The aging skin also loses its ability to mount an inflammatory response, leading to muted clinical presentations of cutaneous disease.

Benign Epidermal Lesions

Seborrheic Keratoses

Seborrheic keratoses are common, benign, flat-topped papules or plaques composed of hyperproliferating keratinocytes. They typically appear during the fifth decade, although early lesions can present in the fourth decade. Early lesions manifest as discrete 1–3 cm skin-colored to dark brown patches that progress to form slightly elevated, warty, greasy plaques. Their exophytic growth pattern makes them appear waxy and “stuck on.” [9] Although seborrheic keratoses can be found on any part of the body, they are most prevalent on the face and upper trunk (Fig. 1). These lesions are not UV induced and sometimes present with itch. They occur more frequently in Caucasians and affect males and females equally.

A histologically identical variant of the seborrheic keratosis, dermatosis papulosa nigra, is commonly found in patients with darkly pigmented skin. Clinically, these lesions present as multiple 0.1–1.0 cm rough brown to black papules of the face. They are especially common on the malar cheeks, forehead, neck, back, and chest.

Seborrheic keratoses remain unchanged for the lifetime of the individual once they appear. They are benign lesions with no malignant potential. However, the eruption of multiple lesions in a short duration of time, known as the sign of Leser–Trelat, has historically been thought to point to internal malignancy, particularly gastrointestinal adenocarcinoma, breast carcinoma, and lymphoma. Despite a large number of case reports and anecdotal evidence in support of an association between widespread eruptive seborrheic keratoses and internal malignancy, the data to support this phenomenon as a true paraneoplastic process is largely lacking [10].

Fig. 1 Seborrheic keratosis, the most common benign cutaneous tumor in the elderly. Its significance lies in its potential to mimic malignant melanoma. Although treatment is not normally indicated, the lesion, which may appear rough or greasy, may be irritated necessitating removal. Alternatively, if there is suspicion about melanoma, biopsy is indicated

For an atypical seborrheic keratosis resembling a malignancy such as a pigmented basal cell carcinoma (BCC) or melanoma, surgical excision is appropriate for diagnostic purposes. Otherwise, treatment options include curettage, cryotherapy, or trichloroacetic acid (TCA).

Epidermal Appendages

Marked age-related changes also occur in the epidermal appendages. There is an overall reduction in the number and function of both eccrine and apocrine sweat glands, leading to a decrease in thermoregulatory capacity [6]. Sebaceous glands enlarge with age, but their sebum production is paradoxically reduced. These changes in sebaceous glands manifest clinically as sebaceous hyperplasia and xerosis.

Solar Lentigo (Senile Lentigo, Actinic Lentigo)

Chronic sun exposure can induce melanocytes to proliferate locally forming multiple 0.5–2.0 cm brown macules known as solar lentigos, “liver spots,” or “age spots.” Their presence in more than 90% of individuals over the age of 70 has led to the unflattering descriptive term “senile lentigo,” but they are often found on light-skinned persons of any age. These lesions are localized to sun-exposed areas, such as the cheek, forehead, nose, dorsa of hands and forearms, upper back, and chest (Fig. 2). They are more commonly seen in Caucasians than in Asians and affect males and females equally.

Solar lentigos have virtually no malignant potential although a small proportion of lesions occurring on the face rarely develop into lentigo maligna [9]. Solar lentigos can be confused with other benign lesions, such as early seborrheic keratoses, and premalignant lesions such as pigmented actinic keratoses and lentigo maligna. To differentiate solar lentigos from seborrheic keratoses and pigmented actinic keratoses, the lesion must be examined with a hand lens in oblique light. Seborrheic keratoses and pigmented actinic keratoses generally display features of epidermal change, whereas solar lentigos are completely flat. Lentigo maligna, like solar lentigo, may not show epidermal changes. However, it has distinct variations in color from light brown to dark brown with flecks of black. A biopsy is taken to exclude melanoma from any solar lentigo that develops a highly irregular border, increase in pigmentation, or thickening.

If the patient finds these “age spots” cosmetically unacceptable, treatment can be accomplished in several ways. Bleaching agents like hydroquinone are not particularly effective. Cryotherapy and topical retinoids, particularly 0.05% retinoic acid, have demonstrated efficacy in randomized controlled trials. Among laser treatments, Q-switched ruby and 532 nm Nd:Yag have been shown effective in controlled trials without randomization [11]. Regardless of treatment methods chosen, the preventive use of sunscreen to prevent new lesion should be emphasized.

Melanocytic Nevi (Moles)

Melanocytic nevi or moles are small, well-circumscribed macules and papules that vary in color from skin-colored to tan and brown (Fig. 3).

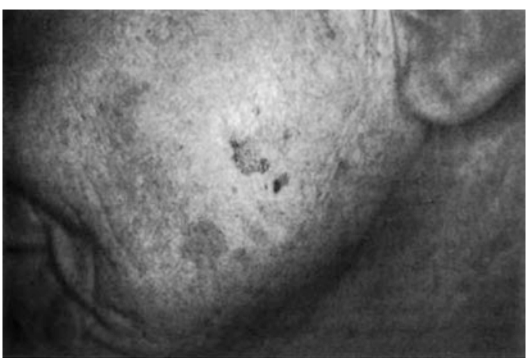

Fig. 2 Solar lentigo, seen mostly on the face and dorsa of the hands, has tan to brown pigmentation and is flat. They may be of cosmetic concern and occasionally must be biopsied to rule out lentigo maligna

Fig. 3 Nevi of medical significance are uncommon in the elderly, but new pigmented lesions that are not seborrheic keratoses should be evaluated

They are composed of nests of melanocytes located in the epidermis, dermis, and rarely subcutaneous tissue. If the cluster of melanocytes is localized to the dermal–epidermal junction, the nevus is classified as a junctional nevus. Junctional nevi tend to have smooth regular borders and are often found on the palms and soles. Intradermal nevi are found on the face and are also skin-colored, homogenous, and dome-shaped. Compound nevi combine the feature of both junctional and intradermal nevi and may appear very dark. They are round or oval and raised above the epidermal surface.

Melanocytic nevi are acquired during childhood and early adulthood. They typically increase in number up to the age of 40, after which they begin to involute. With the exception of dermal nevi, most nevi disappear by the age of 60. As some junctional and compound nevi age, their melanocytes migrate into the dermis and assume features of dermal nevi. Nevi are rarely premalignant. However, if new melanocytic nevi are acquired after mid-adulthood, they should be regarded with a high degree of suspicion and followed closely to rule out the development of malignancy [12].

Benign Dermal Lesions

Acrochordons (Skin Tags)

Acrochordons or skin tags are composed of loose fibrous tissue and usually occur as multiple skin-colored pedunculated lesions typically 2–3 mm in diameter and located on the neck, axillae, or major flexures. Skin tags are prevalent in postmenopausal women, pregnant women, and obese individuals, suggesting a hormonal influence on their development [13]. The exact etiology of skin tags is unknown, though some familial groupings have been noted.

Skin tags have no malignant potential but may cause pain or itch in areas exposed to friction such as the belt line. They can also cause considerable discomfort when infarcted. Treatment consists of simple excision requiring no local anesthetic.

Xanthelasma Palpebrarum (Eyelid Xanthomas)

Xanthelasma palpebrarum develop in adults in their fourth to fifth decade. They present as yellow velvety plaques confined to the eyelids. The lesions often begin as small yellow spots that initially may be confused with milia or senile closed comedones. They grow over a span of months coalescing into plaques on the upper eyelids and around the inner canthus (Fig. 4). Once growth stabilizes, these plaques are permanent. Histologically, xanthelasma palpebrarum is characterized by lipid-laden macrophages in the superficial dermis.

Approximately 50% of elderly patients who present with these xanthelasma palpebrarum have an underlying disorder of lipid metabolism, such as familial hypercholesterolemia or familial dysproteinemia. Patients with these disorders typically have elevated low-density lipoprotein (LDL) and apoprotein E levels and are prone to atherosclerotic cardiovascular disease. Patients who present for the first time with xanthelasma palpebrarum should have their serum lipoproteins and apolipoproteins checked. If the levels are within normal limits, no further testing is needed.

The etiology of xanthelasma palpebrarum in patients with no lipid disorder is unknown. Systemic therapy with lipid-lowering agents rarely affects the appearance of these lesions. Prior to the advent of laser therapy, excision, cryotherapy, and topical application of 30% trichloroacetic acid were the preferred methods of treatment. With most of these treatments, however, recurrence is

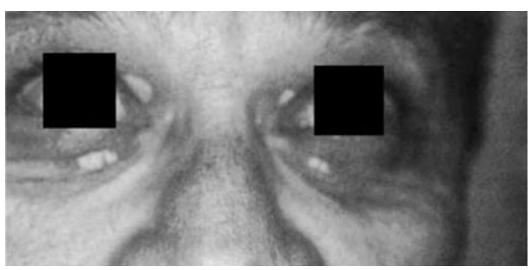

Fig. 4 Xanthelasma. These cholesterol deposits occur on the upper and lower lids and can best be removed surgically. They are yellowish with a smooth surface

common. Excision with primary closure is effective in only 60% of patients and is limited by the location of the lesions [14]. Some authors have advocated excision with secondary intention healing, thereby minimizing the risk of ectropion and complications with skin grafting. Healing by secondary intention may allow greater margins of resection and therefore minimize the rate of recurrence to as low as 7% [15]. Recently, various laser modalities including erbium:YAG [16], argon [17], and 1064 Q-switched Nd:YAG [18] have been utilized in the treatment of xanthelasma with good cosmetic outcomes. Ultrapulse CO_2 laser in only one treatment session has shown excellent results without complications or recurrence at 1-year follow-up [19].

Sebaceous Hyperplasia

Sebaceous hyperplasia is a benign lesion that is often found on the face of older patients. It typically presents as a cream- or yellow-colored umbilicated papule on the forehead, cheeks, eyelids, and nose of individuals over the age of 30 (Fig. 5). 25% of patients over the age of 65 carry these lesions, and the incidence increases with age. The etiology of sebaceous hyperplasia is unknown, but genetic factors likely play a role in its pathogenesis. Most lesions occur independent of sun exposure and arise in patients of northern European heritage.

Fig. 5 Sebaceous hyperplasia. These lesions represent benign hypertrophy of the sebaceous glands. With their central umbilication and rounded edge, they are occasionally confused with basal cell carcinoma

Sebaceous hyperplasia often begins as a small, 2–3 mm papule with a central depression. This depression represents the opening of a wide sebaceous duct that is surrounded by enlarged sebaceous glands, lending the lesion its characteristic lobular configuration. Some lesions of sebaceous hyperplasia contain central telangiectasias. This feature, combined with the papule's translucent appearance, often leads clinicians to confuse sebaceous hyperplasia with basal cell carcinoma (BCC). A clue to the correct diagnosis can be obtained with diascopy (applying pressure on the lesion with a glass slide), which reveals the yellow-white color of sebaceous hyperplasia. However, relying on diascopy for diagnosis is not perfect: the yellow-white color sometimes leads to the incorrect diagnosis of xanthoma. Xanthomas can usually be differentiated by their larger size and absence of umbilication [20].

When the clinical diagnosis is uncertain, a biopsy should be performed to rule out malignancy. Otherwise, no treatment is necessary for sebaceous hyperplasia unless cosmetically desirable.

Chondrodermatitis Nodularis Helicis

Chondrodermatitis nodularis helicis (CNH) typically presents as a painful, erythematous nodule on the helices of men over the age of 40. Approximately 30% of cases of CNH occur in young individuals and in women, but the location varies to include the antihelix, tragus, antitragus, and concha [21]. The tender nodule, which often displays central crusting and ulceration, is typically surrounded by hyperemic skin. It enlarges within a few months to reach a size of 0.5–2.0 cm and then remains unchanged without evolution to malignancy (Fig. 6).

This disorder is thought to be due to compromised local blood supply as a result of pressure or cold temperatures. It often arises in individuals who habitually sleep on one side. Aggravating factors include cold temperatures, pressure from head gear, and trauma.

Despite the characteristic exquisite tenderness of these lesions, CNH is often mistaken for squamous cell carcinoma (SCC). Biopsy is indicated

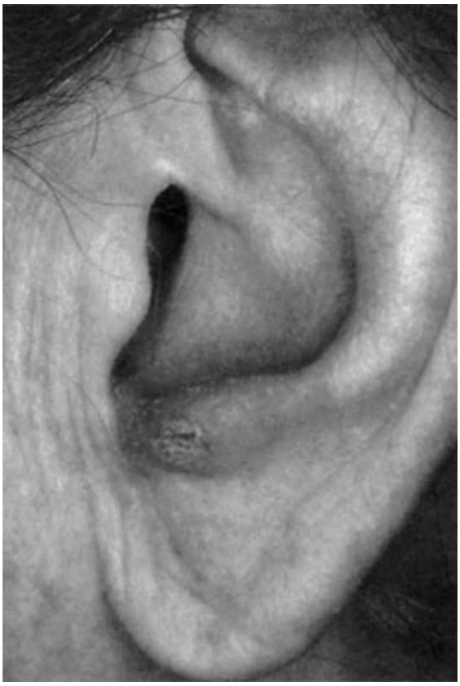

Fig. 6 Chondrodermatitis nodularis helicis. This benign condition of the ear is painful and may present with eroded epidermis. It can be confused with squamous cell cancer of the ear, which usually is not painful

only if there is high suspicion for SCC. Histopathology of CNH reveals degenerated collagen surrounded by vascular granulation tissue with a central ulcer and overlying acanthotic epidermis. The thickened perichondrium shows a lymphocytic infiltrate.

Treatment of CNH may be medical or surgical. Medical therapies include intralesional injection of steroids and collagen [21] and cryotherapy. Conservative management has been advocated as the first line of treatment [22]. Techniques for surgical excision vary widely: some advocate removal of abnormal auricular cartilage only [23–26], whereas others recommend removal of the skin overlying the involved cartilage as well [4, 27]. A cure rate approaching 100% over a 2-year follow-up period has been reported using CO_2 laser surgery [28, 29], but recent data from large-scale comparative trials are not yet available. To prevent recurrence, the patient should be instructed to minimize pressure and trauma to the ear.

Fig. 7 Hemangioma. This deep-seated hemangioma on the upper lip is benign, but in the absence of the ability to blanch on compression, it should be biopsied to rule out other tumors

Cherry Hemangioma (Campbell de Morgan Spots)

Cherry angiomas are small, benign, bright red to violaceous, dome-shaped papules that are commonly found in middle-aged and older adults. They are distributed over the trunk and proximal extremities, vary in size from 2 to 8 mm in diameter, and become more numerous with age (Fig. 7). Their etiology is unknown.

Histologically, cherry angiomas are characterized by the presence of numerous dilated capillaries lined by flattened endothelial cells with edematous surrounding stroma and collagen homogenization. The overlying epidermis is frequently thinned with fenestrations.

Cherry angiomas are diagnosed clinically and require no treatment. If nodular melanoma or metastatic carcinoma is suspected, an excisional biopsy should be performed. If a cherry angioma is at a site of recurrent trauma and therefore prone to ulceration or if it is at a site that is cosmetically unacceptable to the patient, it can be treated by shave excision, cryotherapy, electrodesiccation, or laser ablation.

Venous Lakes

Venous lakes are angiomatous dilations of venules occurring on the face, lips, and ears of patients who are usually above the age of 50.

They manifest clinically as dark blue to violaceous papules with an irregular, cobblestone appearance. After an initial growth phase, venous lakes stabilize and do not regress. The etiology of these lesions is unknown and they occur with equal incidence in both sexes. Microscopically, the lesion reveals small, single-layered interconnected vessels (or one large dilated space) in the upper dermis surrounded by a thin wall of fibrous tissue. A venous lake can resemble a pyogenic granuloma or a nodular melanoma, requiring excisional biopsy for definitive diagnosis. In most instances, however, venous lakes can be distinguished clinically by applying prolonged pressure to the lesion, which causes it to lose its violaceous hue as the venous bed empties.

Treatment of venous lakes is cosmetic. They can be obliterated with electrocoagulation or laser; the long pulse Nd:YAG has recently shown promise [30]. Alternatively, they can be surgically excised with the risk of a cosmetically unacceptable scar.

Premalignant Lesions

Actinic Keratoses (Solar Keratoses)

Actinic keratoses (AKs) are discrete, scaly, pink to red papules that are found on chronically sun-exposed skin of the face, ears, neck, forearms, and dorsal hands. They have a rough quality, allowing them to be more easily felt than seen. Typically, they arise in middle-aged individuals, though they may occur at younger ages in people living in latitudes closer to the equator. Actinic keratoses are generally considered premalignant lesions with a conversion rate to invasive SCC ranging between 0.075% and 0.096% per lesion per year [31]. For the average person with multiple actinic keratoses, the chance of developing invasive SCC has been estimated at 10–20% over a 10-year period if those AKs are left untreated [32]. An alternate viewpoint characterizes actinic keratoses not as premalignant lesions but rather as malignant lesions akin to SCC in situ [33] (Fig. 8).

Fig. 8 Actinic keratoses. This is one of the most common sun-related lesions in the elderly. It is biologically and clinically premalignant and should be treated because of the risk of malignant transformation. The lesions can vary in size from 1 to 2 mm up to more than 1 cm and have a rough surface overlying a reddened background

Because AKs are considered premalignant, treatment is ablative and the method determined by the number and location of lesions. If a patient presents with fewer than 10 AKs, cryotherapy is the method of choice. Flat to slightly raised lesions are treated with liquid nitrogen until frosted. For lesions that are thick and hyperkeratotic, 3–5 s of freezing may be necessary. With this technique, cure rates as high as 98% have been reported [33, 34]. Light electrodesiccation and curettage and CO_2 lasers are other effective methods for scattered lesions but have the disadvantages of requiring local anesthesia and may increase the risk of scarring.

For more than 10 AKs, topical fluorouracil (5-FU), which selectively targets abnormal keratinocytes, is an effective treatment option. It is applied as a 1%, 2%, or 5% cream or solution once or twice daily until the AKs become inflamed and ulcerate. The treatment period can last 2–6 weeks and can cause significant discomfort, which may hamper patient compliance. Inflammation can be minimized with mid-potency topical steroids during the healing phase without affecting the efficacy of the treatment.

Clinical investigation of daily topical imiquimod has revealed clinical clearance rates ranging from 45% to 84% [35–37].

Growing data support the use of photodynamic therapy (PDT) in the treatment of actinic keratoses with response rates better than cryotherapy and 5-FU. A number of prospective trials have been performed with clearance rates ranging from 77% to 99% with recurrence rates as high as 30% after 1 year [38].

Patients presenting with AKs usually have a history of chronic sun exposure, which places them at increased risk for developing other skin cancers. Therefore, it is important to follow these patients at regular intervals and to emphasize preventive care by recommending sun protection strategies.

Actinic Cheilitis

Actinic cheilitis is a premalignant disorder of the lip. It usually localizes to the mucosal surface of the lower lip where sunlight exposure is greatest but occasionally occurs on the upper lip (Fig. 9). The lesion initially presents as an edematous erythematous patch that progresses to an indurated, scaly plaque with a whitish-gray to brown discoloration. Vertical fissuring and crusting can occur and become painful. Vesicles may arise and burst, giving rise to superficial ulcerations, which may then become secondarily infected. Eventually, warty nodules may form that can undergo malignant transformation to SCC.

The main risk factor for developing actinic cheilitis is chronic sun exposure, as evidenced by a higher incidence of the lesions in light-skinned individuals who work outdoors. Its decreased incidence in women may be due to the protective effects of lipstick [4].

The propensity for actinic cheilitis to develop into SCC should alert the clinician to look for

Fig. 9 Actinic cheilitis. This confluent, hyperkeratotic tumor of the lip is sun-induced. It can be asymptomatic or develop painful fissures. It is premalignant and biologically analogous to actinic keratoses on nonmucosal skin

features associated with malignancy such as ulceration, persistent flaking, or crusting. Any lesion with suspicious features should be biopsied. If the lesion is not indurated, a trial of conservative therapy with opaque zinc oxide or titanium dioxide containing sunscreens and topical steroids may be initiated. Because of the sensitivity of the lip area, ablative treatments can be painful and problematic. Topical agents can be used but can also cause a painful reaction. In one approach, topical 5% fluorouracil can be applied three times daily for 9–15 days resulting in brisk ulceration followed by a 2–3 week period of healing. Even with good compliance, recurrence rates range from 17% at 22 months to 60% at 50 months [39, 40]. Vermilionectomy, which involves excision of the vermilion border down to orbicularis oris muscle with subsequent advancement of a labial mucosal flap, is reserved for cases of actinic cheilitis that recur or do not respond following topical 5FU, laser, or photodynamic therapy [41].

Leukoplakia

Leukoplakia appears as a white plaque on the oral mucosa and is the most common precancerous lesion of the oral cavity. These lesions must be differentiated from those resulting from chronic irritation (usually from smoking), candida, or HPV infection. Malignant transformation occurs in 10–20% of patients and should be biopsied if growth or ulceration of the plaque is present.

Cutaneous Horn

Cutaneous horn is a clinical term used to describe a hard, yellowish brown, conical outgrowth of skin, resembling an animal's horn. Cutaneous horns develop on sun-exposed areas such as the scalp, upper part of the face, tips of the ears, and dorsum of hands; they may grow as long as 20 cm [41]. They can arise from benign, premalignant, or malignant epidermis.

More than 60% of cutaneous horns derive from benign lesions of epithelial hyperplasia, such as warts, skin tags, seborrheic keratoses, and nevi; 24% arise from premalignant lesions including actinic keratoses, and the remaining 16% arise from mostly squamous cell cancer. Horns arising from basal cell cancer and metastatic and sebaceous carcinomas have also been reported.

A cutaneous horn, characterized histologically by a compact hyperproliferation of keratin, is considered a premalignant variant of actinic keratosis. Surgical excision is indicated as approximately 15% of cutaneous horns contain SCC [41, 42].

Bowen's Disease (Squamous Cell Carcinoma In Situ)

Squamous cell carcinoma in situ localized to the epidermis is referred to as Bowen's disease. It typically arises in individuals over the age of 60 and demonstrates a slow, indolent course.

Although not invasive into the dermis, it must be considered a variant of squamous cell cancer. Approximately 5% of the lesions progress to invasive SCC [43].

Bowen's disease initially presents as a solitary, slowly enlarging, erythematous macule with a sharp border that can evolve into a scaling, crusting plaque usually 2–6 cm in diameter (Fig. 10). When this lesion develops on the penis, it is known as erythroplasia of Queyrat. Its etiology has been associated with chronic irritation, HPV infection, and immunosuppression [44]. Ulceration or bleeding may be a sign of invasive malignancy. Bowen's disease can be treated with excision, Mohs micrographic surgery, or destructive therapies such as cryotherapy, electrodesiccation and curettage, topical 5-FU, imiquimod, and photodynamic therapy. Histologic confirmation should be obtained before using one of the destructive modalities. Cure rates of 90–97% have been reported using cryotherapy [34, 45].

Fig. 10 Bowen's disease. This large plaque is an extreme example of squamous cell carcinoma in situ or Bowen's disease. This noninvasive cancer may extend down the hair follicles, so failure to eradicate cells at this level, surgically or otherwise, may result in recurrence of the tumor

Lentigo Maligna (Hutchinson's Freckle)

Melanoma In Situ

Lentigo maligna is a noninvasive disorder of atypical melanocytes limited to the epidermis. This flat, pigmented lesion develops into invasive melanoma in about 1 of 750 cases per year [46]. As a result of its malignant potential, most authors view lentigo maligna as a melanoma in situ [47]. The major risk factors for developing lentigo maligna are chronic sun exposure and light skin color. Additional risk factors include a history of severe sunburn, radiation exposure, estrogen and progesterone therapy, and use of nonpermanent hair dyes [48]. The incidence of lentigo maligna, which is slightly higher in women, peaks during the seventh and eighth decades, with the average age of onset around 65 years.

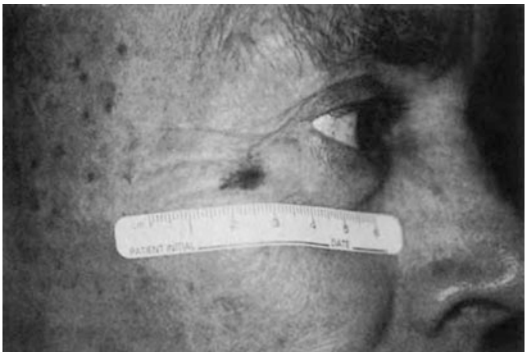

Fig. 11 Lentigo maligna is melanoma in situ on sun-exposed skin. Although this lesion is small and easy to excise, these lesions are often long-standing in the elderly and can reach sizes that make excision unfeasible

Clinically, lentigo maligna presents as a uniformly flat macule ranging in size from 3 to 20 cm with intralesional variations in color (Fig. 11). The color often appears as a disorganized array of dark browns and black on a background of light browns, pinks, and white. The borders of the lesion tend to be irregular with a notched, "geographic" shape.

Biopsy of lentigo maligna reveals cytologically atypical melanocytes proliferating in distinct units throughout the basal layer. These atypical melanocytes can extend far beyond the clinical margin, leading to a high recurrence rate. The black areas of the lesion often display the most advanced histologic changes, whereas the white areas show signs of regression. Regions with surface irregularity may signify invasion.

Several lesions can simulate lentigo maligna, including seborrheic keratoses, solar lentigos, pigmented actinic keratoses, pigmented Bowen's disease, and pigmented BCC. However, these lesions tend to be more uniform in color and rarely contain black pigment. Seborrheic keratoses can usually be distinguished based on their characteristic verrucous surface. Solar lentigos do not exhibit variations in color as seen with lentigo maligna. Pigmented carcinomas tend to be raised. To confirm the diagnosis, an incisional punch or shave biopsy that includes the most darkly pigmented area is recommended.

Complete excision is the treatment of choice for lentigo maligna. Conventional surgery, which provides a 91% cure rate [49], should be performed with 0.5 cm margins if feasible [50]. Depending on the clinical circumstance, mapped serial excision may be required to ensure removal of what can often be very large lesions. This approach is especially helpful for periocular and other cosmetically sensitive areas of the face [51–53]. Cure rates as high as 97% have been achieved using Mohs surgery [54, 55]. However, the technical issues related to frozen section interpretation of melanocytic lesions make use of conventional margin analysis preferable at this time, either in a staged fashion or single excision where feasible.

Some lesions of lentigo maligna do not lend themselves to excision because of their size, location, or the patient's comorbid conditions. In such cases, destructive therapies such as CO_2, ruby laser, electrodesiccation and curettage, radiation therapy, cryotherapy, topical azelaic acid, and topical imiquimod have been used [56]. The major disadvantage of these methods is that they do not provide a specimen to confirm that the cancer has been properly and completely eliminated. These methods may also fail to treat the adnexal melanocytes, which can lead to recurrence. This is suggested by the high recurrence rate of lentigo maligna that occurs with these modalities: 20–25% for electrodesiccation and curettage, 6–36% for cryotherapy, up to 100% for azelaic acid, and up to 38% for irradiation [48].

Malignant Lesions

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) accounts for 15–20% of all skin cancers in the United States. SCC is a malignant tumor of keratinocytes arising on sun-damaged skin and mucous membranes. The incidence is higher in men but occurs more frequently on the extremities in women. Individuals over the age of 55 are most frequently affected, with the mean age of onset at 60 years.

Approximately 3,000 patients die from SCC annually in the United States, and the incidence of more aggressive or advanced tumors is increasing [57].

The biggest risk factor for SCC is chronic sun exposure. This is evidenced by the fact that SCC occurs most frequently in geographic areas that have sunny climates, such as California and Florida. Also, the incidence of SCC is higher in people who work outdoors. Other predisposing factors include prior trauma, frostbite, ionizing radiation, PUVA therapy, exposure to chemical carcinogens (arsenic, topical hydrocarbons, nitrogen mustards), viruses (human papilloma virus strains 16,18,31,33, and 35), and chronic immunosuppression following organ transplantation which increases the risk of SCC up to 250 times the general population [58, 59].

SCC may arise from preexisting pathology, such as the chronic inflammatory lesions of discoid lupus, burn scars (Marjolin's ulcer), osteomyelitis sinuses, lichen planus, and chronic stasis dermatitis. SCC of the lip is associated with tobacco use.

Up to 80% of SCC tumors arise in association with a preexisting actinic keratosis, although <1% of all actinic keratoses undergo malignant transformation annually [60–62]. Malignant transformation in these lesions is associated with increased induration and inflammation. Patients often notice that the lesion is growing or changing. Well-differentiated SCC typically presents as an indurated papule, plaque, or nodule with overlying adherent hyperkeratosis. It may become ulcerated or bleed with formation of a central crust surrounded by a firm, scaly margin. If the carcinoma is undifferentiated, it may appear as a fleshy, granulating nodule with central ulceration and a necrotic base [63].

Clinically, SCC may resemble actinic keratoses, amelanotic melanoma, granulomatous disease, or adnexal tumors.

If a lesion appears suspicious for malignancy, it must be biopsied (Fig. 12).

SCC has the capacity to metastasize. For SCC arising from actinic keratoses, the metastatic propensity is low (approximately 0.5%) [64], whereas for those developing de novo, the risk is 7.7–13.7%. Tumors arising from preexisting pathology, such as a burn scar, have a much higher rate of metastasis, estimated to be 20–40%. Patients presenting with an SCC should have regional lymph nodes examined clinically, as regional lymphadenopathy is often the first sign of metastasis. The prognosis for tumors that have spread is poor, with an estimated 5-year survival rate of 26% if the metastasis is localized to regional lymph nodes and 23% if it has spread systemically [65].

Fig. 12 Squamous cell cancer. This large lesion was present for many months. Occasionally, when the lesion arises over a 6-week period, keratoacanthoma, a variant of squamous cell cancer, must be considered

Although primary tumors can be locally invasive, SCC is frequently diagnosed in the early stages when it is a highly curable disease. Simple excision of low-risk lesions with 4 mm margins is often adequate for most lesions up to 0.5 cm. Six to ten millimeter margins are recommended for larger or higher-risk lesions. For tumors that are large, deep, and recurrent and demonstrate aggressive histology or are located in areas with high metastatic potential (e.g., lips or ears) or anatomically complex areas of the face, Mohs micrographic surgery is the treatment of choice.

Mohs surgery is a tissue-sparing, office-based procedure that involves the sequential excision and mapping of the cancer. The final defect can be repaired immediately or is allowed to heal by secondary intention. Mohs excision has a 3% recurrence rate compared to an 8% recurrence rate with simple excision.

As an alternative to excision, small, superficial tumors (<0.5 cm) can be destroyed by electrodesiccation and curettage, which yields a 5-year cure rate of approximately 90%. Radiotherapy can also be effective but is typically reserved for patients who cannot undergo surgery or as adjunctive therapy in high-risk areas with perineural invasion. This method relies on patient compliance. If used properly, however, it has a 5-year cure rate similar to that of electrodesiccation and curettage [66]. Topical retinoids have also been shown to be effective for some inoperable lesions [67]. Lymph node dissection is not indicated unless nodes are clinically involved.

Sentinel lymph node biopsy to determine staging is indicated for high-risk SCC without palpable nodes. However, more controlled prospective randomized trials are required to determine whether detection of subclinical nodal metastasis results in better clinical outcomes [68]. Chemotherapy is reserved for patients with distant metastasis or advanced local disease not amenable to surgery or other treatment modalities.

Keratoacanthoma

Keratoacanthomas (KAs) represent a well-differentiated or low-grade variant of SCCs. Interestingly, in some cases, they involute and resolve spontaneously. KAs most often appear as isolated lesions on sun-exposed areas in middle-aged or older individuals. The lesion begins as a small papule that rapidly enlarges over 4–8 weeks to form a painless nodule often containing a central keratin-filled crater. KAs occur twice as often in men as in women and are most commonly found in Caucasians.

The cause of keratocanthomas is unknown. They are usually solitary, but multiple lesions may arise as part of a syndrome such as Muir–Torre, Ferguson-Smith, or generalized eruptive KAs of Grzybowski [69].

Unlike most other SCCs, KAs have a history of rapid onset and are not usually associated with regional adenopathy. The history of rapid onset (4–6 weeks) is key to making the diagnosis of KA. While KAs can spontaneously regress, they have also been shown to metastasize and ultimately be fatal [70]. Therefore, surgical excision is warranted.

Basal Cell Carcinoma

Basal cell carcinoma (BCC) is the most common type of skin cancer, constituting 75% of all non-melanoma skin cancers. BCCs are not thought to be associated with a premalignant lesion. Though they are slow-growing tumors that rarely metastasize, they can be locally invasive and destructive. BCCs most commonly present on habitually sun-exposed skin of the head and neck in fair-skinned individuals over the age of 40. Aside from chronic sun exposure, race, and age, other predisposing factors include genetic defects (basal cell nevus syndrome, xeroderma pigmentosum, Bazex syndrome, Rombo syndrome), radiation exposure, immunosuppression, and prolonged contact with chemical carcinogens such as arsenic. The incidence of BCC in the United States has been estimated at approximately 150 cases per 100,000 per year, with men more frequently affected. One exception to this trend is in the lower extremities where the lesion arises three times more commonly in women.

Morphologically, BCCs can be classified into at least five subtypes: noduloulcerative, cystic, pigmented, superficial, and morpheaform. The most common is the noduloulcerative variant, which usually starts as a small papule that slowly enlarges, appearing translucent and pearly with a rolled border and overlying telangiectasias (Fig. 13). As the tumor continues to grow, it eventually exceeds its own blood supply and becomes necrotic and centrally ulcerated (“rodent ulcer”). Most lesions are asymptomatic, though some are pruritic. Noduloulcerative BCC may resemble melanocytic nevi, sebaceous

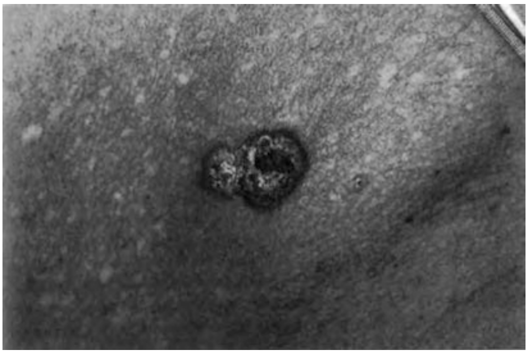

Fig. 13 Basal cell cancer. The large nodule on the chest is a neglected basal cell cancer. Actinic keratoses and severe solar damage are noted on the rest of the chest

hyperplasia, molluscum contagiosum, SCC, verruca vulgaris, keratoacanthoma, amelanotic melanoma, atypical fibroxanthoma, or an adnexal tumor.

Cystic BCC presents as a smooth, pearly, erythematous nodule that rarely ulcerates. The cystic cavity may contain necrotic debris or mucin. This BCC variant can mimic other cystic lesions, such as epidermal inclusion cysts and hidrocystomas.

Excess melanin from epidermal melanocytes can cause BCCs to become pigmented. Pigmented BCCs often occur in dark-skinned individuals and can be clinically confused with melanoma. Unlike melanoma, the border of this BCC variant is often rolled, and the color is browner in contrast to the black–brown hue of malignant melanomas.

Superficial BCC is the second most common type and appears as an erythematous, scaly plaque with irregular borders on the trunk and extremities. This tumor does not invade beyond the superficial dermis. It is often confused clinically with benign processes (e.g., localized eczema, psoriasis, or fungal infection). Superficial BCC can be differentiated by biopsy.

The most aggressive BCC subtype is the morpheaform, or infiltrative/sclerosing, variety, usually found on the head and neck. This locally destructive lesion typically appears as a whitish, sclerotic patch, resembling a scar without history of trauma. Morpheaform BCC is firm upon palpation due to the extensive fibrous stroma associated with the tumor. The strands of tumor cells can travel well beyond the clinical margins into the deep dermis, making these tumors notoriously difficult to treat without Mohs surgery.

Rarely, BCC will metastasize with a reported incidence of 0.0028–0.5% [71]. Metastatic BCC tends to occur more frequently in Caucasian men, occurs on the head and neck, and has no increased risk with a particular histologic subtype although many so-called metastatic basal cell cancers have had squamous features. In contrast to the relatively benign course of primary BCC, metastatic BCC has a 5-year survival of 10% [71] and commonly affects the lymphatics, lungs, bone, and skin.

Knowledge of the pathology of these five primary BCC subtypes is important when choosing the appropriate method of treatment. In addition to taking the morphologic type into account, the proper treatment modality also depends on the size and location of the tumor, the age and comorbid conditions of the patient, and patient preference. For patients who can undergo surgical procedures, electrodesiccation and curettage, simple excision, and Mohs surgery are the methods of choice. With the exception of the morpheaform subtype, most small, nonrecurrent varieties of BCC can be treated with simple excision, achieving a cure rate exceeding 95% [72, 73].

For tumors <1 cm, an excisional margin of 4–5 mm is recommended. Wider margins of 5–10 mm are recommended for tumors >1 cm [74].

For recurrent BCC, infiltrative subtypes, or tumors involving complex or aesthetically sensitive areas of the face, Mohs surgery is recommended. It has the added benefit of being tissue-sparing and offers a cure rate approaching 99% for nonrecurrent lesions [75]. Based on a recent randomized clinical trial, Mohs surgery resulted in better outcomes for treatment of recurrent basal cell tumors, compared to direct excision [76].

Nonsurgical treatment methods include radiotherapy, photodynamic therapy, and topical chemotherapy with agents such as 5-FU and imiquimod. Both topical agents are reserved for the superficial type of BCC because they cannot readily penetrate beyond the dermis. The treatment course can last from 2 to 6 weeks or more, thus requiring high patient compliance. For 5-FU, clinical clearance rates up to 90% have been reported with extended treatment courses of up to 12 weeks [77]. For imiquimod, five times weekly use for 6 weeks has produced 1-year clearance rates as high as 85% and 5-year clearance rates approaching 80% [78].

Radiotherapy can also be used to eradicate BCCs but is best reserved for patients who cannot undergo treatment with other ablative modalities. Cutaneous atrophy at the treatment site is a common side effect. The overall cure rate approaches 90%.

Treatment of metastatic BCC relies on aggressive surgery, irradiation, and/or palliative chemotherapy with cisplatin, cyclophosphamide, 5-fluorouracil, bleomycin, and vincristine.

Overall, BCC generally carries a good prognosis as the tumors tend to grow slowly and metastasize rarely. Local invasion especially in the head and neck can result in significant morbidity. Routine monitoring every 6 months for the first year following treatment and annually thereafter is essential as one-third of recurrences occur in the first year following treatment, half in the second year, and two-thirds in the third year regardless of the treatment modality [75, 79].

Melanoma

Melanoma is a malignant tumor of epidermal melanocytes. It is the fifth most prevalent cancer among men and the sixth most prevalent cancer among women in the United States. Melanoma represents a significant healthcare problem as its incidence is rising faster than any other cancer [80] despite both the presence of a modifiable risk factor (sun exposure) and its curability when detected in its early stages.

In 2016 an estimate of 91,270 adults (55,150 men and 36,120 women) in the United States were diagnosed with melanoma involving the skin. Melanoma is the fifth most common cancer among men and the sixth most common cancer in women. Before age 50, more women are diagnosed with melanoma than men. However, by age 65, the rate is more than two times higher in men. By age 80, the rate in men is nearly three times higher than in women. The average age of the diagnosis of melanoma is 63 years of age in both men and women. Melanoma accounts for about 1% of all skin cancers diagnosed in the United States, but it causes most of the skin cancer deaths. It is estimated that 9,320 deaths (5,990 men and 3,330 women) from melanoma will occur this year [81].

Chronic sun exposure is the main risk factor particularly in those with fair skin, an inability to tan, and an antecedent blistering sunburn. Pigment is a protective factor, as demonstrated by the relative rarity of melanoma in dark-skinned individuals. Other risk factors include blond or red hair, a family history of melanoma (familial melanoma accounts for approximately 10% of all cases), and congenital giant or atypical nevi.

Melanoma is traditionally classified into five clinicopathologic variants: superficial spreading melanoma, nodular melanoma, lentigo maligna melanoma, acral lentiginous melanoma, and desmoplastic melanoma. Superficial spreading melanoma (Fig. 14) is the most common subtype, comprising 40–50% of all cases in patients over age 65 [82]. It typically presents on the trunk in men and on the legs in women in their fourth to fifth decade. The tumor often begins as a small pigmented lesion that develops irregular features such as marked variations in color involving reds, whites, blues, and blacks, as well as notched borders. The tumor is characterized by a radial

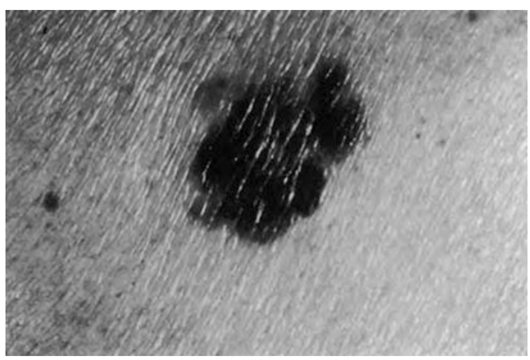

Fig. 14 Melanoma. This example of superficial spreading melanoma has irregular edges and variable coloration. The elderly have an increased incidence of melanoma relative to other age groups, and early diagnosis is the key to cure

growth phase, where malignant cells are localized to the epidermis, followed by a vertical growth phase, which signifies dermal invasion. Elevation, bleeding, and ulceration of the lesion herald the vertical phase.

The second most common type of melanoma in the elderly is the nodular melanoma. These lesions present as elevated, dome-shaped, reddish-brown nodules most commonly localized on the legs or trunk; they arise more frequently in men. They have a short radial growth phase and therefore rarely grow to more than 2 cm in diameter. As they quickly enter their vertical growth phase, nodular melanomas can easily bleed and ulcerate and develop satellite lesions with surrounding inflammation. The tumors begin to develop during the fifth to sixth decade and peak in incidence during the eighth decade, with men more frequently affected than women. Nodular melanomas must be differentiated from seborrheic keratoses, pyogenic granulomas, and pigmented BCCs. Amelanotic melanoma, considered a subtype of nodular melanoma, displays a similar rapid vertical growth phase. These lesions may lack pigment and prove difficult to diagnose.

Lentigo maligna melanoma develops in preexisting lentigo maligna lesions. Although lentigo maligna melanoma represents only 5% of all malignant melanoma cases, it accounts for 10% of melanoma cases in the elderly. Lentigo maligna is, in essence, an in situ melanoma that is in a horizontal growth phase that can last for decades before proceeding to a vertical growth phase. Transformation to lentigo maligna melanoma is defined as invasion of malignant melanocytes into the dermis and is heralded by the formation of an elevated nodule.

Like lentigo maligna melanoma, acral lentiginous melanoma also occurs with disproportionately greater frequency in the geriatric population. Unlike all other subtypes, however, these melanomas most commonly affect Blacks, Asians, and Hispanics. Acral lentiginous melanoma appears as a macular, hyperpigmented area with irregular borders and a blue to black color; it arises on the plantar or palmar surfaces of the hands and feet, on mucous membranes, and in the subungual areas of nails. Subungual variants commonly present as a longitudinal line of pigment extending the length of the nail plate, with the hallmark spread of the pigment to the proximal nail fold referred to as Hutchinson sign. Its location on extremities often leads to the mistaken diagnosis of traumatic hematoma. These tumors are often diagnosed at an advanced stage with an aggressive course compared with the other subtypes.

Finally, desmoplastic melanoma is a relatively uncommon subtype that presents as an unremarkable plaque or nodule which can easily be misdiagnosed at an early stage. It affects older patients most commonly in the head and neck and occurs in men twice as often as in women. Desmoplastic melanoma is frequently associated with nerve invasion and spread along fascial planes and tends to be thicker at the time of diagnosis. They are locally aggressive with a higher rate of local recurrence but exhibit a low incidence of lymph node involvement.

Any pigmented lesion that has undergone changes in size, shape, or color; is inflamed, oozing, bleeding, or itching; or is larger than 5 mm in diameter should be considered malignant until proven otherwise by biopsy. The most frequently occurring colors in melanomas are shades of brown, red, white, or blue and black. Pinks and reds signify inflammation. A blue color arises from light scattering from pigment deep within the dermis (Tyndall effect) and is a poor prognostic indicator.

Full-thickness excisional biopsy with a 1–2 mm margin of normal tissue is the method of choice for suspicious lesions. For large tumors or those that cannot be completely excised because of their anatomic location, an incisional biopsy, such as a punch or elliptical biopsy, is recommended. Histologic characteristics of melanoma obtained from definitive biopsy are powerful independent predictors of 5- and 10-year survival rates.

Clinical subtypes of melanoma vary in aggressiveness. For example, lentigo maligna melanoma has a long horizontal growth phase and is usually recognized prior to the development of metastases. Although prognosis depends on the type of lesion and the presence or absence of lymphatic

Table 1 Clark and Breslow classification of malignant melanoma Clark's level

I Tumor does not invade dermis.		
II Tumor invades only papillary dermis.		
III Tumor expands into papillary dermis but spares reticular dermis.		
IV Tumor invades reticular dermis.		
V Tumor invades subcutaneous tissue.		
Breslow level (mm)	Excision margin	Sentinel node studies
1	1 cm	No
1.0–1.5	1–2 cm	+/–
1.5–4.0	2–3 cm	+
4	3 cm	No

Breslow depth does not correspond precisely to Clark's level. It is used for prognostic purposes and to direct therapy

invasion, the single strongest prognostic factor is the depth of the melanoma measured in millimeters (Breslow depth) (Table 1). Clark's level is sometimes reported but is no longer used as reliably as the Breslow depth.

The American Joint Committee on Cancer has devised a classification system for melanomas that not only takes depth into account but also the extent of regional or distant metastasis. The seventh edition was published in 2010 and is currently the system in use [83]. This clinical staging system is designated the TNM classification. The T component is based on Breslow thickness and histologic evidence of ulceration. Mitotic index was added for small, T1 lesions, less than 1 mm in thickness. The N component is based on the extent of regional lymph node involvement and the tumor burden of the nodes. While the sixth edition allowed the use of microscopic staging of lymph nodes, the seventh edition added the immunohistochemical designation of positive lymph nodes using melanoma-associated markers such as HMB-45 and Melan-A/MART-1. The M component is based on anatomic site of distant metastases and the serum lactate dehydrogenase level. The TNM classification defines five stages based on prognosis: stage 0 (in situ melanoma), stage II (local disease), stage III (regional nodes, in-transit and satellite metastases), and stage IV (distant metastases). The stage groupings and clinical/pathologic criteria are described in Table 2.

Elderly patients tend to present with poor prognostic features and therefore have increased mortality rates. Malignant melanoma in the elderly tends to present later, be thicker, have histologic ulceration, and be of nodular type. Additionally, elderly patients present more frequently with satellite and in-transit metastases and have anatomic localization to areas other than the head and neck [84]. The reasons for this are complex but likely include some combination of decreased vision, increased tolerance for skin lesions, decreased social support, and increased comorbidity.

Most authorities agree that excision based on the thickness of the primary lesion is the mainstay of melanoma treatment. Over the past few decades, however, the guidelines for surgical margins have been redefined by several randomized prospective clinical trials [85–91].

In situ lesions (Clark's level I, TNM stage 0) are by definition noninvasive. The goal for treatment of these lesions is to remove all tumor cells locally. If standard excision is the method of choice, 0.5 cm margins are usually adequate for in situ lesions. However, if the tumor is clinically ill-defined, wider margins may be advisable. The tumor margins should be assessed with a Wood's lamp and marked prior to administration of anesthesia. Lesions that have invaded the dermis and that are up to 1 mm in depth require excisional margins of 1 cm. Margins of 2 cm are recommended for lesions with a Breslow depth of 1.0–4.0 mm. Any lesion more than 4 mm thick should undergo wide excision with margins up to 3–5 cm.

The role of lymphadenectomy in malignant melanoma remains controversial. Prophylactic lymphadenectomy is not indicated for in situ lesions, as they do not show evidence of metastasis. Sentinel lymph node biopsy, a procedure that permits biopsy of the first node that drains a regional lymphatic plexus and is thought to be representative of all nodes in that region, is advocated for all patients with primary melanomas >1 mm thick and for patients with high-risk thin (<1 mm) or stage IB (ulcerated) melanomas. The role of sentinel node biopsy versus clinical observation has recently been addressed by the Multicenter Selective Lymphadenectomy Trial-1

Table 2 American Joint Committee on Cancer classification for malignant melanomas

Stage	Classification			Clinical and pathologic criteria
O	Tis	NO	MO	In situ melanoma
IA	T1a	NO	MO	1.0 mm_2 or less in thickness, no ulceration, mitoses less than 1/mm_2++
IB	T1b	NO	MO	With ulceration or mitotic rate more than 1/mm_2
	T2a	NO	MO	1.01–2.0 mm_2 in thickness
IIA	T2b	NO	MO	1.01–2.0 mm_2 with ulceration
	T3a	NO	MO	2.01–4.0 mm without ulceration
IIB	T3b	NO	MO	2.01–4.0 mm_2 in thickness with ulceration
	T4a	NO	MO	> 4.0 mm_2 in thickness without ulceration
IIIA	T1-4a	N1a	MO	Any invasive T excluding > 4 mm_2 in thickness with ulceration, 1 regional node with micrometastases[a]
	T1-4a	N2a	MO	Any invasive T excluding > 4 mm_2 in thickness with ulceration, 2–3 regional nodes with micrometastases
IIIB	T1-4b	N1a	MO	Any invasive T, 1 regional node with micrometastases
	T1-4b	N2a	MO	Any invasive T, 2–3 regional nodes with micrometastases
	T1-4a	N1b	MO	Any invasive T excluding > 4 mm_2 in thickness with ulceration, 1 regional node with macrometastases
	T1-4a	N2b	MO	Any invasive T excluding > 4 mm_2 in thickness with ulceration, 2–3 regional macrometastases
	T1-a/b	N2c	MO	In-transit or satellite metastases without nodal metastases
IIIC	T1-4b	N1b	MO	Any invasive T, 1 regional node with macrometastases
	T1-4b	N2b	MO	Any invasive T, 2–3 regional macrometastases
	Any T	N3	MO	Any T, >/= 4 regional nodes including in-transit or satellite metastasis with positive metastatic nodes
IV	Any T	Any N	M1	Any lesion with distant skin, subcutaneous, lymph node, or organ metastases

[a]Micrometastases now include those seen on standard H&E staining or with melanoma-specific immunohistochemical markers

[92]. This prospective randomized multicenter trial demonstrated that the result of the sentinel node biopsy is the most powerful independent predictor of survival, but it did not demonstrate that the sentinel lymph node biopsy itself leads to a survival advantage. Contrary to previous speculation, the performance of the sentinel lymph node biopsy was not associated with the development of in-transit metastases. Despite the absence of a clear survival benefit, the sentinel node biopsy does provide valuable staging information and can lead to better management of regional disease. Nodal status is the most important prognostic factor in staging malignant melanoma. The revised AJCC staging system for melanoma accounts for the number of positive nodes as well as the overall tumor burden. Patients with only one positive node have a better prognosis than patient with multiple nodes.

Because malignant melanoma is considered a radioresistant tumor, the role of irradiation in metastatic disease is mostly palliative.

In the treatment of advanced metastatic disease, immunotherapeutic strategies are a focus of great interest. Specifically, an increasing number of clinical trials with interleukin-2, interferon, allogeneic whole-cell vaccines, recombinant viral vectors, adoptive immunotherapy combined with lymphodepletion, CTLA-4 blockade, allogeneic cell lysates, and dendritic cell manipulation are advancing our understanding of tumor immunology and potentially extending survival [93, 94]. The prognosis of patients with widely metastatic disease remains poor, but the full development and refinement of these strategies are progressing.

The perception that aggressive systemic therapy may have unacceptable toxicity in the elderly has limited our understanding of the effect of patient age on chemotherapy efficacy and toxicity. In the treatment of melanoma with isolated limb perfusion, patients of increased age demonstrated similar response rates with no increase in local or systemic toxicity [95]. Similarly, in a small group of elderly patients treated with high-dose IL-2 for melanoma and other tumor types, there was no demonstrated increase in adverse events to warrant their exclusion in future studies [96]. Therefore, while chronological age itself may not affect the efficacy or toxicity of any particular therapy, practical considerations necessitate the careful evaluation of comorbid disease, functional and mental status, support network, and patient willingness to tolerate the difficult side effects of treatment.

Patients who have been diagnosed with melanoma need close follow-up because they may be prone to developing a second primary tumor. Most recurrences arise within the first 18 months but can be delayed for many years. Follow-up should occur four times a year for the first year and at least twice a year thereafter [97]. Early recognition of local or regional disease or new primary melanoma lesions in this population can significantly alter the mortality rate from malignant melanoma.

Atypical Fibroxanthoma

Atypical fibroxanthoma is a spindle cell neoplasm of mesenchymal origin that develops on the head and neck of elderly, light-skinned individuals. The tumor presents as an asymptotic, solitary, firm nodule less than 2 cm in diameter which may go on to ulcerate or hemorrhage. Grossly, the lesion can resemble a SCC, BCC, epidermoid cyst, or pyogenic granuloma. Risk factors for tumor development include chronic sun exposure, radiation, local trauma, and male gender.

One of the unique features of this tumor is its malignant-appearing histology. Aside from the well-defined tumor margins and absence of deep tissue invasion, the tumor appears histologically indistinguishable from malignant fibrous histiocytoma [98].

Electrodesiccation and curettage is not considered adequate treatment because it does not remove the deep tissue, which may be invaded by tumor cells. The recurrence rate with tumors treated by wide excision is estimated to be approximately 10% [99]. Mohs surgery, which has the added advantage of conserving more normal tissue than wide excision, is currently the preferred method of treatment with recurrence rates ranging from 0 to 6.9% [100].

Merkel Cell Carcinoma

Merkel cell carcinoma is a rare malignant tumor of the neuroendocrine-derived Merkel cell. This tumor of unknown etiology typically affects persons over the age of 65, though cases of Merkel cell carcinoma developing in individuals as young as 7 years of age have been reported [101].

Merkel cell carcinoma manifests as a rapidly growing, solitary, pink to violet dome-shaped nodule on sun-exposed skin. These tumors are most commonly distributed on the head and neck (50% of cases), extremities (40% of cases), and trunk (10% of cases) of elderly Caucasians. The overlying epidermis may be shiny and intact with fine telangiectasias, or it may be ulcerated. Because of its nonspecific presentation, Merkel cell carcinoma is often not recognized prior to biopsy. It may be misdiagnosed as an SCC or BCC, a desmoplastic or amelanotic melanoma, or a pyogenic granuloma. Light microscopy may not be diagnostic because the tumor mimics other poorly differentiated small cell tumors. Confirmation of the diagnosis may require electron microscopy, which shows the characteristic secretory granules and paranuclear fibrous bodies.

Once the diagnosis of Merkel cell carcinoma is confirmed, a complete physical examination with attention to regional lymphadenopathy and organomegaly, and a thorough work-up including chest radiography and baseline laboratory tests, with liver function tests, should be performed.

Merkel cell carcinoma is an aggressive tumor with local recurrence rates of 40 to 45% following excisional biopsy with 2–3 cm margins [102]. In anatomically complex areas, Mohs surgery should be considered.

Sentinel lymph node biopsy or elective lymph node dissection is also recommended because of early lymphatic spread. Radiation therapy following surgical excision is considered for tumors >2, whereas chemotherapy currently has a very limited role in treatment.

Five-year survival rates for localized disease range from 44% to 68% and for regional or metastatic spread 23% to 42% [103, 104].

Conclusions

Common cutaneous neoplasms that afflict the elderly arise from the epidermis or dermis and can be benign, premalignant, or malignant. Recognizing these lesions is important for providing the appropriate care to a growing geriatric population. A routine, thorough skin examination enables physicians to monitor the elderly patient closely for the development of precancerous and cancerous lesions, which can ultimately be life-threatening. Minimizing the risk of malignant tumor development by avoiding risk factors such as UV radiation should be emphasized in the elderly population.

Case Study

Recurrent Basal Cell Carcinoma on the Nose of a 75-Year-Old Woman

A 75-year-old woman presented with a slowly growing scar-like lesion at the junction of the right nasal ala and cheek. It was present for approximately 3 years. She noted a 1-month history of a nonhealing lesion at the same site. Dermatologic history was significant for a BCC of the right nasal ala that was treated by electrodesiccation and curettage 5 years earlier. There was no history of radiation therapy. Her medical history was significant for insulin-dependent diabetes and hypertension. Social history was significant for loss of her husband 2 years ago. She lives alone.

Examination of the right cheek and right nasal ala demonstrated a 1.5 × 1.5 cm irregular, indurated, smooth-surfaced, shiny plaque with an indistinct border. Within this lesion, on the right ala, was a 3 mm crusted telangiectatic papule with hemorrhagic crust.

Laboratory data, including CBC, LFTs, and renal function tests, were normal. A biopsy from the edge of the plaque demonstrated irregular, narrow, strand-like proliferations of palisading, basaloid tumor islands in a dense fibrous stroma that extended to the base of the biopsy. These histologic features were consistent with BCC, sclerosing or morpheaform subtype. Mohs surgery was selected as the treatment of choice.

The first stage of Mohs surgery revealed a BCC with distinct nodular and morpheaform features. There was a focal area of epidermal ulceration and a nodule of palisading basaloid tumor islands extending from the deep epidermis into the superficial and mid-dermis. In the deeper and lateral sections, there were morpheaform strands of basaloid cells extending to the margins of the specimen. The tumor was cleared after the second stage of Mohs surgery. The postoperative defect extended to the cartilage of the ala and measured 2.5 × 2.3 cm. The wound was repaired under local anesthesia only in the office setting with an auricular cartilage graft and subcutaneous hinge flap. The secondary defect was closed in a linear fashion, and the area over the graft was left to epithelialize by second intention.

Discussion

Morpheaform BCCs and BCCs of mixed type that have morpheaform features are slow-growing and asymptomatic and resemble scars, making them easily neglected by elderly patients. The clinical borders are indistinct, and the histologic tumor often extends far beyond what the clinical appearance would suggest. These cancers have a propensity for invasion and destruction of adjacent tissues, and they have a higher risk of recurrence than other subtypes of BCC.

Superficially destructive procedures such as cryotherapy, electrodesiccation and curettage, topical imiquimod, or elliptical excision have an increased risk of recurrence as demonstrated in this case. Mohs micrographic surgery is the treatment of choice as it offers the most complete margin evaluation and provides for immediate reconstruction if indicated. Mohs surgery is an office procedure performed using local anesthesia and is generally well tolerated. To facilitate the procedure, there should be proper preoperative consultation that addresses mental status issues, medication use, anticoagulants, the need for prophylactic antibiotics, and comorbid conditions. In the perioperative period, elderly patients often require additional support including attention to positional and emotional comfort as well as monitoring for orthostatic hypotension, hypoglycemia, and cardiovascular events. Anxiety can often be allayed with casual conversation.

Because of the large defects that may result from excision of morpheaform lesions, comorbidities such as diabetes, vascular disease, and the generalized slower wound healing in the elderly must be considered. It must be remembered that complex multistage repairs, while technically possible, may not be advisable in the elderly considering longer operative times and prolonged recovery.

In the postoperative period, pain is most often managed with acetaminophen alone. When more potent analgesics are required, slower drug metabolism, decreased glomerular filtration rates, and potential drug interactions from polypharmacy must be considered. Additionally, the postoperative need for complex or prolonged dressing changes with uncommon materials should be avoided. In general, wound care instructions are discussed with the patient as well as any caregiver present. Before discharge, adequate time is provided for patients to ask questions including concerns for cosmesis and recurrence. As follow-up, we advocate same evening and 24 h phone calls with wound check at 1 week.

Pressure Sores in the Elderly

Pressure sores represent localized soft tissue injury from unrelieved pressure over a bony prominence. The most common bony surfaces involved, in order of occurrence, are the sacrum, ischium, and greater trochanter [105]. In these areas, capillary perfusion pressures (30 mmHg) are exceeded when lying supine, sitting, or lying on the side, respectively [106]. Clinical studies have demonstrated that external pressure greater than 60 mmHg for 2 h leads to irreversible tissue damage [107]; More importantly, soft tissue injuries can be prevented when pressures as high as 450 mm Hg are relieved for as little as 5 min [108]. This observation affirms the key preventive role of repositioning.

Pressure sores are a disease of the elderly: two-thirds of pressure sores occur in patients over 70 years of age [109]. Most of the remaining occur in spinal cord injury patients. Fourteen percent to seventeen percent of patients in a US acute care hospital have pressure sores [106]. The majority of pressure sores occurring in the acute care hospital setting develop within the first 2 weeks of admission [110], probably because elderly patients remain bed-bound until their acute issues are diagnosed and stabilized. In the elderly, the presence of multiple comorbidities contributes to the etiology of pressure sores. Although pressure sores are associated with a twofold increase in mortality, they are not usually the immediate cause of death [111]. More commonly, comorbidities that lead to pressure sores such as cardiovascular, neurological, or orthopedic diseases have their own high mortality rates [112].

Aside from the devastating clinical and psychosocial consequences of pressure sores, they represent a burgeoning health economic crisis. Pressure sores cost $9.1–$11.6 billion per year in the United States. The Medicare estimated in 2007 that each pressure ulcer added $43,180 in costs to a hospital stay [113]. In 2008, the Centers for Medicare and Medicaid Services (CMS) discontinued reimbursement for hospital-acquired stage III or IV pressure sore, emphasizing the hospital's responsibility in documenting and preventing pressure sores.

Goals in the prevention and management of pressure sores are identification of the etiological factors, elimination of these factors, debridement, and wound care. Surgical coverage may be considered when benefits of repair outweigh the perioperative risks, including anesthesia, and pressure sore recurrence.

Pathophysiology

Both extrinsic and intrinsic factors contribute to the development of pressure sores. Extrinsic factors include unrelieved pressure as seen in the debilitated elderly patient, in addition to factors that worsen the local wound environment, such as perineal moisture [114], incontinence [115], and shearing forces from patient repositioning [116].

Intrinsic factors that lead to poor wound healing include skin fragility in advanced age secondary to decreased tensile strength [117, 118], edema, malnutrition, diabetes, end-stage renal disease, and low BMI. Edema in the elderly, due to systemic illness, sets up a downward spiral of ischemia-reperfusion soft tissue injury in which dependent edema is worsened by pressure exceeding the capillary venous outflow pressure (Table 3).

Extrinsic pressures can also be exacerbated by positioning, and clinical studies show that some common positions are particularly problematic. For instance, in a semi-recumbent position with the head of the bed elevated, only friction keeps the patient from sliding down. This situation leads to shearing forces on the skin and soft tissue overlying the sacrum [119]. These shearing forces

Table 3 Extrinsic and intrinsic factors contributing to pressure sore formation

Extrinsic	Intrinsic
Limited mobility	Advanced age
Loss of protective sensation	Skin fragility
Abnormal positioning due to spasticity or contracture	Poor nutritional status
Friction and shearing forces	Dependent edema
Chronic moisture	Immunoincompetence
Other mechanical factors that increase pressure	Infection
	Medical conditions

may result in microvascular thrombosis further contributing to tissue ischemia: topographic pressure maps show why certain areas, such as the sacrum, heels, and ischii, are prone to ischemic damage (Fig. 15) [106].

Malnutrition increases the likelihood of developing pressure sores at least twofold. The 2002 Nutritional Screening Initiative estimates the rate of malnutrition among the hospitalized elderly as 40–60%, nursing home residents as 40–85%, and home care elderly patients as 20–60% [120].

The Braden Scale for Predicting Pressure Sore Risk is a widely used nursing assessment tool to help predict a patient's risk of developing pressure sores. Although there is no clear evidence that risk assessment scales decrease the incidence of pressure sores, the Braden Scale has reasonable predictive capacity with high interrater reliability [121]. The Braden Scale accounts for several extrinsic and intrinsic etiologic factors by scoring six subscales: sensory perception, moisture, activity, mobility, nutrition, and friction/shear. The lower the combined Braden score (ranging from 6 to 23), the higher the risk of pressure sore development.

Intrinsically, different tissues can tolerate ischemia at varying levels. Muscle, with its high metabolic requirements, is more sensitive to hypoxia than skin or subcutaneous fat. Studies confirm that ischemic injury of the muscle overlying the bone precedes damage to the skin producing the cone or "iceberg" model of pressure sores [122]. Although most pressure sore severity indices recognize early skin changes as "low-grade," some degree of muscle damage is inevitable by the time the skin shows changes.

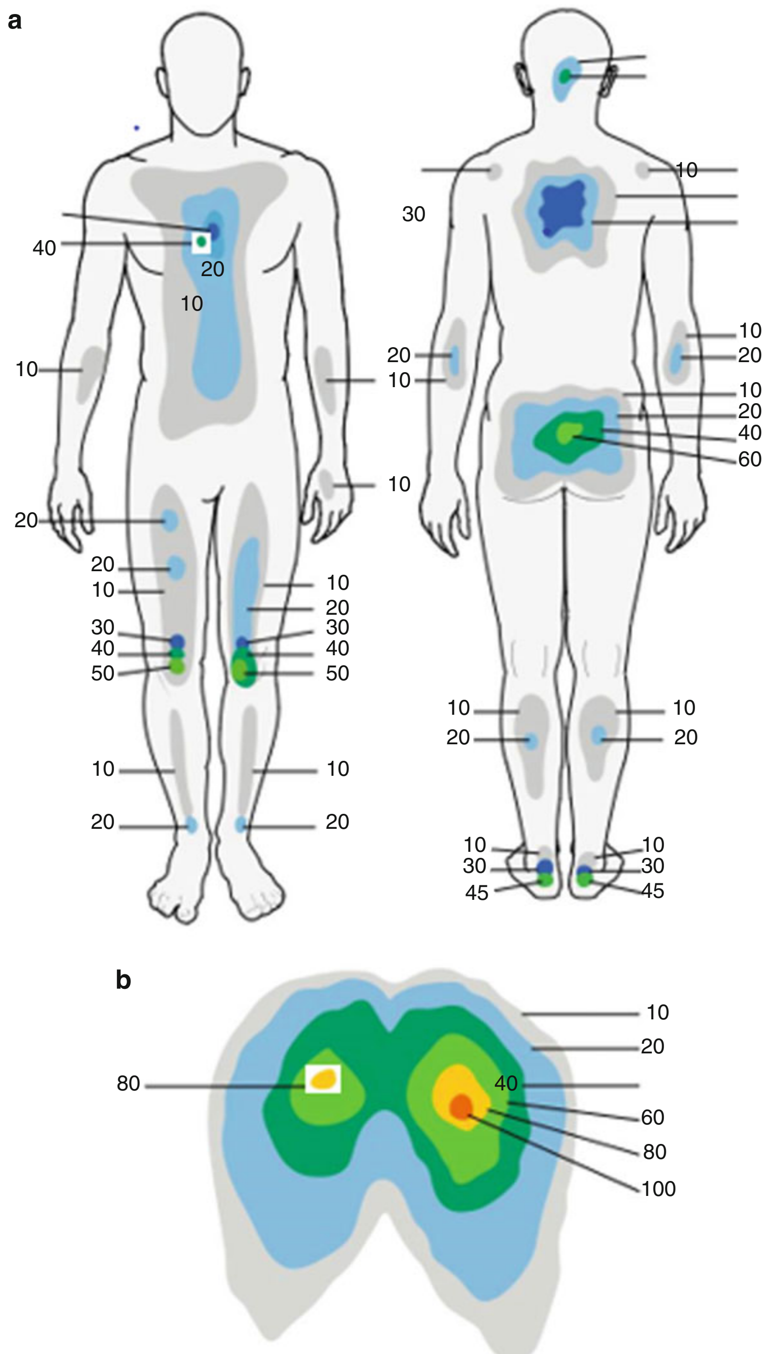

Fig. 15 Topographic pressure maps of the human body in millimeters of mercury. (**a**) Supine (*left*) and prone (*right*) positions. Note that in the prone position, the highest pressures are centered on the sacrum and heels, exceeding 30 mmHg. (**b**) Seated position reveals pressures much greater than 30 mmHg for the ischii. Evaluation

The evaluation of a pressure sore begins with a thorough history and physical examination elucidating the extrinsic and intrinsic factors that contribute to the etiology and chronicity of the wound. Therapeutic efforts, whether nonsurgical or surgical, will fail if these factors are not addressed. For example, a sacral pressure sore in an elderly stroke patient with limited mobility will inevitably recur after surgical coverage if a turning schedule is not planned and implemented.

The most common pressure sore classification system is the National Pressure Sore Advisory Panel consensus development conference scale developed in 1989 and revised in 2007 to include the original four stages and two additional stages allowing identification of clinically suspicious deep tissue injury and unstageable pressure sores: [123].

Stage I: Skin intact but reddened for more than 1 h after relief of pressure. This wound is reversible if extrinsic and intrinsic wound healing factors are controlled.

Stage II: Blister or other break in the dermis with or without infection. Subcutaneous fat is exposed. However, these wounds can generate granulation tissue and heal by secondary intention. The local environment must be monitored for moisture and soiling for healing to progress. Stage I and II pressure sores are the most prevalent [105].

Stage III: Subcutaneous destruction into muscle with or without infection. Theoretically, the soft tissue can heal and contract over the unexposed bony prominence. However, as muscle is sensitive to ischemic necrosis, this is usually a transient stage quickly reaching the final stage of exposed bone.

Stage IV: Involvement of bone or joint with or without infection. This is the stage most commonly prompting a surgical consultation to determine the optimal treatment for providing soft tissue coverage over desiccated, contaminated, and potentially infected bone.

In 2007, the staging system was updated with two new stages: [124].

Suspected deep tissue injury: Purple or maroon localized area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. This new stage allows clinically suspicious deep tissue injury to be identified.

Unstageable: Full-thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black). Eschar or necrosis makes it difficult to determine depth of destruction and frequently represents only the superficial aspect of a deep wound, as seen in Fig. 16.

Osteomyelitis within a pressure sore is definitively diagnosed when bone is excised for biopsy and bacterial culture during surgical debridement. Imaging modalities to diagnose osteomyelitis include tagged white blood cell scans and magnetic resonance imaging (MRI) [125]. However, by the time clinical suspicion is raised by findings such as deep pus not accessible with bedside debridement, surgical exploration is more urgent and appropriate than imaging. As a preoperative adjunct, radiographic imaging may help determine the extent of necrosis in high-risk surgical

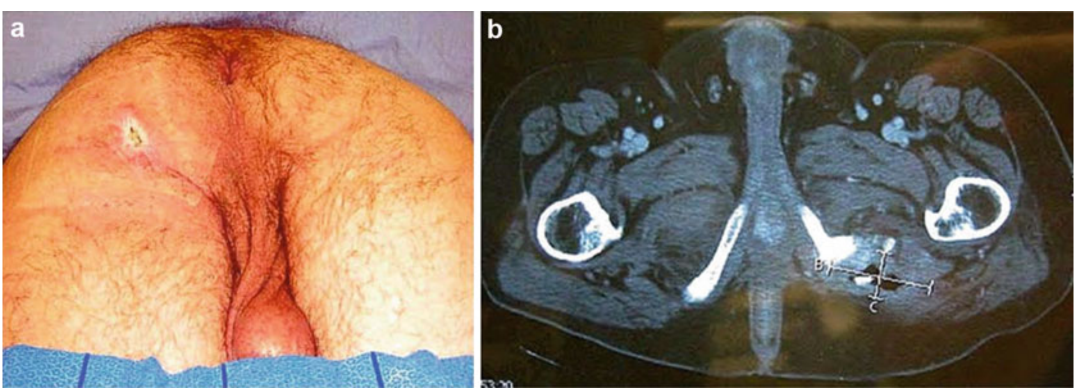

Fig. 16 (below left) Elderly homeless man found sitting on the corner of a street, confused. (**a**) Right ischial pressure sore completely covered with eschar, making it unstageable. (**b**) After bedside debridement of necrotic tissue, the wound extends to the ischial tuberosity

patients or identify the source of infection in atypical pressure sores potentially associated with a perianal fistula or spinal hardware abscesses (Fig. 17).

Infections associated with pressure sores are often polymicrobial due to urine or fecal contamination. Thus, *Proteus*, *Bacteroides*, *Pseudomonas*, and *Escherichia coli* may accompany the more prevalent staphylococcal and streptococcal species. More than half of long-term care patients harbor methicillin-resistant *Staphylococcus aureus* (MRSA) organisms [126]. Whereas swab cultures are invariably positive due to local contamination, intraoperative soft tissue and bone cultures provide more reliable sensitivities.

Pressure sores are always associated with localized inflammation and/or infection. However, unless high-staged or long neglected, they are rarely the cause of sepsis. A urinary tract infection or pneumonia must be suspected and ruled out first as a source of systemic infection in the elderly patient presenting with a pressure sore.

Management

Surgical reconstruction of a pressure sore soft tissue defect is not indicated until unrelieved pressure, local wound environment, and chronic medical illness are stabilized. Otherwise, postoperative recurrence of the pressure sore is inevitable. During preoperative assessment and wound management, there will usually be a period of time in which the pressure sore can be observed and perioperative wound care can be optimized.

Reduction of Pressure and Deleterious Extrinsic Factors

Elderly patients may be acutely obtunded or chronically debilitated and require repositioning every 1–2 h to break the cycle of constant pressure. Meta-analysis suggests that air-fluidized mattresses are better at reducing pressure sores than standard hospital mattresses [127]. Patients who use wheelchairs must learn to shift their weight constantly. Many elderly patients are confined to regular household chairs all day long. Even with intact skin sensation, they remain at risk of developing ischial pressure sores. Bedridden patients must have their lower legs monitored and elevated on foam pillows to prevent heel ulcers.

Elderly patients can demonstrate varying degrees of fecal and urinary incontinence which contribute to the contaminated environment surrounding pressure sores. Urinary incontinence may need to be managed with a sheath or indwelling catheter until the wound begins to heal. For fecal incontinence, a temporary or permanent colostomy may be indicated to increase the likelihood of wound healing or successful surgical repair.

Restoration of Nutrition and Other Wound-Promoting Intrinsic Factors

Elderly patients with pressure sores generally have nutritional intake inadequate to heal their wounds. Dietary intake of nutrients and protein is predictive of pressure sore development [118, 128]. Serum metabolic panels can help with diagnosis and treatment of malnutrition by monitoring markers such as albumin, prealbumin, C-reactive protein, retinol-binding protein, and transferrin. A nutritional analysis of nitrogen exchange and food choices helps determine caloric and protein intake, as well as estimate requirements. Other supplements and treatments to consider include the vitamins A and C which are implicated in wound healing, zinc, protein shakes, pharmacologic enhancement of appetite (megestrol), tube feeding, and parenteral nutrition [121, 129].

Additional intrinsic medical conditions affecting pressure sore healing include anemia, diabetes, HIV, and conditions that lead to edema such as congestive heart failure, renal disease, liver disease, and other causes of hypoalbuminemia.

Wound Care (Active Debridement and Regular Maintenance)

Debridement of devitalized tissue and wound care are the foundation of pressure sore management. Nonviable tissue can appear as dry gangrene or eschar that is not actively infected and may be amenable to mechanical or chemical debridement. Mechanical debridement relies on irrigation, lavage, whirlpool therapy, and sharp excision which can be performed at the bedside or in the operating room. Again, the extent of necrosis may be surprisingly extensive due to the greater sensitivity of muscle to ischemia. For this reason, undermining of the wound beyond the skin edges characterizes pressure sores, and the wound may be substantially larger than the opening in the skin. The use of debriding agents such as proteolytics, fibrinolytics, collagenases, and sterile maggots has been described. Wet gangrene is necrotic tissue that is already superinfected and requires prompt sharp debridement.

In certain areas, such as the heel, pressure sores often are stable and dry. In these wounds, like frostbite injury, local wound care permitting gradual separation of the eschar may be preferable to sharp debridement to maintain as much viable tissue as possible. For heel sores, dry dressings or topical antibacterials such as silver sulfadiazine are useful.

After debridement, several management options are available. The wound can be allowed to heal by secondary intention using a variety of packing materials on a regular basis to allow the wound to heal from the base and to prevent premature skin closure and abscess formation.

Negative pressure therapy with a vacuum-assisted device can be used to facilitate healing by secondary intention. These devices stimulate the formation of granulation tissue and encourage wound contraction, but the wound should be free of infection before sealing it under an occlusive vacuum dressing. Negative pressure therapy may help to downsize the surface area of a wound so that more complex reconstruction options of local or free flap can be replaced with simpler ones such as skin graft or primary closure [130].

Enzymatic debridement ointments have been utilized since the 1950s and continue to be a valuable tool. A recent Cochrane review, however, found that while the data demonstrate a beneficial effect of available dressings including enzymatic debridement, growth factors, and adjunctive therapies such as negative pressure wound therapy, there is no strong evidence to indicate that any given wound care regimen is superior. As a consequence, none has become a dominant or standard form of treatment [131].

Principles of Surgical Treatment

Once nonsurgical management of a pressure sore addresses the etiology and the factors that predispose to pressure sore recurrence, the risk–benefit ratio of surgery versus the perioperative risks for the individual elderly patient can be weighed. Well-recognized flaps have been developed for the most common pressure sores of the sacrum, ischium, and greater trochanter, but management must begin with adequate debridement of non-viable tissue, sinus tracts, and the bursa-like capsule that lines a chronic wound. Pressure sores that come to surgery almost always track to bone, and ostectomy is performed to debride the exposed bone and to obtain biopsies for bacterial culture. Ostectomy also serves to reduce the prominence of bone responsible for the pressure sore.

Pressure sores are rarely repaired by operations on the basic rungs of the reconstructive ladder such as delayed primary closure or a skin graft. Delayed primary closure is prone to dehiscence as it places the surgical suture line directly over the area of pressure.

A skin graft is a thin, fragile coverage option similarly vulnerable to the shearing forces that created the pressure sore in the first place. Skin grafts require a clean, healthy recipient site with a robust blood supply and no exposed bone. Only the most superficial pressure sores meet these requirements.

For full-thickness sores, the guiding surgical principle is provision of vascularized tissue to cover exposed bone, fill the wound completely with adequate padding, and close the surface with durable soft tissue and skin that is under no tension. The ideal flap moves the closure and scar away from the area of pressure.

Flap coverage is a closure option for select patients with the understanding that flap failure and high rates of pressure sore recurrence are inevitable if the multiple factors responsible for pressure sore development are not corrected preoperatively. Unlike a skin graft, a soft tissue flap carries its own blood supply that is preserved, while the flap is transferred into the wound. Flaps are often described by their anatomic makeup. Cutaneous flaps are supplied by direct cutaneous vessels and axially oriented perforating vessels ending in a subdermal plexus. Fasciocutaneous flaps include the skin, subcutaneous fat, and deep fascia. The blood supply originates from septocutaneous vessels that pass up along fascial septae and fan out at the level of the deep fascia to form a plexus from which smaller perforator vessels supply the subcutaneous fat and skin. Musculocutaneous flaps include the muscle, fascia, subcutaneous fat, and skin combined as one unit, based on one or more vascular pedicles.

Previous incisions, whether from trauma or prior surgery, can preclude certain flaps since these incisions and scars are areas where previous blood supply was likely transected. A complete surgical history is mandatory to understand the surgical anatomy when previous flaps were used. A recent large meta-analysis demonstrates the high complication and recurrence rates following surgical reconstruction of pressure sores. Therefore, another important consideration in flap selection is choosing one that preserves blood supply for potential future flaps [132].

Free microvascular flaps are the most complex reconstructive options. They require harvesting a distant flap with its accompanying arteries and veins and transferring it to the recipient bed with microvascular anastomoses to recipient vessels. Elderly patients have comorbidities such as cardiovascular disease and poor general health that often preclude these lengthy microsurgical tissue transfers.

Sacral Pressure Sores

Sacral pressure sores are the most common pressure sore in the elderly who remain bedridden and supine [105]. Given the thinness of soft tissue overlying the sacral prominence, most of these wounds come to the surgeon with exposure of sacral bone. This precludes a skin graft in the sacral area, except in the shallowest of wounds. In general, flap coverage is the better option in elderly patients with intact sensation who will recover mobility. The soft tissues surrounding the sacrum receive their blood supply from perforators from the superior and inferior gluteal arteries supplying the gluteus maximus muscles (see Fig. 18). Cutaneous, fasciocutaneous, musculocutaneous, and muscle flaps can be developed based on these vessels. The gluteus maximus can survive on vascular pedicle alone [132]. Utilizing both pedicles can increase flap reliability and the volume of overlying muscle and soft tissue. However, because the gluteus maximus extends and rotates the thigh laterally

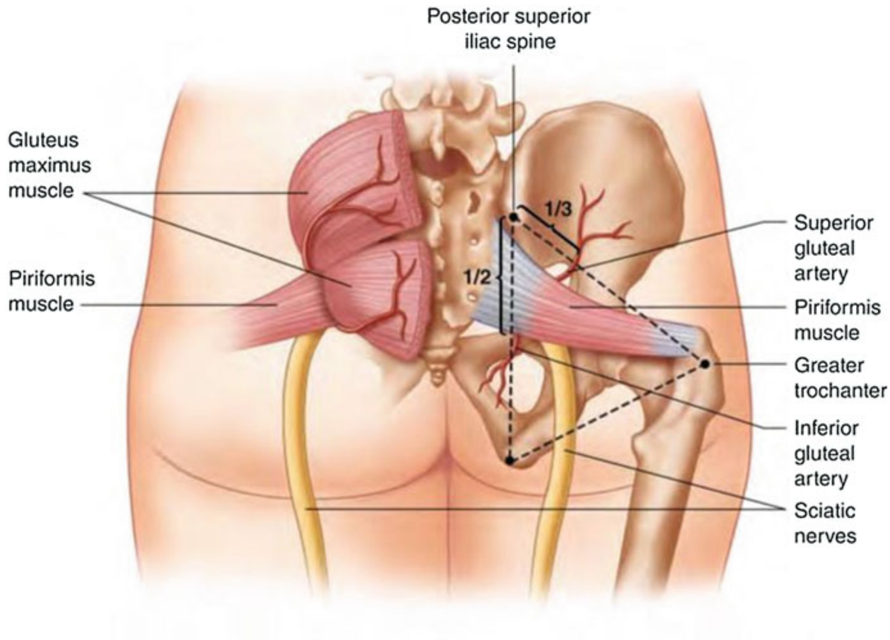

Fig. 18 (Below) The blood supply to the gluteus maximus muscle supplies perforators to the overlying soft tissue surrounding the sacrum. The piriformis muscle marks the midportion of the gluteus maximus muscle, with the superior and inferior gluteal arteries arising above and below the piriformis. The superior gluteal artery can be found one-third of the distance from the posterior superior iliac spine to the greater trochanter. The inferior gluteal artery appears halfway between the posterior superior iliac spine and the ischial tuberosity. (Reprinted from McCarthy J. Current Therapy in plastic surgery. WB Saunders © Elsevier (2005))

and is required for ambulation, this muscle is not considered expendable except in the spinal cord injury patient. If the patient has a chance of recovering ambulation, only the superior or the inferior half of the muscle should be used. For sacral coverage, the superior half of the gluteal muscle is preferred as it is closer to the wound. Alternatively, a cutaneous or fasciocutaneous flap can be used to spare the muscle entirely. The V–Y advancement technique involves creating a triangular-shaped skin island over the gluteus maximus muscle, with one side being the defect and the other two sides forming a "V." The central "V" is shifted into the open wound and the defect is closed in a "Y" configuration. A V–Y advancement flap can be designed in different ways. If not much bulk is needed, a fasciocutaneous flap based on the gluteal perforators can be advanced over the defect without needing to mobilize the muscle. Another way to provide extended coverage of the sacrum is the use of bilateral V–Y advancement flaps, one based on the right gluteal area and one on the left gluteal area (see Fig. 19).

Ischial Pressure Sores

The ischial tuberosities are under high pressure in a seated patient. Unilateral or bilateral ischial sores develop in individuals who are seated for protracted periods of time without adjusting their position and weight distribution. Ischial wounds are challenging for several reasons. The pressure points are bilateral, which means that relieving pressure over one ischium shifts increased pressure onto the contralateral side. Resecting bone on both sides risks shifting weight onto the perineal soft tissues, resulting in scrotal or urethral sores. Chronic and deep ischial pressure sores can develop fistulae involving the rectum or urethra. Control of the fistulae and/or fecal or urinary

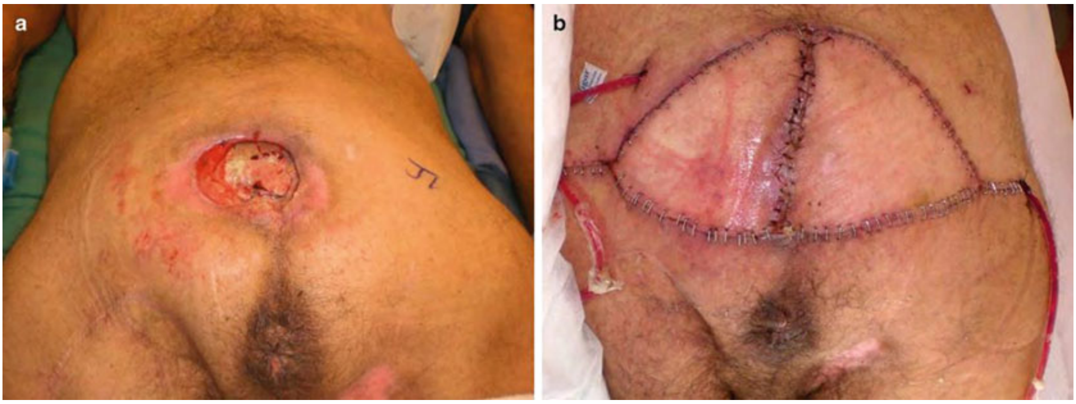

Fig. 19 **(Above)** This male nursing home patient had a stage IV sacral pressure sore with exposed sacrum. (**a**) Preoperative view in the prone position. (**b**) Postoperative view after bilateral gluteus maximusmusculocutaneous V–Y advancement flaps. Note the use of surgical drains under the flap donor sites

diversion must be considered before addressing ischial sores. Finally, because of the strong hip flexors, there can be flexion contractures with varying degrees of deformity which reduce mobility and the capacity for normal weight distribution in either the sitting or the lying position.

Because the ischium has a number of surrounding muscles, a variety of suitable flaps for coverage have been described. These include the inferior gluteal fasciocutaneous thigh flap, inferior gluteus maximus rotational flap, V–Y hamstring advancement flap, gracilis muscle flap, tensor fascia lata rotational flap, and rectus abdominis rotational flap. The first two are considered the most durable flaps and are described in more detail below.

The inferior gluteal fasciocutaneous thigh flap, also called the posterior thigh flap, is a good first choice. This flap is robust and reliable and preserves the gluteus maximus muscle for use in case of future recurrence. The posterior thigh region is supplied by perforators from the descending branch of the inferior gluteal artery. This artery descends deep to the gluteal muscles in a midline axis between the ischium and the greater trochanter and courses toward the popliteal fossa. The distal limit is about 8 cm proximal to the popliteal fossa [133]. The base of the flap should be about 10–12 cm wide, and the point of rotation is 5 cm superior to the ischial tuberosity (see Fig. 20a, b). The descending branch of the inferior gluteal artery is transected distally and preserved proximally as the flap is raised from inferior to superior up to the gluteus maximus muscle and rotated medially to fill an ischial defect (see Fig. 20c, d). If excess length of the flap is available, the distal end can be the de-epithelialized and the subcutaneous tissue tucked into the ischial crater to further eliminate dead space (see Fig. 21).

The other useful flap is the inferior gluteus maximus rotational flap which can be rotated into the ischial wound as a rotational advancement (see Fig. 22) or a rotational island flap. In the latter case, a skin island over the inferior half of the muscle, lateral to the ischial defect, can be elevated with the muscle and rotated medially (see Figs. 23 and 24).

Despite the variety of flaps available to cover an ischial defect, surgical repair is associated with recurrence rates as high as 75 to 77% since patients almost always return to sitting after flap repair [134].

Greater Trochanter Pressure Sores

Given the mobility of the hip, pressure sores over the greater trochanter characteristically have extensive bursa formation with less skin involvement. After resection of the entire defect, obliterate the dead space, and close the ischial pressure sore. Note the two surgical drains: one for the posterior thigh donor site and one for the ischial recipient site.

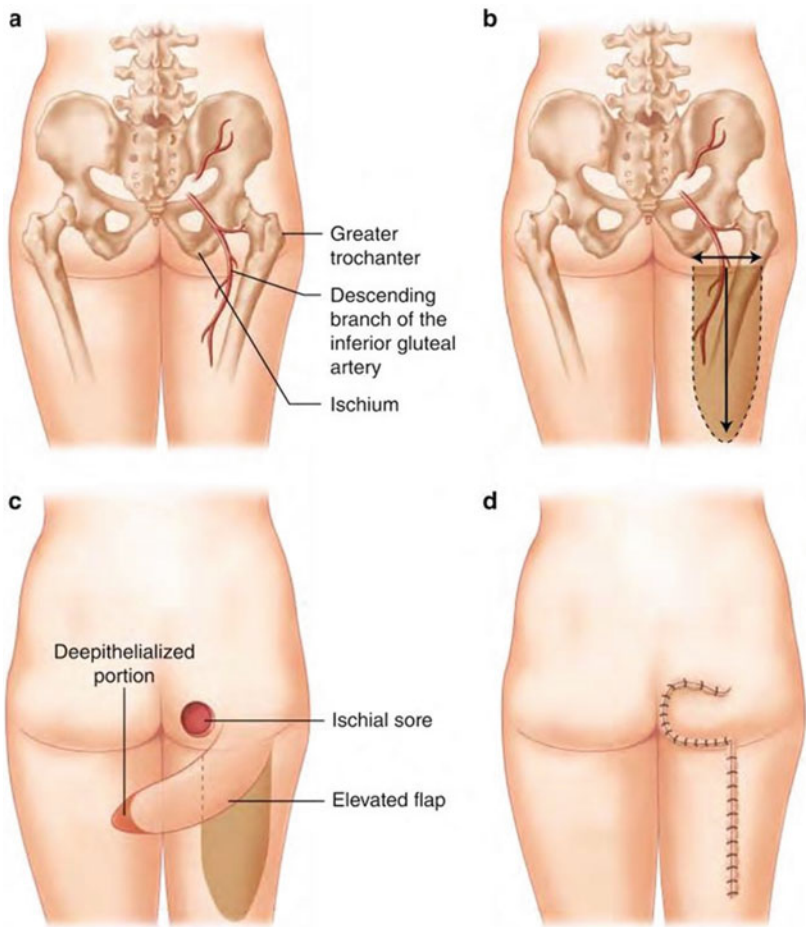

Fig. 20 **(Right)** The inferior gluteal thigh flap. (**a**) The descending branch of the inferior gluteal artery comes off at the midline of the posterior thigh. (**b**) This descending branch supplies the posterior thigh soft tissues, so a flap is designed to allow rotation into the ischial defect and primary closure of the donor site. (**c**) Rotation of the posterior thigh flap medially, inset of the flap into the wound, and primary closure of the donor site. (**d**) Immediate postoperative view after inset of the flap. Foot Pressure Sores

Unlike pressure sores within the pelvic girdle, most pressure sores over the heels, malleoli, and the plantar surfaces of the feet are modest in size and depth. Pressure sores of the feet respond favorably to conservative treatment, particularly in non-weight-bearing areas where less durable soft tissue coverage is required. A scar left by wound contraction and epithelialization may suffice. In larger wounds, debridement and split-thickness skin grafting may expedite closure if the wound bed demonstrates vascularized soft tissue granulation capable of supporting a skin graft. Osteomyelitis of the calcaneus, or any devitalized bone of the foot, must be recognized and debrided if present. Where flap coverage is mandatory, muscle flaps of the abductor digiti minimi, abductor hallucis, and flexor digitorum brevis are described. Fasciocutaneous flaps based on the dorsalis pedis, medial plantar, and lateral plantar arteries can also provide coverage.

Postoperative Care

The postoperative care of surgical flaps includes intravenous antibiotics when indicated for culture-positive osteomyelitis and protection of surgical wounds from urinary and fecal contamination.

Repositioning is critical to protecting a newly transferred flap vulnerable to pressure necrosis in the early postoperative period.

Fig. 21 **(Left)** This man had a chronic left ischial pressure sore that would not heal. (**a**) Preoperative view of ischial pressure with markings for a posterior thigh flap. (**b**) Elevation of the posterior thigh flap, showing it as a fasciocutaneous flap. (**c**) *Inset* of posterior thigh flap to fill the inferior half of the gluteus maximus muscle maintaining the perforators to the overlying soft tissue island. (**d**) Island flap is rotated medially into the defect and the donor site primarily closed. Note the two surgical drains: one in the donor site and one in the ischial wound recipient

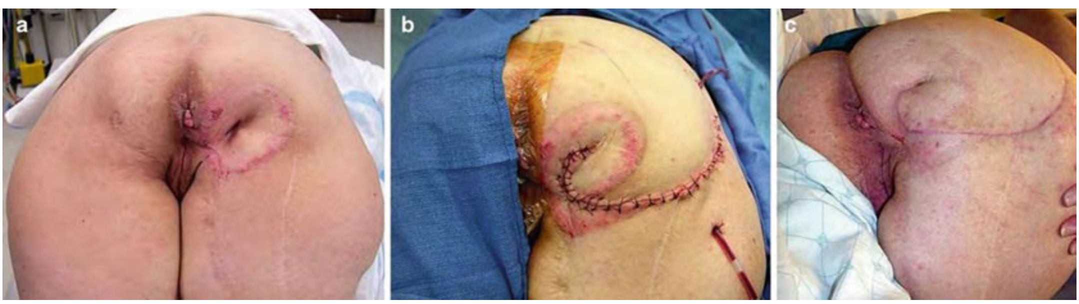

Fig. 22 **(Bottom)** This woman had a recurrent right ischial pressure sore. (**a**) On her preoperative view, note the two vertical scars on her posterior thigh, evidence of a previous hamstring advancement flap. These scars preclude the use of a posterior thigh flap. (**b**) After debridement of the wound and rotational advancement flap of the inferior half of the gluteus maximus muscle with its overlying soft tissues, the flap is *inset*, closing the ischial defect. Note the two surgical drains: one superiorly for the donor site and one inferiorly for the ischial wound recipient site. (**c**) Postoperatively with good healing and intact closure at 3 months

Closed surgical drainage systems are often placed between flaps and the recipient bed to reduce the incidence of postoperative seroma and infection. Drainage should be maintained until the patient has recovered some degree of mobility and fluid output has tapered to a small volume per day.

Spasticity of large muscles, such as the hip flexors, can impede wound healing and compromise surgical flap closure by placing repeated

tension over incisions and bony prominences. Spasticity can be addressed pharmacologically with muscle relaxants and antispasmodics, such as benzodiazepines, baclofen, and cyclobenzaprine. Refractory spasticity may respond to infusion pumps, nerve blocks, rhizotomies, or epidurals [135]. Physiatry should also be consulted for splinting and physical therapy.

The postoperative protocol is customized depending on the patient, the pressure sore, and the specific flap repair performed.

Air-fluidized mattress can assist in off-loading pressure following sacral or ischial flap closure as these patients will require prone positioning with frequent side-to-side turning. When it is time to begin ambulation or resume sitting in a chair, typically between 3 and 6 weeks, the transition is carefully planned and customized. A common protocol, for example, gradually adds 30 min increments of daily sitting as tolerated [116].

Regardless of immediate postoperative success, pressure sore flap coverage has a high rate of recurrence of about 40% over the long term. Many studies consistently report postoperative pressure sore recurrence within the first 15–22 months [136]. These observations attest to the difficulty of controlling the multiple etiologic factors of this disease including the underlying medical conditions, glucose control, malnutrition, and altered mentation and sensation. Frequent repositioning, vigilant flap monitoring, and daily local wound care are labor-intensive for caregivers and their families. Social issues such as lack of financial resources, inadequate family and/or community support, and drug and alcohol abuse also contribute to the high rate of postoperative pressure sore flap failure and recurrence in the elderly.

Case Study

A 72-year-old man with Alzheimer's dementia is having significant difficulty taking care of himself and performing the activities of daily living (ADLs). He has a history of two myocardial infarctions, congestive heart failure, chronic obstructive pulmonary disease, and insulin-dependent diabetes mellitus and is recovering from a colectomy for stage III cancer, complicated by acute respiratory decompensation requiring ventilatory support. During his convalescence from the colectomy, he developed a 4 cm sacral pressure sore that is fibrinous and foul-smelling and tracks to bone. Discuss the evaluation and management of this pressure sore.

Elderly patients with dementia and those with severe, acute conditions may be deconditioned and debilitated; being bedridden results in chronic pressure over the sacrum and the development of a pressure sore with soft tissue injury deeper than appears on the surface. Correction of the intrinsic and extrinsic factors contributing to the pressure sore is the first step in treatment.

Since the wound is foul-smelling, necrotic tissue harboring infection is present. The first step is excisional debridement, at bedside or in the operating room, with cultures of the deep tissue for both treatment and staging. In addition to serial debridement, enzymatic agents such as collagenase and negative pressure therapy should be considered, while the appropriate lab tests and radiographic imaging is performed.

Intrinsic factors in this patient's case include stabilizing his cardiopulmonary disease, managing his diabetes, and addressing his nutritional status. Obtaining baseline albumin, prealbumin, transferrin, calorie, and protein counts will help determine if wound healing vitamins and protein supplements are needed to maintain caloric intake.

Extrinsic factors: Frequent turning and repositioning on an air-fluidized mattress will eliminate pressure over the sacrum. Prognosis and treatment of the patient's colon cancer should be discussed with his oncologist and colorectal surgeon. If appropriate, a diverting colostomy would eliminate incontinence and soiling of the sacral pressure wound.

If this patient's general condition is deemed unsuitable for surgical closure, a plan for chronic wound care with dressings or negative pressure therapy should be initiated. For positive bone cultures, a schedule for intravenous antibiotics should be developed with an infectious disease specialist. Social services will help determine eligibility either for a long-term care facility or arrangements for home care with the provision of a low-pressure bed and nursing care.

If the patient is a good surgical candidate, debridement followed by flap closure would be planned. After debridement, the wound is 8 cm in diameter. The soft tissues surrounding the sacrum receive their blood supply from the superior and inferior gluteal arteries. Since this patient has no previous surgical scars, either a rotational or V–Y advancement flap may be considered. He will be ambulatory, so sparing the gluteus maximus muscle is desirable. Given the size of the wound, bilateral V–Y fasciocutaneous advancement flaps would be a good choice.

The patient's postoperative care would include the use of surgical drains, protective dressings with routine flap monitoring, bed rest on an air-fluidized mattress, deep vein thrombosis prophylaxis, antibiotic adjustments as dictated by intraoperative cultures, and management of his medical conditions. Provided the wound heals satisfactorily, graduated mobilization could begin at about 3–4 weeks.

Conclusions

Pressure sores are a common problem, with a majority of them affecting the elderly population. The etiology or pressure sores is complex, and multidisciplinary treatment is needed. Extrinsic and intrinsic factors must be addressed before considering surgical flap closure with its anesthetic risks, long healing process, and high recurrence rate. A clean open wound, even with exposed bone and osteitis, can be maintained with consistent wound care and repositioning in elderly patients who are high risk for surgery or pressure sore recurrence.

Abstract

Abdominal wall hernia repair is the most common surgical procedure in the United States. With the US elderly population expected to nearly double in size from 2012 to 2050 (Ortman et al., US Census 1964:1–28, 2014), physicians should expect to see an increasing

R. A. Rosenthal et al. (eds.), *Principles and Practice of Geriatric Surgery*,
https://doi.org/10.1007/978-3-319-47771-8_54

number of elderly patients presenting for evaluation and treatment of abdominal wall hernias. The elderly population deserves special attention as this population often has more comorbidities and shorter life expectancy as compared to a younger population. Thus, it is important for clinicians to discuss goals of care and the risks of treatment options with their elderly patients. Although there is a general paucity of data on outcomes in the elderly hernia population, more data is becoming available for review. Laparoscopic herniorrhaphy appears to be a safe technique for many elderly patients. Watchful waiting has also arisen as a potential option for patients with asymptomatic or minimally symptomatic groin and ventral hernias. This chapter will focus on the preoperative evaluation, repair, and complications of inguinal and incisional/ventral hernias in the elderly. Other hernias will be discussed separately at the end of the chapter.

Elderly hernia · Inguinal · Ventral · Incisional · Herniorrhaphy

Case Studies

Case Study #1

Background

A 67-year-old male with a past medical history notable for an asymptomatic right inguinal hernia presents to the emergency room with chief complaint of increasing right groin pain. The patient was first diagnosed with a right inguinal hernia 10 years ago after he noticed it in the shower. After thorough discussion with his physician, he was deemed a candidate for elective repair or watchful waiting. The patient opted for watchful waiting as he was currently the primary caregiver for his ill mother who lived with him at home. Although initially not painful, in the last few weeks he has been experiencing intermittent pain in his right groin. Today, his hernia became "stuck out" and has become progressively more painful. He cannot remember the last time that he had a bowel movement. On exam, he is mildly tachycardic. His right inguinal hernia is incarcerated, and due to some erythema over his groin, there is concern for strangulation.

Management

The patient is taken urgently to the operating room for repair of his right incarcerated inguinal hernia. An open approach is selected by the surgeon, and general anesthesia is administered due to concerns that a local anesthetic will not be effective alone due to the inflammation. During the operation, bowel is found within the hernia sac but appears to be viable, so no bowel resection is performed, and a mesh repair ensues. The patient recovers without incident and is sent home the next day. At his 2-week follow-up appointment, there is no erythema or evidence of recurrence. At his 6-week follow-up appointment there is again no evidence of recurrence, and he is cleared to begin lifting items heavier than 10 pounds.

Case Study #2

Background

A 70-year-old female with a past surgical history notable for an open right hemicolectomy 3 years ago presents to the general surgery clinic with the chief complaint of a painful abdominal bulge. The patient reports that the bulge has been present for 6 months. At first, she did not have pain at the site, but in the last 1 month she has been experiencing daily pain especially when lifting heavy objects. She notes that she can press the bulge back into her abdomen but that as soon as she does, it pushes back out. She denies any changes in her bowel movements. Her past medical history is otherwise notable for well-controlled hypertension and migraines. She has no history of COPD, diabetes mellitus, or falls, and she does not use tobacco products. She lives with her husband who is healthy. On exam, the patient's vital signs are stable, and her BMI is 29. She has a large abdominal bulge at her well-healed laparotomy scar. The bulge is soft and nontender, and there is no overlying edema or erythema. The edges of the rectus fascia are palpated and estimated to be 12 cm apart.

Management

After examining the patient, the surgeon discusses treatment options with the patient including open ventral hernia repair versus watchful waiting. Given the patient's daily pain and overall good health, the general surgeon recommends proceeding with elective open repair with bilateral components separation. Prior to the operation, an abdominal CT scan is recommended to better delineate her anatomy. The general surgeon also discusses involving a plastic surgeon to assist with the components separation. The patient agrees to the plan and meets with the plastic surgeon 1 week later. Her preoperative abdominal CT scan confirms a 12 cm mid-abdominal wall defect. After obtaining her scan, she undergoes an open ventral hernia repair and a bilateral components separation with placement of a bridging mesh in an underlay fashion followed by primary repair of the fascia. During closure, no increase in peak airway pressures is noted. Two subcutaneous drains are placed, and a well-fitted abdominal binder is put on the patient prior to extubation. The patient recovers without complication, and she is discharged from the hospital 2 days later. One week later she is seen by the general surgeon and reports normal bowel movements and minimal pain. One of her surgical drains is removed. Two weeks after this, she is seen by the plastic surgeon and her sutures are removed as well as her final drain. At her 6-week follow-up appointment, she is cleared to begin lifting items greater than 10 pounds and to begin weaning her abdominal binder. At 12 weeks, she is back to her normal activities.

Introduction

Abdominal wall hernia repair is the most common surgical procedure in the United States, with more than 1,000,000 herniorrhaphies being performed annually. Of these, 750,000 are inguinal, 166,000 are umbilical, 97,000 are incisional, and 25,000 are femoral [2]. The incidence of groin hernias in men over age 65 is approximately 13 per 1,000 population [3]. The incidence in women is 12–25% that of men. In a British study of more than 30,000 inguinal hernia repairs, 27% were in an elderly population, 85.5% of repairs on patients aged 65 or older were elective, and the remaining 14.5% were classified as emergency procedures [4]. With the US elderly population expected to nearly double in size from 2012 to 2050 [1], surgeons should expect to see an increasing number of elderly patients presenting for evaluation and treatment of hernias. Given that the majority of all hernias are inguinal and given the great surgical comorbidity that may be associated with incisional/ventral hernia repair, this chapter will focus on the preoperative evaluation, repair options, and complications of inguinal and incisional/ventral hernias in the elderly. Umbilical, Spigelian, and other hernias will be discussed separately at the end of the chapter.

Special Considerations

The elderly population deserves special attention when considering management of abdominal wall hernias as this population often has more comorbidities and shorter life expectancy as compared to a younger population. Additionally, the elderly may suffer from malnutrition, cognitive impairment, and functional dependence. Given this, it is easy to see how an operative complication could lead to prolonged hospital stay, inability to be discharged to home, and overall decreased quality of life in this special population. While several adult surgical risk calculators have been developed to help guide clinicians in discussions with their patients, important risk factors specific to the elderly population have often been left out. Additionally, there is a lack of data regarding the general disease course of hernias in the elderly [5]. Thus, it is imperative that health-care professionals have open and frank conversations with elderly patients before any decision is made regarding treatment of abdominal wall hernias.

For an elderly patient who presents electively for hernia repair, several important considerations must be made after the diagnosis is established. First, the patient must be determined to have decision-making capacity. Second, the provider must assess the patient's overall goals of care. Thirdly, the patient's functional status should be evaluated as this is a strong predictor for surgical outcomes. Next, the provider should discuss the varying treatment options and their risks and benefits for the specific patient. If surgery is considered, all modifiable risk factors should be identified and optimized prior to the procedure [5].

Generally speaking, femoral hernias and groin hernias in females should be surgically repaired due to the high risk for incarceration. Consideration for surgery is given for both symptomatic and asymptomatic groin and ventral hernias. For asymptomatic groin hernias in males, watchful waiting has arisen as option over elective surgery and will be discussed further in detail later in the chapter. Trusses have been historically used to palliate the symptoms of inguinal hernias; however, the data have shown that they are infrequently worn, uncomfortable, improperly fitted, and under the best circumstances, provide appropriate relief in only 31% of patients [6].

When discussing elective hernia repair with an elderly patient, the provider must determine whether or not surgical interventions are in line with the patient's goals of care. Goals of care may include prolongation of life, maintenance of functional independence so as to live at home alone or to not be a burden on family members, and maximizing comfort. Surgical interventions must then be assessed for the ability to decrease the chance of death, cure the hernia without recurrence, improve function, and/or relieve chronic pain. In hernia surgery specifically, the risk of incarceration and strangulation must be weighed against the need for general anesthesia such as in laparoscopic surgery versus the availability of repair under local anesthesia such as in open repairs, the risk for major visceral and vascular injuries, expected length of hospital stay, and rate of recurrence. These details as related to specific hernia type will be discussed further later in this chapter.

As a population ages, the incidence of comorbidities increases while functional status decreases. Functional status may be classified into one of three categories depending on the ability to perform activities of daily living (ADLs): independent, partially dependent, totally dependent. Elderly patients with decreased functional status may report difficulty with ambulating or a history of falls in addition to difficulty bathing or eating. A history of falls or difficulty ambulating is particularly concerning in patients considering an open hernia repair who may have a large incision postoperatively and whose ambulation may be further limited by pain. Poor preoperative functional status has been associated with increased surgical complications and length of stay. In an analysis of over 76,000 patients undergoing ventral hernia repair, totally dependent patients had an increased risk for all adverse short-term outcomes: wound occurrence, pneumonia, pulmonary embolism, deep venous thrombosis, urinary tract infection, myocardial infarction, sepsis, and return to the operating room. Mortality was also increased [7]. In the orthopedic literature, poor preoperative functional status has also been associated with increased risk of discharge to a facility versus home after hip repair [8]. Given this data, physicians may consider nonoperative management in functionally dependent elderly patients. Notably, however, emergent surgery also leads to significant morbidity and mortality in this special population. Thus, physicians must appreciate the added risks in functionally dependent population and counsel these patients carefully.

Prior to elective repair of abdominal hernias, all modifiable risk factors should be optimized. For those with poor functional status, preoperative work with physical and occupational therapists may be beneficial in addition to obtaining home assistive medical equipment and planning for postoperative rehabilitation therapy [9, 10]. Conditions that may cause increased intra-abdominal pressure should also be investigated and corrected, if possible. Increased intra-abdominal pressure puts stress on the repair, interferes with normal wound healing, and may predispose to recurrence. Constipation, symptoms of prostatic hypertrophy, chronic cough, and obesity are common conditions associated with increased tension on the abdominal wall. Managing the first three conditions with medications sufficiently to proceed with operation can often be accomplished in several weeks. Obesity cannot, however, and should not be controlled rapidly. Therefore, significant weight loss should not be used as an absolute prerequisite for repair. Other modifiable risk factors that should be addressed prior to surgery include things such as active smoking, poor control of diabetes or hypertension, anemia, and lack of a support system.

Groin Hernias

The inguinal and femoral canals are anatomically one of the most confusing areas of the human body (Fig. 1). The inguinal canal is bordered anteriorly by the external oblique fascia and posteriorly, also called the floor of the canal, by the transversalis fascia. The superior border is the transversus abdominus and the inferior border is the inguinal ligament, which is itself the inferior edge of the external oblique muscle. The inguinal canal houses the ilioinguinal nerve, the genital branch of the genitofemoral nerve, and the spermatic cord (men) or the round ligament (women). There are two openings to the inguinal canal called the deep inguinal ring and the superficial inguinal ring. The deep inguinal ring is the entrance to the canal and is found above the inguinal ligament at its midpoint, lateral to the epigastric vessels. The deep inguinal ring is made up of an invagination of the transversalis fascia. The superficial inguinal ring is immediately superior to the pubic crest and marks the end of the canal. It is formed by the evagination of the external oblique aponeurosis. The spermatic cord in males or round ligament in females courses through the inguinal canal from the deep inguinal ring to the superficial inguinal ring. The spermatic cord itself is composed of the cremasteric muscle, pampiniform plexus, testicular artery, genital branch of the genitofemoral nerve, vas deferens, cremasteric artery, lymphatics, and the processus vaginalis which may or may not be patent (Fig. 1b). The conjoint tendon, made of the common aponeurosis of the internal oblique and transversus abdominus muscles, inserts onto the pubis immediately behind the superficial inguinal ring and makes up the medial part of the posterior wall of the inguinal canal.

An important concept in groin anatomy is the myopectineal orifice (Fig. 2). Through this

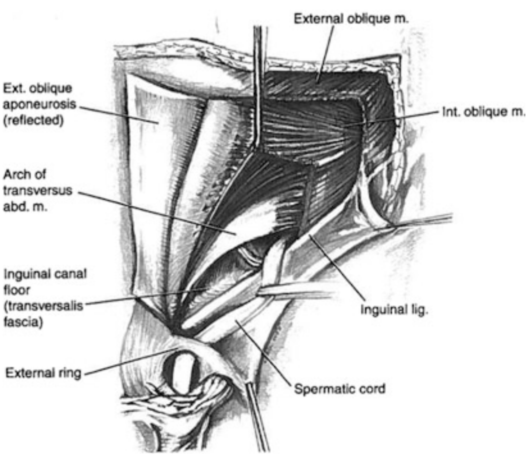

Fig. 1 Anatomy of the inguinal region (reprinted from Mulvihill; Surgery: Basic Science and Clinical Evidence; 2001, with kind permission of Springer Science + Business Media)

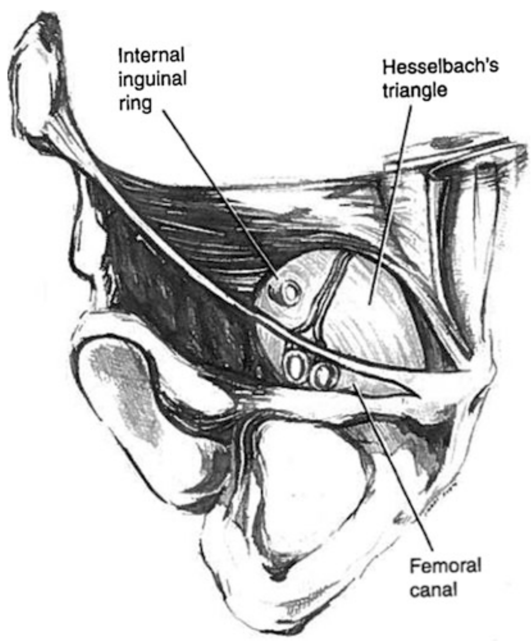

Fig. 2 Myopectineal orifice (reprinted from Mulvihill; Surgery: Basic Science and Clinical Evidence; 2001, with kind permission of Springer Science + Business Media)

anatomic opening, structures traverse from the pelvis to the leg. The myopectineal orifice is bound by the rectus abdominus muscle medially, the iliopsoas muscle laterally, the internal oblique and transversus abdominus muscle superiorly, and the superior pubic ramus with Cooper's ligament inferiorly. The inguinal ligament divides the orifice with the spermatic cord and the femoral vessels passing anterior and deep to the ligament, respectively. The transversalis fascia spans the inner surface. Groin hernias begin as a weakness in the myopectineal orifice when the transversalis fascia attenuates, allowing for a peritoneal bulge [11]. Hernia repair involves fixing the myopectineal orifice or using mesh to replace the attenuated transversalis fascia [12].

The myopectineal orifice can further be divided into three triangles – the medial, lateral, and femoral [13] (Fig. 2). The medial and lateral triangles are separated from the femoral triangle by the inguinal ligament. The inferior epigastric vessels divide the medial and lateral triangles from each other. Groin hernias are either inguinal or femoral. Inguinal hernias occur through the medial or lateral triangles and are termed direct or indirect inguinal hernias, respectively. As such, indirect hernias pass through the deep inguinal ring, lie anterior and medial to the vas deferens within the spermatic cord, and descend through the inguinal canal to the scrotum. These are more commonly congenital and arise from a patent processus vaginalis. Direct hernias pass directly through the floor of the inguinal canal and point anteriorly. This area in the floor of the canal is referred to as Hesselbach's triangle and is bordered by the lateral border of the rectus abdominis muscle, the inferior epigastric vessels, and the inguinal ligament. These are acquired hernias that are due to a weakness of the inguinal floor. A pantaloon hernia has both a direct and indirect component. Femoral hernias occur through the femoral triangle of the myopectineal orifice, medial to the femoral vessels and below the inguinal ligament. Femoral hernias are a variation of direct hernias in which the inguinal ligament prevents the sac from protruding through the inguinal floor. Instead, the sac passes through the femoral canal [14].

Inguinal hernias in elderly persons present very specific challenges. For example, they are frequently long-standing. Many have been present for 10–20 years, although some may have occurred as long as 50–60 years prior to presentation for repair [15–17]. As a result of the chronic nature of these hernias, the surrounding normal anatomic architecture is disrupted and there is loss of appropriate tissue planes to facilitate repair.

Furthermore, with age comes the anticipated loss of muscle mass and tissue strength, making an anatomic repair more difficult. By the age of 80 up to 40% of muscle mass may be lost, with a proportional increase in body fat [18]. Increased comorbidities in this age group can make elective repair challenging, but operative morbidity and mortality is still remarkably low. Prolonged neglect, however, can result in a high incidence of preoperative complications, such as bowel obstruction, incarceration, and strangulation. These conditions frequently necessitate emergency treatment. In a Swedish study, patients undergoing emergent operation for inguinal hernias were on average 12 years older than those undergoing elective repair (70 vs. 58 years old) [19]. However, data suggest that watchful waiting may be a viable option for some in this population [20, 21]. There is also increasing data to suggest that the use of laparoscopy and biologic materials may be of particular interest to this demographic. These issues will be discussed in more detail later in the chapter.

Etiology and Distribution

The etiology of groin hernias differs somewhat in the elderly population. Indirect inguinal hernias, which are often congenital, comprise 90% of the hernias in young men, but account for only 50–60% of hernias in older men. The incidence of direct hernias increases to 35% in men over age 65 years old [16]. Furthermore, the incidence of sliding hernias also increases from 0.5% during the third decade of life to as much as 13% during the sixth to eighth decades of life [22].

There are several reasons for this shift in the incidence of hernia types with age. Acquired hernias are more common with increasing age and are often associated with other physiologic changes or disease processes. In most cases the pathophysiologic mechanism of an acquired hernia is a structural inadequacy of the inguinal floor, which manifests as a direct inguinal hernia. A recent study compared the structure of the rectus sheath in patients undergoing inguinal hernia repair and those undergoing appendectomy and found a significant difference between the patients in terms of alignment and quality of collagen and elastic fibers. In those with inguinal hernias, there was increased disorganization of collagen fibrils, thinning of elastic fibrils, and generalized replacement with ground matter [23]. A similar study showed that these changes were present in the transversalis fascia of both the herniated side as well as the nonherniated side [24].

The inguinal floor may therefore be weakened by any factors that interfere with normal collagen and elastin production. These include congenital connective tissue disorders such as Marfan and Ehler–Danlos syndromes, as well as metabolic defects in collagen formation. Cigarette smoking also plays a significant role in hernia formation. The same proteases and elastases found in the lungs of smokers that lead to emphysema are also found in their serum and can bring about the destruction of elastin and collagen in other tissues. Systemic illnesses with an enhanced leukocyte response can also lead to the release of proteases and antioxidants having a similar effect [25].

Other factors associated with groin hernia formation involve conditions that lead to chronically increased intra-abdominal pressure, such as longstanding constipation and straining, bladder outlet obstruction, chronic cough, obesity, and kyphoscoliosis. Increased intra-abdominal pressure puts tremendous forces on the abdominal wall where there are natural weaknesses, such as the internal inguinal ring and the transversalis fascia. In the elderly patient, it is not uncommon for several of these predisposing conditions to be present simultaneously. Occasionally, this confluence of factors contributes to the development of a giant hernia or one with a large scrotal component. These hernias can become extremely large and may contain a significant portion of the abdominal viscera. When forced reduction of the viscera into the contracted abdominal cavity is attempted, severe respiratory compromise due to increased intra-abdominal pressure and decreased diaphragmatic excursion may occur.

Approximately 15–30% of all herniorrhaphies in the elderly are performed on an emergent basis as a result of incarceration. Overall, 50–60% are indirect and 17–25% are femoral. When separated by gender, 73% of incarcerated hernias in men are indirect and 15% are femoral, whereas femoral hernias account for 50% of incarcerations in women [15, 26, 27]. Although rare, once strangulation has occurred, the hernia changes from a simple mechanical problem to a complex life-threatening systemic illness, and the repair changes from correction of a simple mechanical defect to reversal of a major abdominal catastrophe.

Diagnosis

Up to one-third of patients with groin hernias are asymptomatic [28]. In 70% of patients, complaints typically include the presence of a groin or scrotal mass and pain in the inguinal region. Other symptoms include a heaviness or a dragging sensation in the groin which is often worse at the end of the day. The pain may also wax and wane if the hernia is reducible. In many cases the patient has been aware of, or diagnosed with, a hernia for many years.

Historic factors that contribute to the development of inguinal hernias should always be elicited. Respiratory symptoms with chronic cough, chronic constipation, and symptoms of bladder outlet obstruction are most prevalent in an older population. Examination for the presence of groin hernias should be part of the standard physical exam. Patients should be examined in the erect position, as a reducible hernia is sometimes more difficult to appreciate in the supine position. The only visible abnormality may be groin asymmetry.

Indirect inguinal hernias appear as a small mass in the region of the deep ring, midway between the pubic tubercle and the anterior superior iliac spine. Direct hernias appear more medially, although this distinction is not always clear. Invaginating the skin of the scrotum and introducing the examining finger along the spermatic cord structures into the external inguinal ring will allow for diagnosis. Prolonged standing or increasing intra-abdominal pressure by coughing or with Valsalva maneuver causes the sac and its contents to descend toward the examining finger, where it is felt as a mass or a transmitted impulse. A small hernia defect or a sac that is difficult to reduce presents the greatest risk for future incarceration. In women, inguinal hernias may be difficult to diagnose until they become quite large.

It is not always easy to distinguish an inguinal hernia from a femoral hernia. Femoral hernias more often present with poorly localized pain in the groin area without an obvious, visible bulge. It is important when examining the groin to include an examination of the upper thigh below the inguinal ligament in order to assess for femoral hernias. Most femoral hernias can be felt as a soft mass medial to the femoral vessels. Frequently, hernias in this location are mistaken for inguinal lymph nodes or lipomas. Increased intra-abdominal pressure may transmit an impulse through the sac, but this too can be mistaken for normal transmission of the increased pressure in the femoral vein. Unfortunately, because of these subtle findings, femoral hernias are frequently not diagnosed until they incarcerate. In one review of 83 femoral hernias over 40% were repaired emergently for incarceration [29].

The differential diagnosis of a groin mass is extensive and includes hernias as well as lipomas, lymphadenopathy, abscess, varicocele, hydrocele, testicular mass, testicular torsion, epididymitis, and femoral artery aneurysm [30]. Additionally, some patients with groin hernias may present with typical symptoms but demonstrate no visible bulge on exam. For these reasons, an imaging modality for the diagnosis of groin hernias has been sought for years. Ultrasound has been shown to have an accuracy of 92% for all groin hernias and a 75% accuracy for those without a palpable bulge (Fig. 3) [31]. Therefore, it may be a useful adjunct in qualified hands. Computed

tomography and MRI scans may also be beneficial in the evaluation of the difficult groin, with MRI having the highest sensitivity and specificity (Fig. 4) [32, 33].

The diagnosis of an incarcerated hernia is usually not difficult to establish. Most often patients present with a previously recognized hernia that has recently “stuck out.” In the case of a femoral hernia, a painful mass in the groin may be the first indication. Obstructive symptoms such as nausea, vomiting, and obstipation may not be present early in the course but develop if the incarceration goes untreated and progresses to strangulation. Notably, some patients may live with chronic incarceration and experience no symptoms [11]. Strangulation, or ischemia to the incarcerated portion, is indicated by increasing pain and signs of systemic sepsis. On physical examination, a tender, nonreducible mass is present in the groin. Erythema and edema of the overlying skin are suggestive of strangulation of bowel in a hernia sac, as is severe tenderness to palpation. Evidence of strangulation is an indicator for immediate surgical correction.

Numerous studies have shown an association between increasing age and risk for incarceration and strangulation of groin hernias [34–36]. A representative study reports incidence of incarcerated inguinal hernia as 16.8% in patients over age 65, compared to only 4.4% in younger patients [37]. Strangulation has been shown to occur in 1.3–3.0% of all groin hernias, most often in the elderly and children [38]. Indirect inguinal and femoral hernias are the most likely hernias to strangulate although scrotal and recurrent groin hernias have also been associated with increased risk for acute hernia surgery [39]. The probability that an indirect inguinal hernia will strangulate is reported as 2.8% within 3 months of diagnosis and 4.5% after 2 years, compared to 22% at 3 months and 45% at 21 months for femoral hernias [40]. Even among the elderly, older age groups have been shown to be at increased risk for requiring emergent repair, with one study reporting nearly that nonagenarians were three times more likely to present for emergent repair of groin hernias as compared to octogenarians (12% vs. 4.4%) [34].

Kulah et al. examined risk factors for strangulation and bowel resection in elderly patients with acutely incarcerated hernias. In examining 189 patients over 65 years old, it was found that femoral hernias were more frequently strangulated and required bowel resection at presentation. Although males were more likely to present with incarcerated hernias, females were likely to have strangulated hernias, possibly due to the increase in femoral hernias in this population. Late admission was also a significant risk factor for strangulation, bowel resection, and increased hospital stay. Importantly, morbidity increased from 15% to 33% when admission was delayed 48 h after onset of symptoms, and mortality increased from 2% to 9% [19].

Emergency Repair

The approach to an incarcerated hernia in the elderly depends on the nature of the incarceration. Chronic incarcerations pose less of a threat of strangulation and can be treated on an elective basis. Acute incarcerations, on the other hand, require immediate surgical treatment. Forceful attempts at nonoperative reduction may result in an en masse reduction of a compromised loop of intestine within the hernia sac. This ischemic bowel may not produce significant abdominal findings in the older patient until full-thickness necrosis and perforation occur. Any patient with skin changes or systemic symptoms – tachycardia, hypotension, fever, leukocytosis, or lactic acidosis – should raise suspicion for progression to strangulation which requires immediate surgical intervention.

The type of repair for incarcerated hernias depends to some extent on the viability of the contents of the hernia sac. A general or regional anesthetic is usually necessary. In the presence of inflammation, local anesthetic agents are usually not effective. In addition, the muscle relaxation provided by regional or general anesthesia may facilitate reduction of the incarcerated organ. If the incarceration is of short duration and there is no erythema or induration of the overlying skin suggesting strangulation, the choice of approach is less critical. Open anterior repair, which allows careful inspection of the sac contents outside the peritoneal cavity, is usually preferred. Frequently, a recently incarcerated hernia is reduced spontaneously or with minimal force when anesthesia is induced. In this setting, identifying the incarcerated loop of bowel through the hernia defect may be difficult but is usually not impossible.

Skilled laparoscopists may prefer to inspect the bowel and repair the hernia laparoscopically through a transperitoneal approach. A study examining TAPP repair of 28 strangulated inguinal hernias demonstrated a conversion to open rate of 10.7%, for either extensive adhesions or bowel distention. Morbidity was only 4% and there were no deaths or recurrences [41]. The same precautions mentioned previously for laparoscopic herniorrhaphy should be considered here.

If the incarceration is of longer duration or there are signs of local inflammation suggestive of strangulation, an open procedure is safest and most expeditious. Many surgeons prefer a direct anterior approach to the hernia. If ischemic bowel is found in the hernia sac, resection can generally be accomplished through the hernia defect. Open repairs are classified as either synthetic repairs (mesh is used) or suture repairs (tissue-only). If there is minimal contamination and broad-spectrum antibiotics are given, a synthetic mesh repair (Lichtenstein repair) is acceptable [42, 43]. If there is gross contamination or concern for bacterial translocation due to partial obstruction, prosthetic mesh should not be placed, and a suture repair method such as the Shouldice method should be used, accepting a higher risk of recurrence in exchange for a lower chance for infection. Others advise that if there is high suspicion for compromised bowel preoperatively, a small lower midline laparotomy or laparoscopy should be performed for more careful inspection of the bowel and a more controlled resection. After the abdomen is closed, an open anterior repair of the hernia with mesh can be accomplished through a re-prepared field. A detailed description of synthetic and suture repair methods can be found in the "Surgical Treatment" section of this chapter.

The consequences of emergency surgery in the elderly population cannot be understated. There is a threefold increase in morbidity and mortality after emergent operation, regardless of the type of procedure [44]. In addition to age, specific risk factors linked to worse outcomes in emergent groin surgery include a history of COPD or dyspnea [36], delay between onset of symptoms and surgery greater than 12 h, femoral hernia site, nonviable bowel, and American Society of Anesthesiologists (ASA) class 3 and 4 [45]. In a Swedish study looking at over 100,000 patients presenting for groin hernia repair, mortality risk as compared to the general population was increased sevenfold for patients who underwent emergent groin operations and 20-fold for patients that underwent bowel resection [46]. Along with increased morbidity and mortality comes the increased need for intensive care and extended hospital stay in these patients, as well as rehabilitative services. Thus, for elderly patients with multiple comorbidities, emergent surgery could be devastating.

Watchful Waiting Versus Elective Repair

Surgical repair has been the gold standard of care for even asymptomatic hernias for decades. Awareness of complications from hernia repairs in addition to cost concerns and a predicted low annual incident of hernia accident have led surgeons to consider watchful waiting as a viable option for male patients with asymptomatic inguinal hernias. To further evaluate this option, Fitzgibbons et al. randomized over 700 North American patients with asymptomatic groin hernias to either open mesh repair or watchful waiting. Thirty-three percent of patients in each group were over 65 years of age. After 3 years of follow-up, pain and health outcomes were similar in each group. Eighty-five patients crossed over to the repair arm mostly because their hernias became more symptomatic. The rate of hernia accident was only 1.8 per 1,000. There were no deaths associated with hernia accidents [47]. This study seems to support a trial of watchful waiting in all asymptomatic or minimally symptomatic patients. A cost analysis performed as part of the Fitzgibbons study showed that a 2-year watchful waiting was a cost-effective option for such patients [48].

An additional study by O'Dwyer sought to answer a similar question looking at the geriatric population in the United Kingdom. One hundred and sixty patients over the age of 55 were randomized to watchful waiting or operation. Over 12 months, there were 23 patients who crossed over to the repair arm, which is over 20% of those randomized to watchful waiting. This article argues that given longer follow-up there would be more crossover to surgery and that elderly patients' health would only deteriorate over that time, making the risks associated with a hernia accident more severe [49]. In this study, like that of Fitzgibbons, the incidence of hernia accident (strangulation) was rare. There were two patients who crossed over from watchful waiting to repair and experienced significant postoperative complications not related directly to the hernia repair (myocardial infarction and stroke) but presumably to the decrease in the patient's overall health. Clearly as a patient ages, his or her general risks for undergoing any type of procedure increases. Notably, in both study populations, patients had presented to their doctors to discuss their hernias. Thus, the results may not be applicable to those patients with hernias who do not present to their physicians.

In updates to both studies, authors found that with increased follow-up there were increased rates of crossover from watchful waiting to surgery [20, 21]. In the North American trial, 68% of patients crossed over at 10 years; in the UK trial, 72% crossed over at 7.5 years. In both studies, increasing pain was the most common cause for crossover. Only a few patients required emergent hernia repair. A further analysis of the North American data showed that delaying hernia repair did not result in differences in hernia characteristics at time of surgery, degree of difficulty of surgery, or rate of surgical complications [50]. Recurrence rates were also similar between the immediate repair group and the crossover from watchful waiting group. From these studies, the authors concluded that although watchful waiting is a safe option, most patients with painless inguinal hernias will eventually develop symptoms warranting surgery [20, 21]. Thus, elective surgical repair should be considered in medically fit patients [21].

In an effort to optimize patient selection for watchful waiting versus surgical intervention, Sarosi et al. analyzed data collected from the American College of Surgeons Hernia Trial, a trial of 336 patients randomized to watchful waiting versus surgical repair for asymptomatic inguinal hernias. Five risk factors were found to be predictive of crossover to surgery: pain with strenuous activity, chronic constipation, prostatisim, being married, and good health (ASA Class 1 vs. 2). From this data, a crossover risk worksheet was created for clinicians to use when presented with a male patient with asymptomatic hernia. While ~1/3 of Sarosi's study population was patients older than 65 years of age, most were white and ASA I or II, making the generalizability of the results to a larger elderly population unknown [51].

Studies have shown that elderly patients undergoing elective inguinal hernia repair experience similar rates of complications as compared to the younger population [34, 39, 52]. In a retrospective review of NSQIP data on nearly 20,000 patients undergoing inguinal hernia repair (open and laparoscopic), Wu et al. found that overall mortality was extremely low for all ASA classes (<0.2%), even in patients older than 80 years of age. However, the data demonstrated an increase in mortality with emergent repair that was related to age (0.6% with age <65 years of age compared to 10.3% with age >80 years of age). No increase in mortality relating to age was seen in elective repair. Additionally, although an odds ratio analysis showed an increased risk of mortality and morbidity with COPD, dyspnea, smoking, hypertension, and diabetes, the overall risk was still low, leading the authors to conclude that elective hernia repair in elderly patients, even those with comorbid conditions and those older than 80 years of age, is safe [53].

Although surgical repair of groin hernias appears to be safe for elderly patients in general, not all elderly age groups may fare the same. To better assess the risk of increasing age on outcomes, a review of over 2,000 patients aged 80 years or older in the NSQIP database who underwent inguinal hernia repair was performed. Compared to octogenarians, nonagenarians had an increased 30-day overall complication rate as compared to octogenarians (6.1% vs. 3.2%). Mortality was increased tenfold (3 vs. 0.3%). Preoperative variables associated with increased morbidity included totally dependent functional status, congestive heart failure, and emergent nature of the procedure. Preoperative variables associated with increased mortality included older age, emergency repair, and having an open wound. From these results, the authors concluded that elective inguinal hernia repair could be safely performed in octogenarians with low morbidity and mortality but is increased in nonagenarians [34].

Anesthesia

The first step in elective hernia repair is the choice of anesthesia. Avoiding anesthetic techniques that place unnecessary stress on cardiac, pulmonary, and renal reserves may minimize the surgical morbidity and mortality. This is more important in elderly patients who often present with multiple comorbidities. Both general and spinal anesthetic techniques are associated with perioperative complications. Guillen and Aldrete reported that in men over age 70 undergoing elective inguinal hernia repair the incidences of hypotension with spinal and inhaled anesthetic were 43% and 36%, respectively [54]. In a randomized trial of local versus general and regional anesthesia, those patients receiving local anesthesia had less postoperative pain, fewer micturation complications, and shorter hospital stays. These results have been backed up by multiple other studies [55–57]. These data support the concept that local field block is the ideal anesthesia method for elective hernia repair in the geriatric age group. There are, however, a few limitations to this method. Patients with dementia or those who for other reasons are unable to understand commands and lie still on the operative table, as well as those who are unusually anxious, are considered poor candidates for local blocks. The excessive use of sedation necessary to control these patients frequently worsens the confusion and results in respiratory complications, which defeats the whole purpose of using local anesthetic. Further problems are encountered in obese patients for whom adequate local anesthesia may not be achievable because of limitations in dose and absorption.

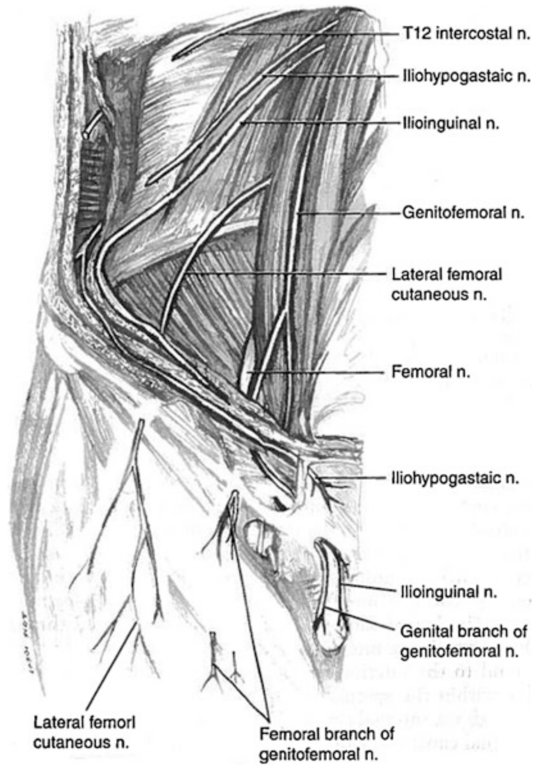

Fig. 5 Nerve supply to the groin (from Mulvihill; Surgery: Basic Science and Clinical Evidence; 2001, reprinted with kind permission of Springer Science + Business Media)

With a detailed understanding of the neuroanatomy of the inguinal region, painless inguinal herniorrhaphy may be accomplished in the elderly patient. The innervation of the inguinal region is complex (Fig. 5). A clear understanding of the intercostal nerve supply is paramount. Following the pattern of dermatome distribution, the tenth thoracic nerve innervates the umbilicus, the first lumbar nerve innervates the inguinal area, and the twelfth thoracic nerve innervates the area in between. The iliohypogastric and ilioinguinal nerves lie deep to the external oblique fascia and lateral to the anterior superior iliac spine. The iliohypogastric originates at the first lumbar nerve and lies under the external oblique aponeurosis after penetrating the internal oblique muscle. This nerve supplies sensory fibers to the suprapubic region. The ilioinguinal nerve follows the same course as the iliohypogastric nerve but lies

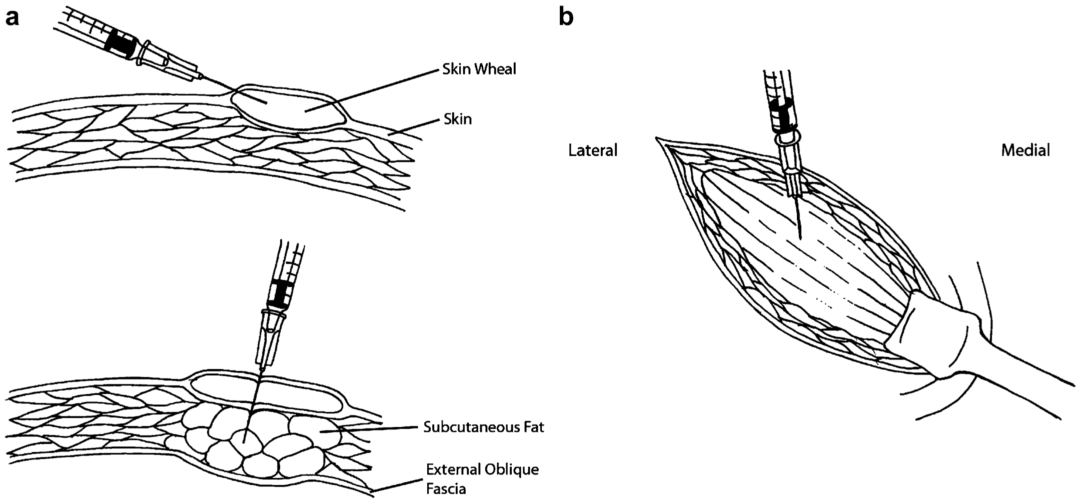

Fig. 6 (**a**) Making the skin wheal. (**b**) Subfascial infiltration

closer to the crest of the ileum and inguinal ligament. The ilioinguinal nerve penetrates the internal oblique muscle approximately 1.0 cm from the anterosuperior iliac spine and supplies sensory innervation to the base of the penis and part of the scrotum (and comparable areas in the female body). The penile skin and a small area of the scrotum are supplied by sensory fibers from the sacral plexus.

When repairing a femoral hernia, more attention must be paid to the ilioinguinal nerve and the femoral branch of the genitofemoral nerve, which supply the upper thigh. The genitofemoral nerve originates from the first and second lumbar nerves to supply sensory fibers to the scrotum and upper thigh and motor fibers to the cremasteric muscle via the genital branch. The genital branch reaches the inguinal canal at the internal abdominal ring. When performing herniorrhaphy under local anesthesia, pain is also felt when traction is applied to the sac or the spermatic cord or when a finger is inserted into the peritoneal cavity. Knowledge of this anatomy is also paramount during the operation to avoid injury to these nerves and thus postoperative inguinodynia.

A simple five-step method has been advocated for the use of local anesthetic during inguinal herniorrhaphy. Appropriate use of this method requires minimal IV sedation with Midazolam and does not necessarily require monitoring or the use of anesthesia staff. A 50:50 mixture of 1% Lidocaine and 0.5% Bupivicaine is used. (1) Approximately, 5 mL of solution is injected subdermally along the entire length of the proposed incision. (2) A skin wheal is then raised using an additional 3 mL along the same path. (3) A total of 10 mL is then injected subcutaneously 2 cm apart. (4) After making the skin incision and beginning to expose the external oblique fascia, 10 mL of solution is injected directly underneath the fascia. This bathes the entire inguinal canal and should anesthetize all three major nerves in this area. (5) Additional injections of a few milliliters of solution may also be injected into the pubic tubercle and the hernia sac and additional solution may be used to bathe the incision prior to closure of the external oblique as well as the skin (Fig. 6a, b) [58]. In this era of cost analysis and health-care economics, inguinal herniorrhaphy is becoming predominantly an outpatient procedure. Even though outpatient general anesthesia is possible, local block facilitates earlier ambulation and is associated with fewer immediate postoperative complications.

Surgical Treatment

Hernia repair may be performed either through an open approach or a laparoscopic approach. Open repairs may be either tissue-only "tension" or suture repairs, or they may be "tension-free" synthetic mesh repairs. Laparoscopic repairs involve two main methods: transabdominal preperitoneal (TAPP) and totally extraperitoneal (TEP).

Suture Repair

Inguinal hernia repair has previously been dominated by an anterior, open approach that uses sutures to reconstruct the inguinal floor with no placement of mesh. This basic tenet of hernia repair has undergone many modifications, with various combinations of suturing the transversalis fascia, conjoint tendon, internal oblique muscle, or transversus abdominis muscle to the inguinal or Cooper's ligament. One of the earliest suture repair techniques was the Bassini technique, first described in 1887 by Edoardo Bassini. In the Bassini technique, the inguinal floor (transversalis fascia) is divided, and the superomedial portion of the fascia along with the conjoint tendon is sutured to the inguinal ligament. Since its first description, the Bassini suture repair has undergone numerous modifications including the Shouldice repair, a technique still used today in select centers. The Shouldice repair, similar to the Bassini repair, opens the inguinal floor; excises redundant, weakened transversalis fascia; and reconstructs the posterior wall using a four-layered suture closure of transversalis fascia flaps [59].

Regarding femoral hernia repairs, one of the classic suture methods described is the Cooper's ligament repair, or the McVay technique. With this technique, the aponeurosis of the transversus abdominus and the transversalis fascia (conjoint tendon) are sewn to Cooper's ligament from the pubic tubercle to the femoral vein. The floor is restored by suturing the femoral sheath to the Cooper's ligament [12].

Synthetic Repair

In 1909, McGavin was the first to use a prosthetic material, a filigree of silver wire, to repair an inguinal hernia [60]. Throckmorton introduced tantalum gauze for use when there was insufficient tissue for adequate primary tissue repair. This material, however, did not prove to be durable. During the 1950s and 1960s, Usher et al. used polypropylene mesh to bolster primary tissue repairs of direct and indirect hernias [61–63]. The premise behind using synthetic materials is to provide a tension-free repair with fewer recurrences and a quicker return to normal activity. It was not until 1986, with the published work of Lichtenstein and Shulman, that synthetic mesh became accepted for primary hernia repair without approximation of the underlying hernia margins (Fig. 7) [64]. With this technique, one single layer piece of mesh is secured over the inguinal floor with a slit to go around the internal ring.

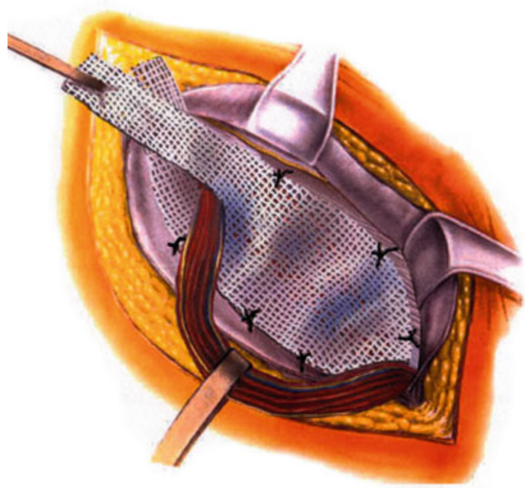

Fig. 7 Lichtenstein repair (from Fitzgibbons RJ, Jr., Abdominal Wall Hernias, Fig. 8. Available at: http://knol.google.com/k/bob/abdominal-wall-hernias/Ilo7ZexB/MyZquQ#What_is_an_abdominal_wall_hernia(3F). Reprinted with kind permission of Springer Science + Business Media)

Data regarding recurrences with a particular hernia repair technique can be difficult to interpret because so much of it comes from specialized hernias center. However, in a recent study comparing the Shouldice (a tissue repair) and the Lichtenstein repair in a general surgery practice, recurrence rates for the mesh repair were 0.7% compared to 4.7% for the tissue repair [65]. A meta-analysis comparing over 11,000 patients from various institutions demonstrated an overall recurrence rate of 2.0% for Lichtenstein mesh repair compared with 4.9% for various tissue repairs and persistent groin pain in 5.1 and 10.1% of patients, respectively [66]. Additionally, a 2002 Cochrane meta-analysis reported a 50–75% decreased risk of hernia recurrence as well as a lower risk for chronic inguinodynia and an earlier return to work with the tension-free approach [67]. Although the Shouldice repair for inguinal hernias has been shown to have a recurrence rate of less than 1% in experienced hands [68], non-specialized centers have been unable to achieve this same low rate [69–71], suggesting that the learning curve is too steep [72]. Suture repairs are typically now used only in cases where mesh may be contraindicated, such as infected or grossly contaminated fields [11].

Since the institution of the Lichtenstein method was first described, a multitude of other methods have attempted to supplant it. The plug-and-patch system was first described in 1993 and utilizes a polypropylene mesh plug to obliterate the defect in the internal ring or the inguinal floor. An additional patch is often used to provide additional support to the inguinal floor (Fig. 8) [73]. Recurrences remain as low as the Lichtenstein method but complications of plug migration and shrinkage have been reported [74].

The Kugel Patch consists of two layers of mesh placed preperitoneally through an anterior approach, thus placing the mesh where it would be placed during a laparoscopic approach. A small muscle splitting incision is used to gain access to the preperitoneal space [73]. Though initial results were very promising showing a recurrence rate of 0.45, these results have never been reproduced and there is a very steep learning curve with recurrence rates as high as 18.2% in the initial learning period and rates as high as 27.8% for recurrent hernias [75, 76].

The Prolene Hernia System (PHS) is another method of prosthetic repair. It consists of two pieces of mesh that serve to overlay and underlay the inguinal floor attached by a mesh connector that is placed either through the internal ring or a defect in the transversalis fascia. The benefits of the PHS are that it touts to repair indirect, direct, and femoral hernias all at once by covering the entire myopectineal orifice preperitoneally [73]. Theoretically, this should reduce hernia recurrence through the lateral triangle of the orifice. As of now, studies demonstrating long-term recurrences with the PHS have not been performed but preliminary results show similar operating times and short-term recurrence rates as both the Lichtenstein and plug-and-patch methods. Some studies have demonstrated less pain with the PHS (Fig. 9) [77, 78].

Currently, there are no studies comparing any of the above techniques specifically in the elderly population. In fact, the majority of studies exclude elderly patients or those with elevated ASA status. It would stand to reason though that any repair amenable to local anesthesia with a relatively

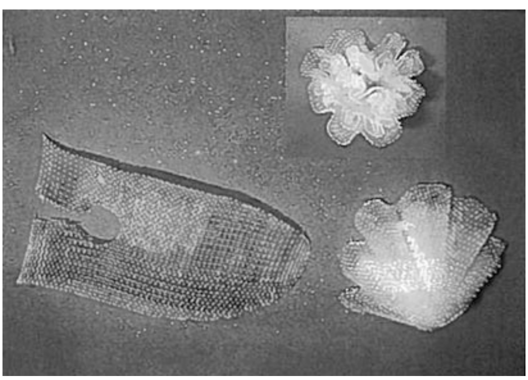

Fig. 8 Plug and patch repair (from Mulvihill; Surgery: Basic Science and Clinical Evidence; 2001, Chap. 43; reprinted with kind permission of Springer Science + Business Media)

Fig. 9 Placement of the Prolene Hernia System

short operating time in the hands of experienced surgeons would suit the elderly population well. Currently, all of the above techniques qualify.

Laparoscopic Repair

Shortly after the success of laparoscopic cholecystectomy became apparent, surgeons began to apply minimal access techniques to a wide variety of other surgical procedures. This approach has become generally accepted for some procedures, whereas for others there is still disagreement. Hernia repair is one of the latter group. Although some skilled laparoscopists prefer the approach for all inguinal hernias, others believe the benefits do not outweigh the risks, particularly in the elderly.

The laparoscopic approach to the inguinal hernia may be performed by either a transabdominal preperitoneal (TAPP) approach or a totally extraperitoneal (TEP) approach. In a TAPP repair, the abdomen is entered in the typical laparoscopic fashion and, once anatomy is appropriately identified, a peritoneal flap is made. The hernia sac is then reduced and dissected free. A piece of mesh is then rolled out over the entire myopectineal orifice and, in most instances, is tacked in place being careful to avoid the bladder and the epigastric vessels. The peritoneal flap is replaced and tacked in place as well (Fig. 10). In the TEP repair, the preperitoneal space is entered. This is most often done with a balloon dissector placed through the umbilical port (Fig. 11). Once the preperitoneal space is insufflated the anatomy of the groin is identified and the hernia sac dissected in a similar fashion as the TAPP repair. Mesh is placed and may be tacked in place. Any defects in the peritoneum are repaired. Previous lower abdominal incisions and radiation are a relative contradiction to the TEP repair, due to the difficulty of dissecting the peritoneum free from the abdominal wall [79].

The difficulty when operating from either the TAPP or the TEP approach is the ability to obtain adequate exposure of the inguinal anatomy. Most recurrences are due to incomplete dissection of the region or inadequate placement of mesh to cover

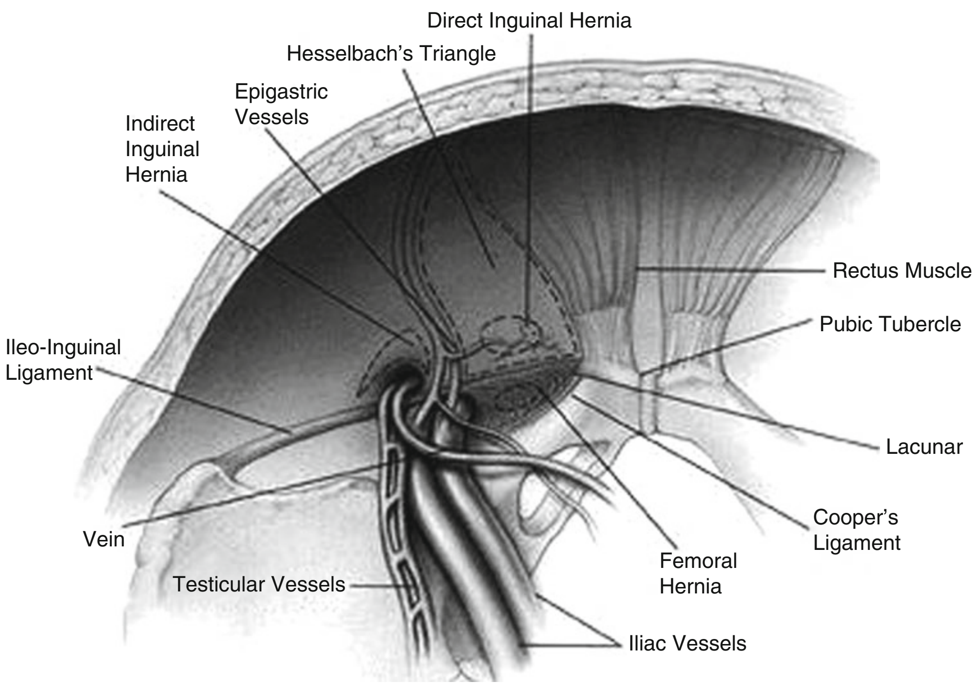

Fig. 10 View of inguinal anatomy (printed with permission from Charles H. Booras, M.D., All about Inguinal Hernias: Symptoms and Causes 5/16/98 http://jaxmed.com/articles/surgery/inguinalhernia.htm)

the defect. The TAPP repair provides the largest operating space and the most unobstructed view of the inguinal region and is probably the procedure of choice when learning to perform laparoscopic herniorrhaphy and master the elements of the preperitoneal space. There is no doubt that the more proficient a surgeon is in either of these techniques, the fewer complications they will encounter.

Reported advantages of laparoscopic inguinal herniorrhaphy include less postoperative pain, reduced recovery time and earlier return to full activity, and improved cosmesis. The laparoscopic approach also has the advantage of allowing access to both groins through a single set of incisions, making it the preferred approach for repair of bilateral primary hernias [80–82]. Although the increased time to return to full activity may be an important consideration in a young person, the length of recovery may not be as important in old patients so long as mobility is not significantly compromised. Postoperative pain after the tension-free open approach is rarely severe enough to curtail activity.

There are some significant disadvantages to the laparoscopic approach. Laparoscopic herniorrhaphy requires general anesthesia, is frequently performed by a transperitoneal route, is technically more difficult to understand and learn than open mesh repairs, and in most hands, takes considerably longer. In comparisons of anesthetic techniques for open hernia repair, general anesthesia in the elderly is associated with far higher complication rates than local anesthesia. Therefore, the need for general anesthesia alone could obviate most of the benefits of the laparoscopic approach in some elderly patients. Notably, laparoscopy carries an additional risk for serious vascular and visceral injuries, which in any age group could be devastating (0.9 and 1.8 per 1,000, respectively) [83]. A history of prior pelvic surgery should be weighed carefully when considering laparoscopic repair, as adhesions may make visualization of relevant anatomy very difficult. For those with compromised cardiovascular reserve, laparoscopic repair should be approached cautiously due to the possibility that the patient will not tolerate pneumoperitoneum [84]. Laparoscopic repair has also been shown to be more expensive with some arguing that the increased cost is offset by quicker return to work [85]. In the elderly population where fewer are working, this cost offset may not be as relevant.

Reports of differences in recurrence rates between laparoscopic versus open mesh repairs have been inconsistent. A meta-analysis performed in 2003 compared open versus laparoscopic tension-free herniorrhaphy in over 7,000 patients at 41 facilities and found no significant difference in recurrence between the two repairs. One year later, a multicenter, randomized trial of 2,000 patients found that recurrences were more common in the laparoscopic group 2 years after primary repair (10.1% vs. 4.9%) [86]. In 2015, a large cohort study of more than 125,000 patients reported a reoperation rate of 4.1% in laparoscopic repairs versus 2.1% in open tension-free repairs at 1.5 years after primary herniorrhaphy. Perhaps most notably, the study also found that surgeon case load was strongly inversely related to reoperation after laparoscopic repair of primary inguinal hernia but not after open repair [87]. Because there is a steep learning curve in laparoscopy, some surgeons may prefer to reserve the laparoscopic approach for bilateral and recurrent hernias. Although studies have reported an increasing rate of laparoscopic repairs in the United States and Australia [53, 88], open repair continues to be the most common repair type in many places [89–91].

There is a paucity of studies specifically involving the elderly population and herniorrhaphy techniques. One study evaluated 110 patients over 65 years old with an ASA of either 2 or 3. Laparoscopic operative time was longer than that for open repairs; however, return to work was similar. Fifteen percent of patients experienced complications, the overwhelming majority of which were urinary retention. There was an alarmingly high recurrence rate of 9.7%. Hospital length of stay correlated with ASA status, but recurrences, complications, and return to activities did not [92]. A more recent retrospective review of 104 octogenarians who underwent laparoscopic versus open inguinal hernia repair found no difference in perioperative complications or length of stay between the two repair types. Postoperative urinary retention was more common in the laparoscopic group [93]. A similar study found no significant differences in operating room time, morbidity, or mortality related to the surgery, but found that the length of stay was significantly longer in the open group (1 day vs. 0 days in the laparoscopic group) [94]. Though laparoscopic hernia repair in the elderly appears safe [84, 92, 95–97], its superiority to open repair for primary, unilateral hernias in this population has not yet been determined.

Of note, in addition to a general lack of data regarding specific herniorrhaphy techniques in the elderly, there is even less data regarding female patients. Given the higher frequency of femoral hernias in the female population, the difficulty in diagnosing femoral hernias, and the resultant concern for strangulation, women are often excluded from trials and taken to the operating room faster. If the Lichtenstein approach is used to treat a groin hernia in a female, the entire femoral region may be missed [98], leading experts to recommend that all groin hernias in women be repaired laparoscopically [98–101].

Bilateral Hernias

Numerous authors have recommended that patients with bilateral groin hernias should have both hernias treated at the same time and that the laparoscopic approach should be considered [85, 93, 102–105]. This treatment plan allows for one administration of anesthesia and limits the number of incisions. Bilateral hernias should be managed with a single piece of mesh, large enough to cover both groins, the so-called bikini repair [106]. In patients with multiple comorbidities especially those with decreased cardiopulmonary reserve, the laparoscopic approach may be less ideal due to the need for general anesthesia, the physiologic changes seen with the induction of pneumoperitoneum, and the potential increased length of operating time with inexperienced surgeons. An alternative approach is to first repair the more symptomatic side using an open technique. After the patient recovers from the initial procedure, an open repair of the contralateral side may then be pursued.

Recurrence

When performing hernia repairs, the primary focus of success is determined by the incidence of recurrence. There is a wide variation in the time frame over which recurrences are reported. Hernias recur for one or more reasons: tension on the tissues created by the repair, inherent abnormalities in collagen that predispose to the development of new hernias, an unrecognized second hernia component at the time of the initial repair (usually a small indirect component), and technical error. Hernia recurrences can be classified as early or late. Most early recurrences are due to undue tension on the repair. For instance, when a hernia is due to a defect of the musculofascial abdominal wall, covering the defect with endogenous tissues results in suturing together tissues that are not normally juxtaposed. This then subjects these structures to undue tension [107]. Suture lines under tension exhibit an inadequate fibroblastic response for healing, which results in a weak scar and a subsequent recurrence of the hernia. Furthermore, these suture lines are subject to the same degenerative process that resulted in the initial herniation. The increasing use of tension-free repairs has significantly reduced this type of recurrence.

Late recurrences are usually due to missed components or new hernias at the site of a previous repair or in a new location. This type of recurrence is more appropriately termed reherniation. Following a mesh repair, reherniation occurs because the mesh was not sutured in place or it was not of sufficient size to cover beyond the inguinal floor. Progression of tissue degeneration is of great concern and can be compensated for by placing a large sheet of mesh underneath the external oblique aponeurosis well beyond Hesselbach's triangle. This dissection is extensive but can be necessary, particularly in some patients with severe tissue loss. This is of particular importance when performing a preperitoneal or laparoscopic repair. Appropriate and extensive dissection of the entire myopectineal orifice is necessary to facilitate choosing the right size mesh and performing appropriate fixation. The most common causes of failure are mesh size being too small or inappropriate fixation either inferomedially or inferolaterally [108, 109]. Another study found that the vast majority of recurrences after laparoscopic herniorrhaphy were medial. For this reason, a large piece of mesh should be chosen, sufficient enough to cross the midline with multiple tacks in the pubic tubercle and Cooper's Ligament (Fig. 12).

Patient risk factors for recurrence of hernias are similar to those for the formation of primary hernias. It would stand to reason that the elderly would be more susceptible to recurrence because of an increased risk of those factors already known to cause hernias: obesity, chronic cough, constipation, bladder outlet obstruction, and general degradation of tissue. Age >50 has been shown to be an independent risk factor as well. Those undergoing repair for a recurrent hernia are at greater risk for recurrence than those undergoing a primary repair, as are those with two or more relatives who also suffered from a recurrence [110].

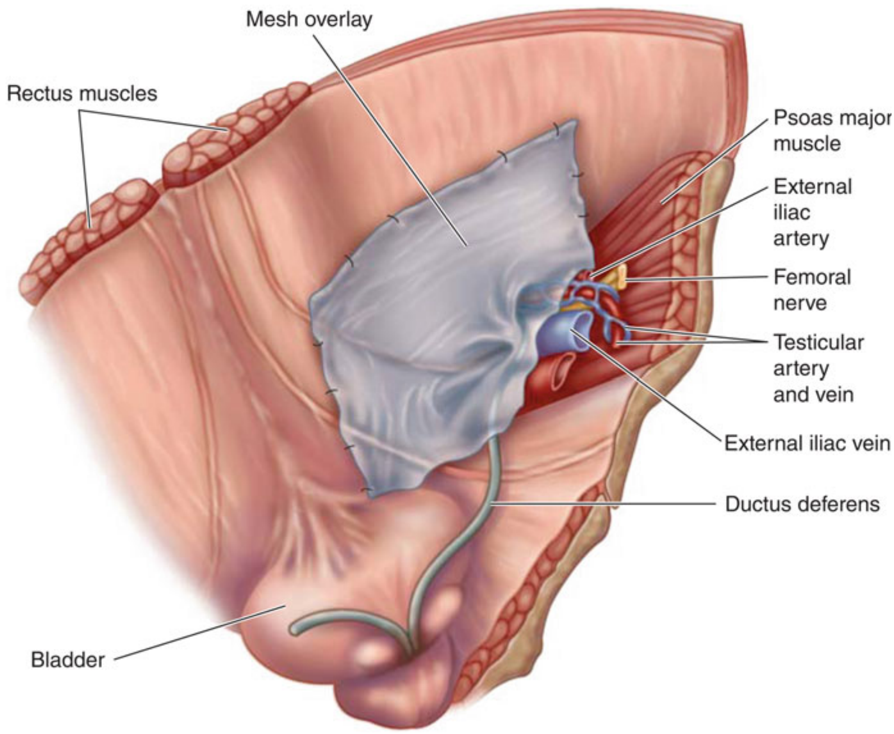

Fig. 12 Appropriate placement of mesh in a laparoscopic hernia repair (from Online Laparoscopic Technical Manual, Laparoscopic Inguinal-Femoral Hernia Repair, Step 5, Deploying and Anchoring the Mesh; http://www.laparoscopy.net/inguinal/ingher11.htm)

For recurrences after open repair, laparoscopic repair is preferred because it allows for dissection through un-operated tissues. For this same reason, the open approach is preferred for hernia recurrences after laparoscopic repair [111]. Notably, in the 2004 large, multicenter, randomized trial previously mentioned, rates of recurrence after repair of recurrent hernias was similar between the laparoscopic and the open tension-free groups (10.0% and 14.1%, respectively) [86]. This finding has been supported by multiple studies [87].

Inguinodynia

As recurrence rates continue to decrease with advances in inguinal hernia repair techniques, a greater emphasis is being placed on other complications of the surgery. One of the most common is inguinodynia or inguinal pain. Although not proven, the potential causes include partial transection or entrapment of a nerve, which eventually leads to neuroma formation and chronic pain. In an open repair, the most common nerves involved are the ilioinguinal, iliohypogastric, and genital branch of the genitofemoral nerve. All three of these nerves supply sensation to the genitals and medial upper thigh. Refer to the previous section on anesthesia for a more in-depth discussion of this anatomy. The nerves most commonly injured during laparoscopic herniorrhaphy are the lateral femoral cutaneous nerve (supplying the upper lateral thigh), and the femoral branch of the genitofemoral nerve (supplying the skin over the femoral triangle), all of which lie near each other. These nerves lie near each other in a space nicknamed the “triangle of pain” (Fig. 13).

A study from the Swedish Hernia register examined 3,000 patients undergoing unilateral primary hernia repair. All techniques (tissue, mesh, laparoscopic) were examined. Overall, 30% of patients were still experiencing pain over

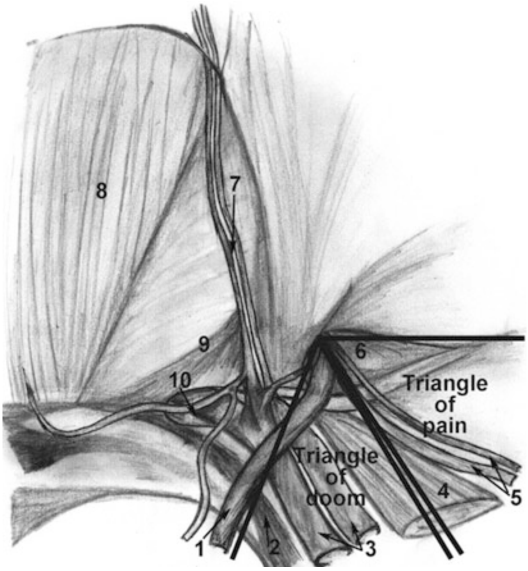

Fig. 13 Triangles of doom and pain – representing where injuries to vessels and nerves occur, respectively, during a laparoscopic inguinal hernia repair (from [92] © Moore and Hasenboehler; licensee BioMed Central Ltd. Available from: http://www.pssjournal.com/content/1/1/3)

a year after surgery and 6% were having significant enough pain to impair their activities of daily life. Risk factors for inguinodynia included age, with those >59 years old having significantly less pain than those younger (21 vs. 33%). Patients having pain prior to their operation were more likely to continue to experience pain afterwards. Operative technique was also important. Anterior approaches, either tissue repair or mesh repair, had the highest incidence (~30%), whereas preperitoneal repair, either open or laparoscopic, had a significantly lower incidence (~20%) [112].

A more recent study looked at chronic pain and numbness in 750 patients up to 5 years after undergoing either laparoscopic TEP repair or open tension-free repair of inguinal hernias. The data demonstrated a higher rate of groin pain in the open group versus the laparoscopic group, although the difference diminished with time – 7.9% difference at 12 months, 5.1% at 24 months, and 2% at 60 months. At all time points, the open group reported groin numbness at rate nearly twice that of the laparoscopic group. There was no difference in thigh numbness between the groups [113].

During an open repair, careful dissection and identification of all the nerves is the best way to avoid injury. If injury is already suspected, complete transection of the nerve is preferable. During laparoscopic repair, careful dissection is also important, as well as judicious tack placement avoiding the "triangle of pain." Some have advocated not securing the mesh, which effectively alleviates this problem [28]. Recent studies have advocated prophylactic ilioinguinal neurectomy during open hernia repair. A double-blind randomized study showed a significant reduction in groin pain in the neurectomy group (8 vs. 28%) without any difference in postoperative numbness [114].

Patients suffering from injury to these nerves typically have pain in the immediate postoperative period, which intensifies over the next few weeks. In most cases, it will regress over 2 months, and in up to one-third of patients it will completely resolve by 6 months [11]. Thus, the initial management consists of injections of local anesthetic and corticosteroids, as well as analgesics and anticonvulsants. In refractory cases, the surgical treatment of choice is a triple neurectomy of the ilioinguinal, iliohypogastric, and genitofemoral nerves. This has shown 85% complete resolution and 15% partial resolution of pain in some case series [115].

Incisional Hernias

Incisional hernias in the elderly are common and often can be challenging to repair. The incidence of hernias in patients with a midline surgical incision is 10–15% [72]. Often, incisional hernias are also referred to as ventral hernias although the term ventral hernias also encompasses epigastric hernias. The etiology of these hernias is often multifactorial. Wound infection, suture failure, malnutrition, increased age, obesity, excessive abdominal straining, smoking, ascites or peritoneal dialysis, chemotherapy, steroids, and tension on the wound closure are factors that have been implicated. Only 60% of these patients will go on to develop symptoms [72]. This typically begins with a noticeable bulge in a previously healed incision. Incarceration is the presenting symptom in 17% of patients leading to a perioperative mortality rate three times higher than that for elective repair [116].

Repair of minimally symptomatic or asymptomatic ventral hernias has remained controversial. Due to concerns for enlargement with time making repair more difficult and due to concerns for incarceration of small bowl obstruction, elective repair of ventral hernias has been recommended [47]. However, primary care physicians may recommend watchful waiting for some of their patients, especially those with multiple comorbidities [117, 118]. More data is needed to better guide recommendations. Recently, a study of 41 patients assigned to watchful waiting for ventral hernia management found a low risk of hernia accidents at 2 years and no change in disease-specific quality of life, leading the authors to suggest that a trial of watchful waiting may be safe for management of minimally symptomatic incisional hernias [47].

There are several special considerations for patients seeking elective incisional/ventral hernia repair. First, patients with a history of falls and difficulty ambulating who may require a large abdominal incision should be approached cautiously as falls in the early postoperative period could lead to dehiscence. Second, patients with breathing difficulties such as those with chronic obstructive pulmonary disease (COPD), asthma, bronchitis, or Pickwickian syndrome may have difficulty with pneumoperitoneum required for laparoscopy, difficulty weaning off of the vent after a large incisional hernia repair, and difficulty wearing a binder postoperatively. Other risk factors for adverse outcomes that have been identified include ASA classes 3 and 4, poor functional status, and COPD among others [119, 120]. Finally, just as in inguinal hernia repair, older elderly patients may fare worse than younger elderly patients. One study of nearly 5,000 patients ≥80 years of age who underwent laparoscopic ventral hernia repair demonstrated a more than threefold increase in mortality as compared to younger adults undergoing repair [121].

Technically, incisional/ventral hernias may be challenging for several reasons. First, it is possible for most of the abdominal contents to become a fixed part of the hernia, which may result in a decrease in the intra-abdominal compartment volume. This in turn complicates complete reduction of the contents at the time of repair. This is known as a loss of domain. Often, a components separation technique is required to reapproximate the abdominal wall when there is loss of domain and/or a large abdominal wall defect. Up to 20 cm of additional medial advancement of the rectus fascia can be obtained in the mid-abdomen with a bilateral components separation [122] either through an open or endoscopic approach. Mesh may be used to reinforce the repair. A second challenge in repairing ventral hernias is that the defects are usually multiple, reflecting failure of wound healing throughout the length of the incision. Identifying all the defects in the "Swiss cheese"-type abdominal wall and freeing all of the underlying adhesions may be tedious and time-consuming. Finally, extreme care must be exercised not to enter the bowel lumen during dissection because most incisional hernias are large and require synthetic materials for repair without tension. Biologic materials mentioned previously are now used to repair these hernia defects, especially in the presence of the contaminated operative field. They may also be used to overlay primary repairs to provide additional stability to weakened tissues, not uncommon to the elderly.

Laparoscopic techniques are being used with increased frequency to repair these large defects. Relative contraindications to laparoscopic approach include loss of domain, abdominal skin grafts, prior surgeries with planned removal of mesh, a small defect with a large sac, incarcerated hernias, active enterocutaneous fistula [123], and large oncological burden with a high chance of needing reoperation. Reported benefits of the laparoscopic approach include shorter length of hospital stay [124–127], decreased rate of wound infection [125, 126, 128], and no difference in recurrence rate as compared to the open technique [125–128]. Additionally, one study found no increase in complications with the use of laparoscopic repair in the elderly as compared to younger adults [129]. New Society of American

Gastrointestinal Endoscopic Surgeons (SAGES) guidelines reflect these findings and point to decreased wound infection rates with the laparoscopic approach but no difference in recurrence or quality of life as compared to the open approach [123]. Further studies specific to the elderly population are still needed.

Umbilical Hernias

The umbilical hernia was first noted in 1 AD by the Hindu physician Charaka, who mistakenly believed it to be an abdominal tumor. Umbilical hernias present as 6% of all abdominal wall hernias. Ninety percent of umbilical hernias are acquired and 10% are congenital [130]. Those less than 2 cm upon birth are likely to close spontaneously. In adults, umbilical hernias occur through an umbilical canal that is bordered by the umbilical fascia posteriorly, the linea alba anteriorly, and the two rectus sheaths laterally [131]. The sac may include omentum, colon, or small bowel. These hernias typically present with complaints of a lump around the umbilicus, pain, or pressure. In adults, prompt repair is recommended after the diagnosis is made due to the increased risk of strangulation.

Umbilical hernias are common in cirrhotic patients and in those with ascites of other etiologies because of the increased intra-abdominal pressure against a thinned umbilical ring and fascia. Umbilical hernia is also an important consideration in patients on peritoneal dialysis. Dialysis must be interrupted and ascites controlled prior to repair to decrease the incidence of recurrence. There are significant difficulties in closing this type of hernia, in order to prevent complications such as ascitic leak, wound infection, and recurrence. Therefore, every effort should be made to avoid strangulation and protect the thin skin over the defect. When necessary, these hernias may be repaired under local or regional anesthesia. Primary repair is optimal, but occasionally a prosthetic or biologic material is needed for tension-free closure.

For years the "vest over pants" method of repair as first described by Mayo was the standard of care. As with inguinal hernias, mesh repairs have begun to supplant primary repairs. There are a variety of meshes available, from simple sheets, to plugs and a combination of the two. A recent study by Shankar et. al. investigated long-term outcomes in patients receiving umbilical hernia repairs. Recurrence rates were noted to be higher in those patients who received a primary repair (9.8% vs. 2.4) with complications between the two being insignificant. Of the factors studied, primary repair, diabetes, and liver disease were noted to be independent risk factors for recurrence. Obesity and ascites were also associated with increased risk of recurrence [132].

Richter's Hernia

A partial enterocele is a form of hernia that bears the name Richter's hernia after August Gottlieb Richter, who first described it in 1785. This hernia is unique because only one side of the bowel wall becomes entrapped in the hernia defect (Fig. 14). Richter's hernias are most often diagnosed in the sixth and seventh decades of life. It requires a small, firm defect for the bowel to partial protrude. The most common sites include femoral ring, inguinal ring, and fascial defects from previous incisions. The terminal ileum is most commonly

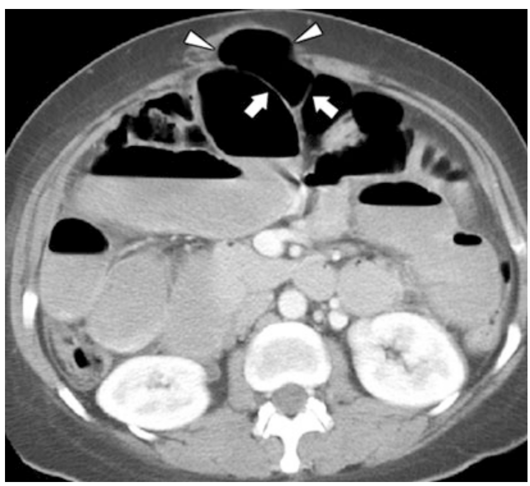

Fig. 14 Richter's hernia (from [93], reprinted with permission of the American Journal of Roentgenology)

implicated. Five to ten percent of these hernias will present as incarcerated and are diagnosed at the time of treatment [133]; however, the first indication of incarceration may not become apparent until strangulation and necrosis occurs. In those diagnosed, there is a notably longer delay to diagnosis and treatment resulting in higher rates of incarceration requiring small bowel resection in up to 50% of patients [134].

There is some concern that the incidence of Richter's hernia may be increasing as laparoscopic surgery becomes more prevalent. Small port-site hernias are the perfect size to involve only a small portion of the bowel. These hernias more commonly present in trocar sites that did not undergo fascial closure [135].

Obturator Hernias

Arnaud de Ronsil first described the obturator hernia in 1724 at the Royal Academy of Science in Paris. This hernia is rare, accounting for 0.05% of all hernias and 0.2% of bowel obstructions [136]. It is usually found in frail, elderly debilitated women, but may also be associated with profound weight loss in other groups. Obturator hernias may be bilateral or associated with hernias through the femoral canal. The obturator foramen, through which the hernia occurs, is the largest foramen in the body. The obturator membrane, however, occludes most of the foramen. The obturator canal consists of a 1–2 cm long and 1 cm wide opening in the superolateral part of the foramen. Usually, this canal is obliterated with fat, which prevents herniation of abdominal contents. In the frail and malnourished, this fat disappears and the potential space is unmasked.

A preoperative diagnosis is difficult because the complaints are not specific and the physical manifestations are minimal. A history of symptoms suggestive of intermittent or partial intestinal obstruction may be elicited. The Howship–Romberg sign – pain radiating down the medial aspect of the leg to the knee due to compression of the obturator nerve – is pathognomonic and is present in up to 50% of cases [29]. However, this sign is often overlooked in the elderly or attributed to other causes. The optimal way to look for an obturator hernia is with the patient supine and the thigh flexed, abducted, and externally rotated. The hernia mass is often concealed underneath the adductor muscles in the thigh. Occasionally, it is possible to feel a small mass on vaginal or rectal examination. The four indicators of obturator hernia – intestinal obstruction, Howship–Romberg sign, prior similar symptoms, a palpable mass on vaginal or rectal examination – are rarely seen together.

Many of the recent studies have looked at ways to decrease time to operative fixation in order to decrease mortality. Most obturator hernias are only correctly diagnosed at the time of operation, with only 30% diagnosed preoperatively. Several studies have looked at algorithms for diagnosis and care of obturator hernias. One should always be suspicious for obturator hernia in elderly patients with signs of bowel obstruction and no previous abdominal operation. Other signs and symptoms are mentioned above and include the Howship–Romberg sign and a palpable groin mass. CT scan should be obtained early in these patients and is the primary diagnostic tool for obturator hernias. CT scan is both sensitive and specific for diagnosis of an obturator hernia and can decrease the diagnostic time by 3 days. The treatment of an obturator hernia found on CT is urgent laparotomy or laparoscopy (Fig. 15). If no hernia is found on CT scan but the patient is exhibiting recurrent symptoms or partial

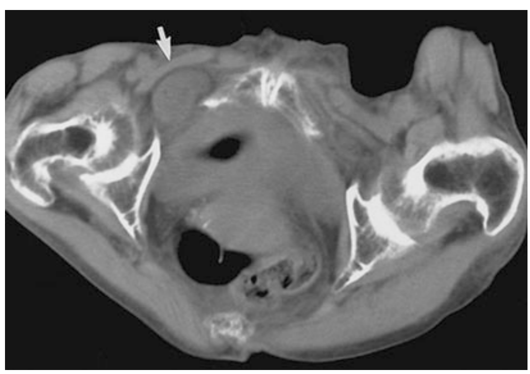

Fig. 15 Preoperative CT showing Spigelian hernia (from [94]. Available at: http://www.rcsed.ac.uk/Journal/vol45_3/4530046.htm)

obstructive symptoms, elective laparoscopy may be performed. It is important to note that one should not delay surgery while attempting to make the definitive diagnosis as these hernias can cause severe morbidity and mortality (up to 70%) [137, 138].

Primary repair of an obturator hernia is impossible because the surrounding tissues are immobile. Some studies have reported using sac ligation alone or flaps of bladder, periosteum, uterine ligament, or rib cartilage to close the defect [139, 140]. These repairs are unsuitable for large or bilateral hernias and may lead to postoperative pain and bladder dysfunction. A synthetic material is usually necessary. A plug system has been described as tension free and easy to perform; however, there is the potential for chronic obturator neuralgia [141]. If the diagnosis has been established preoperatively, the most suitable approach is an open preperitoneal repair, as described by Stoppa et al. [142]. With this repair, a large piece of mesh is placed extraperitoneally to cover both sides of the pelvic floor. If the viability of the incarcerated bowel is questioned once the hernia is reduced, the peritoneum may be opened. In the usual case where the diagnosis is not known preoperatively, an initial transabdominal approach with a preperitoneal mesh repair is optimal. The use of laparoscopic methods has also been described, but there is no current data supporting benefits of this approach.

Spigelian Hernias

The Spigelian hernia, another unusual abdominal wall hernia, is named for Adriaan van den Spiegel, who was the first to describe the semilunar line. The semilunar line is the demarcation from muscle to aponeurosis in the transversus abdominis muscle. Protrusion of a peritoneal sac, organ, or preperitoneal fat from its normal location through this aponeurosis is termed a spigelian hernia. These hernias are usually found at or near the arcuate line. This area is particularly weak due to the anterior position of the transversus abdominis aponeurosis, perforators of the epigastric artery that leave a fascial defect, and the orientation of the fibers of the transverse and internal oblique muscles [143]. Once the hernias enter Hesselbach's triangle, they are termed low Spigelian hernias. These hernias are often located within different aspects of the abdominal wall and may also be termed interparietal, interstitial, intermuscular, intramuscular, or intramural.

Spigelian hernias affect less than 1–2% of the population with hernia defects [144], but some authors have suggested this is an underestimate [145]. Patients most commonly are ages 40–70 years of age. Symptoms of Spigelian hernia include abdominal pain, obstruction, and palpable mass. It is uncommon for these hernias to be visualized directly on the abdominal wall due to the habitus of patients predisposed to them. Factors that may increase the risk of Spigelian hernia include increased abdominal pressure from obesity, rapid weight gain, COPD, multiple pregnancies, chronic constipation, ascites, and previous surgery [143].

The diagnosis is difficult in patients with defects too small to produce overt manifestations on the abdominal wall. It is best to examine patients by having them alternately tense and relax the abdominal wall. Imaging studies are usually necessary to elucidate the source of the localized symptoms. Ultrasonography is a good method for determining a hernia orifice and locating hernia contents. CT scan may also be used to examine the abdominal wall, but the sections must be close together to enable localization of the hernia orifice. Helical CT scans may increase the diagnostic yield. The CT scans may also provide information about the hernia sac and the nature of the abdominal contents in the sac (Fig. 16).

Due to a high risk for incarceration, surgical treatment is recommended. Both open and laparoscopic repairs may be performed [145]. A recent prospective randomized trial comparing open versus extraperitoneal laparoscopic repair showed significant improvement in complications and hospital stay in the laparoscopic group [143]. Regardless of approach, there is often enough laxity in the surrounding tissues to allow for primary closure, although mesh can be used [29].

Fig. 16 CT scan of obturator hernia (reprinted with permission from [91], Copyright © Radiological Society of North America. Available at: http://radiographics.rsnajnls.org/cgi/content-nw/full/21/2/341/F8)

Conclusion

Abdominal wall hernias in the elderly, whether common or unusual, are ultimately surgically correctable disorders. With the increasing number of elderly patients expected to present to general surgeons for evaluation of abdominal hernia, it is important that physicians are knowledgeable about the special considerations for this population. For each elderly patient, the physician should lead an open conversation focused on defining goals of care, assessing functional status, and identifying the specific risks and benefits for each intervention.

Recent studies have shown that watchful waiting may be safe for asymptomatic or minimally symptomatic inguinal hernias. Other hernias wherein the fascial defect is large can also be managed nonoperatively if not symptomatic. Pain is frequently what leads the patient to operative repair.

Elective repair of inguinal hernias, in particular, is safe even in patients with significant comorbidities. With local anesthesia and tension-free repairs, nearly all patients can ambulate immediately, and they can obtain excellent pain control with minimal oral pain medication. Complications are uncommon, and mortality is very low in many large series.

Patients with chronically incarcerated hernias are not at significant risk for strangulation while those with an acute incarceration do have some risk of progressing to strangulation. Therefore, acutely incarcerated hernias present more of an urgent to emergent situation, and surgical consultation early in the patient's course is of utmost importance.

Once strangulation has occurred, a hernia is no longer just a defect in the abdominal wall, and repair is not just patching the hole. The systemic consequences of bowel obstruction and ischemic tissue stress the limited reserves that define the physiologic state of the older patient. Once the inflammatory state is initiated, the cascade of events demands a response that the elderly are frequently unable to mount. Fluid and electrolyte imbalance, dehydration, and systemic sepsis become the major problems, and the mechanical issue of fixing the hernia defect fades in comparison. Morbidity and mortality rates soar.

For those hernias that are rare or the presentation more obscure, an increased level of awareness is necessary to avoid the consequences of incarceration. Although we may have to accept the higher complication rates that accompany the unusual hernia, we should never allow the common hernia to progress from a simple mechanical problem to a deadly systemic illness.

Abstract

Benign conditions of the esophagus and esophagogastric region may have implications in elderly patients that differ from those encountered in younger age groups. Special consideration must be given to the unique presentations as well as to the physiologic impact of treatments and treatment complications in this vulnerable population. Minimally invasive approaches are now preferred for most esophageal diseases that require surgical treatment. Despite these and other improvements in therapy, benign esophageal disorders continue to present great challenges to practitioners treating the geriatric population.

Gastroesophageal Reflux Disease

The full spectrum of gastroesophageal reflux disease (GERD) symptoms and complications are observed in elderly patients and present specific management considerations. Although GERD does not itself present a significant risk for mortality in the elderly, it may impair quality of life and lead to considerable complication-related morbidity. Patient tolerance of severe symptoms is often poor, and complications such as chronic upper aerodigestive manifestations, esophagitis with ulceration, peptic stricture, and Barrett's esophagus may pose significant management challenges in the elderly.

Pathophysiology

The antireflux barrier at the gastroesophageal junction (GEJ) is an anatomically and physiologically complex zone, which consists of (1) the intrinsic lower esophageal sphincter (LES) pressure (10–30 mmHg), (2) intra-abdominal location of the LES (3–4 cm below the diaphragm), (3) extrinsic compression of LES by the crural diaphragmatic sphincter, (4) integrity of the phrenoesophageal ligament, and (5) maintenance of an acute angle of His. Disruption of the antireflux barrier and abnormal clearance of esophageal contents results in increased exposure of the esophageal lumen to gastric refluxate (acidic or alkaline) [1] (Table 1).

Asymptomatic elderly patients differ physiologically from their younger counterparts (Table 2) [2–10]. They may have decreased LES pressure, abnormal esophageal motility and clearance, and an increased pain threshold. Older patients may be more likely to take medications that decrease LES tone and potentiate reflux events. These include nitrates, calcium channel blockers, theophylline, benzodiazepines, anticholinergics, and tricyclic antidepressants. Translocation of the esophagogastric junction and LES into the mediastinum through the esophageal hiatus (type 1, sliding hiatal hernia) (Fig. 1) occurs more frequently with increasing age [11] and is thought to contribute to pathologic reflux by exposing the LES to less extraluminal pressure in the chest as compared to the abdomen. This

Table 1 Pathophysiologic factors contributing to GERD

Increased frequency and duration of transient LES relaxation
Hypotensive LES (0–4 mmHg) leading to free reflux
Disruption of phrenoesophageal ligament and diaphragmatic sphincter (hiatal hernia)
Shortening of intra-abdominal LES
Decreased clearance of esophageal contents due to loss of primary and secondary esophageal peristalsis
Decrease in rate of salivation and salivary bicarbonate
Decreased gastric emptying and increased intragastric pressure

GERD gastroesophageal reflux disease, *LES* lower esophageal sphincter

Table 2 Physiological changes of the esophagus in the elderly

LED
Decreased LES pressure [2]
Decreased LES length [3]
Increase in gastroesophageal reflux events during the postprandial period from pharyngeal stimulation [3]
Esophageal motility
Aperistalsis without any specific etiology [4]
Absent or decreased secondary peristalsis with esophageal distention [5]
Increased tertiary contractions (multiple, simultaneous, nonperistaltic contractions) [6]
Decreased amplitude and velocity of peristaltic waves [2, 7]
Impaired esophageal clearance [8, 9]
Higher pain threshold with esophageal distension [10]

LES lower esophageal sphincter

relatively lower extraluminal pressure permits LES tone to be more easily overcome by intragastric pressure, leading to reflux. Patti et al. have shown that the degree of reflux symptoms, LES dysfunction, and esophagitis increases with hiatal hernia size [12].

Polypharmacy is a relatively unique challenge in geriatric patients, and many common medications can promulgate GERD by impeding esophageal function, delaying gastric emptying, or causing direct esophageal injury. These medications include calcium channel blockers, nitrates, narcotics, alpha-agonists, ferrous sulfate, and nonsteroidal anti-inflammatory drugs [13] A thorough medication reconciliation should be a part of

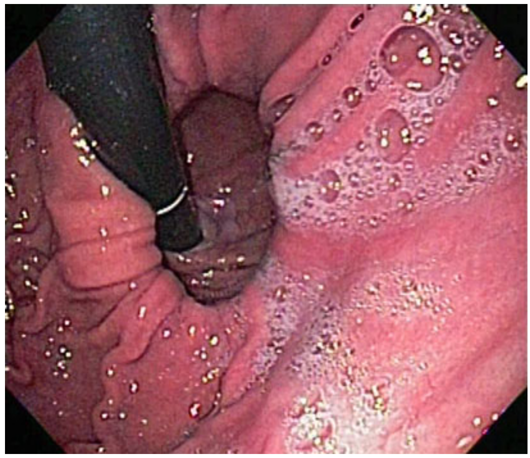

Fig. 1 Retroflexed endoscopic view of type I sliding hiatal hernia. The endoscope is seen emerging from the true esophagogastric junction into the hernia above the muscular ring of the hiatus

the workup of patients presenting with GERD, especially if a simple adjustment will preclude more drastic measures.

Clinical Presentation

A population-based study in Olmsted County, Minnesota, defined the general incidence of GERD symptoms as 19.8% without significant differences with age [14]. Triadafilopoulos and Sharma similarly reported no clear age-related difference in clinical prevalence of GERD above and below age 65 [15]. However, GERD symptom severity may not correlate as well with the severity of pathology in elderly patients. Johnson and Fennerty reported that 34% of patients >70 years old had severe heartburn with a 37% incidence of endoscopically evident severe esophagitis. In contrast, 82% of patients <21 years old with severe heartburn had severe esophagitis only 12% of the time [16]. Furthermore, Collen et al. reported that for a given level of severe reflux symptoms, patients >60 years old had more severe esophagitis compared to younger patients [17]. Zhu et al. reported that 21% of patients >65 years with GERD present with endoscopically severe

Barrett's esophagitis	

GERD gastroesophageal reflux disease

esophagitis, while only 3.4% of patients under 65 years have severe esophagitis [18]. Patients with GERD present with symptoms which can be described as typical or atypical or a combination of both (Table 3). Atypical symptoms may be more prevalent in the elderly [14, 19]. Alkaline reflux may also be more frequent and can be associated with respiratory symptoms more often than with heartburn [20]. Pellegrini et al. found that individuals with alkaline reflux have less heartburn, regurgitation, and dysphagia but at least as much esophagitis and stricture risk as those with acid reflux, as well as a higher frequency of pulmonary symptoms [21].

Long-standing GERD can result in complications which may lead to significant morbidity. The incidences of erosive esophagitis (45.4%), esophageal ulcers (6%), and esophageal strictures (8.4%) all increase with age. Furthermore, patients with esophageal ulcers or strictures are generally older than patients with uncomplicated esophagitis [22]. In one report, esophagitis was the cause of upper gastrointestinal bleeding in 21% of patients >80 years [23].

Barrett's esophagus, or columnar metaplasia, is a marker of severe chronic esophageal mucosal injury and has been reported to occur in as many as 10–12% of patients with GERD [24, 25]. The prevalence of Barrett's esophagus increases with age and plateaus by the seventh decade [26]. It occurs more frequently in patients greater than 60 years of age (34 vs. 12%) [17]. Elderly patients with Barrett's esophagus experience less severe symptoms compared to younger patients, which may lead to delayed recognition of the condition [15]. The outcome of Barrett's esophagus which is of utmost concern is its progression to adenocarcinoma, but there are no compelling data that define this risk in the elderly. In a meta-analysis of 41 Barrett's esophagus surveillance studies, the reported cancer incidence was found to be between 6 and 9 per 1000 person-years follow-up [27]. The presence of ulcers, strictures, and nodules was associated with increased cancer incidence. Patients who developed cancer had significantly longer Barrett's segments compared to patients who did not. However, these data did not stratify risk by age, and it is uncertain to what extent age may be an independent risk factor for either dysplasia or cancer.

Treatment for Barrett's esophagus is close surveillance and either medical or surgical control of reflux with the aim to avoid progression of disease. Standard therapy for high-grade dysplasia in Barrett's is esophagectomy. Mucosal ablative therapies (photodynamic therapy, argon plasma coagulation, and cryoablation) for high-grade dysplasia have seen expanded use and could offer benefits to elderly patients, if the morbidity and mortality risk associated with esophagectomy can be avoided. However, uncertain efficacy and potential to undertreat cancer present at the time of the therapy remain a matter of concern.

Diagnosis

Tests to diagnose GERD, GERD complications, and responses to therapy are listed in Table 4. GERD symptoms are frequently under treatment with proton pump inhibitors (PPI) or histamine receptor antagonists (HRA) before any diagnostic

Table 4 Diagnostic studies for GERD

Test	Purpose of study
Cine esophagram	Evaluate anatomical causes for dysphagia; document presence of hiatal or paraesophageal hernia; rule out achalasia, scleroderma, strictures, diverticula, webs, and masses
Endoscopy	Evaluate endoscopy positive vs. negative reflux disease; document healing esophagitis; rule out complications of GERD (esophagitis, stricture, and BE), peptic ulcer disease, and cancer
Esophageal manometry	Evaluate LES function; rule out esophageal dysmotility before proceeding with antireflux surgery
pH monitoring	Document abnormal acid exposure in symptomatic endoscopy-negative patients being evaluated for endoscopic or surgical antireflux therapy; evaluate patients on PPI therapy with persistent typical symptoms; document adequacy of PPI therapy in patients with complications due to GERD
Esophageal impedance testing	Evaluate endoscopy-negative patients with persistent symptoms despite PPI therapy
Bile acid reflux monitoring	Evaluate patients with persistent reflux symptoms with normalization of distal esophageal acid exposure confirmed by pH studies

GERD gastroesophageal reflux disease, *BE* Barrett's esophagus, *PPI* proton pump inhibitor

tests are done. There should be a low threshold to proceed with endoscopy in elderly patients because of the recognized risk of more advanced disease in the face of less severe or atypical symptoms in comparison to younger patients. Endoscopy with biopsy is currently the only study that can effectively identify esophagitis, rule out Barrett's and cancer, as well as document healing of esophagitis with therapy. Cine esophagography can help characterize anatomic and functional features of the esophagus during the passage of ingested barium materials of varying consistencies. Some motility characteristics and disorders (Table 4) as well as esophagogastric junction anatomy can be defined with the study, and it can be particularly useful in evaluating dysphagia.

Complex or suspected reflux disease and persistent or atypical symptoms should be further evaluated using more objective tests, especially when antireflux surgery is being considered. The 2007 American College of Gastroenterology practice guidelines recommend ambulatory pH monitoring to identify pathologic esophageal acid exposure in endoscopy-negative patients being considered for endoscopic or surgical antireflux procedures and patients who are symptomatic on PPI therapy. Symptom correlation index can establish likelihood of causality in the relationship between symptom occurrence and episodes of esophageal acid exposure. Although pH monitoring can also be used to evaluate effectiveness of PPI therapy, a specific threshold value for adequate suppression of esophageal acid exposure has not been defined [28], and no age-specific guidelines for the use of this test are available.

Ambulatory pH monitoring can be performed using a nasopharyngeal catheter system or a wireless pH capsule ("Bravo" probe, Medtronic, Minneapolis, MN) that transmits information to an external receiver. Results from the two systems correlate well, but there may be advantages with wireless pH monitoring. The most important is that the modality is associated with less discomfort, less interference with daily activities, and better patient satisfaction compared to the traditional catheter system. Less interference with daily activities will provide more accurate information about reflux episodes [29]. Furthermore, pH monitoring can be performed for more than 24-h periods, and it may be more feasible to study patients on and off PPI therapy. Disadvantages include the need to place the capsule endoscopically, which adds cost and the potential problems of an invasive procedure. Some patients may have severe chest pain, and the capsule may either dislodge early or not dislodge at all, both of which are problematic situations. Wireless pH monitoring might offer advantages in elderly patients based on improved tolerance, but there are no data that specifically support this assumption.

Esophageal impedance monitoring detects changes in resistance to electrical current across adjacent electrodes with the movement of solids, liquids, and gases. It can detect both acid and alkaline reflux (even very weak patterns of reflux) and evaluate esophageal bolus transit when combined with motility studies. Specific monitoring of bile acid reflux is possible by using a probe that detects bile by spectrophotometry. AGA guidelines suggest that these tests may be useful in patients with reflux symptoms despite PPI therapy and normal pH monitoring studies [28]. They are not widely used at this time because the long-term clinical implications of non-acid reflux are not well studied. It is unclear at this time how recognition of this entity might change management in elderly patients.

Chest pain symptoms in the elderly deserve special mention. The most obvious concern lies in the physician's ability to distinguish cardiac from noncardiac chest pain (NCCP) and to institute the appropriate treatment. Although most patients with GERD-induced chest pain will give a history of antecedent reflux symptoms, the possibility of myocardial ischemia ought to be considered and basic investigations conducted so as not to miss this diagnosis. There is considerable overlap in symptoms attributable to GERD or of cardiac origin. DeMeester et al. performed 24-h pH probe studies in patients with typical angina pectoris symptoms and normal cardiac catheterizations and demonstrated reflux to be present in 46% [30]. A positive correlation between chest pain episodes and acid reflux during the pH probe study can be demonstrated in up to 50% of patients with NCCP [31].

Treatment

Irrespective of patient age, the goals in the treatment of GERD are to ameliorate symptoms, promote healing of esophagitis, maintain remission, and prevent long-term complications. These goals may be achieved using various modalities.

Nonsurgical Treatment

Lifestyle or behavioral modifications can alleviate symptoms in mild reflux disease when employed alone or with medical therapies. These might include the elevation of the head and chest during sleep, avoidance of supine position or sleep less than 3 h after meals, weight loss in overweight patients, smoking cessation, and avoidance of foods associated with reflux (e.g., high-fat foods, chocolate, peppermint, coffee, and alcohol). As mentioned previously, selected medications may decrease LES tone. Caution with these as well as with medications that might predispose to pill esophagitis (potassium tablets, iron sulfate, and alendronate) should be exercised.

Histamine receptor antagonists (cimetidine, ranitidine, famotidine, and nizatidine) may be effective but are used less frequently than proton pump inhibitors (PPIs) as first-line therapy. PPIs (omeprazole, lansoprazole, rabeprazole, pantoprazole, and esomeprazole) inhibit the H+/K+ ATPase proton pump. They have become the mainstay of medical therapy for significant GERD and are now available over the counter (omeprazole). If symptoms are suggestive, empiric treatment is usually started before diagnostic tests are done, and prompt clinical improvement is generally taken as confirmatory of the GERD diagnosis. Historical exceptions to prompt use of PPIs rather than investigations include long-standing GERD and alarm symptoms such as anemia, weight loss, and dysphagia [32]. Since elderly patients may present with more advanced disease and less severe symptoms, an argument can be made for the use of endoscopy prior to starting prolonged acid suppression in order to clearly establish the presence of esophagitis.

Almost 50% of patients with GERD suffer frequent relapses and need some form of maintenance therapy. PPIs are currently regarded as the most effective medications available for acute as well as maintenance therapy for GERD [33], although H2 receptor antagonists may also be effective if PPI treatment cannot be given. Since PPIs are long-acting medications, dosing is convenient for older patients. Added potential advantages include easy administration in older patients with swallowing problems (granules can be mixed in soft food or liquids) and the fact that dose adjustments are not necessary in hepatic and renal insufficiency [34]. Some studies have shown an increased risk for respiratory infections, *Clostridium difficile* colitis, and osteoporosis with PPI use [35].

Cisapride is a prokinetic agent which may be available for use in GERD outside the USA, having been removed from the US market in 2000 due to increased risk for cardiac arrhythmias. Metoclopramide can be problematic in elderly patients due to CNS side effects (sedation and tardive dyskinesia). Other promotility drugs such as tegaserod (serotonin agonist) and baclofen (GABA agonist) may have some efficacy in GERD but are not standard therapies. Singh et al. cross-referenced the interactions of antacids, H_2 blockers, proton pump inhibitors, and sucralfate with common medications for hypertension, diabetes, dyslipidemia, arthritis, and psychiatric conditions. Although the analysis was by no means comprehensive, it found surprisingly few interactions. Notably, omeprazole in combination with diuretics increased the risk of hypomagnesemia, and ranitidine in combination with metformin increased the risk of elevated metformin levels [36]. As noted earlier, a thorough medication reconciliation can prevent complications secondary to polypharmacy.

Surgical Treatment

Indications for surgical treatment of GERD include (1) patient choice in order to discontinue medical therapy, (2) intolerance of medical therapy, (3) persistence of symptoms on medical therapy, and (4) complications of GERD including persistent esophagitis on medication, peptic strictures, and Barrett's esophagus (although the latter indication may be controversial).

The goals of surgery are to repair any associated hiatal hernia, establish an intra-abdominal length of esophagus, and perform a fundoplication as a barrier to reflux. Nissen or 360° fundoplication (Fig. 2) is the most frequently performed antireflux procedure. Toupet or 270° fundoplication has generally been reserved for GERD patients with ineffective esophageal motility, although its efficacy as compared to a loose Nissen fundoplication is controversial [37, 38]. There are numerous other types of antireflux procedure intended for use via transabdominal or transthoracic access methods, but a full discussion of surgical antireflux treatments is beyond the scope of this chapter. It can currently be stated that laparoscopic antireflux procedures represent the surgical standard of care for GERD, and advantages relative to open procedures are well established [39]. Investigations of surgical treatment of GERD in the elderly have generally shown that outcomes are favorable. Table 5 summarizes eight studies that compare surgical outcomes in "older" (>60 years) and "younger" patients (<60 years of age) [40–47]. These have established that postoperative symptom relief is not adversely affected by advancing age with mean follow-up of between 3 months and 5 years. There may be a perception that postoperative complication rates are higher and length of hospital stay are greater for patients >60 years of age, but this has not been consistently observed for antireflux surgery. Although patients >60 years had significantly higher American Society of Anesthesia (ASA) score in four studies and a higher rate of comorbidities in one study, this did not closely correlate with an increase in complication rate and length of stay. The likelihood of mortality with antireflux surgery is very close to zero in both populations.

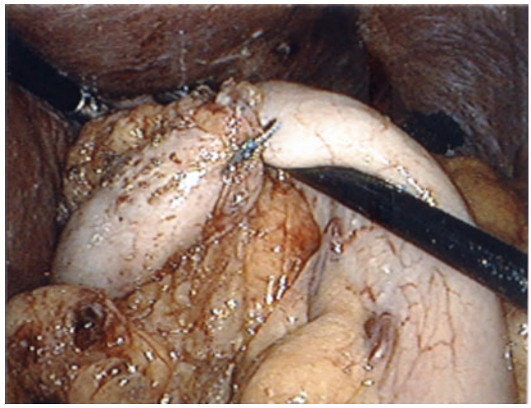

Fig. 2 Laparoscopic Nissen fundoplication. The loose nature of this complete (360°) wrap of gastric fundus around the esophagogastric junction and distal esophagus is demonstrated by the insertion of an instrument below the left-sided fundic component of the wrap

Current data suggest that antireflux surgery can improve formally measured quality of life in elderly patients. Kamolz et al. reported the use of the gastrointestinal quality of life index (GIQLI) to

Table 5 Laparoscopic antireflux surgery outcomes in elderly (>60 years) versus adult (<60 years) patients

Year	Author	Age (years)	*n*	Symptom relief	Complications	LOS (days)	Mortality in elderly
1998	Trus et al. [38]	69 (65–79)	42	=	=	=	None

assess postoperative outcomes in 72 patients greater than 65 years of age. Scores were significantly improved 3 months after surgery compared to preoperative values. This improvement persisted 1 and 3 years after surgery and was similar to scores in healthy individuals [48]. Fernando et al. [43] and Wang et al. [47] showed that SF 36 health survey and GIQLI assessments of global and disease-associated quality of life postsurgical outcomes were not significantly different in patients <60 years and >60 years of age. The overwhelming weight of evidence indicates that antireflux surgery is both effective and safe in the elderly and that outcomes are comparable to those achieved in younger patients.

Intraoperative complications of antireflux surgery are uncommon. Esophageal perforation is rare and may result from dissection or bougie injuries. Common causes of intraoperative bleeding are adhesiolysis or injury to the left lobe of liver or the spleen. Bleeding is generally controlled by local measures and rarely requires conversion to an open procedure. Splenic injuries and splenectomy, which were surprisingly common events with open fundoplication (2–5%), are rare occurrences in laparoscopic antireflux surgery. Pneumothorax is also rare and is thought to be due to extensive dissection into the mediastinum. Chest tube placement is rarely required due to the rapid uptake of CO_2. Conversion rates from laparoscopic to open procedures are less than 5%.

Coelho et al. evaluated complications of laparoscopic fundoplication in 77 patients >70 years of age and reported 7.8% gas bloat syndrome, 5.2% dysphagia, and 2.6% gastric ulceration incidences [49]. Although most dysphagia after fundoplication either resolves or responds well to modest dietary measures, severe dysphagia symptoms may on rare occasions require endoscopic dilatation or surgical revision of fundoplication. Technical considerations that minimize the likelihood of postoperative dysphagia include routine division of the gastrosplenic ligament and short gastric vessels and adequate fundic mobilization for a loose wrap. The incidence of anatomic failure of antireflux procedures ranges from 3 to 6%. These cases include fundoplication disruption or slipping or axial herniation of the fundoplication into the mediastinum. Pledgeted suture repair of the hiatus and reinforcement of the defect with a mesh may decrease incidence of some types of anatomic failure [50].

Endoscopic Treatment

Endoscopic therapy for GERD has shown to significantly decrease PPI use, improve symptoms, and decrease but never normalize acid exposure in patients with mild forms of GERD. Proposed exclusion criteria include hiatal hernias greater than 2 cm, esophagitis greater than grade II, and disease refractory to PPI therapy [51]. Currently there are several devices available for GERD endoluminal therapy: (1) LINX (Torax Medical, Inc., Shoreview, MN), (2) Stretta (Mederi Therapeutics, Inc., Norwalk, CT), and (3) EsophyX (EndoGastric Solutions, Inc., Redmond, WA). Many other devices in this area have been discontinued due to poor outcomes. The principles by which these current devices operate are (1) reinforcement of the LES with magnetic beads (LINX), (2) full-thickness serosa-to-serosa plication at the GEJ (EsophyX), and (3) radiofrequency thermal therapy delivered to LES to promote thickening (Stretta). Potential advantages in elderly patients include performance with conscious sedation and relatively short-procedure duration. There may be applications in poor surgical candidates or as a bridge between medical and surgical therapy. However, based on current literature, there are no clear indications based on perceived or measured superiority relative to traditional surgical measures. Published studies have been small and more focused on safety and feasibility than on long-term durability and efficacy. With increasing experience, evolving techniques and hardware, as well as more thorough investigation, endoluminal therapies may become a viable option in the treatment of GERD, with specific applications in the elderly.

Paraesophageal Hernia

Case Study: Part 1

Presentation: A 77-year-old retired policeman with oropharyngeal squamous cell carcinoma s/p radiotherapy was referred to surgical clinic for evaluation of GERD and a right inguinal hernia. His primary symptom was heartburn, but he also suffered from occasional regurgitation, bloating, and chest/epigastric pain. A proton pump inhibitor provided reasonable relief of his heartburn, but he was leery of taking this medication indefinitely. Of note, he already had dysphagia primarily to solids secondary to poor dentition and decreased saliva from his radiotherapy. Regarding his groin, the patient started noticing right groin discomfort several months prior to presentation. Since then the discomfort progressively worsened, and he developed a large bulge extending into his scrotum. He denied obstructive symptoms.

Exam and Workup: On exam the patient was well appearing but clearly underweight. Breath sounds were symmetric. He had a flat abdomen that was soft and nontender. The right groin was remarkable for a large but reducible inguinal hernia. There were no relevant laboratory findings. Additional workup included an upper gastrointestinal fluoroscopic series (UGI), manometry with impedance, and a CT scan of her abdomen and pelvis. The UGI series revealed a large type 3 hiatal hernia with organo-axial rotation and reflux to the midesophagus, new since a comparable study in 2013. High-resolution manometry showed normal lower esophageal sphincter (LES) tone and relaxation, normal peristalsis, and lax upper esophageal sphincter (UES) tone. The CT scan confirmed the presence of the hiatal hernia and showed a right inguinal hernia containing loops of small bowel.

Paraesophageal hernia is primarily a disease of the elderly, and the average age of diagnosis is 60–70 years. The true incidence of hiatal hernias is difficult to determine because majority of patients remain asymptomatic and therefore undiagnosed. There are four types of hiatal hernias. (1) Type I (sliding hiatal hernia): esophagogastric junction migrates through the hiatus and is commonly associated with GERD. (2) Type II: gastric fundus herniates through the hiatus with esophagogastric junction in an intra-abdominal position. This is a true para-esophageal hernia. (3) Type III (combination of Type I and Type II). In this hernia type, gastric fundus and esophagogastric junction herniate into the mediastinum (Fig. 3). (4) Type IV: Type III hernia with herniation of other viscera such as spleen or colon [52]. Type II, III, and IV hiatal hernias are called paraesophageal hernias, and Type III hernia is the most common among

Fig. 3 Barium esophagram of a type III (paraesophageal) hiatal hernia. In this case, there is clear demonstration of the relationship between the axially rotated gastric fundus and the adjacent esophagus, which tapers at the expected location of the diaphragmatic hiatus

them (90%). Type I or sliding hiatal hernias are at least seven times more common than para-esophageal hernias [53].

Pathophysiology

Paraesophageal hernias occur more frequently with advancing age and are believed to result from progression of a sliding hiatal hernia. Prolonged repetitive stretching of the phrenoesophageal membrane due to movement of the esophagus during swallowing, as well as increased intra-abdominal pressure due to conditions such as morbid obesity, COPD, asthma, and chronic constipation, may contribute to more complex patterns of gastric herniation into the chest [53].

Clinical Presentation

Symptoms associated with paraesophageal hernias are primarily related to partial or complete gastric obstruction. Patients present with nausea, bloating, early satiety, chest pain, and fullness relieved with vomiting and dysphagia. Fifteen to thirty percent of patients with paraesophageal hernias complain of GERD symptoms [54, 55]. Patients with larger hernias may suffer from chest pain and shortness of breath. Paraesophageal hernias may be associated with chronic blood loss and anemia due to gastric erosions from prolonged trauma [56]. Gastric volvulus is a possible complication of paraesophageal hernias, with rotation either along the long axis of the stomach (organo-axial) or along a perpendicular axis (mesenteroaxial). Patients with completed volvulus can present emergently with acute gastric obstruction and potentially with gastric strangulation. Symptoms associated with this presentation are epigastric pain, persistent retching and vomiting, bloody vomitus due to gastric ischemia and ulceration, and an acute abdomen and sepsis if a gastric perforation has occurred. Previous studies have reported an acute presentation in 29% of patients with paraesophageal hernias [57, 58]. However, a recent study by Stylopoulos et al. looked at five studies and estimated the probability of developing acute symptoms to be 1.16% per year. The lifetime risk for developing acute symptoms is 18% for 65 years and decreases as patent's age increases [59]. Arguments for mandatory surgical treatment of paraesophageal hernia are generally based on the need to avoid this variably estimated risk, which may be favorably affected by advancing patient age.

Diagnosis

Chest radiograph may demonstrate an air–fluid level in the left chest. Upper gastrointestinal contrast study with barium is the study of choice to diagnose paraesophageal hernias (Fig. 4). Computed tomography can also establish the diagnosis (Fig. 5). Upper endoscopy can aid in recognition of a paraesophageal component of a hiatal hernia and will provide other information such as the presence of esophagitis or ulcerations. Twenty-four hour pH monitoring and esophageal manometry can be considered in patients with GERD symptoms but may not influence surgical planning.

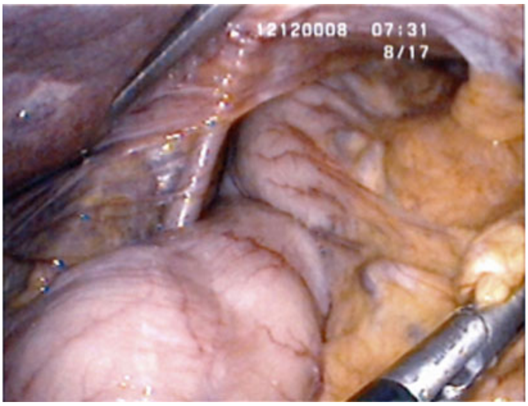

Fig. 4 Laparoscopic view of a type III (paraesophageal) hiatal hernia, with the herniated body and fundus of the stomach above the right crural pillar

Fig. 5 CT chest coronal section of a type III hiatal hernia (paraesophageal), with adjacent contrast-filled esophagus between the distended, herniated stomach, and the thoracic vertebrae. Such studies have become increasingly valuable in more precisely defi ning anatomic relationships in complex hernias of this type. This information can be used to better understand the condition, or as an aid in operative planning

Treatment

Surgical management of symptomatic and asymptomatic paraesophageal hernias has historically represented a mandatory standard of care. This is based largely on reports of a high (28–30%) incidence of acute symptoms necessitating emergency operations, which were associated with high rates of morbidity and mortality [57, 58]. Surgery continues to be the treatment of choice for symptomatic paraesophageal hernias. However, the treatment of asymptomatic and minimally symptomatic hernias has become more controversial. Allen et al. followed 23 patients managed nonoperatively for an average of 78 months and reported that only 4 developed progression of symptoms and that the 2 patients who underwent elective repair did well [54]. Stylopoulos et al. assessed outcomes of elective laparoscopic hernia repair vs. watchful observation in patients with asymptomatic and minimally symptomatic indications based on information from 20 published studies. Using a predictive model, it was determined that less than one in five 65-year-old patients and only one in ten 85-year-old patients will benefit from elective surgical treatment [59].

The goals of operative treatment of paraesophageal hernias are (1) reduction of the herniated stomach (or other viscera), (2) reduction and excision of the hernia sac, (3) hiatal hernia repair with or without prosthetic mesh, and (4) secure subdiaphragmatic positioning of the stomach. Although the use of fundoplication in paraesophageal hernia repair remains controversial, it is frequently used on the assumption that it may reduce recurrent hernia risk as well as reduce postoperative GERD occurrence. As many as 60% of patients with Type III hernias have diminished LES pressures and abnormal esophageal pH monitoring studies [60, 61]. Willekes et al. reported that as many as 30% of patients had preoperative reflux symptoms and that some patients develop postoperative reflux despite the absence of preoperative reflux symptoms. They concluded that GEJ and LES physiology cannot be predicted once it has been surgically disturbed and all phrenoesophageal supporting attachments are divided [55].

Minimally invasive surgery has become the preferred method of management for paraesophageal hernias, with the well-founded expectation of decreased postoperative pain, length of stay, and morbidity and mortality compared to open surgical methods [61–64]. A large series (203 patients) of laparoscopic repair for giant paraesophageal hernia (1/3 or more of stomach herniation into chest) suggests a pattern of disease skewed toward more elderly patients. The mean patient age was 67 years (34–91 years), and median follow-up was 18 months. The median length of hospital stay was 3 days, morbidity was 28%, and mortality was 0.5. Postoperative symptom relief was excellent to good in 92% of patients [63].

Bammer et al. and Grotentuis et al. evaluated outcomes of laparoscopic paraesophageal hernia repair in patients >80 years of age and >70 years of age, respectively. Results were comparable to studies with mixed age groups [65, 66]. Gangopadhyay et al. compared results of laparoscopic paraesophageal hernia repair in three age groups <65 years (Group 1), 65–74 years (Group 2), and >74 years (Group 3). Group 3 had significantly higher ASA scores and hospital length of stay, but their postoperative complication rate, symptom relief, and recurrence rates were comparable to other groups [67]. In a retrospective review of 1005 patients (>80 years of age) who underwent diaphragmatic hernia repair, 43% of procedures were emergent. Emergency operations were more common among older patients, and the concurrent finding of CHF was associated with longer hospital length of stay and mortality (14 ± 1 days and 16%) compared to patients who underwent elective repair (7 ± 1 days and 2.5%) [68]. Laparoscopic paraesophageal hernia repair is a safe and effective option in the elderly, and they should not be denied surgery based on age alone, because emergency surgery in this population is associated with significant mortality. In elderly and debilitated patients with multiple comorbidities, one should consider shorter, less invasive techniques such as anterior gastropexy or placement of percutaneous endoscopic gastrostomy after the reduction of paraesophageal hernias. Agwunobi et al. and Kercher et al. performed these techniques in small series of high-risk patients (13 and 11 patients) with minimal complications and low recurrence rates [69–70].

Case Study: Part 2

Treatment: Based on the patient's constellation of findings and general health, he was offered an elective laparoscopic hiatal hernia repair. The index operation was to include a partial as opposed to full fundoplication in order to minimize the risk of worsening his dysphagia, as well as a possible Collis gastroplasty.

He underwent an uneventful operation with completion esophagogastroduodenoscopy and was subsequently admitted to the surgical ward. There were no medical issues throughout his hospitalization nor did he require anything beyond acetaminophen for pain control. An UGI series on postoperative day 2 showed no obstruction, leak, or malposition of the fundoplication. As such, he was started on a clear liquid diet and ultimately discharged on full liquids with instructions to advance his diet on an outpatient basis. He was symptom-free at his postoperative clinic visit.

Salient Points

1. The hernia sack should be fully reduced and resected.
2. If maximal safe mobilization of the esophagus does not yield adequate intra-abdominal length, a Collis gastroplasty should be performed to mitigate the risk of recurrence. The fundoplication should be wrapped around the neo-esophagus created by the gastroplasty and not below it.

Esophageal Motility Disorders

Esophageal motility may undergo various physiological changes with aging. Among these are decreased secondary esophageal peristalsis, increased ineffective tertiary contractions, and diminished velocity and amplitude of peristaltic waves (Table 2). Esophageal dysmotility may be primary, such as in achalasia, diffuse esophageal spasm (DES), and nutcracker esophagus, or secondary to conditions such as systemic sclerosis, polymyositis, and diabetes mellitus [71].

Achalasia

Achalasia has two incidence peaks: the first between ages 20 and 40 and the second in more elderly patients. Sonnenberg et al. reported an average age of 78 years for patients with achalasia based on hospital admission codes, with a steady increase in hospitalization rates between the ages of 65 and 94 years [72].

Pathophysiology

Achalasia is a primary functional disorder of the esophagus characterized by the absence of peristalsis and incomplete relaxation of the LES during swallowing. These characteristics contribute to a functional obstruction at the GEJ [73]. Although occasional familial clustering of achalasia cases has been reported, most are sporadic and of uncertain etiology [74]. The esophageal manifestations of Chagas disease (*Trypanosoma cruzi*), which is endemic in South America, can be considered a form of achalasia but is accompanied by a host of other infection-related problems. It can be observed in elderly patients and presents particular management challenges largely due to the broader range of systems affected and overall poorer prognosis.

Viral infection has been proposed as a causative factor in achalasia [75, 76]. Reported histologic characteristics are based on resected and autopsy esophageal specimens and most likely reflect advanced disease findings. Wallerian degenerative changes, loss of myenteric ganglion cells, microscopic degeneration of the vagus nerve, and hypertrophy of the muscularis propria of the distal esophagus have been described [77]. A loss of nitric oxide and vasoactive intestinal peptide (VIP)-containing postganglionic inhibitory neurons in the myenteric plexus may be responsible for impairment of LES relaxation due to unopposed cholinergic stimulation [78–80]. Goin et al. have suggested an autoimmune etiology based on the identification of circulating antimuscarinic antibodies in chagasic achalasia [81]. The presence of Lewy bodies in the myenteric plexus and loss of neurons in the dorsal motor nucleus of the vagus in both achalasia and Parkinson's disease suggest a possible link between the two diseases, which appear with high prevalence in the elderly.

Aperistalsis in achalasia is not clearly understood. Inhibitory innervation is believed to be critical to the phasic sequence of esophageal muscular contractions, and it is possible that loss of inhibitory neurons abolishes peristaltic motor function. Long-term aperistalsis and functional GEJ obstruction can eventually result in a massively dilated and tortuous esophagus devoid of any discernible motor function [73].

Clinical Presentation

The most common symptoms of achalasia are dysphagia to solid food, regurgitation of esophageal contents, weight loss, and various patterns of chest pain. Dysphagia is progressive in achalasia and may also interfere with ingestion of liquids. Other clinical complaints may include cervical level dysphagia and difficulty belching. It has been suggested that some symptoms are related to impaired upper esophageal sphincter relaxation [82, 83].

Dysphagia and impaired esophageal emptying in achalasia are due to both impaired LES relaxation and loss of esophageal peristalsis. There is stasis of varying amounts of undigested food proximal to the LES depending on the capacitance of the dilated esophagus and the rate and quantity of food intake. Patients develop techniques to facilitate esophageal emptying, including slow, purposeful swallowing, avoidance of firm foods, postural changes (twisting, stretching), and ingestion of warm liquids with meals. Approximately 40% of patients have chest pain in the xiphoid or substernal areas, which often prompts evaluation for cardiac problems. This pain may be increased by exercise and relieved by rest [84]. Achalasia patients also commonly describe "heartburn," which is most likely related to esophageal stasis [85]. Clouse et al. compared clinical presentations of achalasia in patients greater and lesser than 70 years of age. Although symptom patterns were similar in the two groups, fewer of the older patients complained of chest pain [86].

Patients with achalasia are at risk for developing chronic inflammation, ulceration, perforation, and fistulas as a result of chronic stasis and retention. It has been shown that there is a 33-fold increased risk of esophageal carcinoma in these patients, with a yearly incidence of 3.4/1000. The patients at highest risk are elderly patients with a long-standing history of dysphagia and a markedly dilated esophagus [87].

Diagnosis

A plain chest radiograph may demonstrate a widened mediastinum and an air–fluid level in the posterior mediastinum due to esophageal dilation. A barium esophagram effectively demonstrates the gross esophageal changes, which can include dilation, tortuosity, retention of food and barium, and a symmetric smooth tapering of the esophagus resembling a bird's beak (Fig. 6). The most striking gross feature of achalasia is massive esophageal dilation known as sigmoid esophagus or megaesophagus seen in advanced cases (Fig. 7).

Upper endoscopy should be considered a mandatory study to exclude peptic stricture and malignancy. The latter condition may be associated with clinical changes similar to those of achalasia, particularly in patients over 60 years of age [88, 89]. A diagnosis of pseudoachalasia can be firmly established only by biopsy and histologic demonstration of carcinoma.

Of all currently available studies, esophageal manometry establishes the diagnosis of achalasia most effectively. Although the resting LES pressure is normal in 40% of patients, up to 80% have absent or incomplete LES relaxation with wet swallows. It must be emphasized that the presence of LES relaxation does not exclude achalasia. Post-deglutitive relaxations may appear complete

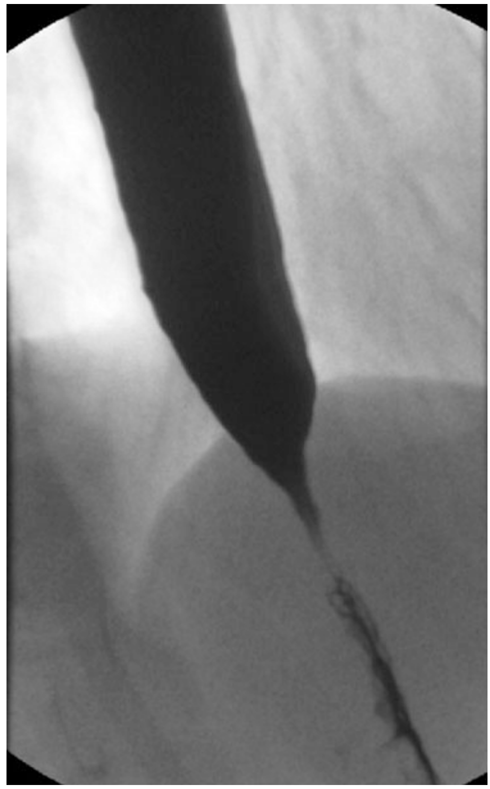

Fig. 6 Bird's beak deformity of the distal esophagus in a patient with achalasia seen on a barium esophagram. This characteristic appearance in a patient with the clinical features of achalasia is strongly suggestive of this condition

Fig. 7 Barium esophagram of a megaesophagus in a patient with advanced achalasia. The barium column may be diluted by retain fluid and food in the enlarged and sometimes tortuous esophagus

but usually are of short duration [90, 91]. Loss of normal esophageal body peristalsis is manifested by simultaneous contractions following wet swallows. Contractile amplitudes are low (10–40 mmHg) with frequent prolonged and repetitive waves. Studies have shown increased basal LES pressure in older patients with achalasia compared to younger patients [92, 93]. Chuah et al. demonstrated a linear correlation between age and LES basal pressure in achalasia patients [93]. Vigorous achalasia is a variant of achalasia characterized by high amplitude (>60 mmHg) simultaneous esophageal contractions, which may be associated with intense chest pain. This form of achalasia may be less frequent in elderly patients.

Treatment

Treatment of achalasia is primarily palliative and is geared toward adequate symptom relief from functional LES obstruction [73]. A variety of nonsurgical and surgical options are available.

Nonsurgical Treatment

Calcium channel blockers and nitrates are the most commonly used pharmacological agents in the treatment of achalasia. Clinical improvement with both sublingual isosorbide dinitrite and nifedipine treatment has been reported; however, symptom relief is variable, 53–87% and 0–75%, respectively [94, 95]. These agents must be taken sublingually immediately prior to meals to achieve the desired result. The major potential side effects that might limit this treatment are headache, hypotension, and tachyphylaxis. However, oral pharmacotherapy has not gained popularity because of its short-lived effects, poor symptom relief, and decreasing efficacy with time. They are definitely an option in patients awaiting definitive therapy and the elderly who have failed botulinum toxin therapy and are poor candidates for pneumatic dilatation and surgery.

Intrasphincteric injection of botulinum toxin type A has shown to effectively reduce LES pressure by inhibiting cholinergic receptors. Pasricha et al. reported a 70% symptomatic relief in patients treated with botulinum toxin with 40% requiring more than one injection [96]. Despite impressive early results, the long-term efficacy of this treatment has been questioned based on high 1-year relapse rates and less successful repeat injection. Older patients and patients with vigorous achalasia have a better response to botulinum therapy [97]. Elderly patients (>60 years) with significant medical problems tolerate this treatment modality well [98, 99].

Pneumatic balloon dilatation has wide acceptance and is a mainstay of treatment for achalasia. This technique employs a rapidly inflated balloon in the distal esophagus to dilate and disrupt the circular smooth muscle fibers of the LES. The procedure is well tolerated with a short hospital stay. The first dilatation results in symptom relief in 50–65% of patients [73]; however, 15–48% of patients require repeat procedures [100–102]. Patients older than 40 years had better 2-year results than patients younger than 40 (67 vs. 29%) [103]. The principal risk of pneumatic dilation is esophageal perforation, which in skilled hands is less than 2%. The risk of perforation is highest with the first dilatation.

Surgical Treatment

Surgical treatment of achalasia consists of longitudinal division of the LES muscle fibers also referred to as *myotomy* or *esophagomyotomy*. This procedure lowers LES pressure and esophageal intraluminal pressure but most importantly eradicates the effects of incomplete LES relaxation. Good to excellent results have been reported in as high as 90% of patients with 1–36 years of follow-up. Follow-up studies have demonstrated an improvement in esophageal emptying, increased LES diameter, and decreased esophageal diameter [104–107]. Although the point in a patient's care at which surgery should be offered is undefined, superior results with laparoscopic myotomy as initial therapy, as compared to pneumatic dilatation and botulinum toxin, have been suggested [108]. Furthermore, Smith et al. reported that complication rates after laparoscopic Heller myotomy were higher among patients who underwent previous endoscopic treatment with GI perforation being the most common complication (9.7 vs. 3.6%) [109].

Laparoscopic esophagomyotomy is currently the most frequently used surgical approach for achalasia, with decreased postoperative pain, length of hospitalization, and technical ease, compared to open and thoracoscopic methods. The peroral endoscopic technique is the latest advance in this field, with efficacy and safety presumably comparable to the laparoscopic approach in skilled hands [110]. Current data indicate that laparoscopic myotomy is a safe and effective option in elderly patients. Kilic et al. reported that in 57 patients >70 years of age who underwent laparoscopic Heller myotomy, there were no perioperative deaths and that there was a 19.3% complication rate and median hospital stay of 3 days. At a mean follow-up of 23.5 months, 96.5% reported improvement in symptoms [111]. Severe preoperative dysphagia, dilated esophagus, and absence of all motility are predictors of poor outcome, and LES pressure >35 mmHg is a predictor of good outcome after laparoscopic Heller myotomy [112, 113]. The overall complication rate for esophagomyotomy is 10%, with GERD being the most common postoperative problem followed by dysphagia from insufficient myotomy [104]. Although partial fundoplication (Dor vs. Toupet) may substantially reduce postoperative reflux with esophagomyotomy, the potential for residual dysphagia has tempered its use.

Diffuse Esophageal Spasm

Diffuse esophageal spasm (DES) is a primary esophageal hypermotility disorder characterized by dysphagia and episodic substernal chest pain. It is a rare condition, the etiology of which is unknown. Although the mean age of occurrence is in the fifth decade, it can occur in elderly patients up to the eighth decade of life. Because the symptom that most often brings DES patients to medical attention is angina-like chest pain, formal workup for a cardiac etiology is almost always undertaken.

Diagnosis

The principal manometric findings in DES are frequent simultaneous and repetitive contractions of abnormally high amplitude or long duration. The finding of 20% or more simultaneous contractions per 10 wet swallows is considered diagnostic of the disorder [114]. LES resting pressures and relaxation with swallows are usually normal. DES activity is intermittent, and ambulatory 24-h manometry allows patients to go about their daily activities and receive whatever typical stimuli are necessary to precipitate an episode [115]. Many patients with DES have an underlying psychiatric history with diagnoses that include depression, psychosomatic complaints, and anxiety. These diagnoses have been reported in 80% of patients with manometric contraction abnormalities [116].

A barium esophagram can help in the characterization of DES. Occasionally, a “corkscrew” esophagus caused by segmental contractions of circular muscle is identified. The finding of an esophageal pulsion diverticulum in a patient with characteristic chest pain is virtually diagnostic of DES. Esophagoscopy should be performed in all patients to exclude the possibility of a tumor, fibrosis, or esophagitis, which might cause esophageal narrowing that may be associated with proximal tertiary esophageal contractions.

Treatment

Treatment of this condition may be difficult. As with achalasia, some patients respond to sublingual nitrates or calcium channel blockers before meals [117, 118]. Esophageal dilation may alleviate symptoms of dysphagia for days to months and can be repeated for continued relief [119]. However, there is an increased risk of perforation with multiple dilations of a hypertrophic, spastic esophagus.

Surgical treatment is generally reserved for medical and endoscopic treatment failures. This consists of a long myotomy aimed at reducing simultaneous contractions and improving compliance at the cost of peristaltic loss and reduced residual muscular contraction amplitude [120]. It can be accomplished thoracoscopically [121], with an 80% rate of diminished symptoms during the early postoperative period. Fundoplication may be performed to avoid reflux but with the same concerns expressed for achalasia. With long durations of follow-up (5.0–10.7 years), surgically treated patients can remain free of chest pain and dysphagia [122].

Other Esophageal Motility Disorders

Nutcracker (hypercontractile) esophagus is another primary esophageal hypermotility disorder that like DES presents as episodic dysphagia and chest pain. It tends to occur later than DES (fifth and sixth decades of life) and can occur in elderly patients as well. It is diagnosed by manometry when average peristaltic pressures are above 180 mmHg and have a prolonged duration. The overall treatment algorithm is similar to DES, except there is no role for dilation, and myotomy may ultimately worsen dysphagia. Secondary esophageal dysmotility disorders occur in conjunction with systemic diseases such as diabetes, hypo- and hyperthyroidism, systemic sclerosis, polymyositis, and amyloidosis. These diseases are prevalent in the elderly and should be kept in mind while working up a patient for a suspected esophageal motility disorder [123].

Benign Tumors of the Esophagus

Benign tumors of the esophagus often go unreported and undiagnosed; their exact incidence is not known. In two large autopsy series, the reported incidences of these tumors were 0.45 and 0.59% [124, 125]. They can be intraluminal, intramural, or extramural. The most common benign tumors of the esophagus are leiomyomas, followed by fibrovascular polyps.

Leiomyomas

Leiomyomas are mesenchymal in origin and account for two-thirds of all benign esophageal tumors. The peak incidence for leiomyomas is between the ages of 30 and 59 but can occur in much older patients [126]. In a review of 838 cases, 56% were found in the lower third of the esophagus, 33% in the middle third, and 11% in the upper third [127]. Majority of leiomyomas are intramural and arise from the muscularis propria, but they can also rise from the muscularis mucosa. Esophageal leiomyomas grow slowly, and 50% of cases are less than 5 cm in size [127] and in some instances maybe as large as 15 cm. They can be single or multiple, spherical well-circumscribed intramural, pedunculated intraluminal, or annular masses.

The most common symptoms are dysphagia (46.9%) and retrosternal or epigastric pain (46.7%). Other symptoms associated with leiomyomas are weight loss, nausea, vomiting, reflux, ulceration, and bleeding [126]. Symptoms do not necessarily correlate with size [126, 128].

Large leiomyomas may present as rounded or lobulated lateral mediastinal growths on chest radiography; this is usually an incidental finding in asymptomatic patients. Barium swallow is the first diagnostic test performed in patients with symptoms suspicious for benign esophageal tumors. Leiomyomas present as a well-circumscribed smooth filling defects with normal overlying mucosa on swallows. Endoscopy confirms the tumor location and further evaluates the mucosa overlying the mass. Mucosa is usually normal and moves freely over the mass in leiomyomas; one may observe luminal narrowing. However, mucosal irregularity, ulceration, and luminal stenosis with obstruction are suspicious for a malignant lesion. Endoscopic ultrasonography is useful in differentiating extrinsic vs. esophageal wall tumors and in delineating their layer of origin. Leiomyomas are well demarcated, uniform, hypoechoic masses, which may arise from the muscularis mucosa or muscularis propria [129, 130]. Identification of leiomyomas that originate in the muscularis mucosa permits consideration of endoscopic removal, while those that originate from the muscularis propria require more invasive surgical enucleation [131]. Computed tomography provides information regarding size, location, and anatomic relationships that may aid in operative planning. Endoscopic biopsy or endoscopic ultrasound-guided fine needle aspiration may provide a definitive tissue diagnosis. This should be reserved for lesions suspicious for malignancy as preoperative endoscopic biopsy is associated with an increased incidence of intraoperative mucosal tears [132].

Indications for surgical treatment are unremitting symptoms, increasing tumor size, mucosal ulceration, to obtain histological diagnosis, and facilitation of other procedures. Although controversial, asymptomatic patients should be managed nonoperatively with periodic radiological follow-up [133]. Symptomatic leiomyomas should be enucleated after performing a longitudinal esophageal myotomy; care should be taken to avoid mucosal injury. Myotomy should be reapproximated to avoid mucosal bulging and postoperative dysphagia. Tumors in the upper and middle third of the esophagus are approached from the right side of the chest, tumors in the lower third are approached from the left, and tumors at the GEJ can be resected through an upper midline abdominal incision. Tumors larger than 8 cm and those that are firmly adherent to the mucosa may necessitate esophageal resection [127, 134]. Resection can be achieved via open and minimally invasive techniques. Thoracoscopic approach has been gaining popularity because of its association with decreased hospital length of stay and postoperative pain in comparison to open procedures [132]. Overall patients tolerate resection well with minimal complications, good symptom relief, and no recurrences [133].

Fibrovascular Polyps

Fibrovascular esophageal polyps are intraluminal polyploid lesions that appear most commonly in the upper esophagus near the cricopharyngeus muscle. These lesions occur predominantly in men during the sixth and seventh decades but are also encountered in much older patients. As a group they include fibromas, fibrolipomas, myomas, myxofibromas, pedunculated lipomas, and fibroepithelial polyps [135, 136]. Early lesions consist of nodular submucosal tissue that may over time elongate into a pedunculated polyp. The geometric forces of peristalsis eventually cause the tip of the polyp to reach the distal esophagus.

Fibrovascular polyps come to medical attention when large enough to cause intermittent dysphagia, substernal fullness, or regurgitation of recently ingested material. The presentation may be more acute if a pedunculated polyp obstructs the esophagogastric junction or becomes ulcerated and bleeds. Although rare, regurgitation of the tumor and asphyxiation secondary to acute glottic obstruction are an additional concern [137]. A barium esophagram demonstrates the smooth polyploid intraluminal filling defect. Upper endoscopy can also be used to visualize the polyp and permits the stalk to be traced to its level of attachment [138].

Fibrovascular polyps are resected to relieve symptoms and prevent aspiration and asphyxiation. The greatest polyp size that might be amenable to endoscopic excision is dictated by the polyp's architecture and location and by the endoscopist's skill. Surgical treatment is undertaken when endoscopic removal is unfeasible. The standard approach is through a cervical incision on the side of the neck opposite the stalk attachment. An esophagomyotomy is performed below the cricopharyngeal muscle, and the polyp is delivered into the wound and amputated at the stalk base. If the base is a significant distance below the cricopharyngeus, a right transthoracic approach can be used.

Esophageal (Zenker's) Diverticula

Diverticula can arise in the cervical, thoracic, and epiphrenic portions of the esophagus as a result of internal (pulsion type) or external forces (traction type). As elsewhere, a true diverticulum contains all layers of the esophagus, whereas a false diverticulum contains merely the mucosa and/or submucosa.

Pharyngoesophageal and epiphrenic diverticula are false pulsion diverticula. One example is Zenker's diverticulum (ZD) which arises in an area of muscular weakness in Killian's triangle proximal to the UES. In contrast, midesophageal diverticula are typically true traction diverticula resulting from an inflammatory process in the mediastinum [139].

Esophageal diverticula are ostensibly rare. Since asymptomatic cases are often unaccounted for, the true prevalence is unknown. Zenker's diverticula are usually discovered between the seventh and eighth decades of life, predominantly in men. The prevalence is estimated to be between 0.01% and 0.11% [140].

Clinical Presentation and Diagnosis

Patients with Zenker's diverticula present with dysphagia (98%), aspiration (33%), regurgitation of undigested food, cough, weight loss, noisy deglutition, halitosis, and voice changes. Although patients with midesophageal and epiphrenic diverticula may present similarly to those with ZD, they are more apt to be asymptomatic and their anomalies discovered incidentally. On rare occasions these patients may also present with chest pain, hematemesis from ulceration, or cardiac arrhythmias from atrial pressure [139, 141]. The risk of malignancy arising within a diverticulum is between 0.3% and 1.5% without relation to size or chronicity [142].

A barium esophogram is often sufficient to diagnose the diverticulum and screen for an associated motility disorder. The radiologist should be forewarned of the risk for aspiration in these patients. Based on the findings of cine esophagography, additional evaluation with endoscopy, manometry, and/or cross-sectional imaging may be appropriate. Specifically, endoscopy is useful in the presence of alarm signs and symptoms to rule out malignancy; manometry is useful to characterize an underlying motility disorder that would affect plans for myotomy; and cross-sectional imaging provides details on associated processes, such as inflammation.

Treatment of Zenker's Diverticula

Diverticula causing mild manageable symptoms can be followed. Treatment is indicated for respiratory compromise (e.g., aspiration), weight loss, and unmanageable symptoms.

Surgical Treatment

Surgical treatment of ZD is approached through a neck incision, usually along the anterior border of the sternocleidomastoid muscle on the left owing to the propensity for left-sided pouches. Once the diverticulum is exposed and dissected free from surrounding tissue, a myotomy is performed approximately 2 cm proximally onto inferior pharyngeal constrictor and 5 cm distally through the cricopharyngeus and along the esophagus. There are three options for addressing the pouch itself: -pexy, resection, or inversion (rare). Small pouches (<2 cm) can be treated with suspension or myotomy alone. Medium-sized pouches (2–5 cm) can be treated with a combination of suspension and myotomy. Larger pouches (>5 cm) are typically excised at the base with a linear stapler [140].

Yuan et al. analyzed 93 studies with over 6000 patients to compare various treatment modalities for esophageal diverticula. In the surgical group, overall mortality and morbidity were 0.6% and 10.5%, respectively. The most common complications were recurrent laryngeal nerve injury (3.3%), leak (3.3%), and cervical infection (1.8%) [143]. Resolution of symptoms ranges from 88% to 95% of patients, with a mean recurrence rate of 3.5% [141].

Endoscopic Treatment

Endoscopic treatment of ZD is carried out using either rigid or flexible endoscopy. Suitable anatomy – adequate neck length, sufficient hypomental distance, cervical flexibility, and modest BMI – is required for the rigid endoscope, whereas most patients are accommodating of the flexible endoscope. Regardless of the approach, the goal is to divide the cricopharyngeus muscle separating the esophagus and the pouch. The optimal pouch size for endoscopic treatment is 3–6 cm as smaller diverticula are difficult to intervene upon and larger ones are likely to have persistent symptoms from the new common channel [141]. The most common methods for dividing the common wall are electrocautery, CO_2 laser, stapling, and various energy devices. There is no conclusive data on a single best cutting technique. Discussion of each technique is beyond the scope of this chapter.

In Yuan's endoscopic group, overall mortality and morbidity were 0.2% and 8.7%, respectively. The most common complications varied by technique, but overall these included cervical/mediastinal emphysema (2.2%) and/or perforation (1.4%) [143]. Endoscopic treatment requires conversion to surgery in 15–68% of cases [140]. Success and recurrence rates in the literature vary from 63% to 100% and 0% to 35%, respectively [143].

	Open surgery	Rigid endoscopic	Flexible endoscopic
Complication rate	Higher	Lower	Unclear
Hospital charge	More	Less	Less
Cervical scar	Yes	No	No
Conversion	Never	Occasional	Rare
General anesthesia	Mandatory	Usual	Optional
Neck extension	No	Mandatory	No
Recurrence	A few	Unclear	Unclear
Treatment sessions	Most 1	Most 1	Most >1
Anatomic limitations, stiff neck, poor mouth opening, etc.	No	Yes	No
Small diverticulum	Suitable	Unsuitable	Unsuitable
Large diverticulum	Suitable	Unsuitable	Unsuitable
Reoperation	Hard, risky	Easy, safe	Easy, safe
Special technique	No	Yes	Yes
Dental injury	No	Occasional	Rare
Recurrent nerve injury	Yes	Rare	Rare

Abstract

There is a proven benefit of transplantation for the elderly in terms of quality of life and survival advantage over alternative therapies like dialysis. Frailty, comorbidity, access to transplantation, increasing wait time, and delayed allograft function negatively affect transplant outcomes for the elderly. Age-related comorbidities increase the risk of early mortality for seniors undergoing transplant. Pretransplantation activity and baseline

cognitive function may impact suitability for transplantation and should carefully be considered during the selection process. The aging immune system, age-associated alterations in drug pharmacokinetics, and the risk associated with over-immunosuppression can make immunosuppression management a challenge in this population. Lack of adequate social support and finances can account for noncompliance leading to a poor outcome. When all these factors are taken into consideration, selective geriatric candidates can experience comparable benefits from transplantation as younger candidates. This chapter provides a concise review of factors that can make transplantation a success in the geriatric population.

Introduction

It is now well recognized that elderly patients undergoing transplantation for end-stage organ failure experience improved quality of life similar to their younger counterparts [1]. The number of transplants performed in the elderly has steadily increased over the last decade [2, 3]. Similarly, elderly patients now account for a significant percentage of the transplant wait lists. As of 2015, 22% of patients on the kidney wait list and 20% on the liver wait list were above the age of 65 years [2, 3]. Projections from the Scientific Registry of Transplant Recipients (SRTR) annual report 2015 show that in the coming years there will be an increase in the number of transplants performed in this age bracket. Once considered a relative contraindication in the elderly, transplantation in this age group now forms a sizable population in any transplant program. Identifying features related to transplant outcomes that are unique to this transplant cohort is crucial for ensuring good results since older patients tend to have decreased patient and graft survival after transplantation when compared to younger recipients [4]. However, transplantation is pursued in the elderly population as it confers a definite survival advantage over remaining on the wait list [3].

The main challenges to transplantation faced in this population are complex medical comorbidities, frailty, and managing immunosuppression. The main reason for graft loss in this population is death with a functioning graft. Therefore, as newer organ allocation systems look to optimize utilization of organs, it is likely that the elderly may be disadvantaged. Approaches to counter this may be found in the use of organs from expanded criteria deceased donors or from living donors. Both have shown to be good strategies to increase patient and graft survival in the elderly [5]. Besides the challenges that transplant centers face when considering transplantation in the geriatric population, these patients also face various dilemmas with the onset of organ failure:

1. What treatment options do I have at this age for organ failure?
2. Should I remain on dialysis or will I be able to tolerate a transplant?
3. Which organ is suitable for me, younger kidney with a longer wait time or marginal kidney with a relatively shorter wait time?
4. Should I be looking for a living donor (either related or nonrelated)?
5. Will I be able to afford the posttransplantation care and medications?

The Elderly: Is It Age or Frailty or Both?

Aging is associated with functional and phenotypic changes in the immune system that presents unique challenges regarding immunosuppression management. Aging is also associated with functional decline in other organs systems and that increase the potential of morbidity and mortality from complications after transplantation. Cognitive decline with age may interfere with medication compliance and competence in understanding transplantation in general. It is widely accepted that there is a gap between chronological and biologic age of an individual. Frailty has a significant role to play in defining this gap.

The prevalence of frailty over the age of 65 years has been estimated to be 7–12% [6]. The concept of frailty has been defined as the increased vulnerability of an individual to stressors accompanied by a decline in reserves and functioning of several physiologic systems [6]. Frailty has a negative impact on the outcome after transplantation over and above that can be accounted for by aging alone. Even though the exact mechanisms are incompletely understood, frailty has been found to be associated with dysregulation of energy metabolism, immunosenescence, inflammatory responses, and a deleterious effect on all physiologic systems [6]. It would therefore be of clinical relevance to identify potentially “frail” recipients early in the evaluation process to assure a survival benefit subsequent to transplantation.

Frailty has been associated with an increased risk for adverse postoperative outcomes across various surgical specialties and has been shown to predict prolonged hospitalization, early hospital readmissions, and 30-day postoperative complications independent of age [7–10]. With regard to transplantation, frailty has been identified as an independent risk factor linked to a twofold risk of delayed graft function and mortality following kidney transplantation [11, 12]. Frailty has also been shown to be an age-independent risk factor for early hospital readmissions, with a 1.5-fold adjusted risk for early readmissions in kidney transplant recipients [13]. Sarcopenia or muscle loss, which is often prevalent in the older population, is associated with an increased risk for infectious complications and mortality following liver transplantation [14, 15].

Given these findings, screening for frailty is highly relevant for determining if transplantation in the geriatric population would be truly beneficial. Even though visual assessment is usually adequate to identify frailty, objective diagnostic tools have been developed to improve accurately and consistency in assigning this descriptor. The two widely used tests include the 5-point questionnaire developed by Fried et al. [12] that asks about unintentional weight loss (10 lbs in the past year), self-reported exhaustion, muscle weakness (grip strength), slow walking speed, and low physical activity and the Frailty index which is based on clearly identifiable deficits (measured by clinical symptoms, functional impairments, and laboratory findings) that are compared to age-expected deficits [12, 16].

What Can Be Done to Address Frailty?

In the presence of old age and frailty, physical rehabilitation in the form of exercise training enables patients to effectively participate in activities of daily living and lessens the morbidity caused by chronic illness. Multiple interventions have been proposed that aimed at increasing aerobic capacity by maximizing oxygen uptake (VO2 peak), improving muscle and bone strength, maintaining body composition, and preserving quality of life by reducing fatigue [17]. Exercise and physical activity also have the ability to mitigate posttransplant complications and long-term side effects of immunosuppression such as hypertension, diabetes, and weight gain. Over 30 randomized controlled trials (RCTs) have been conducted to examine the effectiveness of exercise training on outcomes in solid organ transplant recipients [18]. The combination of frailty and old age on a background of chronic illness is associated with poor nutrition, which promotes anemia and hypoalbuminemia. Improving nutrition in this population, with focus on increased protein intake, prevents progression of sarcopenia [19].

Transplantation in Elderly Patients: Criteria for Selection

A diversity of outcomes has been reported in the literature regarding the outcomes of elderly recipients following liver transplantation [20–22]. There is now a greater understanding that physiological age is far more relevant than chronological age when considering suitability for a liver transplant recipient. For example, the presence of preexisting coronary artery disease and arrhythmia is an independent predictor of poor long-term outcomes following transplantation, and cardiac disease is one of the most common causes of mortality among the elderly transplant recipients [23]. Physiological age or general health in the elderly is usually assessed by a thorough geriatric assessment. There are several well-validated tools available for a geriatric assessment, most of which incorporate comorbidity measurement, functional status, nutrition, social support, and other health-related domains like urinary/fecal continence, etc. [24]. Biologic age has been the term used to represent the true chronologic age, while the concept of physiological age has usually been used to describe someone who is in better health than expected for his age. The concept of frailty on the other hand describes someone whose health status is worse. Both these concepts are crucial in deciding candidacy for transplantation as they have an impact on outcomes [6, 24].

Justification of Transplant in Elderly End-Stage Renal Disease Patients

The last decade has seen an alarming growth of the kidney transplant wait list in the United States from 30,000 to more than 100,000 candidates [25]. Among the population with ESRD, patients over 65 years of age are the fastest growing age group worldwide. It is therefore not surprising that elderly individuals are more likely than ever to receive a kidney transplant [26]. The proportion of kidney transplant recipients $\geq$65 years of age alone has increased from about 10–15% in 1997 to 20–30% in 2014 [27].

The survival benefit of kidney transplantation over dialysis was first demonstrated in 1999 by Wolfe et al. [28] Studies previous to then reported equivalent survival for dialysis and transplantation in patient ages 65–70 years and worse survival outcomes after renal transplantation in comparison to remaining on dialysis [26, 29]. Over time, the transplant survival benefit has extended to various patient subgroups including the elderly patients aging 60–74 years old at the time of transplant [30].

There is no absolute age cutoff for kidney transplant candidacy, however; overall health of the patient, with regard to frailty and coexisting comorbid illness, is an important consideration when selecting elderly candidates for transplantation. The UK Renal Association guidelines state that "age is not a contraindication to transplantation, but age-related comorbidity is an important limiting factor," while the American Society of Transplantation guidelines maintain "there should be no absolute upper age limit for excluding patients whose overall health and life situation suggest that transplantation will be beneficial" [31, 32]. In general, instead of applying definitive age limits, a careful assessment of patient's physiological age rather than chronological age should be considered when determining candidacy for transplant. Several studies have shown that despite age, elderly patients receiving renal transplants fair better than their counterparts on chronic dialysis in terms of general physical health, social functioning and independence, and mental health [33, 34].

Access to Transplantation for Seniors: The UNOS New Allocation Policy

Although it can be assumed that wait-listing of elderly patients is mainly determined by coexisting comorbidities, it has been reported that wait-listing is often not even considered in the absence of any formal contraindications [35]. Reasons for non-consideration for transplantation in the elderly are multifold including lack of referral by treating nephrologists, misconceptions regarding candidacy or criteria for transplantation in dialysis centers, patient uncertainty as potential candidates, physician's belief of "displacing" a kidney from a younger potential recipient, and lack of dissemination of education related to transplantation [36]. In Europe and the United States, only about 10% of ESRD patients aged 65 years or older will be wait-listed and/or transplanted within the first 4 years of ESRD therapy, while in those below 65 years of age, this figure is as high as 60% [37, 38]. It has been shown that the wait time for a deceased donor renal transplant (DDRT) has exceeded the life expectancy for subgroups of the elderly candidates who were non-white, blood type B or O, highly sensitized, 70 or older, diabetic, female, with excessively low or high BMI, or on dialysis [39]. Although access to transplantation for older patients has improved in the recent years, the cumulative probability of transplantation from any donor source (deceased or living) at 3 years after initiating dialysis was only 7.3% [40].

The original national kidney allocation system was based on accumulated time since wait listing. Kidneys were dichotomized into standard criteria donor (SCD) or extended criteria donor (ECD) classification based on the donor organ quality. This classification disadvantaged placement of ECD kidneys, leading to high discard rates of many otherwise transplantable organs. Allocation seemed inefficient with placement of kidneys with long projected posttransplant graft survival in recipients with short posttransplant life expectancy and vice versa. One of the first large-scale initiatives for efficient organ allocation is the old-to-old approach launched by the Eurotransplant Senior Program (ESP) in 1999 [41]. Kidneys from donors age 65 years or older were allocated to recipients age 65 years or older within a narrow geographic area without considering donor HLA matching in order to minimize cold ischemia time with acceptable 5-year patient and allograft survival. In the United States, a new allocation system was implemented in 2014 to overcome shortcomings of the older allocation with several prominent changes including replacement of the SCD/ECD designation to KDPI (kidney donor profile index), which more accurately expresses quality of the donor kidneys. This index uses ten donor parameters and allows calculation of estimated post-transplant survival (EPTS), to enable 20% of candidates with the highest EPTS to receive priority for the top 20% of kidneys and offer efficient combined local and regional placement of kidneys with KDPI >85%. This system enhances utilization of these organs and minimizes the discard of the 15% of kidneys with the shortest estimated potential length of function to [42]. With this allocation in practice, senior recipients are faced with two challenges, a proportional shift of deceased donor kidneys toward younger recipients resulting in increasing wait times and increased availability of marginal or higher KDPI kidneys for transplantation with high perioperative morbidity which could compromise graft and patient survival.

Due to the long waiting list, allocation of kidneys for transplantation needs to be optimized to maximize the utility of kidney allografts. This is relevant when transplanting elderly patients where the lifespan of the kidney can be limited by age-related illness and mortality. In an otherwise healthy recipient 60 or older, this risk is more than double that of a younger adult recipient (9.2% versus 3.5%, respectively) [43]. The risk of mortality in the first year after a DDRT is higher for older transplant recipients compared to those remaining on the wait list, and this further worsens in the presence of age-related comorbidity or other factors such as delayed graft function (DGF) or receiving an ECD kidney. The survival advantage of transplantation markedly decreases along with increasing costs as wait time increases for a deceased donor in older patients. Hence, some transplant centers advocate DDRT for relatively healthy senior patients up to ages 65–70 with wait times up to 2 years and living donor transplantation in other situations or in patients up to age 80 years [44].

Selecting the Right Candidate: Evaluation Issues in the Elderly

Overall, the health status of an elderly individual impacts their chance of being transplanted. An extensive pretransplant evaluation and risk stratification are therefore warranted to avoid transplanting frail patients with comorbidities and maintain the balance between benefits and harms of transplantation. Certain surrogate markers of frailty or poorer general condition includes a prolonged time between start of dialysis and placement on the waiting list since longer dialysis period tends to exacerbate complications and comorbidities. Similarly, period of “inactive status” on the wait list could also indicate poor health. There are varying recommendations for exclusion of elderly patients for transplantation. Patients with an anticipated post-transplant 5-year survival of less than 80% or an anticipated overall survival of less than 2 years, patients predicted to experience worsening quality of life, or those who had a low probability of surviving beyond current waiting times should be preferably excluded from listing [31, 45–48].

There are no clear-cut selection guidelines for transplant candidacy in elderly patients. Most transplant programs adopt their own listing policies depending on wait times for availability of deceased organs, existing comorbid conditions of the potential recipient, and other criteria deemed suitable per the center's policies. Several factors to be considered when determining transplant candidacy in an elderly patient include overall health status; comorbidity from cardiovascular disease and malignancy; "geriatric syndromes" such as delirium, falls, and frailty; functional and cognitive impairment; and adequacy of social and financial support. Due to large geographic variations in the wait times within the 58 donor service areas, local waiting times are equally important [49]. Since waiting time also depends on the blood type, patients with O and B blood types have the longest waiting times, whereas A and AB blood types get transplanted sooner [50]. Hence, an elderly patient with an unfavorable blood type, in an OPO with long waiting times, will have a better chance at survival with a living donor. In the absence of reliable tools to accurately estimate duration of survival posttransplant, pretransplant physical function is highly predictive of posttransplant outcomes [51]. Frailty is highly prevalent in individuals with ESRD, and hence simple evaluation of frailty scores prior to listing can help identify candidates at risk of poor performance posttransplant [52, 53]. In older patients, frailty is independently associated with postoperative complications, length of stay, discharge to a skilled or assisted-living facility, and mortality [7, 9, 54]. A single-center study of kidney transplant recipients found a 25% prevalence of frailty, threefold higher than community-dwelling older adults. Frailty was found to be a strong independent risk factor for DGF and mortality. Frailty is associated with a 94% increased risk of delayed graft function, a 61% increased risk of early hospital readmission, and a 2.2-fold increased risk of mortality compared to non-frail recipients [55]. In liver transplant recipients, sarcopenia, estimated by core muscle size and considered as an effective objective surrogate of frailty, is associated with higher risk of posttransplant infections and mortality [14, 15].

Elderly patients are more likely to have coexisting comorbid conditions; therefore, careful screening of cardiovascular disease and cancer is mandatory to assess perioperative and long-term mortality risk. According to the American Heart Association and the American College of Cardiology Foundation, noninvasive stress testing may be considered in patients $\geq$60 years without any active cardiac conditions but presence of two of the following coronary artery disease risk factors including diabetes, hypertension, dyslipidemia, prior cardiovascular disease, left ventricular hypertrophy, smoking, and more than 1 year on dialysis [56]. On the other hand, the ERA-EDTA guidelines recommend performing a standard exercise tolerance test and cardiac ultrasound such as asymptomatic high-risk patients and restricting noninvasive stress imaging (dobutamine stress echocardiography or myocardial perfusion scintigraphy) only for candidates with a positive or inconclusive exercise tolerance test. Patients with a positive stress test need further evaluation with coronary angiography to assess ischemia [57]. Evaluation for cancer includes colonoscopy, mammogram, Pap smear, prostate-specific antigen, and skin examination as indicated. Atherosclerotic vasculature and lack of appropriate sites for implantation often rule out candidacy in older patients, and hence suitable imaging studies, such as a CT scan of the abdomen and pelvis without intravenous contrast, are necessary part of the evaluation process. Aging is associated with increasing incidence of depression, cognitive impairment, and dementia which is poorly recognized in the ESRD population [58].

Even subtle cognitive deficits may impair a candidate's ability to follow the complex posttransplant medical regimens necessary for successful outcomes. Despite the high prevalence, testing for cognitive impairment is not routinely performed. High-risk elderly candidates should undergo neuropsychologic testing to identify those who are at increased risk of functional decline, repeated hospitalizations, and eventually death. Validated screening tools for detection of cognitive defects in this population are the Montreal Cognitive Assessment tool, Mini-Mental State Examination, and the St. Louis University Mental Test to name a few [58]. Lack of adequate social support and finances may be another impediment in this population. The elderly often face social isolation due to depression, loss of a spouse or partner, financial restraints, visual or functional impairment, and cognitive deficits. Most patients 65 years or older qualify for Medicare that will cover 80% of the cost of transplantation; however, additional supplementary insurance is required to cover medication costs. Absence of social and financial support often leads to noncompliance and poor outcomes [33].

Organ Selection for the Elderly Transplant Candidate

Liver Transplantation

Livers from donors aged over 70 years are much more likely to be discarded than livers from younger donors [59]. However, use of such livers has shown to have acceptable outcomes and, in several cases, results equivalent to those obtained using livers from donors younger than 70 years of age [60, 61]. Important to the success of using older organs is minimizing cold times (<8 h) and the extent of macroscopic steatosis and restricting use of such organs to recipients without acute liver failure or hepatitis C, first transplants, age less than 45 years, and with body mass index below 35 kg/m^2 [62, 63].

Kidney Transplantation

Organ options for kidney transplantation in the elderly include kidneys from a living donor or a deceased donor, i.e., donation after brain death (DBD) or cardiac death (DCD). Living donor offers the least risk of perioperative mortality due to immediate function and the best long-term outcomes in elderly transplant recipients [64]. Even the use of an older living donor in this population has shown acceptable outcomes [65, 66]. Survival advantage over dialysis is now well established with the use of low or high KDPI grafts (>85%, expanded criteria donor per older terminology). However, the survival benefit with DCD donors is unclear. This is due to the risk of perioperative morbidity and mortality from the 40% rate of delayed graft function (in comparison to the 20% rate otherwise), which can further have a negative impact in an elderly recipient [67]. In general, for most elderly patients the choice of an organ will largely depend on local waiting time, recipient age, race/ethnicity, cause of renal failure, and projected survival on dialysis.

The Older Living Donor: Should There Be an Upper Age Limit?

Liver Transplantation

Living donor liver transplantation provides an alternative organ resource to deceased donor livers. Although usually used for pediatric and lower MELD adult liver failure patients in the United States, this is the main resource for liver transplantation in several Asian countries due to the scarcity of deceased donors [68, 69]. The use of older living donors has increased over time, but the number of donors aged over 60 years remains very limited [70, 71].

Though not a common practice, isolated reports of live liver donors over 70 years of age have been cited [72]. The use of elderly living liver donors is controversial not only due to the increased risk of complications to the donor but also due to the risk of primary nonfunction and lower graft survival in such cases. Hence in the United States, age for a liver living donor is limited to less than 60 years [73, 74].

Kidney Transplantation

Living donor renal transplantation is the best option for ESRD not only in terms of a valuable resource for organ shortage but also offers the best outcomes for patients, in terms of graft and patient survival. As the rate of living donor kidney transplantation has gradually increased, the selection of older living donors (>60–65 years) has also increased. Several large cohort studies including older living kidney donors have found no significant differences in perioperative surgical morbidity and mortality for these donors compared with younger donors and similar risk of death and end-stage renal disease (ESRD) to that of matched controls from the general population [75–78]. Older donors not only scored higher than their younger counterparts in post donation quality of life surveys but also reported higher satisfaction with cosmetic outcomes of the surgery [79, 80]. Overall, there is no current evidence precluding kidney donation over the age of 60 or even 70 years.

Age of the donor has a direct impact on the transplant outcome. With regard to graft and recipient survival, outcomes of kidneys from older living donors are inferior to those from younger living donors; however, this difference dissipates over time [65]. Death adjusted and unadjusted allograft survival is comparable between kidney transplantations from old and young living donors [81]. When compared with deceased donors, graft survival with older living donors was still better than that of kidneys from deceased older donors and comparable to that of kidneys from deceased younger donors. Hence, a carefully selected older living donor should never be excluded especially when this may be the best option for a sensitized patient or when it is the only living donor option for a patient.

Immunosuppressive Strategies in Older Recipients

Graft loss in the elderly most often reflects death with a functioning graft, death resulting from existing cardiovascular risk which is further aggravated by immunosuppression in addition to associated infections and malignancies. Hence understanding the structural and functional changes of the immune system in the elderly population is prudent for selecting the best immunosuppressive strategy for this age group.

Immunosenescence and Immunological Characteristics of the Elderly Recipient

Older patients have an age-associated progressive decline in immune functions defined as "immunosenescence." With advancing age, the ability to respond to an immunological challenge decreases. Increased morbidity and mortality associated with aging result from multiple mechanisms altering the innate and adaptive immune system. Senescence affects the innate immune system, which serves as a major barrier against infections, by increasing pro-inflammatory cytokines [82]. This effectively exacerbates ongoing chronic allograft damage by increasing the inflammatory response. Dysregulation and alteration of the receptor-driven functions of neutrophils, such as apoptosis, chemotaxis, and superoxide anion production, in older patients increase the risk of mortality from infectious complications. Natural killer (NK) cells participate in immune response against solid organ grafts through allograft rejection and tolerance and may predict morbidity and mortality in older people through an essential role concerning risk of infections and cancers [83]. Older patients have been shown to have a decreased proliferative response of NK cells when stimulated with IL-2 [84].

Old age-related thymic involution affects adaptive immunity with reduction of the number of circulatory naïve T cells and a compensatory increase in memory T cells [85]. This reduction in naïve T cells has thought to be a reason for lower rates of acute rejection in the elderly. However, this has not translated to successful withdrawal of immune suppression [86]. Humoral response is also altered with reduced number of naïve B cells in comparison to the memory B cells [85]. Overall, this increases morbidity associated with the individual's vulnerability to infection from reduced antibody formation, tendency to form autoantibodies, and enhanced release of inflammatory mediators [85].

Risk and Challenges for Immunosuppression Considerations

In terms of the effect of aging on rejection and infection, patients >65 years of age experience a much lower (20%) risk of acute rejection in comparison to the 37% risk in younger patients and a fivefold increased risk of death due to infection [87, 88]. Risk of acute rejection increases with the use of kidney from an older donor, and this may affect long-term graft survival due to critical nephron loss in an already marginal kidney [89]. Early acute rejection within 90 days of transplantation adversely impacts both patient survival and death-censored graft survival [90]. Immunosuppressed elderly patients with an already compromised immune system are at an increased risk for developing severe infections with an exponential increase in death related to infectious complications [91].

Use of immunosuppressive agents in the elderly is associated with increased rates of post-transplant morbidity. Immunosuppression causes a 30% increase in the risk of new-onset diabetes after transplant per decade of age [92]. Compared to younger kidney transplant recipients (20–29 years old), the relative risk of immunosuppression-associated cancer in elderly recipients is 8.92 for recipients between 60 and 69 years old and 11.6 in recipients >70 years old [93]. Kidneys from older donors are more susceptible to ischemia/reperfusion injury and associated risk of delayed graft function and acute rejection due to vascular and glomerular senescence. As a result, nephrotoxicity from calcineurin inhibitors (CNI) can be exacerbated in aging kidneys, further increasing risk of chronic allograft nephropathy and graft loss [94]. Other aspects that need to be considered when formulating immunosuppression strategies for the elderly include adverse drug reactions, drug-drug interactions, and medication non-adherence that has a strong inverse relationship with the number of drugs prescribed [95].

General Considerations for an Optimal Immunosuppressive Regimen

There is a limited evidence for age-adapted immunosuppressive regimens due to the underrepresentation of this age group in clinical trials. In general, elderly transplant recipients receive the same immunosuppression regimens as their younger counterparts. However, old age is a risk factor for many drug-related adverse effects. Age can affect responses to medication with increased organ susceptibility for drug-related toxicity or drug-drug interactions. Age-related changes in drug pharmacokinetics include decrease in drug absorption, reduced hepatic metabolism due to age-related decrease in hepatic mass and blood flow, and increase in the volume of distribution for lipophilic drugs due to increase in the percentage of body fat compared to body water [96]. Elderly recipients are at higher risk for early acute rejection in the presence of an older allograft, and long-term immunosuppression is associated with an increased risk of infections and malignancies. Hence adequate initial and finely tuned maintenance immunosuppression is the key for optimal long-term allograft outcomes in this group. Despite the absence of randomized trials, CNI and steroid minimization or early steroid withdrawal have been recommended in this population due to the deleterious effects of these medications on blood pressure along with lipid and glucose metabolism [97, 98].

Use of induction immunosuppression in the elderly has been popularized in the United States in the last few years to enable CNI minimization and early steroid taper or withdrawal. More than two-thirds of the recipients over 60 years old receive induction with either anti-thymocyte globulin (ATG) or interleukin-2 receptor antagonists (IL2RA) [99]. Use of ATG in in this situation has shown a reduction of the risk of acute rejection with improved graft survival [99]. However, the use of ATG increases the risk of morbidity and mortality from infections, especially when the cumulative dose exceeds 6 mg/kg [100]. Monitoring of lymphocyte depletion by measuring CD3/CD4 counts can help guide ATG therapy. As such, recipients with high immunological risk benefit with induction therapy using ATG, whereas IL2RA is a safer option for low or intermediate risk [99].

The increased frequency and severity of steroid associated complications including infections, impaired wound healing, fractures, diabetes, and cardiovascular events provides a good rationale for steroid avoidance or early taper in older population. In comparison to standard steroid therapy, steroid avoidance or early withdrawal has been shown to be associated with higher 3-year patient survival (83.6 vs 86.3, $p = 0.004$) despite a modest increase in the rate of rejection (14.3% versus 12.3%, $p = 0.002$) [98]. Attempt at steroid minimization is thus justified in older patients with low immunological risk. CNI minimization also helps reduce early as well as delayed nephrotoxicity. The latter in addition to the cardiovascular side effects of CNIs can result in graft loss [101]. Belatacept is a new costimulatory blockade molecule, targeting the CD80-CD86/CD28 pathway, which has been proposed as an alternative to CNIs [102]. Its use led to comparable rates of DGF and acute rejection but resulted in lesser toxicity in terms of better renal function, better blood pressure control, and better lipid profile and lesser incidence of NODAT at 5-year post-transplantation [102]. As it is administered by scheduled monthly injections, it also has an added benefit of better long-term medication compliance and adherence [103].

There is limited information about long-term immunosuppression management in the elderly. Therapy is usually individualized with modifications made in the face of serious complications of drug-related side effects, life-threatening infections, or cancer.

Outcomes

Transplantation for elderly with end-stage organ failure has a definite survival benefit over other treatment modalities currently available. Elderly individuals who receive kidney transplants benefit from a substantial reduction in mortality with a nearly 4-year increase in their projected lifespan compared to those who stayed on dialysis [28]. This benefit was dependent on the quality of the graft, as patients who received grafts from living donors had a higher probability of survival at 5 years [3]. Also, among elderly recipients of deceased organ donors, those from younger donors have better survival than those from older donors. The 5-year patient survival for kidney transplant recipients above 65 years of age receiving a deceased donor organ was 75.2% while for those who received living donors was 83.9%. For the same age group, 5-year allograft survival for recipients of a kidney from a deceased donor was above 70% while for those with a living donor was 79% [3]. As mentioned above, the main reason for graft loss in this population is death with a functioning graft. Death-censored graft survival on the other hand is no worse in the elderly than it is in their younger counterparts [3].

Mortality for end-stage liver disease in the elderly is significantly higher than mortality in younger patients, resulting in higher wait list mortality in this age group. For patients aged above 65 years, the wait list mortality was the highest of all age groups at 13 per 100 patient years [2]. In comparison, wait list mortality for patients aged 18–34, 35–49, and 50–64 is 8, 11, and 11, respectively, per 100 patient years [2]. In patients aged above 65 years, 5-year graft survival is 63% while patient survival at 5 years is 68% [2]. This was markedly lesser than their younger counterparts. Having said this, another rationale used to justify transplantation in the elderly is the transplant-related survival benefit. It is representative of the difference between life expectancy with and without transplant. Despite lower 5-year survival, the elderly demonstrated a transplant-related survival benefit similar to younger patients [104]. The main reasons for graft loss in this age group were also death with a functioning graft. Overall, graft failure was not an important cause of death, and death-censored graft loss rates were not higher for older recipients when compared to this age bracket [105].

In recent years, outcomes after transplantation have moved beyond morbidity and mortality to incorporate quality of life. Transplantation has a positive impact on the quality of life of the elderly. Data from studies performed by several groups across the country demonstrate QOL metrics at 1 year from transplant are similar to or even higher than age-matched values from the general population. Also, in the case of kidney transplantation, another benefit of transplantation in the elderly is its cost-effectiveness over remaining on renal replacement therapy such as hemodialysis or peritoneal dialysis. However, if wait times for transplantation increased to over 2–4 years for the elderly patient, the cost benefits to be gained from transplant appear to diminish [106]. Strategies to counter the compounding effect of waiting are the early use of living donors or the use of donors from increased risk population and marginal deceased donor kidneys with KDPI >85%.

Conclusion

The recent era has seen an increase in the percent of elderly transplant candidates because of the demographic changes resulting from increased longevity of the population. While there are no absolute age cutoffs for consideration to receive a transplant, frailty and comorbidities in an elderly transplant recipient can reverse the survival benefit offered by transplantation. Frailty, baseline cognitive function, physical impairment, lack of mobility, history of infections or malignancy, and cardiovascular comorbidity assessment during transplant evaluation are critical in the elderly to better predict their suitability for transplantation. The new kidney allocation system, implemented in 2014, made provisions to better age-match donors and recipients as well as directed the best quality of organs to the recipients among the top 20% of wait list candidates with the longest estimated posttransplant survival. This is likely to adversely impact the senior population by decreasing the proportion as well as quality of deceased donor organs available for transplantation. It may also lead to increasing the wait times to transplant for the elderly. Since the survival advantage of transplantation markedly decreases with increasing wait time, increased utilization of increased risk donors, marginal deceased donor kidneys with KDPI >85% (analogous to previous extended criteria allocation) and living donor kidneys have emerged as realistic options for timely transplantation of the elderly recipients. The concept of "old for old" allocation should be judiciously applied taking into consideration the deleterious effects of delayed graft function particularly in this population and the increased risk of first-year mortality. Implementation of measures to reduce the incidence of DGF by quicker allocation of such marginal kidneys to older recipients locally or over a narrow geographic area will help minimize the cold ischemic times. Immunosuppressive protocols should be individualized based on the clinical course and immune monitoring taking into consideration the decreased alloresponse of an older recipient and the increased immunogenicity of older organs. Nonetheless, the 5-year patient and graft survival for elderly recipients are comparable to the younger population with proper candidate selection. By carefully balancing the benefits and risks associated with organ transplantation in elderly recipients, we can offer them improved physical and mental health leading to improved vitality in the elderly.

44 Benign and Malignant Tumors of the Liver

Rebekah R. White and Vijay G. Menon

Contents

Abstract

As the population ages, mortality from cancer has increased, and increasingly cancers of the liver are being encountered in an older population both in the USA and worldwide. The most commonly encountered primary tumor is hepatocellular carcinoma, and the most commonly encountered metastatic tumor is of colorectal origin. Evaluating elderly patients for surgical management involves assessment of their preoperative function, both with overall physiology and evaluation of the liver itself. Prehabilitation regimens to optimize the patient are being promoted, and assessment of the aging liver for cirrhosis and regenerative

capability needs to be assessed or even augmented. Benign tumors in otherwise asymptomatic patients rarely require intervention and are usually observed. Malignant tumors are managed with multiple modalities including surgical resection or transplantation, liver-directed therapies such as ablation or hepatic artery embolization, as well as chemotherapy or biologic therapy targeting the relevant tumor type. Data is conflicted, regarding outcomes of performing complex hepatobiliary surgery in the elderly, but overall advancing age in a patient with appropriate physiological and liver reserve should not preclude surgery.

Keywords
Hepatocellular carcinoma · Cholangiocarcinoma · Liver metastases · Benign liver tumors · Liver resection · Cirrhosis · Liver disease · Liver transplantation · Prehabilitation · Liver regeneration

Introduction

Over the last two decades, the field of hepatobiliary surgery has evolved and continues to push limits with improving outcomes. Multiple studies have shown that major resections can safely be undertaken with good outcomes, but only a small percentage of these studies have specifically looked at surgery in the older population. The purpose of this chapter and this textbook is to evaluate disease processes and their management in the elderly, and to that end we review the existing data as well describe our experiences in managing liver tumors in the elderly.

Case Study

Background

A 78-year-old male with morbid obesity and insulin-requiring diabetes mellitus who presented with RUQ pain and liver function test (LFT) abnormalities. Ultrasound demonstrated

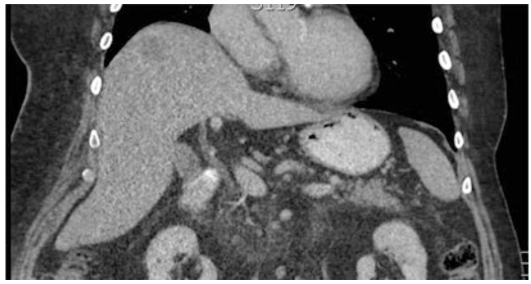

Fig. 1 Triphasic CT with irregularly shaped mass

choledocholithiasis as well as a mass in the dome of the liver. Subsequent triphasic CT demonstrated an irregularly shaped 5 cm mass with slight arterial enhancement but most clearly seen in the venous phase (Fig. 1). The patient underwent ERCP with successful clearance of the common bile duct and resolution of his symptoms. He was transferred to our center for further management. Lab work was remarkable for a mildly elevated CA19-9 (66), a normal AFP and CEA, and normal LFTs except for low albumin (3.1) and mildly elevated transaminases. PET/CT demonstrated mild uptake (SUV3.9) in the mass and no extrahepatic disease.

Management

The patient was taken to the OR for laparoscopic (hand-assisted) wedge resection and cholecystectomy. A thoracic epidural was placed preoperatively for postoperative pain control. His postoperative course was remarkable for an acute increase in his creatinine to a high of 1.9 on POD#2 that was attributed to relative hypotension associated with epidural and which improved after discontinuation. He was discharged to a SNF on POD#5 then subsequently returned to living independently at home. Pathology revealed moderately differentiated hepatocellular carcinoma with negative margins in a background of steatohepatitis. He was doing well without evidence of recurrent disease at his 3 month follow-up visit. This case highlights the challenges of managing liver tumors in elderly patients who often have multiple comorbidities. Minimally invasive approaches may help to shorten hospital stays and are particularly useful in obese patients who are at risk for significant wound complications. The use of epidural anesthesia remains controversial, and – while avoidance of systemic narcotics is certainly beneficial in elderly patients – the risks of associated relative hypotension need to be recognized.

Epidemiology of Liver Neoplasms

With an aging population, cancer diagnosis and mortality from cancer have increased, nearly matching "traditional" causes of death such as cardiovascular disease (Fig. 2) [1]. Recent CDC data from 2014 ranks heart disease, *malignant neoplasms*, chronic low respiratory disease, cerebrovascular disease, and Alzheimer's disease as the five leading causes of death in the population older than 65 years [1]. It is estimated that there will be approximately 600,000 cancer-related American deaths in 2016.

SEER data [3] show that primary liver cancer – hepatocellular cancer (HCC) and intrahepatic bile duct cancer/cholangiocarcinoma (ICC), together – is currently the 13th most common cancer in the USA. However, with an annual increase in incidence of 3.7% and 3.0% in males and females, respectively, primary liver cancer is estimated to become the 11th most common cancer by 2030 [4].

Although there are several more common cancers than HCC and ICC, the mortality rates from these cancers are high with overall 5 year survival of 17.5% in the USA [3]. Currently, HCC and ICC are the fifth leading cause of death in the USA with estimates suggesting that by 2030, these cancers will become the third leading cause of cancer death in the USA [4]. Of note WHO data shows that after lung cancer, liver cancer is already the leading cause of cancer-related death worldwide with 788,000 deaths in 2015 [5].

SEER data show that the median age at diagnosis of liver and intrahepatic bile duct cancer is 63 years (Fig. 3) [3] suggesting that there is a large patient population over 65 years of age who could potentially undergo surgery, although localized disease is seen overall in only 43% [3].

The most common malignant liver tumors in the USA, however, are secondary (metastatic) tumors, with the most common primary origin being colorectal cancer (CRC). The overall

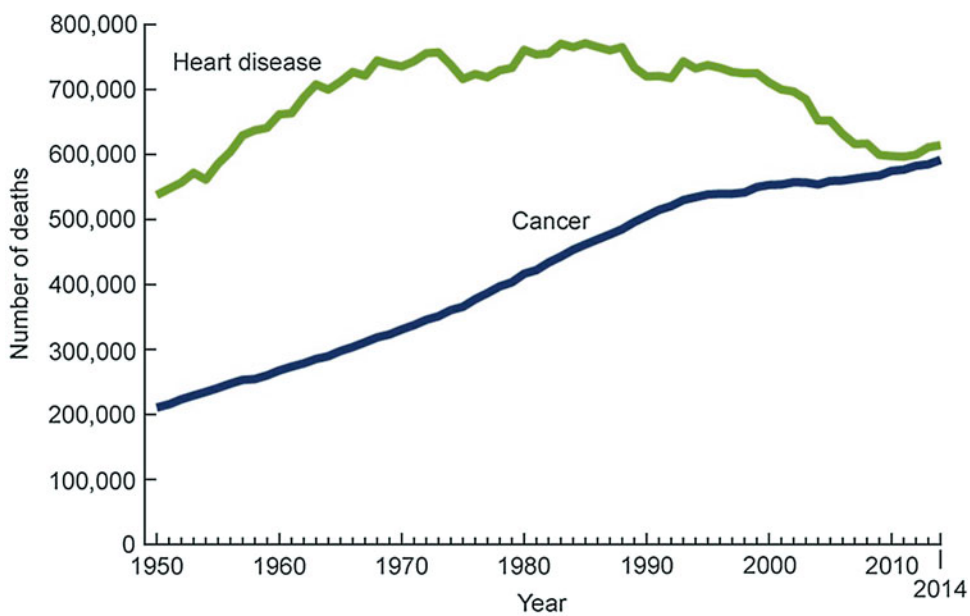

Fig. 2 Number of deaths due to heart disease and cancer [1]

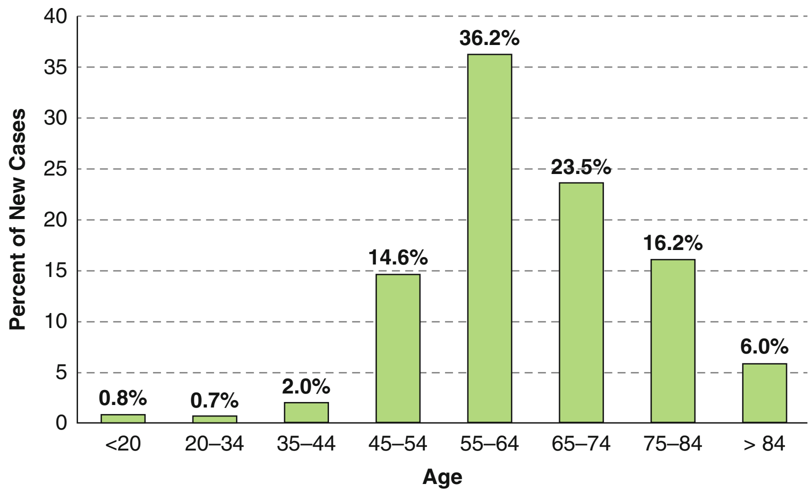

Fig. 3 Percent of new cases by age group: liver and intrahepatic bile duct cancer [3]

incidence of CRC is 41.0 per 100,000, with an overall lifetime risk of 4.4% of persons being diagnosed with CRC. Most cases occur in patients older than 65, with a median age of diagnosis of 68 years, and approximately half of patients diagnosed with CRC will present with or develop liver metastases.

Benign liver tumors are much more common than malignant tumors and are often noted incidentally on ultrasound. They are more commonly seen in patients under 50 years of age, with recent data supporting hemangiomas as being more prevalent (3.6%) than focal nodular hyperplasia (0.18%) and hepatic adenomas (0.04%) [2].

Liver Surgery in the Elderly

Operating in the elderly population is more common and less avoided than in the past. Defining the age for the elderly population itself is variable, with studies making comparisons in patients younger or older than 65 years of age all the way up to a nonagenarian population.

A review of ACS NSQIP data in 2006 [6] showed expectedly that age was significantly associated with morbidity and mortality. However, their focus was specifically on patients older than 80 years of age. Even when ASA scores and cardiac and other comorbidity scores have been controlled for, given their association with elderly populations, studies invariably show worse surgical outcomes in elderly compared to younger populations. However, these outcomes have to be gauged against those of nonsurgical management in the same elderly population.

Hepatobiliary surgery in any population, whether cirrhotic or non-cirrhotic or young or elderly, is not a minor procedure. Perioperative management and decision-making at the pre-, intra-, and post-op stages have improved and advanced over the years, allowing more aggressive approaches to resection with acceptable outcomes [7, 8]. Several studies have reported nearly equivalent outcomes in elderly and younger populations [9–11] or worse but acceptable outcomes in older patients [12–16] with liver resection. A few studies have even shown better outcomes in the elderly after liver resection compared to the young [17, 18], although multiple variables including type of tumor and other factors greatly influence outcomes of these studies. Several studies have also shown better outcomes with surgery compared with ablative or medical management [19, 20] in the elderly, though surgery produces overall higher improved survival in the younger population.

One of the great benefits of minimally invasive surgery is the reduced length of stay, earlier recovery, and less need for opioid pain control with smaller incisions. Multiple studies have shown excellent oncological and survival outcomes with laparoscopic hepatic surgery. A recent large multi-institutional study comparing open and laparoscopic surgery in patients older than 70 showed comparable R0 resection rates, recurrence-free and overall survival, and significantly lower blood loss, overall morbidity, and shorter high dependency unit stay in the laparoscopic group [21]. Of note, however, patients aged 70–74 were more likely to benefit from laparoscopic surgery, with gradual loss of these advantages with increasing age. In the next few sections, we will look more closely at the unique characteristics of an aging liver as well as preoperative evaluation and optimization.

The Aging Liver

Aging decreases volume of the liver, with several studies showing decreases of 20–40% as one gets older [22–25]. Blood flow is also decreased, with an approximately 35% reduction in those over 65 years old compared to a younger population [26]. The liver cells themselves have reduced mass with aging as seen in radioisotope studies [27]. In addition there is polyploidy, decreased smooth endoplasmic reticulum, accumulation of dense bodies, and declining and dysfunctional mitochondria. The biochemical and metabolic effects of an aging liver include a slightly reduced serum albumin concentration, elevated serum gamma glutamyltransferase and alkaline phosphatase levels, reduced serum bilirubin levels, and stable serum aminotransferase levels [28].

Most pertinent to hepatic surgery is the ability of the liver to regenerate. With aging there is a decrease in the regenerative ability with subsequent delay in the restoration of liver function. It is thought that fewer hepatocytes enter S-phase in the elderly after partial hepatectomy and that they enter at a slower rate [25]. Animal studies have suggested that cell growth may be impaired by increased reactive oxidative species in the hepatocytes of aged mice and that ablation of the promoter gene reduced this post-hepatectomy oxidative stress [29, 30]. Investigators have also suggested that reduced cell proliferation in the elderly may be due to loss of hepatocyte telomere length [31, 32], although other studies have countered that other pathways allow for appropriate regeneration [33].

Cirrhosis is the end result of fibrosis resulting in destruction of normal liver architecture and loss of hepatocytes. Histologically, it is characterized by nodular regeneration with dense fibrotic septa and distortion of hepatic vascular architecture. The clinical manifestations of cirrhosis arise from portal hypertension and loss of hepatic synthetic function. Cirrhosis is the 8th leading cause of death in the USA and 13th leading cause of death worldwide [1]. The major causes of cirrhosis are chronic hepatitis B and C virus infection, alcohol, and nonalcoholic steatohepatitis.

Nonalcoholic fatty liver disease and its subtype nonalcoholic steatohepatitis (NASH) have emerged as a leading cause of cirrhosis. The causes of this entity are thought to be obesity with most of the consequences a result of insulin resistance (Fig. 4) [34]. The mortality risk in compensated cirrhosis is 4.7-fold and decompensated cirrhosis is 9.7-fold higher than the general population [35]. Delving into the pathophysiology and management of cirrhosis is beyond the scope of this chapter, but two interesting aspects of cirrhosis should be addressed. Cirrhosis generally takes several years to develop and as a result is more commonly seen in an elderly population. HCC principally occurs in the setting of cirrhosis, and, as discussed earlier, the median age of diagnosis is in the seventh decade of life [3]. Although not as strongly associated with cirrhosis, the risk of ICC is also increased in patients with liver disease [36, 37]. Operating on the elderly should take into consideration whether there is underlying liver disease, even if compensated, as the ability of the liver to regenerate is compromised in the older patient.

Pre-op Evaluation and Prehabilitation

There are relatively few absolute contraindications to liver surgery in general, but certainly there are comorbidities that make surgery and/or the expected recovery more difficult [38, 39]. Several indices and algorithms have been created to estimate the risk of adverse outcomes after

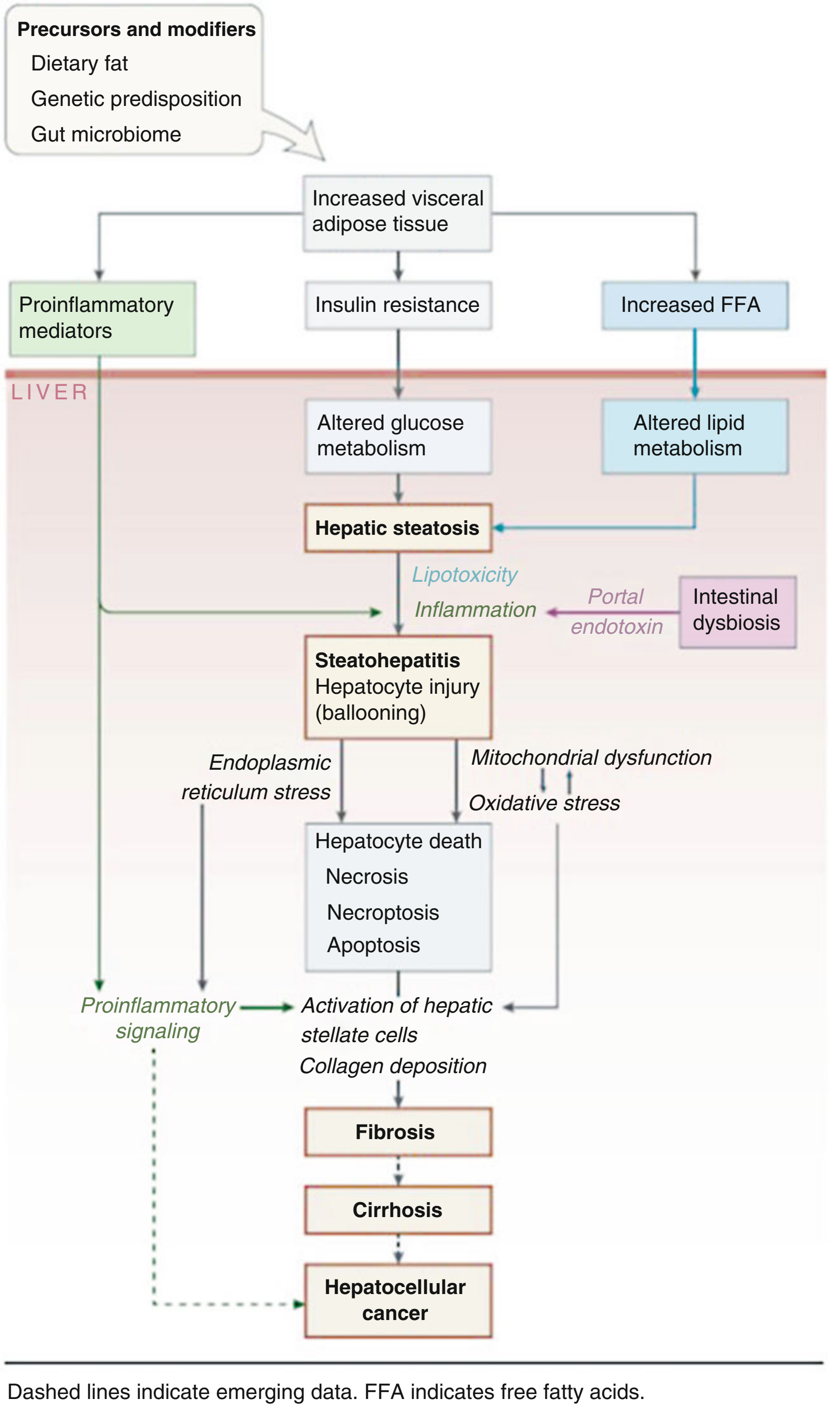

Fig. 4 Mechanisms involved in the pathophysiology of NAFLD [34]

surgery [40–43], and these are likely to be focused on in other chapters of the textbook. Of note, there was an excellent collaboration between the American College of Surgeons and the American Geriatric Society optimal preoperative assessment of the geriatric surgical patient (Table 1) [44].

Several studies have focused on risk factors for cardiac and pulmonary complications after surgery. However, one of the most important predictors of outcomes after liver surgery stems from the liver itself, specifically the presence and degree of cirrhosis with two major scoring systems, Child-Turcotte-Pugh (CTP) and Model for End-Stage Liver Disease (MELD) score, used to stratify mortality.

A study from Duke University [45] analyzed the ability of ASA class, Charlson Index, and CTP and MELD scores to predict mortality and morbidity. They found that only ASA and CTP were predictive, suggesting that MELD – which was originally created for assessing outcomes of transjugular intrahepatic portosystemic shunt and used for liver transplant listing – may not be as useful for hepatic resections, which generally occur in patients with CTP B or less. Other studies have suggested that MELD may be used as surrogate for CTP C, although the C-equivalent MELD score has ranged from 9 to 17 in these studies [46, 47]. Most surgeons perform liver resections only in CTP A and select B patients. In fact, surgery, other than liver transplantation, is generally avoided in CTP C patients unless there is backup of liver transplant for any potential decompensation.

Table 1 Checklist for the optimal preoperative assessment of the geriatric surgical patient [44]

Assess the patient's **cognitive ability** and **capacity** to understand the anticipated surgery
Screen the patient for **depression**
Identify the patient's risk factors for developing postoperative **delirium**
Screen for **alcohol** and other **substance abuse/ dependence**
Perform a preoperative **cardiac** evaluation according to the American College of Cardiology/American Heart Association algorithm for patients undergoing noncardiac surgery
Identify the patient's risk factors for postoperative **pulmonary** complications and implement appropriate strategies for prevention
Document **functional status** and history of **falls**
Determine baseline **frailty** score
Assess patient's **nutritional status** and consider preoperative interventions if the patient is at severe nutritional risk
Take an accurate and detailed **medication history** and consider appropriate perioperative adjustments. Monitor for **polypharmacy**
Determine the patient's **treatment goals** and **expectations** in the context of the possible treatment outcomes
Determine patient's **family** and **social support system**
Order appropriate preoperative **diagnostic tests** focused on elderly patients

Most studies have acknowledged that chronological age itself should not deter surgical therapy. There have been several studies focusing instead on "physiological age," reporting on the use of frailty index or sarcopenia as an aid in surgical decision-making. A study from Johns Hopkins [43] incorporated weakness, weight loss, exhaustion, low physical activity, and slowed walking speed into a five-point scale for frailty and found that frailty independently predicts morbidity in surgical patients older than 65 years of age. A modified frailty index was used by investigators from Emory [48] to assess home discharge rates in elective vascular surgery patients and found that frail patients were significantly less likely to return home, regardless of whether a post-op complication occurred. There are several frailty indices or geriatric assessments available, and overall they correlate well with morbidity in cardiac [49–51], minimally invasive surgery [52, 53], colorectal surgery [54], and overall GI surgeries including liver resection [55, 56].

Sarcopenia is the loss of skeletal muscle mass and can be used independently or as an adjunct with frailty. Several studies have used total psoas area or total psoas volume to measure sarcopenia and have shown adverse outcomes after liver resection or liver transplant [57–60] with a Johns Hopkins study [61] in 2015 reporting a significant difference of 40% vs. 18% complication rate in sarcopenic vs. non-sarcopenic patients with Clavien grade >= 3 occurring in the former group only, although overall survival was not significantly different between the groups.

Assessment of frailty and sarcopenia preoperatively allows for a frank discussion of risks and benefits of surgery but also allows for possible optimization. "Prehabilitation" regimens have been used to improve functional and physiological reserve to potentially negate the effects of "aging" on operative outcomes. A recent systematic review analyzed outcomes in nine studies and overall found no difference in postoperative complication rate in the control groups and the prehabilitation groups, but two studies showed improvement in health-related quality of life [62]. Contrary to this review, another meta-analysis [63] suggested that prehabilitation, consisting of inspiratory muscle training, aerobic exercise, and resistance training, appeared to decrease incidence of post-op complications in patients undergoing intra-abdominal operations. However, the authors caution that the grade of evidence is very low. Studies specifically looking at prehabilitation in liver surgery have not shown significant differences in morbidity or mortality with these regimens despite improvements in cardiopulmonary function [64, 65].

One of the significant drawbacks to these studies in cancer patients is the short duration with which to implement the prehabilitation, as long delays in oncologic surgery are usually not appropriate. Another issue is the lack of uniformity of various regimens. Most regimens include measures to improve physical exercise, but they rarely involve nutritional support and psychosocial support – the trifecta that make up the so-called "trimodal" prehabilitation program.

The liver's ability to regenerate allows major hepatectomy, but this is compromised with aging and cirrhosis, as discussed above. Multiple studies [66–70] over the last decade have shown a minimum future liver remnant (FLR) of greater than 20–30% is essential to preserve post-op liver function and reduce chances of liver failure. In patients who have received extensive chemotherapy or have cirrhosis, FLR of greater than 30–40% is necessary.

However, there are procedures that stimulate liver regeneration and lower the risk of liver failure in patients with small predicted FLR. The two widely reported methods are portal vein embolization (PVE) and associating liver partition and portal vein ligation (ALPPS). Both of these techniques increase the volume of the future liver remnant (FLR), allowing for a potentially better oncologic procedure with lower risk of liver failure. In portal vein embolization, the portal vein supplying the lobe or segment of liver with tumor is embolized, which has the effect of causing hypertrophy to the other lobe. Given the size discrepancy between the right and left liver, PVE is usually used to increase left liver FLR to allow a right hepatectomy or extended right hepatectomy. Studies have showed that, after this treatment, the augmented FLR allows for previously "unresectable" lesions to now become resectable since there is less fear of liver failure post-op [70–72]. The risks of PVE include PV thrombosis, bleeding, and increasing inflammation in the hilum. A more accelerated hypertrophy can be seen with ALPPS. In this procedure, the right portal vein is ligated surgically, and there is in situ transection between the lobes. Within days, the left lobe hypertrophies and the right lobe can be resected along with its right artery and hepatic duct branches [73–75].

Benign Liver Tumors

Benign liver "tumors" can generally be classified as epithelial or mesenchymal. The major mesenchymal "tumor" is hemangioma, and common epithelial "tumors" include adenoma and focal nodular hyperplasia (FNH). Of these, only adenomas are actually neoplasms, but they all present as mass lesions which can sometimes be difficult to distinguish from tumors.

Hemangiomas can be either solitary or present as multiple lesions, with the majority being less than 5 cm. Hemangiomas are more common in the younger population and are more frequent in females. Most hemangiomas are found incidentally during unrelated abdominal surgery or on imaging. Symptoms generally occur in patients with lesions greater than 5 cm and usually consist of pain or fullness. Hemangiomas in children have more serious consequences including high-output cardiac failure and consumptive coagulopathy.

General consensus [76] is that hemangiomas do not need resection and do not even need follow-up imaging. Symptomatic hemangiomas may benefit from surgical resection, which typically consists of enucleation since wide margins are unnecessary.

Hepatocellular adenoma (HCA) is also rarely seen in the elderly population and normally seen in young women of child bearing, with a history of oral contraceptive use. The majority of HCA are solitary and in the right lobe. Similar to hemangiomas, they can vary in size with large lesions more likely to cause symptoms. HCA can occasionally present with acute onset of hemorrhage, necrosis, or infarction [76], and there is a small risk of malignant transformation to HCC [77]. Initial management includes avoidance of oral contraceptives and hormone-containing intrauterine devices. For lesions greater than 5 cm, intervention through surgical or nonsurgical modalities is recommended due to risk of rupture and malignancy, although surveillance can also be utilized in high-risk patients to assess growth pattern and stability of the lesion [76, 78].

Focal nodular hyperplasia (FNH) is also rarely seen in the elderly population and is thought to be a hyperplastic response to hyperperfusion by anomalous arteries in the center of the nodule. FNH is usually solitary and rarely larger than 5 cm. FNH can be usually diagnosed on the basis of imaging characteristics and, once diagnosed, rarely requires further intervention or even surveillance [76].

Overall benign tumors are usually incidental findings in the elderly, and aggressive surgical management is rarely warranted unless there is diagnostic uncertainty.

Malignant Liver Tumors

Malignant tumors are generally classified as primary or metastatic, with the latter being far more common in the liver. Over the course of the next section, we will discuss in more detail the two most common primary tumors, HCC and ICC, as well as the two most commonly resected metastatic tumors, colorectal cancer (CRC), and neuroendocrine tumors (NET). Surgical resectability is based on achieving complete resection while leaving an adequate amount of parenchyma with adequate blood flow and biliary drainage. Detailed operative method of liver resection can be found in specialized textbooks [79–81].

Most patients with malignant liver tumors have unresectable disease and are unable to undergo resection. In patients with disease confined to the liver, other liver-directed therapies, such as thermal ablation (radio-frequency ablation (RFA), microwave ablation, cryoablation), hepatic arterial therapy (transarterial embolization (TAE), chemoembolization (TACE), radioembolization (TARE)), or stereotactic body radiation therapy (SBRT), may be an option.

Hepatocellular Carcinoma

Over 80% of patients diagnosed with HCC have cirrhosis, with a 5 year cumulative risk of development of HCC in cirrhotics ranging from 5% to 30% [82]. Although HCV is more commonly associated with HCC in the USA, chronic HBV infection is more common worldwide. HCC usually occurs in the setting of cirrhosis, but it can occur in patients with chronic HBV without cirrhosis, with factors such as elevated viral loads, infection with HBV genotype C, coinfection with HCV or hepatitis delta virus, family history of HCC, exposure to mycotoxin aflatoxin, alcohol, and tobacco use [83, 84]. HCV risk factors for HCC include older age at time of infection, coinfection with HIV or HBV, and heavy alcohol use. Whereas in HBV HCC can occur in non-cirrhotics, HCV almost always occurs in cirrhotics or in those with advanced fibrosis [85]. Heavy alcohol use, obesity, and metabolic syndrome have been shown to be risk factors for HCC irrespective of chronic viral hepatitis status [86].

The presentation of HCC can be similar to benign tumors, either being asymptomatic or causing abdominal pain due to size. However, unlike benign tumors that rarely occur in the setting or cirrhosis, HCC may present with hepatic decompensation, ascites, Budd-Chiari syndrome,

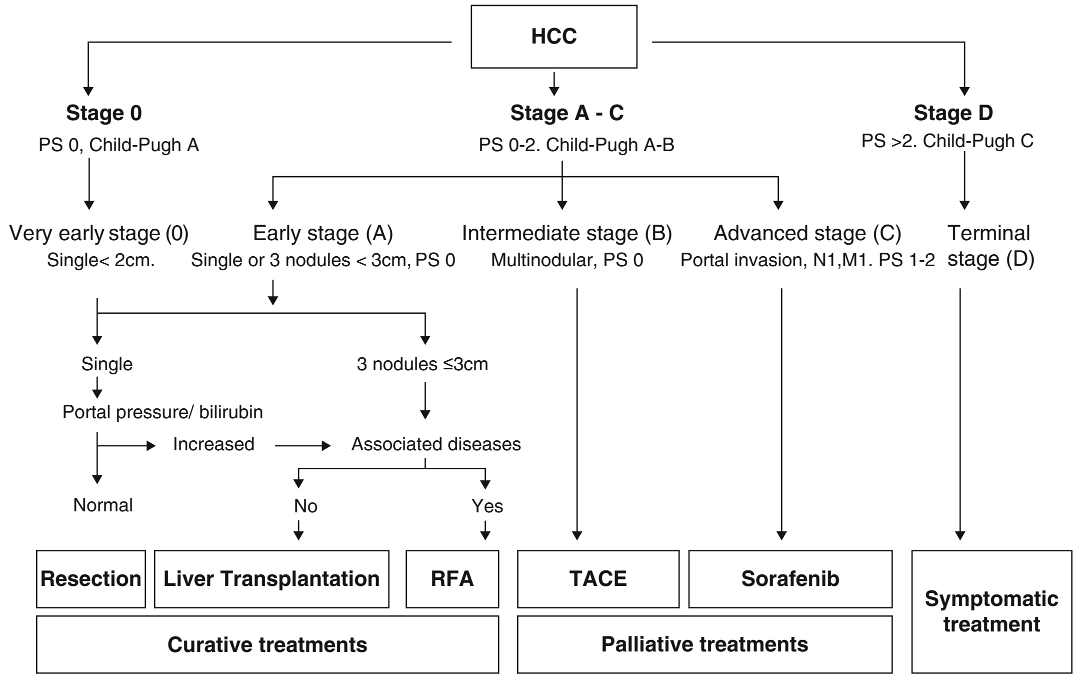

Fig. 5 BCLC staging system for HCC [87]

variceal bleeding, jaundice, or encephalopathy. Also, nonspecific symptoms such as weight loss, anorexia, or fatigue may be present.

The most important component of HCC diagnosis is imaging, supplemented by tumor markers, specifically alpha fetoprotein (AFP). Initial imaging diagnosis may occur in the setting of surveillance studies. Association guidelines recommend surveillance ultrasound screening every 6 months in HBV carriers and those with chronic hepatitis with concurrent measurement of AFP [87, 88]. Nodules less than 1 cm can be reassessed at three to six monthly cycles with ultrasound, but those greater than 1 cm should undergo a multiphase contrast-enhanced CT or MRI. The feeding of the tumor by the hepatic artery and its branches produces very classical imaging findings of early arterial enhancement and delayed washout in the venous phase (see image). Atypical features warrant a tissue biopsy for diagnosis, but otherwise, imaging findings typical for HCC in a patient with liver disease do not require biopsy prior to treatment.

There are multiple staging systems for HCC, but the Barcelona Clinic Liver Cancer (BCLC) staging system is the most widely accepted staging system (Fig. 5) [87].

In HCC, multiple studies have showed a 5 year survival of 60–75% with resection [89–93]. In non-cirrhotic patients, multiple centers have mortality rates less than 5%, and blood transfusion requirement is also becoming less necessary. As mentioned previously, methods to increase the FLR also greatly aid in allowing larger resections. In patients with cirrhosis, resection is often not possible given the prohibitive perioperative risks. Liver resection for HCC in the elderly has been reported by several Asian studies with conflicting outcomes. A large nationwide Japanese database study suggested that increasing age was significantly associated with mortality [94], whereas another study found similar morbidity and recurrence-free and overall survival in patients aged either side of 70 years [95].

Liver transplantation (LT) is an excellent modality for treatment of patients with HCC with or without cirrhosis, although often LT is reserved for high MELD cirrhotics as they would not be able to safely undergo a liver resection. A seminal article from investigators from

Milan detailed outcomes in HCC patients undergoing transplant, by using characteristics of the tumors on explant to determine acceptable outcomes [96]. The United Network for Organ Sharing (UNOS) used these Milan criteria to determine eligibility for liver transplantation. The patient may have a single 5 cm tumor or three 3 cm tumors, overall not totaling more than 8 cm, no evidence of vascular invasion, and no evidence of extrahepatic disease, with the original Milan data reporting 5 year actuarial survival of 74%. LT is rarely indicated or part of the treatment paradigm for non-HCC malignancies, and as such most transplant studies feature HCC. Several studies in the elderly in this population have shown conflicting results with equivalent or worse outcomes [97–100]. Overall, however, due to comorbidities and donor pool shortages, LT is uncommon in patients older than 65 years of age. A UNOS database study [101] analyzed outcomes of transplant in patients with age less than or greater than 70, with or without HCC, and the results unsurprisingly showed that overall 5 year survival was higher in the younger population at 72% vs. 55%. When the young and older populations are separated into HCC or non-HCC subgroups, however, the 5 year survival for the older age group was nearly identical at 54% with HCC vs. 55% without HCC, whereas in the younger population, the 5 year survival was significantly lower at 67.8% with HCC vs. 73.8% without HCC. Overall this suggests that liver transplant survival is not affected by HCC at an advanced age.

The SHARP trial was a landmark study looking at the overall survival and time to symptomatic progression with use of the multikinase inhibitor, sorafenib, in patients with advanced HCC in a primarily western population [102]. Investigators found significantly improved overall survival of 10.7 vs. 7.9 months in the group receiving sorafenib vs. placebo group, though median time to symptomatic progression was similar at 4.1 vs. 4.9 months, respectively. With his study and the near-equivalent results produced from a randomized controlled Asian study [103], sorafenib is now commonly used for advanced HCC with modest benefit and the occasional anecdotal isolated case reports showing occasionally curative responses [104]. Sorafenib was studied for use as adjuvant therapy after resection or ablation, but the STORM trial concluded that sorafenib was an ineffective intervention [105].

RFA, TACE, and TARE have been used to downstage tumors to transplant eligibility but have also been used as stand-alone treatments. RFA has been shown to be safe and effective with 5 year survivals of up to 76% reported in early-stage disease in patients with well-preserved liver function [106]. TACE and TARE are rarely curative and are used most often as a bridging to transplant, with local tumor control up to 70% [107, 108]. The NCCN guidelines [109] recommend the use of liver-directed therapy in patients with disease that is not eligible for resection or transplant, and this may be an appealing option for elderly patients deemed too high risk for liver resection.

Intrahepatic Cholangiocarcinoma

Overall, ICC makes up around 10% of all cholangiocarcinoma and 10–20% of primary liver tumors. It arises in the peripheral bile ducts within the liver parenchyma. The majority of patients are over 65 years at diagnosis, with a slight male preponderance. Risk factors include conditions causing biliary inflammation and fibrosis, such as primary sclerosing cholangitis and primary biliary cirrhosis; congenital malformations such as choledochal cysts and hepatolithiasis; cirrhosis risk factors such as HBV, HCV, and alcohol; as well as parasitic infections of *Clonorchis sinensis* and *Opisthorchis viverrini* [36, 37].

The presentation of ICC is often with nonspecific symptoms of abdominal pain, weight loss, and occasionally painless jaundice when the mass nears the biliary confluence. Diagnosis is typically made with imaging. CT imaging shows a hypodense mass in the unenhanced phase with irregular margins, with peripheral rim enhancement in the arterial phase and progressive hyperattenuation on venous and delayed phases.

Tumor markers are less specific for ICC than HCC, with CA 19-9 levels showing limited sensitivity and specificity.

There are fewer staging systems present for ICC than HCC, and, although no strict consensus, the 7th edition of AJCC/UICCA is favored by most [110]. Stage I and II disease is resectable, and when combined, these stages encompass 30–40% of cases. Hepatic resection is indicated in ICC without evidence of distance metastases, with 5 year survival of 20–40% [111–113]. Recurrence rates are high at approximately 70%. Although the Mayo protocol of neoadjuvant chemoradiation prior to LT was developed for hilar cholangiocarcinoma [114], there is no role for liver transplantation in ICC.

Stages III and IV are considered unresectable, and these patients have options of gemcitabine/cisplatin combination chemotherapy, fluropyrimidine-based therapy, or liver-directed therapy such as SBRT, TACE, or RFA per NCCN guidelines [109]. A recent study from Memorial Sloan-Kettering [115] compared patients with locally advanced, unresectable disease receiving a hepatic artery infusion pump with floxuridine combined with systemic chemotherapy vs. those with systemic chemotherapy alone and found a significantly increased median overall survival of 30.8 vs. 18.4 months, respectively, and 5 year survival of 20% vs. 5%, respectively.

The overall survival for ICC is dismal with SEER data [3] suggesting a localized vs. regional vs. distant stage 5 year survival of 15% vs. 6% vs. 2%, with local and regional disease having significantly lower survival than local and regional extrahepatic bile duct cancer (30% and 24%, respectively).

Colorectal Cancer Metastasis

Colorectal cancer (CRC) is the fourth most common cancer in the USA and has the second highest overall mortality. The liver is the most common site of metastasis, nearly fourfold more than the lung, and occurs synchronously in 15–20% and developing in another 60% of patients during the course of the disease. Unfortunately, only 15–25% of patients with colorectal liver metastases (CLM) are considered to have resectable disease.

Both CT and MRI are important imaging modalities, given their ability to asses at least two phases of vascular enhancement. CLM in general appear as hypoattenuating masses, best visualized during portal venous enhancement. NCCN guidelines [116] recommend a repeat colonoscopy if greater than 6 months since previous colonoscopy or curative colon surgery to assess for a metachronous colon lesion or recurrence at primary site.

CLM usually occur in non-cirrhotic patients, and therefore even large liver resections can be undertaken with lower risk of liver failure than in primary liver cancers, in general. Multiple large series have shown acceptable 5 year survival rates of up to 58% [117–119], with a large SEER database study reporting 32.8% [19]. Historical non-operative patients have had 5 year survival rates of less than 5%. The risk of recurrence is high with up to 60% of patients having recurrence, but repeat resection is sometimes an option for these patients. A Clinical Risk Score developed at Memorial Sloan-Kettering [120] is widely used to predict outcomes after resection. The score takes into consideration five clinical criteria – nodal status of primary, disease-free interval from primary to discovery of liver metastases of <12 months, number of tumors >1, preoperative CEA level >200 ng/ml, and the size of the largest tumor >5 cm with the study that developed this score identifying a 5 year survival of 60% with a score of 0 compared to 14% with a score of 5.

The most controversial issue in the management of CLM is the role of neoadjuvant chemotherapy. 5-Fluorouracil (5-FU) is the cornerstone of therapy, but the addition of oxaliplatin or irinotecan (along with 5-FU and leucovorin known as "FOLFOX" and "FOLFIRI," respectively) dramatically improves response rates and survival over 5-FU alone. The addition of biologic agents targeting VEGF (bevacizumab) or EGFR (panitumumab, cetuximab) to chemotherapy further improves outcomes [121–123]. For patients with unresectable CLM, chemotherapy with or without biologic therapy is used with reevaluation of resectability every 2 months. A large study of 1,104 patients with unresectable CLM [124] treated with neoadjuvant chemotherapy reported that 12.5% became resectable after therapy. A randomized trial in Europe compared "perioperative" (pre- and post-op) chemotherapy to no chemotherapy in patients with resectable CLM and demonstrated improved progression-free survival with chemotherapy but no difference in overall survival [125]. The issue therefore remains controversial, particularly since both oxaliplatin and irinotecan have been associated with liver toxicity that can increase complications after liver resection [126]. The benefits of modern chemotherapy appear to extend to elderly patients with advanced disease [127], but elderly patients are also at increased risk of toxicity due to underlying organ dysfunction and less predictable pharmacokinetics. The potential benefits of neoadjuvant chemotherapy in the elderly population may therefore be small relative to the risks.

The management of synchronous CLM is even more complicated by decision-making around the management of the primary tumor. A large multi-institutional study [117] showed that simultaneous and staged resections for synchronous liver metastases can be performed with comparable morbidity, mortality, and long-term outcomes, although staged procedures were more commonly used for larger hepatic resections. Overall, outcomes for metastatic CRC have improved substantially over the last several years, due to improvements in both medical and surgical management. There are now so many different treatment options that there is little consensus regarding the components and sequence of therapy.

Neuroendocrine Metastasis

Neuroendocrine tumors (NETs) are rare tumors that arise from Kulchitsky's enterochromaffin cells and that are characterized by positivity for chromogranin A and synaptophysin by immunohistochemistry. NETs of the gastrointestinal tract (also known as carcinoid tumors) or pancreas spread to the liver hematogenously in 40–85% of patients. Approximately 75% of liver metastases are synchronous with the primary NET [128]. Neuroendocrine liver metastases (NELM) are considered the most powerful prognosticator of survival of patients with NET regardless of primary site [129, 130]. NETs can occur at all ages but are more commonly seen after the fifth decade, with the exception being appendiceal NET that occurs closer to 40 years of age. Symptoms of disease vary based on the origin of the tumor and whether it is biochemically "functional." The diagnosis of NELM is easier to make if there is a known primary, although often the liver metastasis may be the first manifestation of NET. These are highly vascular lesions, and often it is the hepatic arterial phase that provides the best phase for detection of NELM when using either CT or MRI. Somatostatin receptor scintigraphy is able to identify patients with NET expressing the somatostatin receptor subtype 2 and is specific for NETs but not very sensitive for small tumors. Given the poor outcomes with high-grade tumors, tissue acquisition is often indicated when a primary is not found or previously resected, and markers of proliferation such as Ki-67 and mitotic index are used to guide management.

Because NETs are relatively rare, there are very few randomized studies. In general, liver resection is considered reasonable when all visible disease can be removed but should only be attempted in those with well-differentiated tumors [131]. Subtotal resection of NELM (debulking or cytoreduction of greater than 80% of the tumor) has also been associated with longer survival than with nonsurgical management. The Mayo Clinic [132] reported a large experience of hepatic resection and cytoreductive therapy, achieving a 5 year survival of 61% and 10 year survival of 35%. More recent studies including a large multinational study have shown 5 and 10 year survivals of up to 74% and 51%, respectively [133]. In patients with disease not amenable to surgery, liver-directed therapy has also been associated with prolonged survival [134], as has systemic therapy with somatostatin analogues [135] or peptide receptor radionuclide therapy [136].

The behavior of well-differentiated NETs is so indolent, that risks of treatment have to be weighed carefully against the risks of tumor progression. Many elderly patients will be more likely to die from comorbid conditions than from their NET, and aggressive surgical therapy may not be warranted unless symptoms cannot be controlled by other modalities.

Conclusion

Advancing age should not preclude the use of liver resection for appropriate indications. Chronological age should carry less weight than frailty or sarcopenia, and in older patients comorbidities need to be balanced with the possible benefits of quality and duration of life afforded by complex hepatobiliary surgery. Surgery itself is evolving. Techniques to augment the future liver remnant have allowed us to perform more extensive resections safely. Advances in minimally invasive surgery may allow for liver resection to be performed with reduced length of hospitalization and opioid use. Overall, as the average life expectancy increases, and the incidence of liver tumors increases, further work is needed to not only risk stratify elderly patients but also optimize them prior to surgery.

Abstract

The incidence of most benign and malignant tumors of the pancreas increases with age. A multidisciplinary approach is necessary to ensure appropriate treatment and optimize patient outcomes. Unfortunately, treatment disparities persist when compared with the general population as many patients are denied appropriate therapy based on advanced chronological age. Furthermore, elderly patients are often excluded from clinical trials despite the fact that they are more likely to be affected by these groups of tumors. There is growing evidence to suggest that age alone is not a reason to withhold potentially curative surgery or standard of care chemotherapy. However, several studies have reported increased risk of surgical complications and chemotherapeutic toxicity, which may be explained by the presence of additional comorbidities, frailty, poor functional status, and altered drug metabolism. Various tools, such as the comprehensive geriatric assessment, have been developed to guide clinicians in the management of these complex patients. In the following chapter, we discuss the multidisciplinary approach for diagnosis and management of benign and malignant pancreatic tumors with a focus on the role of surgical resection.

Introduction

Pancreatic neoplasms represent a major healthcare problem for the aging population. The elderly are at risk for the entire spectrum of benign and malignant pancreatic tumors. Pancreatic adenocarcinoma is the most frequent and clinically significant. It is the fourth leading cause of cancer death in the United States, and its incidence increases with age. The diagnosis and treatment of pancreatic cancer often represent a significant clinical challenge in the elderly, as there is a significant bias against aggressive surgical treatment in this population. In recent years, however, advances in diagnostic techniques, improved outcomes with regionalization of care, and a deeper understanding of prognostic factors have improved our ability to treat this challenging disease. However, significant treatment disparities persist and elderly patients are often inappropriately denied potentially beneficial, and sometimes curative, therapy. In addition to pancreatic adenocarcinoma, the recognition and diagnosis of benign and premalignant pancreatic tumors has become more common in the elderly. These tumors require a thorough understanding of their clinical behavior as one weighs these risks with the risk of surgery in the elderly population. Fortunately, many of these tumors are amenable to less invasive therapeutic procedures with lessened perioperative morbidity and mortality.

Epidemiology

According to the National Cancer Institute, the incidence of pancreatic cancer is approximately 53,670 new cases per year, with 43,090 deaths per year from the disease [1]. Pancreatic adenocarcinoma is among the most lethal cancers, with a 5-year survival rate of only 8.2% for 2007–2013. It is most frequently diagnosed in patients aged 65–74, with a median age at diagnosis of 70 years. A total of 97.5% of cases are diagnosed in patients above the age of 45, 66.5% above the age of 65, and 13.6% above the age of 84 (Fig. 1).

Cystic neoplasms of the pancreas are much more common than was once thought. The increased reliance on axial imaging has led to

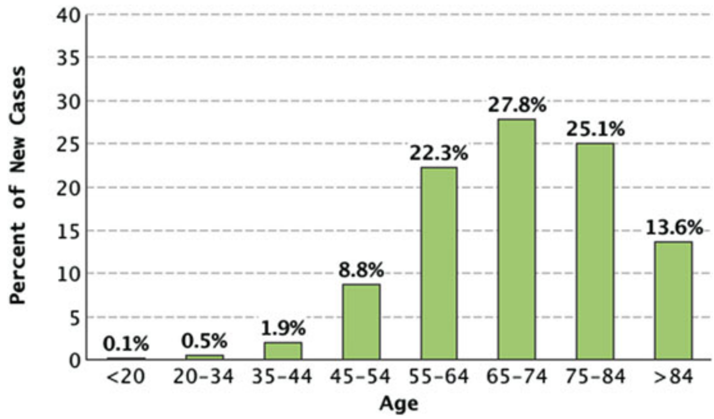

Fig. 1 Pancreatic cancer incidence by age. https://seer.cancer.gov/statfacts/html/pancreas.html. SEER 18 2010–2014, All Races, Both Sexes

the incidental identification of a wide spectrum of asymptomatic benign and malignant disease. Pancreatic cysts are rare in patients younger than 40 years of age. Studies based on axial imaging and autopsies have estimated prevalence rates as high as 19–25% in patients age 70–79 years and 30–37% in patients over 80 years old [2].

Risk Factors

Environmental and genetic factors have been implicated as risk factors for pancreatic cancer. As noted above, advanced age is a significant risk factor for both pancreatic cancer and pancreatic cysts. Male gender and African American race are also associated with higher rates of pancreatic cancer. Among many potential environmental risk factors, cigarette smoking has been confirmed as a major contributor, with a two-fold greater risk of developing pancreatic cancer among smokers compared with non-smokers. Patients with obesity, diabetes, and chronic pancreatitis are also at increased risk.

Percent of New Cases by Age Group

Genetic factors often play a role in the development of pancreatic cancer. There are multiple inherited familial cancer syndromes that increase the risk of pancreatic cancer, including Peutz–Jeghers, hereditary pancreatitis, hereditary nonpolyposis colon cancer (HNPCC), ataxia-telangiectasia, familial atypical mole and multiple melanoma (FAMMM) syndrome, familial breast cancer 2, and familial adenomatous polyposis. There is also a significantly increased risk of developing pancreatic cancer in patients with a family history of the disease without association with a specific syndrome. Patients who have two first-degree relatives with pancreatic cancer have a 6-fold increase in risk, while patients with three affected first-degree relatives have a 32-fold higher risk of developing pancreatic cancer [3]. It is also important to note that age becomes a significant factor in these kindreds, as the age of cancer diagnosis in subsequent generations actually becomes progressively younger.

While the genetic significance in these cancer syndromes is apparent, advances in molecular genetics have led to the identification of frequent genetic mutations even among sporadic pancreatic cancers. These include inactivated tumor-suppressor genes such as p53, p16, and DPC4, each of which are found in >50% of sporadic pancreatic cancers. Mutations in K-ras, an oncogene involved in signal transduction, are found in over 90% of pancreatic cancer.

Perhaps the most increasingly identified risk factor for pancreatic cancer is the presence of a precancerous lesion, such as IPMNs or other mucinous cystic neoplasms. The increasingly frequent identification of these tumors, primarily in asymptomatic patients, has led to the development of management algorithms for the management of precancerous lesions and surveillance for disease progression. The optimal techniques and interval for follow-up may vary based on patient-specific characteristics including age. Nevertheless, for IPMNs, both the incidence of malignancy and invasiveness increases with age.

Pathology

Solid Tumors

Solid tumors of the exocrine pancreas are classified according to their cell of origin, which may include the pancreatic ductal epithelium or the acinar cell. Solid tumors can be either malignant, premalignant, or benign. Ductal adenocarcinoma is the most common neoplasm of the exocrine pancreas, accounting for more than 75% of all malignant pancreatic tumors. Ductal adenocarcinoma arises most commonly in the pancreatic head (65%) but may also be present in the body or tail (15%) or diffusely involve the whole pancreas (20%). Tumors of the head tend to be smaller at diagnosis, as they are more likely to cause obstructive jaundice earlier in their development. Adenocarcinomas arise from pancreatic ductal tissue, often obstructing ductal branches and causing a desmoplastic reaction with associated fibrosis and chronic pancreatitis. They often infiltrate into vascular, lymphatic, and perineural spaces, leading to early local and metastatic spread. Common sites of local invasion are duodenum, stomach, transverse mesocolon, colon, spleen, and adrenal glands. Pancreatic cancer typically metastasizes to regional lymph nodes and then liver, peritoneum, lungs, and adrenal glands. Pathologic examination of resected specimens often reveals the presence of precursor lesions (see below) in close proximity to the cancer. The recognition of these lesions has broadened our understanding of the development of adenocarcinoma.

Pancreatic adenocarcinoma is staged based on the tumor characteristics, node involvement, and metastatic disease (TNM) classification system, as outlined by the American Joint Commission on Cancer (AJCC). This system has considerable prognostic significance, with Stages I and II representing resectable, and therefore potentially curable, disease.

In addition to ductal adenocarcinoma, a very small percentage of solid exocrine tumors is comprised of adenosquamous carcinoma, acinar cell carcinoma, giant cell carcinoma, and pancreatoblastoma. Pancreatoblastoma should rarely be considered in the differential in an elderly patient, however, as it is found almost exclusively in children less than 15 years of age.

Cystic Tumors

Although once considered rare, increased use of axial imaging techniques has led to a surge in the identification of cystic tumors of the pancreas, such that 10% of patients over the age of 70 are diagnosed with a pancreatic cyst. However, great controversy exists as to precisely which patients will benefit from additional work-up, intervention, and follow-up [4]. Inflammatory pseudocysts are commonly diagnosed in association with pancreatitis and their management is well described. Cystic tumors of the pancreas include serous cystic neoplasms, mucin-producing cystic neoplasms (MCN and IPMN), solid pseudopapillary or Hamoudi tumors, and lymphoepithelial cysts.

Serous cystadenomas are relatively common among cystic tumors of the pancreas (Fig. 2). They are benign, slow growing tumors that are most common in elderly women and can manifest anywhere in the pancreas. Typically, the lesion consists of many tiny cysts lined by a cuboidal epithelium that has a honeycomb appearance. Oligo- or macrocystic variants are also possible and represent about 10% of cases. Serous cystadenocarcinoma is an exceedingly rare malignant variant that may be difficult to distinguish histologically from its benign relative. Finally, although almost always benign, these tumors can grow to massive size and compress or occlude visceral vessels, giving the appearance of being "locally unresectable." This is most commonly seen in the elderly population.

Unlike serous neoplasms, which are almost always benign, mucin-producing cystic tumors

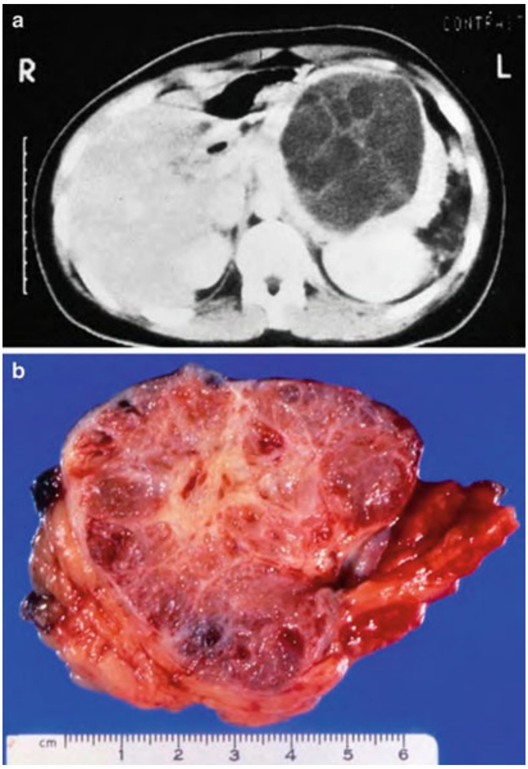

Fig. 2 Serous cystadenoma seen in (**a**) cross-sectional imaging and (**b**) histologic section

of the pancreas have considerable malignant potential. There are two distinct types of mucin-producing pancreatic tumors, mucinous cystic neoplasms (MCNs, or mucinous cystadenomas), and intraductal papillary mucinous neoplasms (IPMNs). Both types are characterized by abnormal growth of mucin-producing epithelial cells, but IPMNs involve the main pancreatic duct or ductal branches, while MCNs do not. MCNs occur almost exclusively in women and are most common between age 40 and 50. They are typically found in the body or tail and contain a distinctive subepithelial ovarian-type stroma (Fig. 3). The degree of dysplasia of MCNs can vary from benign to malignant, with up to one-third containing an invasive component. In contrast to MCNs, IPMNs are slightly more common in males, do not contain ovarian stroma and are more common in the pancreatic head, neck, and uncinate process, but can occur anywhere within the gland (Fig. 4 and Table 1).

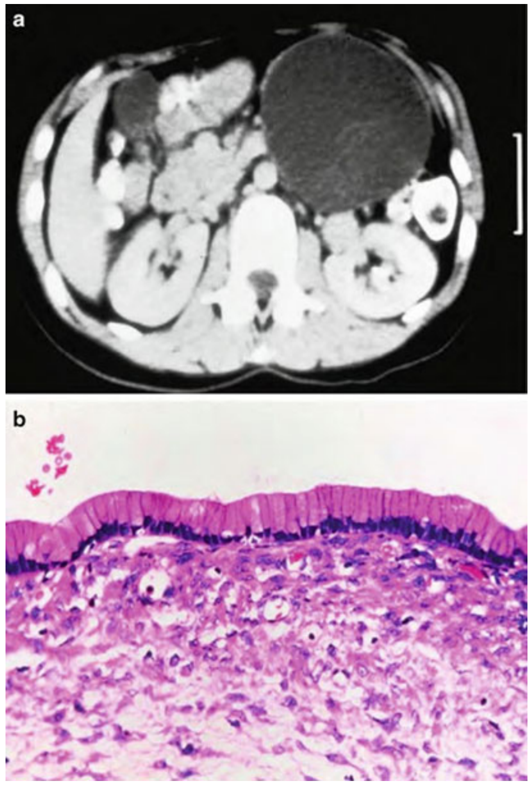

Fig. 3 Mucinous cystic neoplasm seen in (**a**) cross-sectional imaging and (**b**) histologic section showing typical histologic feature of “ovarian stroma”

Fig. 4 Multidetector CT (MDCT) scan with IV contrast showing main-duct type IPMN

IPMNs are classified into 3 types: main duct, branch duct, and mixed type. All subtypes may be benign, but all are also at risk for malignant transformation. The risk is greatest with main-duct

Table 1 Comparison between MCN and IPMN

	MCN	IPMN
Age (years)	40–50	60–80
Gender	F>M	M>F
Location	Body/tail	Head
Pancreatic duct involvement	No	Yes
Mucin found at ampulla	No	Yes
Ovarian-like stroma	Yes	No

Table 2 Likelihood of malignancy in main duct IPMN [5] (*Source*: Data from Salvia et al. [5])

	Benign	Malignant	Total	*P* (benign vs. malignant)
n	57	83	140	–
Gender (M/F)	31/26	40/43	71/69	NS
Median age	60.9	67.3	64.8	0.042
Smoking history (%)	35 (61%)	43 (52%)	78 (56%)	NS
Abdominal pain (%)	43 (76%)	47 (57%)	90 (65%)	0.038
Jaundice (%)	2 (3.5%)	21 (26%)	23 (16.5%)	0.001
Weight loss (%)	23 (40%)	39 (47%)	62 (44%)	NS

IPMN with 20% of tumors harboring high grade dysplasia and 45% with invasive carcinoma at the time of resection (Table 2). The epithelial lining of most main duct IPMNs has an intestinal phenotype and expresses intestinal lineage markers, such as CDX-2 and MUC-2.

Branch duct IPMNs are the most common cystic tumor of the pancreas. They typically display a gastric type epithelium, though oncocytic, intestinal, and pancreaticobiliary subtypes also exist. They are associated with a field defect within the pancreas and can occur throughout the gland, with 24–41% of patients presenting with multifocal disease [6]. Pathologic features associated with increased likelihood of malignancy include the presence of mural nodules, ductal dilatation and, the size of the cyst. The average rate of malignancy within a surgically resected branch-duct IPMN is approximately 25% [7]. In addition, there is an increased risk of concomitant pancreatic ductal adenocarcinoma in the entire pancreas.

Much less common, the solid pseudopapillary tumor, also known as Hamoudi tumor, or solid cystic neoplasm, is found predominantly in young women. This tumor is considered to be malignant but with very low metastatic potential.

Precancerous Lesions

The recent increase in identification and understanding of premalignant lesions of the pancreas has elucidated the processes associated with the progression from benign to malignant disease. Multiple precursors to adenocarcinoma exist, including pancreatic intraepithelial neoplasia (PanIN), and the cystic precursors IPMN and MCN. PanIN is divided into three grades of increasing dysplasia. PanIN-1 is characterized as a proliferative lesion without nuclear atypia; PanIN-2 is associated with a moderate degree of architectural and cytonuclear abnormalities; PanIN-3 has severe nuclear abnormalities with abnormal mitoses, but without invasion through the basement membrane. PanIN-3 is also referred to as carcinoma in situ and is almost always found in close proximity to an invasive cancer [8]. The prevalence of PanIN lesions increases with age. 33% of patients greater than 60 years old and with no known pancreatic disease have a PanIN-1 lesion. It is proposed that advanced age, in addition to other factors, must be present for a PanIN-1 lesion to progress to PanIN-3 and then to invasive cancer. These factors include genetic events such as telomere shortening, K-ras and p16 mutations, and clonal expansion [9].

IPMNs are macroscopic precursor lesions, which can also progress from benign to malignant histologically. About half the resulting invasive neoplasms are actually colloid (mucinous) carcinomas, with the remainder being the typical tubular adenocarcinoma. The progression to malignant IPMN is directly related to age, with multiple clinical studies demonstrating an increased percentage of malignant lesions in patients of increasing age [5, 10].

Clinical Presentation

History and Physical

Tumors of the exocrine pancreas in their early stage are often asymptomatic or present with the insidious onset of nonspecific symptoms. Tumors in the head of the pancreas typically lead to obstructive jaundice (80%), which is often the only specific symptom pointing to the diagnosis. In an elderly patient, the development of jaundice, with dark urine, acholic stools, and pruritus, should lead to prompt diagnostic workup with a high index of suspicion for malignancy. Abdominal and/or back pain (72–87%) and weight loss (90–100%) are common presenting symptoms and often signify locally advanced disease. New-onset diabetes or the development of "acute pancreatitis"-like symptoms should also raise concern. Nonspecific gastrointestinal symptoms may also exist. Fatty stools may signify pancreatic exocrine insufficiency.

Physical examination may reveal jaundice, and in some cases a palpable gallbladder. Signs suggestive of advanced cancer, such as cachexia, ascites, abdominal mass, migrating thrombophlebitis, palpable supraclavicular lymphadenopathy (Virchow's node), periumbilical lymphadenopathy (Sister Mary Joseph's Node), and pelvic drop metastases (Blumer's shelf), are obvious evidence of advanced disease with a poor prognosis. Among elderly patients, the presenting signs and symptoms of pancreatic cancer are not significantly different compared with younger patients [11, 12].

Laboratory Studies

There is no screening test or definitive laboratory test for pancreatic cancer. In patients with cancer in the body or tail of the pancreas, laboratory values are typically normal. In patients presenting with jaundice, laboratory studies will reveal an increase in total bilirubin and alkaline phosphatase, with occasional mildly elevated transaminases. Biliary obstruction can also lead to malabsorption of fat-soluble nutrients, which can lead to malnutrition and subsequent decreases in albumin, iron, hemoglobin, and vitamin-K-dependent clotting factors.

The most widely used tumor marker to aid in the diagnosis of pancreatic cancer is CA 19–9, a Lewis blood-group-related mucin glycoprotein. CA 19–9 is present at low levels (<38 U/ml) in most healthy patients, but often elevated in pancreatic cancer and has been shown to correlate with the stage of disease and survival in patients with resectable disease [13]. CA 19–9, however, may be falsely elevated in patients with obstructive jaundice, cirrhosis, pancreatitis, and other malignancies. CA19–9 has an overall sensitivity of 83% and specificity of 82%, but by raising the cutoff value to 200 U/ml and combining it with other testing modalities, the accuracy increases to 95–100% [14].

Management of Malignant Neoplasms

Diagnosis and Staging

When clinical symptoms or laboratory abnormalities are suspicious for a malignant pancreatic neoplasm, the first step toward diagnosis is noninvasive imaging. Computed tomography (CT) scan or magnetic resonance imaging (MRI) with or without cholangiopancreatography (MRCP) are useful noninvasive imaging studies. Transabdominal ultrasound can confirm obstructive jaundice by demonstrating a dilated biliary tree but lacks the sensitivity of CT and MRI in actually defining a pancreatic mass. Most clinicians regard pancreatic protocol CT scan with multiphase intravenous (IV) contrast enhancement as the initial imaging modality of choice. In recent decades, the development of multidetector CT (MDCT) has reduced acquisition time and dramatically enhanced image resolution [15] (Fig. 5). In addition, when dual phases of IV contrast are used, both arterial and venous structures can be well visualized to determine local involvement by the tumor and resectability (Fig. 6). The inclusion of a “pancreatic phase” of IV contrast often leads to improved pancreas-to-lesion distinction. As well as visualizing the lesion and any associated blood vessels, CT is able to detect extrapancreatic disease, including liver, lung, and peritoneal metastases, to further optimize preoperative staging [16]. In spite of these advantages, clinicians may be hesitant to expose elderly patients to the potential toxicity of IV contrast. The effect of patient age on contrast enhancement during CT scans of the pancreatobiliary region has been evaluated, and the ideal dose of IV contrast in the elderly may be about 10% less than the general population, or 0.07 mL/kg instead of 0.08 mL/kg. This dose, which takes into account changes in cardiac output and blood volume in the elderly, optimizes tumor enhancement and lessens the risk of nephrotoxicity [17].

Fig. 5 Multidetector CT (MDCT) scan with IV contrast revealing a 1 cm tumor in the head of the pancreas (*arrow*)

Fig. 6 Dual-phase contrast MDCT allows clear delineation of peripancreatic vessels, showing a detailed angiographic reconstruction. Note the tumor encroachment of the superior mesenteric vein

Most studies have found no advantage of MRI over MDCT, with the exception of possible improved visualization of small liver metastases and peritoneal implants [16]. MRCP has the added benefit of 3D visualization of both the bile and pancreatic ducts, often revealing the “double duct” pattern of obstruction and can eliminate the need for invasive cholangiography. Another potential modality for the diagnosis and staging of pancreatic cancer is the positron emission tomography (PET) scan. Although PET scanning shows increased uptake of the glucose tracer by both the primary tumor and metastases in other cancers, it has not been shown to reliably provide useful diagnostic information in patients with pancreatic cancer [18].

When noninvasive studies raise concern for a malignant pancreatic lesion, or when noninvasive studies are inconclusive, invasive studies may be indicated to confirm the diagnosis. Endoscopic retrograde cholangiopancreatography (ERCP) provides an endoscopic view of the ampulla and visualizes the biliary and pancreatic ductal systems (Fig. 7). ERCP can also be used to obtain cytologic brushings of suspicious areas in the pancreatic ductal system. While cytology results approach 99% specificity, the sensitivity is <50% due to a high false-negative rate [19, 20]. ERCP has been shown to be safe and well tolerated in elderly patients [21]. Rodriguez-Gonzalez et al.

reported 159 ERCPs performed on patients 90 years of age or older. Complication rate (2.5%) and procedure-related mortality (0.7%) were low, and therapeutic interventions were able to be performed in 96% of indicated cases [22]. Although ERCP is a safe and valuable tool, its role in the diagnostic work-up pancreatic cancer has diminished with the use of MRCP. ERCP is now currently used predominantly for endoscopic stent placement, for both palliative and preoperative biliary decompression.

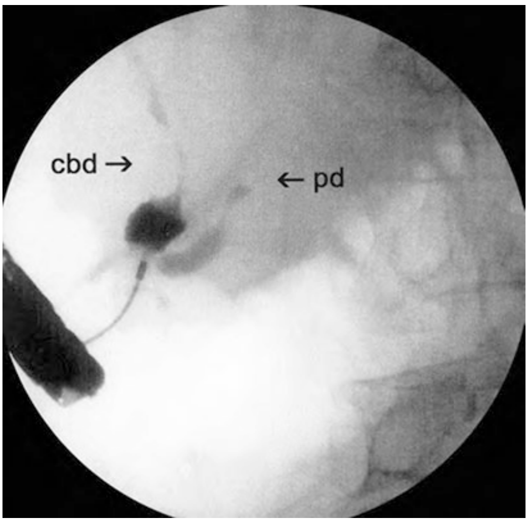

Fig. 7 ERCP of patient with adenocarcinoma of the pancreatic head. Note the involvement of both the common bile duct (cbd) and pancreatic duct (pd)

Endoscopic ultrasound (EUS) has gained acceptance as a critical tool in both the diagnosis and staging of pancreatic cancer. EUS sensitivity and specificity in detecting pancreatic cancer are 85–100 and 80–100%, respectively (Fig. 8). Multiple studies have demonstrated greater diagnostic accuracy of EUS compared to MDCT, particularly in the detection of small tumors less than 2 cm in size [23–26]. EUS can also be used to obtain a cytologic diagnosis via fine needle aspiration (FNA). This technique is typically more accurate than ERCP with brushings. Sensitivity with EUS-guided FNA ranges from 75 to 90%, and specificity approaches 100%. Complications of EUS are uncommon, even in the elderly.

A preoperative histologic or cytologic diagnosis of pancreatic cancer is not necessary in patients with a clearly defined presentation – obstructive jaundice and a pancreatic mass on CT – in a patient who is considered to be a candidate for surgical resection, regardless of age. When a tissue diagnosis is indicated, EUS-guided FNA has become the preferred method. Yet, even in the elderly patient, a high level of clinical suspicion should override a negative cytologic diagnosis. EUS offers the advantage of the close proximity to the tumor, and for cancers of the pancreatic head, the needle traverses the duodenum, which

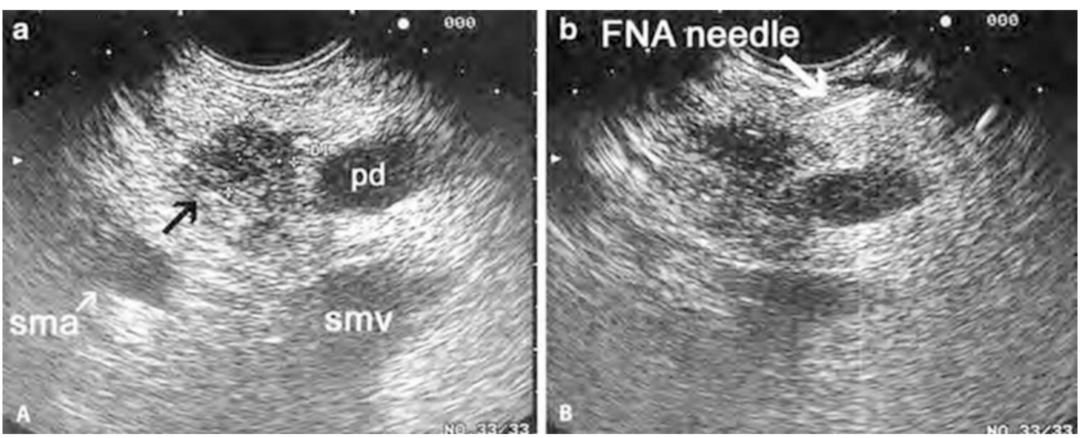

Fig. 8 Endoscopic Ultrasound. (**a**) The tumor (*black arrow*) is clearly visualized, as well as its relationship to the superior mesenteric artery (sma) and vein (smv). (**b**) Fine-needle aspiration of the tumor for cytologic examination

will be resected. Conversely, percutaneous fine needle aspiration has fallen out of favor both due to the fact that the distance of the pancreatic tumor from the skin surface leads to a higher incidence of false-negative aspirations, as well as the risk of seeding of the tumor along the needle tract, leading to intra peritoneal spread of the tumor.

Surgical resectability of a pancreatic cancer requires that the tumor both shows no evidence of metastatic disease (liver, peritoneal cavity) or local invasion of key adjacent structures. For most surgeons, direct extension of tumor into adjacent organs, encasement of the celiac or superior mesenteric arteries, significant encasement or occlusion of the portal – superior mesenteric vein (SMV) complex, involvement of distant lymph nodes, or obvious metastatic disease will preclude resection of a pancreatic head cancer [27–29]. For tumors of the pancreatic body and tail, extensive involvement of the celiac axis or SMA, the SMV/portal vein, adjacent organs, or the presence of distant metastasis typically renders the tumor unresectable. Isolated splenic vein or splenic artery involvement does not preclude resection. Most surgeons find CT scan to be the most useful tool in predicting resectability, but some studies indicate that EUS may be more accurate in determining local invasion of surrounding vasculature [16, 23, 26].

Unfortunately, neither MDCT nor EUS is able to detect small peritoneal or liver metastases, which are common with pancreatic cancer. This is best assessed with diagnostic laparoscopy. The role of routine laparoscopy has become less clear as the sensitivity of CT scanning has increased. Several reports have shown that routine laparoscopy for pancreatic head cancer would spare very few patients from a laparotomy (5–15%) [30, 31]. The value of laparoscopy is increased in evaluating cancers of the body and tail, however, as these patients are found to have occult metastatic disease at operation 50% of the time [32]. Diagnostic laparoscopy in the management of pancreatic cancer must be used on an individualized basis, taking into account the age and comorbidities of the patient, as well as the likelihood of finding occult metastatic disease. It would seem appropriate, however, if suspicion exists in an elderly patient that laparoscopy, to spare the patient an unnecessary laparotomy, might be in order. The degree of CA 19–9 elevation may also be taken into consideration [33]. Finally, the need for surgical palliation of biliary and duodenal obstruction must also be taken into account, as patients who require palliative bypass will not benefit from laparoscopy. On the other hand, as the endoscopic and laparoscopic technical ability has advanced, many palliative procedures can be performed using these techniques, avoiding the need for open surgical procedures.

Preparation for Operation

If the decision is to proceed with an operation for pancreatic cancer in an elderly patient, proper preoperative preparation is required. Thorough multidisciplinary assessment of cardiopulmonary status, renal and hepatic function, the state of hydration, nutrition, anemia, and coagulation abnormalities is necessary. All efforts should be made to optimize the patient's overall health prior to proceeding with operation for resection or palliation. Nutritional status can have a major impact on surgical outcomes after major abdominal surgery, including pancreatectomy [34, 35]. The importance of optimal preoperative nutritional status is further amplified in elderly patients. A team-based approach can help ensure that patients have the necessary resources to ensure appropriate preoperative nutrition. Referral to a nutritionist may be helpful to optimize oral intake in patients that are able to take food by mouth. In patients that are unable to tolerate an oral diet because of gastric outlet obstruction, gastroparesis, or delayed gastric emptying, the available data support placement of a nasojejunal feeding tube, which allows for enteral nutrition with less risk than percutaneous feeding tubes. Parenteral nutrition, once used routinely in the preoperative period, is now generally discouraged and reserved for patients that are unable to tolerate any form of enteral feeding [36].

The role of preoperative biliary decompression with ERCP and stenting should be discussed in a multidisciplinary fashion with the patients surgeon and gastroenterologist. Biliary decompression can be performed by percutaneous transhepatic drainage or by placement of an endoscopic stent at the time of ERCP. Endoscopic stent placement has become the preferred method, as it is usually accomplished with less pain and complications and is better tolerated by patients. The benefit of routine preoperative biliary drainage is questionable, however, with multiple series suggesting that the use of preoperative stenting increases the incidence of perioperative complications, especially wound infection [37]. Therefore, preoperative biliary drainage is indicated only in selected patients, with advanced malnutrition, sepsis, or correctable medical conditions. Preoperative biliary drainage may be useful in allowing time for improvement of the patient's overall health status, particularly in an elderly patient. Furthermore, if surgery is to be delayed to facilitate referral of the patient to a high-volume center, endoscopic biliary stenting can be advantageous. Finally, if preoperative neoadjuvant therapy is considered, biliary drainage is often necessary before such therapy can be initiated.

In more recent years, there has been a focus on standardization of perioperative care and creation of care pathways, which may apply to or be specific for elderly patients. In particular, geriatrics evaluation and a frank preoperative discussion concerning the possibility of prolonged hospitalization and recovery are mandatory. Care-givers for the postoperative setting should be identified and the possibility of inpatient rehabilitation after hospital discharge should be discussed so that appropriate plans are made in advance. Furthermore, careful discussion regarding the patient's goals and values is necessary and should occur prior to surgery. Although clinicians typically focus on postoperative mortality and discrete complications such as pancreatic leak, sepsis, bleeding, and pneumonia, the higher than average risk of postoperative functional and cognitive decline should be addressed explicitly as for many elderly patients the effect on quality of life can be significant [38]. Existing tools such as the comprehensive geriatric assessment (CGA) and the preoperative assessment of cancer in the elderly (PACE) have been shown to be effective in identifying modifiable risk factors and predicting complications and death [39, 40].

Resection of Lesions of the Pancreatic Head

Pancreaticoduodenectomy (Whipple procedure) is the appropriate procedure for resectable cancers of the head of the pancreas, regardless of the age of the patient (Fig. 9) [41]. While many clinicians have regarded advanced age as a relative contraindication for major surgery, there is clear evidence that age alone should not preclude surgery for pancreatic cancer. Prior to 1980, when the morbidity and mortality for pancreatic resection were substantially higher in all age groups, several studies found that elderly populations fared worse than their younger counterparts. For example, Herter et al. observed that operative deaths rose from 7.7% in patients in the 41- to 50-year age group to 25% in patients 61–70 years of age [42].

Lerut and colleagues also noted a significant increase in mortality, 41% versus 5% ($p < 0.001$), and morbidity, 58.8% versus 16.3% ($p < 0.01$), in patients undergoing pancreaticoduodenectomy over the age of 65 when compared to that in younger patients [43]. Finally, Obertop et al. reported 33% mortality following pancreaticoduodenectomy in patients over age 70 compared to 4% in younger patients [44].

Since these early studies, countless authors have challenged the view that pancreaticoduodenectomy is unsafe in elderly patients. One of the first series to show equivalent outcomes in elderly patients was from The Johns Hopkins Hospital, which reported 145 consecutive pancreaticoduodenectomies performed without mortality. Subgroup analysis, which separated patients by age (≤ 70, $n = 37$; <70, $n = 108$), revealed no significant difference in the incidence of postoperative complications. No specific complication was significantly more frequent in the older group, and the incidence of many serious complications seemed to be lower in patients older than 70 years. Operating time, blood loss, and length of stay were also without significant

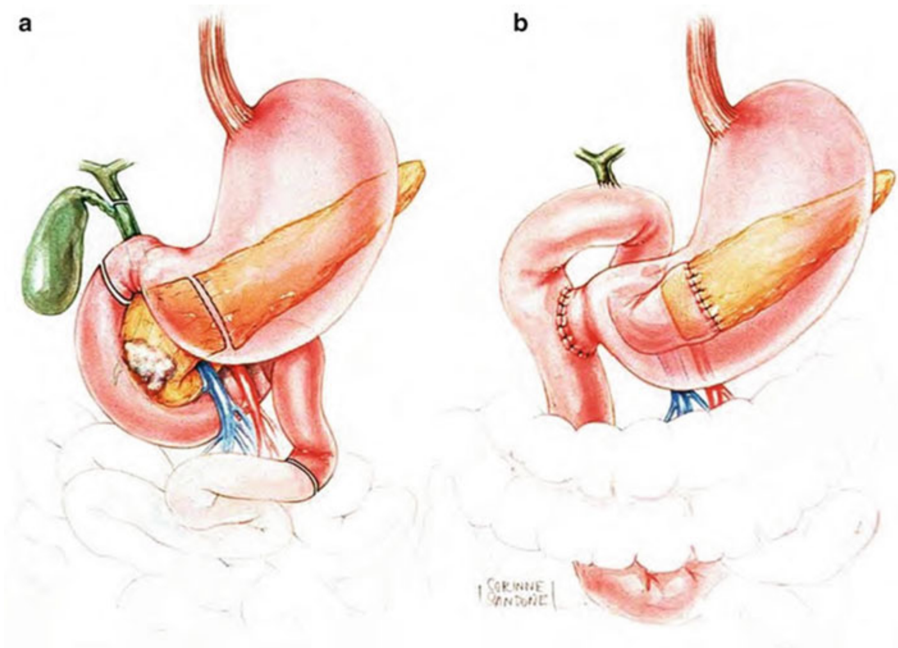

Fig. 9 Pylorus preserving pancreaticoduodenectomy (**a**) Depicts the extent of resection for a pylorus-preserving pancreaticoduodenectomy for cancer of the head of the pancreas. (**b**) Depicts reconstruction with an end-to-end pancreaticojejunostomy, end-to-side hepaticojejunostomy, and a retrocolic duodenojejunostomy (Reprinted with permission from Cameron [41])

difference between the two groups, and no deaths occurred in either group [45].

Since 1990, numerous single-center series have reported the perioperative outcome of pancreatic resection in the elderly [46–65]. Most of these studies found equivalent or acceptable morbidity and mortality rates in elderly patients compared with younger cohorts, suggesting that chronologic age alone should not be seen as a contraindication to surgery.

In one such study, Delcore et al. reported a series of 42 patients between age 70 and 80 who underwent pancreaticoduodenectomy. The incidence of major complications was 14%, with 2 operative deaths (5%) [66]. Hannoun and colleagues reported perioperative morbidity and mortality in 223 patients undergoing pancreaticoduodenectomy, with 44 patients who were of age 70 and over. Perioperative morbidity was similar in the two groups (35%), while mortality was actually decreased in the older patients (4.5% vs. 10%) [49]. In a large series from Memorial Sloan Kettering Cancer Center, Fong et al. analyzed the results of 138 elderly patients (≥70 who underwent major pancreatic resection compared to 350 patients under age 70) [50]. Length of stay (20 days vs. 20 days), frequency of complications (39% vs. 45%), and perioperative mortality (4% vs. 6%) were no different in the younger versus older groups. In fact, there were no deaths among the 24 patients aged over 80 years who underwent pancreatic resection. Analysis of the complications in this study identified that a history of cardiopulmonary disease, abnormal preoperative ECG or chest radiograph, and operative blood loss of >2000 ml were the most powerful predictors of a complication [50].

Ultimately, experienced groups of surgeons have extended the operative indications for resection to patients over 80 years of age and several groups have reported outcomes in this age group (Table 3). A series of 46 patients aged 80 and over, undergoing pancreaticoduodenectomy over a 10-year period at Johns Hopkins, were compared to 681 patients under 80 who underwent the procedure during the same time period [51]. The two

Table 3 Summary of publications comparing perioperative outcome between octogenarians and younger patients

Reference	Number of patients by age	Perioperative mortality	Perioperative complications	Median overall survival (months)	Comments
Sohn et al. 1998 [51]	46 ≥ 80 years 681 < 80 years	4.3% 1.6%	57% 41% ($p = 0.05$)	18 m 17 m	Survival is 3-year. No significant differences

Lee et al. 2014 [61]	475 ≥ 80 years 4102 < 80 years	6% 2% ($p < 0.0001$)	Increased pulmonary complication, stroke, sepsis, and wound disruption in patients older than 80 years	NR	
Frakes et al. 2015 [62]	26 ≥ 80 years 26 = 76–80 years 35 = 70–75 years 106 < 70 years	0% 11.5% 0% 2.8%	No difference in leak, wound infection, fistula, or medical complications	18.7 16.1 23.4 m 23 m	No significant differences in complications, mortality, and long-term survival. Elderly less likely to receive adjuvant therapy

groups were similar with respect to gender, race, intraoperative blood loss, transfusions, and type of resection performed. The older patients had a shorter mean operative time (6.3 ± 1.3 vs. 7.1 ± 4.0 h, $p < 0.05$) but a longer postoperative length of stay (median 15.0 vs. 13.0 days,

$p < 0.05$) than their younger counterparts. A higher incidence of overall complications was seen in the older patients (57% vs. 41%, $p = 0.05$), with a statistically significant increase in delayed gastric emptying among the elderly (33% vs. 18% $p = 0.03$). Perioperative mortality was slightly higher among the elderly patients (4.3% vs. 1.6%), but this was not statistically significant. Another study several years later by the same group examined the outcomes of pancreaticoduodenectomy in the very elderly, which included patients aged 90 and older [52]. Three groups that underwent pancreaticoduodenectomy between 1970 and 2005 were compared: under age 80 ($n = 2491$), age 80–89 ($n = 197$), and age greater than 90 ($n = 10$). While the patients aged 80–89 did have a higher mortality rate (4.1% vs. 1.7%, $p < 0.05$) and complication rate (52.8% vs. 41.6%, $p < 0.05$) than their younger counterparts, these differences were not significant after adjusting for preoperative comorbidities. Multivariate analysis found that coronary artery disease and COPD were independent risk factors for mortality after pancreaticoduodenectomy, but age alone was not.

Over the last decade, several other groups have reported increased, but still acceptable morbidity and mortality in very elderly patients [52–58], while others have found no difference in major complications or mortality in patients above the age of 80 years [59, 60] (Table 3). The very elderly are more likely to have increased lengths of stay and although the majority can be discharged home, there is increased utilization of inpatient transitional care facilities in this population. Despite a slightly higher rate of perioperative complications in the very elderly, most studies report no difference in overall or disease free survival.

In addition to the numerous studies that looked specifically at patient age, several large series examined all patients after major pancreatic resection to elucidate overall prognostic indicators for outcome. One such study came from the Massachusetts General Hospital, in which 733 consecutive pancreatic resections performed from 1990 to 2000 were reviewed. The authors found that mean age of patients increased significantly over that time period, from 57 to 65 years of age. Multivariate analysis of this series of patients did not identify age as a significant prognostic indicator of poor outcome [67].

In recent years, the fundamental question has shifted from whether elderly patients with pancreatic cancer can be treated safely with surgical resection, but how to optimize patient selection and streamline care to improve outcomes. Pancreatic cancer is more prevalent in the elderly, and given the aging population, it is now commonplace to operate on patients well into their 80s and beyond. It is clear that chronologic age alone should not be a contraindication to resection with curative intent. Whenever possible, we recommend utilization of high-volume centers for these complicated patients [68–70]. Diligence is required in the postoperative setting to appropriately identify and rescue patients with complications.

Finally, in recent years, series of minimally invasive pancreaticoduodenectomy either by standard laparoscopic [71] or robotic techniques [72] have been reported with comparable short-term outcomes to traditional open resection. It might be hoped that as these techniques are more widely applied, elderly patients might benefit from a less morbid incision.

Resection of Lesions of the Body and Tail

The opportunity to resect cancers of the body and tail of the pancreas is typically more limited than that of the pancreatic head, due to high frequency of advanced disease at diagnosis. If an elderly patient appears to have resectable disease based on available imaging, many surgeons favor diagnostic laparoscopy to look for occult metastatic disease before proceeding with resection. In the absence of metastatic disease, distal pancreatectomy with splenectomy is the operation of choice. Although less well studied than outcomes after pancreatic head resection in the elderly, available data indicate that elderly patients tolerate distal pancreatectomy well. In a study of the risk factors predicting outcome after distal pancreatectomy, multivariate analysis found that age was not an independent predictor of outcome [73].

Even more than with patients undergoing pancreatic head resection, minimally invasive distal pancreatectomy has been applied with multiple series reporting advantageous short-term outcomes [74]. It would again appear that elderly patients may benefit from such techniques in the appropriate setting.

Palliation

The vast majority of pancreatic cancers are unresectable at the time of diagnosis. Thus, optimal palliation of symptoms to maximize quality of life, and possibly allow for systemic chemotherapy, is of great importance. The three primary symptoms warranting palliation are obstructive jaundice, gastric outlet obstruction, and pain. Palliation in patients with unresectable pancreatic carcinoma has evolved with the increased use of endoscopic biliary and duodenal stenting. Endoscopic stent placement is associated with decreased procedural morbidity and mortality, but is not always feasible and lacks the durability of surgical bypass [75]. Most surgical series report mortality rates of less than 5% and a much lower incidence of late jaundice when compared to endoscopic palliation [76]. Nuzzo and colleagues compared the outcomes of elderly patients (over age 70) undergoing surgical versus endoscopic palliation, surgical palliation resulted in better long-term outcomes with similar morbidity [77]. Mean survival after surgery was significantly higher than that after stent placement (13.2 months vs. 7.29, $p < 0.001$), and total readmissions were fewer after surgery than stenting (1 vs. 25, $p = 0.001$) (Table 5).

Although the role of endoscopic palliation in patients found to be unresectable during preoperative evaluation has been well defined, many surgeons still favor surgical biliary bypass, should the tumor be unresectable at the time of laparotomy. This is best accomplished by an anastomosis of the bile duct to the small intestine as a hepaticojejunostomy. If patients have duodenal obstruction, a gastrojejunostomy is also performed. (Fig. 10) [41].

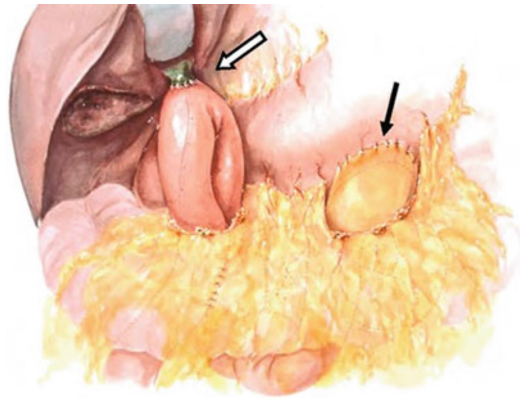

Fig. 10 Roux-en-Y hepaticojejunostomy (*white arrow*) is performed for biliary decompression, and a retrocolic gastrojejunostomy (*black arrow*) relieves gastric outlet obstruction (Reprinted with permission from Cameron [41])

The role of prophylactic gastrojejunostomy for palliation in patients found to have unresectable pancreatic cancer intraoperatively has been addressed by two prospective randomized trials. The first randomized 87 patients with unresectable periampullary cancer at the time of laparotomy to either prophylactic retrocolic gastrojejunostomy or no gastrojejunostomy. None of the patients who underwent gastrojejunostomy developed late gastric outlet obstruction, whereas the patients without gastrojejunostomy had a 19% rate of late gastric outlet obstruction requiring intervention ($p < 0.01$). Length of stay, morbidity, mortality, and long-term survival were comparable between the two groups [78]. In a second prospective, randomized multicenter trial, patients with unresectable cancer at the time of laparotomy underwent either a biliary bypass alone (single bypass) with hepaticojejunostomy or a double bypass with both a hepaticojejunostomy and a retrocolic gastrojejunostomy [79]. The group who underwent double bypass had significantly decreased incidence of late gastric outlet obstruction without any increase in complication rate, providing evidence that prophylactic double bypass should be strongly considered in these patients.

A recently reported series from the ACS NSQIP database evaluated perioperative morbidity and 30-day mortality in patients that underwent surgery for unresectable pancreatic cancer [75]. This series included patients determined to have locally advanced and/or metastatic disease at the time of planned resection, as well as those with known unresectable disease taken to the operating room specifically for palliative purposes. Not surprisingly, patients that underwent biliary and/or gastrojejunal bypass experienced increased morbidity (12 vs. 20%, $p < 0.001$), but equivalent mortality rates (5 vs. 6.5%, $p = 0.21$). On multivariate analysis, age greater than 70, emergent operation, disseminated cancer, albumin less than 3 g/dl, and renal insufficiency were independent risk factors for death. Dependent functional status, diabetes, and preoperative leukocytosis were independently associated with serious morbidity [75]. This underscores the point that in patients with multiple risk factors, the risks of surgical palliation must be carefully considered.

Laparoscopic gastrojejunostomy and metallic stent placement are less invasive alternatives that may be better tolerated. A number of series have shown excellent results with laparoscopic gastrojejunostomy [80, 81]. In addition, the role of endoscopic stenting for duodenal obstruction has quickly expanded (Fig. 11). Several retrospective studies have compared outcome after duodenal stent placement versus surgical bypass. In one study, 42 patients who underwent gastrojejunostomy were compared with 53 patients who underwent stent placement [82]. There were no differences between the groups as far as minor complications, early major complications, and long-term survival, although the surgical group had fewer late complications (22% vs. 60%), and the stented group had a shorter length of hospital stay (6 days vs. 18 days, $p < 0.001$). For patients with advanced unresectable disease or elderly patients with poor performance status, duodenal stent placement has become the procedure of choice.

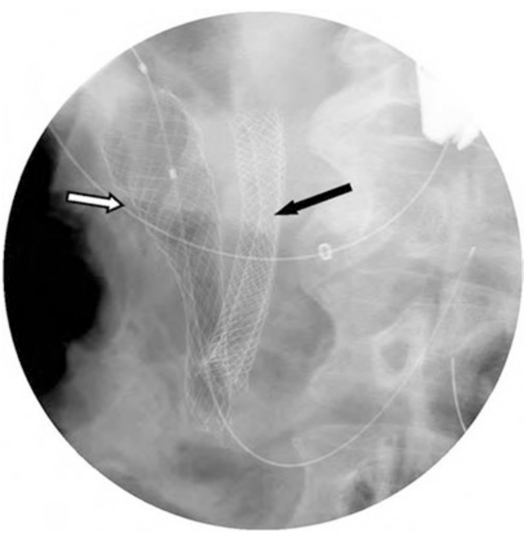

Fig. 11 Enteric palliation using an endoscopically placed duodenal stent (*white arrow*) and relief of biliary obstruction with biliary stent (*black arrow*)

The management of pain in patients with advanced pancreatic adenocarcinoma is one of the most important aspects of care, and multiple complementary treatment strategies are available. Most patients can be successfully managed with a combination of short- and long-acting oral opiates, often combined with topical sustained-release opiates. However, appropriate dosing of opioids in the elderly must be considered. Inadequate treatment of pain in elderly cancer patients has been well documented [83]. Unrelieved cancer pain in the elderly can lead to disturbances in mood, sleep, appetite, and cognition. Many health-care providers have misconceptions about pain perception in the elderly, tolerance and addiction, and increased potency of medications.

When pancreatic cancer pain is intractable despite appropriate opioid analgesics, local procedures that target either the celiac plexus or the splanchnic nerves are recommended. Two methods exist for absolute alcohol neurolysis of the celiac plexus: standard needle placement through the midback (with CT or fluoroscopic guidance) or endoscopic ultrasound (EUS)-guided needle placement. Both methods have been shown to significantly reduce pain for sustained periods of time, with the EUS-guided approach having fewer complications [84–86]. When a pancreatic cancer is determined to be unresectable at laparotomy, intraoperative chemical splanchnicectomy can be performed with direct injection into the area of the celiac axis (Fig. 12) [41] Lillemoe and colleagues performed a prospective, randomized, double-

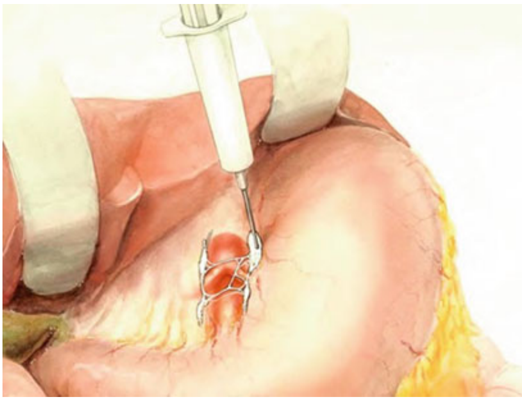

Fig. 12 Chemical Splanchnicectomy. After identification of the celiac axis in the lesser sac, 50% ethanol is injected into the celiac plexus for pain control (Reprinted with permission from Cameron [41])

blind, placebo-controlled trial comparing chemical splanchnicectomy with 50% alcohol to a sham saline injection [87]. The patients who received alcohol injections had significantly improved pain scores compared to those who received saline at 2-, 4-, and 6-month follow-up assessments, as well as at the final assessment ($p < 0.05$). This procedure can also be performed during laparoscopic staging for pancreatic cancer. Neurolytic celiac plexus block also improved multiple quality-of-life measures in those patients. In the elderly population, EUS-guided neurolytic celiac plexus block likely delivers the least invasive, most effective option for intractable pancreatic cancer pain.

Postop Care and Complications

Frailty and comorbidities are common in the elderly. Attention to detail is required in the postoperative setting to insure early identification of complications and appropriate management. Adequate fluid and electrolyte maintenance, glucose regulation, pulmonary toilet, and pharmacologic prophylaxis for deep venous thrombosis are routine. Unfortunately, complications are common in all age groups after pancreaticoduodenectomy, with typical rates of 30–40%. The difference in complication rates between elderly and younger patients has been addressed by multiple retrospective comparisons [46–65]. Although numerous studies have found no difference in complication rates between these two groups, others have reported higher rates of delayed gastric emptying [51, 57], cardiopulmonary morbidity [54], stroke [61], or sepsis [61]. Several studies report that elderly patients with comorbidities have increased complication rates compared to younger patients with the same comorbidities [52]. This suggests that careful preoperative patient selection and increased postoperative diligence are warranted in elderly patients who undergo major pancreatic resection.

Chemotherapy/Radiation Therapy

The multimodal approach to pancreatic cancer has realized significant advances over the last decade. Treatment approach varies considerably based on local characteristics of the tumor at presentation. Patients with localized, clearly resectable pancreatic cancer should undergo surgery with curative intent. The role of neoadjuvant therapy in these patients is a matter of debate and best considered in the context of a clinical trial, which is often not an option for the elderly. There are several theoretical advantages to a neoadjuvant approach, including enhanced patient selection for a morbid operation, earlier treatment of micrometastatic disease, and the opportunity to monitor response to systemic therapy in vivo that make this approach appealing [88–90].

Patients with borderline resectable and locally advanced pancreatic cancer have a high risk of positive margins if surgical resection were to be pursued. Several criteria have been offered to better define these terms and are based on the involvement of surrounding vascular structures [91–93] (Table 4). In patients with borderline resectable and locally advanced disease, there is general consensus that the initial approach should be neoadjuvant chemotherapy and chemoradiation with the goal of downstaging the tumor such that resection is possible. Stereotactic body radiation therapy (SBRT) is an important recent advance in radiation therapy and is frequently used in borderline resectable or locally

Table 4 Common definitions of borderline resectable pancreatic cancer

Blood vessel	NCCN [91]	AHPBA/Consensus [93]	MD Anderson [92]
Celiac axis	Distortion or narrowing of the vessel wall, and/or reconstructible occlusion	Uninvolved	Short segment occlusion/ reconstructible
Superior mesenteric artery	Tumor-vessel interface ≥180 degrees of the circumference of the vessel wall	Abutment	Abutment
Hepatic artery	Reconstructible short segment interface between tumor and vessel	Abutment or short segment encasement	Abutment or short segment encasement
Superior mesenteric vein/ portal vein	Distortion of narrowing of the vessel wall, and/or reconstructible occlusion	Abutment, impingement, encasement of the SMV/ PV or short segment occlusion	Short segment occlusion/ reconstructible

Table 5 Palliative biliary bypass versus biliary stenting in patients >70 years of age with unresectable pancreatic cancer [77] (*Source*: Data from Nuzzo et al. [77])

	Surgery ($n = 24$)	Stent ($n = 35$)	p Value
Mortality (%)	1	3	NS
Morbidity (%)	6	10	NS
Patients readmitted	1	15	0.006
Number of readmissions	1	25	0.001
Mean survival (months)	13.2 ± 8.06	7.29 ± 2.25	<0.001

advanced pancreatic cancer. Follow-up imaging is planned to assess treatment response and suitability for resection. It should, however, be noted that radiographic changes on CT may not adequately reflect tumor response to therapy [94, 95]. A more aggressive surgical approach involving exploration and serial biopsies along potentially involved vascular structures has been recommended. Although operative times and blood loss appear to be increased after neoadjuvant therapy, decreased postoperative morbidity has been reported [95]. The optimal neoadjuvant approach is yet to be determined and regimens are typically extrapolated from the metastatic setting.

A recent series from the Medical College of Wisconsin reported outcomes of 246 patients, including 36 (15%) patients age ≥ 75, with pancreatic cancer treated with moderate course (2–4 months) neoadjuvant therapy [96]. Patients older than 75 years were equally likely to undergo successful surgical resection. Failure to complete neoadjuvant therapy and surgical resection was increased with borderline resectable versus resectable disease at presentation, increased posttreatment/preoperative CA 19–9, and Charlson Comorbidity index ≥6. Overall survival in this series was 24 months for all comers and 37 months in patients that completed surgical resection. Older patients in this series were more likely to be discharged to a transitional care facility, but there was no significant difference in perioperative morbidity, mortality, or overall survival [96].

A modest, though significant, benefit of adjuvant chemotherapy therapy has been demonstrated after resection of pancreatic cancer and is thus the recommended by the NCCN. 5-FU was considered standard of care until the landmark CONKO-001 trial published in 2007 demonstrated improved 5-year and median survival with adjuvant gemcitabine compared with resection alone [97].

The landscape of systemic therapy for metastatic pancreatic cancer shifted dramatically in 2011 with the ACCORD-11 trial [98]. This trial demonstrated that overall survival with fluorouracil, leucovorin, oxaliplatin, and irinotecan (FOLFIRINOX) was significantly improved compared with previous standard of care gemcitabine for patients with metastatic pancreatic cancer (6.8 vs. 11.1 months, $p < 0.001$). However, this can be a toxic regimen and patients with performance status >1 and age $\geq$ 75 were excluded from the trial. Furthermore, only 29% of patients were older than 65 years. Age was an independent predictor of poor survival, but patients older than 65 years did benefit from FOLFIRINOX (HR = 0.48). Studies are ongoing to assess the tolerability and efficacy of dose-adjusted FOLFIRINOX in the elderly.

The MPACT trial also demonstrated improved survival with combination gemcitabine and nab-paclitaxel compared with gemcitabine monotherapy [99]. Elderly patients and those with poor performance status were included in this trial and 10% of the patients were above the age of 75 years. Given the available data, it is reasonable to consider FOLFIRINOX in fit patients age 65–75, and gemcitabine combination chemotherapy for patients older than 75 or those with poor functional status. Palliative gemcitabine monotherapy may be considered for the very elderly or frail. Adjuvant chemoradiotherapy has also been used for many years, but its benefit has not been definitively established and is an area of active investigation. Additional experimental strategies including immunotherapy, molecular targeted therapy, and vaccine-based therapy are also of great interest, particularly in the adjuvant and metastatic setting.

Long-Term Outcomes and Quality of Life

Despite improvements in surgical management and perioperative mortality, long-term survival remains poor following resection for pancreatic adenocarcinoma. Despite advances in multimodal therapy, 5-year actuarial survival rates after pancreaticoduodenectomy rarely exceed 20%. A large study of a statewide database of 2230 patients diagnosed with pancreatic cancer found that advanced age at diagnosis was an independent risk factor for decreased survival (hazard ratio 1.23, CI 1.18–1.29). However, this is likely explained by underutilization of surgery in the elderly [100]. When the elderly are treated with appropriate surgery and adjuvant therapy, several series have shown that age is not an independent prognostic factor for long-term survival. Most analyses find tumor characteristics, such as tumor size, nodal status, margin status, and tumor differentiation, stage, CA 19–9 and treatment approach to be the most influential prognostic factors for survival [101, 102].

Numerous studies have examined long-term outcome after pancreatic resection in the elderly compared to younger patients (Table 3). The majority of series report similar 5-year survival rates in elderly patients as those in younger patients [51, 53, 58, 59, 60, 62, 103].

As with short-term outcomes, hospital volume is an important determining factor in long-term outcome after pancreatic resection. High-volume, single-institution series report postresection 5-year survival rates as high as 29%, while population-based studies report rates of 15–16% [68, 69, 104]. A study by Birkmeyer and colleagues investigated the relationship between hospital volume and 5-year survival after major cancer surgery. This study showed that for pancreatic cancer resection, there was a difference in long-term survival between low- and high-volume hospitals (10.8% vs. 15.9%) [105]. These data, like those regarding perioperative outcome, suggest that elderly patients are best served at high-volume institutions.

Data with respect to quality of life after resection for elderly patients with pancreatic adenocarcinoma are lacking. One study compared subjective quality of life scores in patients older than 70 years after pancreaticoduodenectomy with matched individuals that underwent laparoscopic cholecystectomy. Three months postoperatively, patients that underwent pancreaticoduodenectomy reported more fatigue, nausea, vomiting, diarrhea, weight loss, pain, and loss of efficiency. However, by 6 months there were no significant differences between the cohorts [106]. Additional data are needed to further address quality of life after pancreatic resection in the elderly.

Treatment Disparities in the Elderly

Unfortunately, most patients with pancreatic cancer (52%) are found to have distant disease at the time of diagnosis.

A dismal prognosis has led to an overall pessimism for the aggressive treatment of this disease. According to the SEER National Cancer Registry database, 7% of patients have localized disease, and 26% present with regional disease. When these 33% of patients with locoregional disease have been studied, only about half of them underwent any form of surgical or radiation treatment [107, 108]. Even among Stage I patients, who are potentially curable with resection, Bilimoria et al. found that 71% did not undergo surgery. Analysis of these patients showed that 6.4% were excluded due to comorbidities, 4.2% refused, 9.1% were excluded due to age alone, and 38.2% were not offered surgery for undetermined reasons [107]. In addition to the 9.1% who were excluded due to age, the average age of patients who were not offered surgery was significantly higher, 71.7 versus 62.1 ($p < 0.0001$). This study suggests that age has a major influence in the management options that are offered to patients, including referral to a surgeon (Fig. 13). Gawron et al. found similar differences, with a much higher percentage of older patients treated nonoperatively [109]. This unfortunate trend is true for cancer-directed surgery in other diseases as well, with underutilization in elderly populations [110]. This disparity has continued over time [111]. A more recent analysis of the SEER database reported similar findings: 10,505 patients older than 65 years with locoregional pancreatic adenocarcinoma, only 51% received treatment (chemotherapy and/or surgery). Of these patients, only 11.1% received multimodal therapy [112].

Management of Benign and Premalignant Neoplasms

Diagnosis

The diagnosis and management of benign pancreatic neoplasms has become an increasingly frequent problem in recent years. This is in part due to the increased detection of asymptomatic lesions due to the widespread use of cross-sectional imaging studies. The challenge is determining which lesions are malignant, benign but premalignant, or benign with no malignant potential. Most asymptomatic lesions are cystic and include mucinous cystic neoplasm (MCN), intraductal papillary, mucinous neoplasm (IPMN), and serous cystadenoma (SCA). Cross-sectional imaging (with or without pancreatography), endoscopic ultrasound, and cyst fluid analysis are the

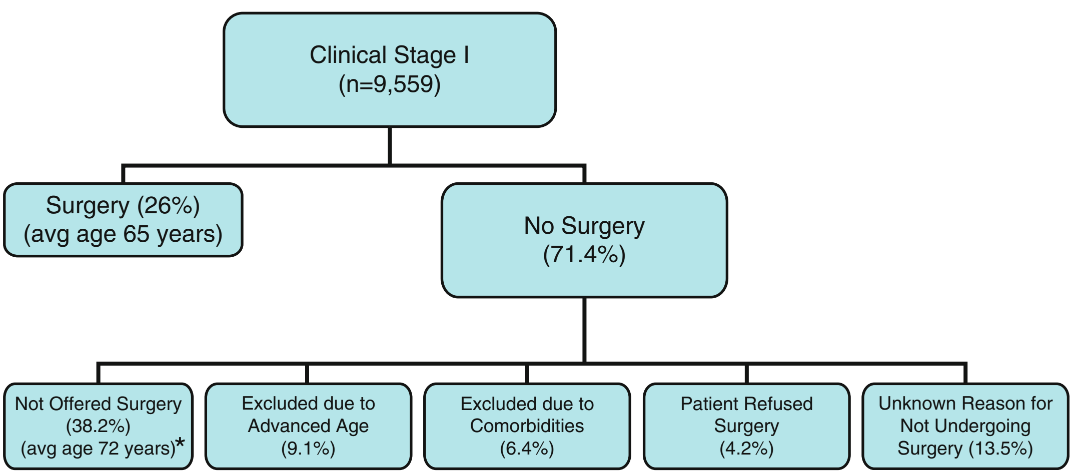

Fig. 13 Failure to operate on stage I pancreatic cancer. Note the role of age in the chances that a patient will be offered surgery. *$p < 0.0001$ compared to age of patients who underwent surgery (Data from Bilimoria et al. [107])

principal methods for evaluating cystic lesions of the pancreas.

Multidetector CT scan is generally the first technique used, whether it reveals an incidental, asymptomatic lesion, or has been obtained in the workup of abdominal symptoms. CT can often help discern between several types of cysts, based on specific characteristics. For example, the presence of multiple small-diameter microcysts, stellate scar, and sunburst calcifications is characteristic of SCAs and distinguishes these lesions from mucinous cystic tumors (Fig. 2). In addition to aiding in classification of cysts, several findings on cross-sectional imaging can predict the likelihood of malignancy of a cystic pancreatic lesion: peripheral calcification, dilated pancreatic duct, and presence of a solid component [113]. A noninvasive alternative to CT is MRCP, as this technique can determine if the lesion communicates with the pancreatic ductal system. IPMNs typically communicate with the pancreatic ductal system, whereas MCNs do not. MRCP or ERCP, as an invasive procedure, can classify IPMN into main duct type, branch duct type, or mixed type IPMN, which has important management implications [114]. Endoscopic ultrasound with fine-needle aspiration (EUS-FNA) is useful in differentiating between cyst types. The viscosity of aspirated fluid is the first clue to diagnosis, as mucinous neoplasms have a higher fluid viscosity than serous ones. Fluid analysis revealing a high mucin content and high carcinoembryonic antigen (CEA) is diagnostic of a mucinous neoplasm, with an accuracy of 79% [10]. This differentiation between mucinous and nonmucinous is essential, as serous tumors are very rarely malignant and in most cases can be managed without surgery.

Estimating the Malignant Potential

When a pancreatic cystic lesion has been classified as mucinous, whether it be MCN or IPMN, the clinician must then determine the likelihood of malignancy. Management of asymptomatic pancreatic cysts can be challenging and optimal treatment approach remains an area of controversy. The American Gastroenteroligal Association (AGA) [115] and International Association of Pancreatology (Fukuoka) [116] have provided recommendation to better delineate criteria for EUS and surgery. Surgery is recommended for high risk features, which include mucinous cysts $\geq$3 cm associated with main duct dilation and/or a definitive mural nodule. *KRAS* and or *GNAS* mutations with *TP53* and *PIK3CA* or *PTEN* mutations are also worrisome. Cytology that raises concern for malignancy is an indication for surgery. In patients with IPMN, a main-duct subtype, side branch tumors with a dilated main pancreatic duct, elevated serum CEA or CA19–9, presence of jaundice, and new-onset diabetes have all been shown to be predictors of malignancy [117]. In addition, cyst fluid analysis revealing markedly elevated levels of CEA is associated with malignancy [103, 104]. Cytology of the cyst aspirate may also be used, which has a specificity of 83%, but the high false-negative rate creates a low sensitivity (34.5%) [118]. Finally, advanced age is also associated with increased likelihood of malignancy, as most series find the average age of patients with malignant lesions to be 5–6 years older than patients with benign tumors [119].

Indications for Resection

In elderly patients, the decision to proceed with surgical resection must take into account the patients symptoms, the likelihood of malignancy, the patient’s general medical condition, and the expected morbidity and mortality of the procedure. In patients with serous cystadenoma, the likelihood of malignancy is less than 1%, so surgery should only be offered to symptomatic patients in relatively good heath or for tumors demonstrating significant growth. In the case of mucinous cystic neoplasms (MCNs), resection is indicated in symptomatic patients and in cases with a high suspicion of malignancy. Because it is impossible to determine malignancy preoperatively with absolute certainty, many surgeons advocate surgical resection for all patients with MCN who are suitable operative candidates. For patients with branch duct IPMN, malignancy is extremely rare in asymptomatic patients with lesions less than 3 cm. Therefore, only those patients who are symptomatic or have large (>3 cm) lesions should undergo resection. In contrast, main duct IPMN has a malignancy rate of 60–92%, leading to most authors recommending resection for all patients [120].

Resection

When the decision is made to resect a benign or premalignant tumor of the pancreas, most resections are performed using traditional pancreaticoduodenectomy or distal pancreatectomy. However, in recent years, multiple new minimally invasive and/or pancreas-sparing techniques have become popular options for surgical management. These include laparoscopic distal pancreatectomy with or without splenic preservation, and central pancreatectomy. For lesions of the body and tail of the gland, laparoscopic distal pancreatectomy, with or without the spleen-preserving procedure, has gained favor with many surgeons [121, 122]. The laparoscopic technique has become widely applied for benign tumors or small tumors of undetermined malignant status. In patients considered to have a high probability of malignancy, splenectomy should be considered. For benign small lesions in the mid-pancreas, a central pancreatectomy may be an appropriate choice, as it preserves as much pancreatic tissue as possible to ensure maintenance of endocrine and exocrine function. An even less invasive option for benign neoplasms is enucleation, in which the lesion is essentially "cored" out from the pancreatic parenchyma. This procedure is most appropriate for lesions that are not in communication with the main pancreatic duct [123].

Outcomes

Theoretically, the long-term survival after resection of a benign or premalignant pancreatic tumor should be comparable to age-matched controls. However, patients with IPMNs are at risk for recurrent disease in the remnant gland after partial pancreatectomy. The extent of surgical resection of IPMNs should be determined by the extent of disease (especially the presence of multifocal lesions) and intraoperative frozen section of resection margins. After resection, patients with even benign or noninvasive IPMNs require careful follow-up for recurrent disease, which has been reported in approximately 10% of patients [5]. Survival for patients with resected invasive IPMNs is substantially better than for pancreatic ductal carcinoma and in some series approaches 50% at 5 years [10]. The role of postoperative adjuvant therapy for invasive IPMN has not been specifically determined but in general has been applied similarly to ductal carcinoma.

Conclusions

Tumors of the exocrine pancreas are a significant issue in the elderly. In general, older patients should be treated aggressively with similar indications for surgery and similar procedures as in younger patients. The morbidity and mortality of major pancreatic resection have decreased among all age groups over time, making safer surgery an option. Great care should be taken, however, in assessing an older patient's preoperative risk factors, potential for increased life expectancy, and hospital volume before proceeding with major surgical resection. In patients with pancreatic malignancy, multidisciplinary management is mandatory, and resection, which offers the only chance of cure, should not be withheld based on chronological age alone.

Case Study

Mr. Smith is an 80-year-old man who presented with painless jaundice, dark urine, clay-colored stools, and pruritus. His workup at an outside hospital consisted of a CT scan, which showed a potentially resectable 2.5 cm mass in the head of the pancreas, and an ERCP, which demonstrated pancreatic and biliary ductal obstruction. A biliary endostent was placed. Finally, an endoscopic ultrasound was performed, which showed a pancreatic mass with no evidence of visceral vessel invasion. Fine-needle aspirate performed at the time of EUS was positive for pancreatic cancer. The patient was referred for surgical evaluation.

The patient's past medical history is significant for a 40-year smoking history, although he stopped smoking 20 years ago. He has long-standing atrial fibrillation and has been on anti-coagulation with warfarin. The patient has an internal cardiac defibrillator in place. He has type II diabetes managed with oral medications. He has a history of prostate cancer treated with radiation therapy, which has resulted with neuropathic bladder, which requires self-catheterization. He also has a history of a left hip replacement.

After determining that the patient was indeed a potential candidate for surgical management, follow-up with his cardiologist was obtained where echocardiogram revealed an ejection fraction of 20–25%, likely due to a nonischemic cardiomyopathy. His medications included avandia, corgard, glucosamine, iron, lasix, metformin, and norvasc. On review of systems, he denied chest pain, but exercise tolerance was limited with shortness of breath at one block or one flight of stairs. He had no history of cerebral vascular accident or stroke. He had lost a total of 10 pounds since the presentation. He denied nausea, vomiting, or blood in his stool.

The patient was evaluated preoperatively by cardiology as well as in our preoperative assessment and testing center and was brought to the operating room for a planned pancreaticoduodenectomy. His warfarin was stopped 5 days before surgery and on the morning of admission, he had a normal INR. General anesthesia was induced following placement of an epidural catheter for intraoperative anesthesia and perioperative pain control. After general anesthesia was obtained, the patient underwent a diagnostic laparoscopy, which showed no evidence of metastatic disease. A classic pancreaticoduodenectomy was then performed with an estimated blood loss of 400 ml and no intraoperative complications. After the reconstruction, a feeding jejunostomy was placed. At completion of the surgical procedure, the patient was extubated and transferred to the ICU. He was maintained in the ICU overnight and then transferred to a progressive care unit in the morning following surgery. On postoperative day two, tube feeds were initiated, and on postoperative day 3, the patient was started on a clear liquid diet. The patient was maintained with perioperative prophylaxis with lovenox, and on postoperative day four, with no evidence of bleeding in the drains, the patient was started on therapeutic heparin for the remainder of his hospitalization. On postoperative day 3, he developed an episode of atrial fibrillation with rapid ventricular response, and cardiology follow-up was obtained. His heart rate was eventually controlled with digoxin and beta blockers which were not associated with hemodynamic instability. Perioperatively, he had some confusion, thought to be due to intervenous narcotic PCA, but this cleared, and his pain was eventually well controlled with tylenol. He was able to tolerate a diet although oral intake was only marginal, and he was, therefore, maintained on cycled tube feeds throughout the remainder of his hospitalization. The patient was discharged to a rehab center on postoperative day 10 with drains removed and on therapeutic lovenox until his anticoagulation was adequate on oral warfarin.

The patient was seen in follow-up on 1 month after discharge. He has recently been returned to his home where he lives independently with family nearby. He tolerates a diet although we are still using the feeding jejunostomy for daily boluses of tube feeds but felt that his oral intake was adequate. He had no new cardiac events and was therapeutically anticoagulated with warfarin. His feeding tube jejunostomy was removed. His incision was well healed.

Final pathology revealed a $2.7 \times 2.2 \times 1.6$ cm ductal carcinoma of the pancreas. All margins were negative. One of 13 pancreatic lymph nodes showed direct invasion by the cancer, but all other lymph nodes were negative. (AJCC Stage pT3, N1, M0). After consultation with the patient and his family, it was felt that his recovery was adequate for referral to medical oncology for consideration of postoperative adjuvant chemotherapy.

Abstract

America's population is aging, and the number over the age of 80 will double by the year 2050. This, combined with the fact that colorectal cancer is a common malignancy, with an increasing incidence with age, explains why treating the elderly patient with colorectal cancer is becoming increasingly commonplace. This chapter focuses on how the disease may present differently in elderly patients; how the risks of treatment and surgery can be assessed and used to guide treatment decisions; how various aspects of colorectal cancer treatment may be different, or the same, for geriatric patients; and finally, how outcomes in the perioperative period can be optimized by choices in surgical technique and perioperative care. Caring for these elderly patients requires considerable skill and judgment that takes into consideration their comorbidities, the various options for treatment, and a global understanding of how the risk and benefit equation works for the various treatments such that appropriate care is rendered to optimize short-term outcomes balanced with the desire to achieve good long-term cancer control.

Introduction

Colorectal cancer is common and the risk of developing this malignancy increases with age. An aging population further compounds this: by the year 2050, 84 million Americans will be over the age of 65, nearly double the 43 million who were that age in 2012, and accounting for over 20% of the population [1]. Furthermore, the number of those who are considered the "Oldest of the Old," those over the age of 80 years, will double by 2050 [1]. Treating the elderly colorectal cancer patient is becoming increasingly commonplace, and since surgery forms the basis of colorectal cancer treatment, surgeons often find themselves on the front line, maneuvering around the elderly patient's co-morbidities, trying to avoid early morbidity and mortality, while balancing concerns over quality of life and advantageous short-term outcomes, with the desire to achieve good long-term cancer control.

This is a population of patients that is incredibly heterogeneous, not only in terms of comorbidities, but also in terms of daily activities and social functioning. Caring for these patients requires considerable thought and skill to manage and treat their ailments. A more global picture of each individual may be what is best suited for optimal outcomes. Unfortunately, little is clearly understood as to how well elderly patients tolerate any number of treatments as they are often excluded from clinical trials due to multiple comorbidities and other confounding factors.

The aim of this chapter is not a thorough review of colorectal cancer and its treatments, to which we would refer you to any number of excellently written chapters, articles, and guidelines on the subject that provide an extensive explanation [2–5]. Rather, this chapter will focus on how aspects of the disease and its treatments may be different, or the same, for geriatric patients. We aim to provide the clinician with an improved understanding of items and options to consider when caring for elderly colorectal cancer patients. Specifically, we will address how the disease may present differently in elderly patients, how the risks of treatment and surgery can be assessed and used to guide treatment decisions, how outcomes in the perioperative period can be optimized by choices in surgical technique and perioperative care, and how neoadjuvant and adjuvant treatments may be differently utilized in geriatric patients. Furthermore, we will focus the discussion on adenocarcinoma of the colon and rectum as this represents the vast majority of colorectal cancer seen in this patient population.

Case Study #1

An 80-year-old female with a history of chronic kidney disease, atrial fibrillation, congestive heart failure, pulmonary hypertension, and previous transient ischemic attacks on oral anticoagulation presented to the emergency department with gastrointestinal bleeding and anemia. She required several transfusions of packed red blood cells and colonoscopy demonstrated a large ascending colon mass, which was biopsied and confirmed to be moderately differentiated adenocarcinoma. Additional staging evaluation was negative and her carcinoembryonic antigen level was normal. On questioning, she was very physically active prior to struggling with symptoms of anemia, participating in aerobics and weight training at her local gym. She had an active social life and lived independently with her husband. She denied any significant weight loss in the months prior to her admission. Her exam was remarkable for a petite, alert, vibrant elderly woman in no acute distress with good cognitive functioning and an unremarkable abdominal exam with no previous abdominal surgery. She was taken for a laparoscopic right hemicolectomy once her oral anticoagulation was reversed, which was well tolerated and proceeded without complication. The operation took slightly longer than 2 h and the estimated blood loss was less than 100 mL. Postoperatively, she was treated according to our postoperative enhanced recovery pathway with early ambulation, early advancement of diet on the first postoperative day, and minimization of narcotics using transversus abdominis blocks and intravenous acetaminophen. She was evaluated by physical and occupational therapy and met criteria for discharge to home, which occurred on postoperative day five. Her pathologic assessment revealed a Stage IIIB (pT3 N1b M0) moderately differentiated ascending colon cancer with 2 of 28 nodes positive, no lymphovascular or perineural invasion, and negative margins. She was evaluated for adjuvant chemotherapy and elected to forgo this to avoid the impact of medication-related side effects and to maximize her quality of life. She did well for 34 months after her surgery, returning to her previous level of activity, without any evidence of recurrence on imaging or serum markers, at which time she succumbed to her cardiac disease with an acute event.

This case highlights several principles of caring for geriatric colorectal cancer patients. First is a thorough understanding of the patient beyond their acute cancer diagnosis. The woman in this case study clearly functioned at a level above most of her peers, demonstrating high-level physical and mental functioning as well as good nutrition despite symptoms of anemia that had crept in over a few months. Furthermore, she had an ample social support system of family and friends to help in her recovery. While using metrics to objectively assess frailty, such as the CGA and the Fried criteria, can give an objective "definition" to a patient's frailty, inquiring about these issues during history taking is also quite valuable, as often an accurate assessment can be made and a rough categorization of frailty and risk-assessment can be obtained without an excess of time spent in the effort.

Secondly, the use of a minimally invasive surgery and an enhanced recovery pathway was helpful in speeding recovery and minimizing the impact of surgery. While the operation likely took longer to complete than a typical open right colectomy, the laparoscopic approach offers minimal incisions, and therefore, a reduction in postoperative pain and minimization of narcotic use, which is especially helpful in geriatric patients. She used minimal narcotics, she was able to ambulate soon after her operation, and she was able to avoid any issues with postoperative delirium, which is so common in geriatric surgery patients. Our practice is to also include our patients on a predefined enhanced recovery pathway for all nonemergent surgery, regardless of disease process, age, or comorbidities.

In addition to the use of a minimally invasive operation, a care path that includes strategies to minimize narcotic use in the postoperative period with preference given to nonnarcotic options for pain control and use of regional anesthetics such as epidurals and blocks can be very helpful in the geriatric population. Patients are also allowed clear liquids after surgery and advanced to low fiber soft diet as tolerated, often by the first or second postoperative day. Furthermore, standard activity instructions ensure that patients are ambulating the night of surgery, in many cases, with the help of a dedicated and well-trained nursing staff. Another component of the care path is setting the expectation of the surgical recovery plan prior to surgery so patients are aware of what to expect and the time-line at which milestones often occur. Such management of expectations sets up what is "normal" for the patient and allows them to feel comfortable in their recovery.

Lastly, this case also emphasizes the impact competing comorbidities can have on overall survival in the geriatric patient population. Certainly, this patient had a number of significant comorbidities, one of which ultimately ended her life. From all available evidence, her cancer had not recurred and she continued to have a durable benefit of surgery at the time of her death. By intervening and treating her colon cancer, we were able to allow her to enjoy nearly another 3 years with an excellent quality of life that she would not have had otherwise.

Case Study #2

An 86-year-old woman presented to the emergency department with abdominal pain, constipation, and distension. Her radiographic imaging suggested a mass in the rectosigmoid colon and she underwent a flexible sigmoidoscopy that showed and obstructing mass at 30 cm. A biopsy was taken that demonstrated poorly differentiated adenocarcinoma. She also underwent a stent placement to relieve the obstruction. She lived with her husband, and her regular activities including caring for him, as he suffered from dementia, and caring for their home. She had several adult children and grandchildren who lived nearby and helped her and her husband. Her comorbidities were limited to hypertension and diabetes, controlled on oral medications. After completing a slow bowel prep over several days, she underwent a completion colonoscopy which demonstrated only the known mass at 30 cm.

Subsequently, she underwent a hand-assisted laparoscopic sigmoid resection. On abdominal exploration, a small area of peritoneal metastases was noted at the left side of the anterior peritoneal reflection near her primary tumor in the rectosigmoid colon. She underwent a sigmoid resection with mobilization of the splenic flexure, followed by a pelvic peritonectomy. Her recovery was unremarkable and she was discharged home on postoperative day number four in the care of her family with home physical therapy. Her pathologic report documented a moderately differentiated adenocarcinoma with mucinous features, pT3 N2a, M1b, with 5 of 28 lymph nodes positive for adenocarcinoma along with peritoneal metastases, negative colonic margins, and evidence of lymphovascular and perineural invasion. She was evaluated by her medical oncologist, who repeated her cross-sectional imaging after surgery. She was noted to have evidence of pelvic peritoneal recurrence at 2 months after surgery in the location of the previous peritonectomy. Therefore, she was treated with oral capecitabine and bevacizumab for 6 months. Repeat imaging has shown stability of her pelvic disease and she has continued to do well in the 16 months since her surgery.

This case highlights several other considerations when caring for geriatric patients. In the emergency setting, several options are available to manage large bowel obstruction, including proximal diversion and gastrointestinal stenting. The authors' practice is to use stents primarily as a bridge to surgery, as illustrated in this case, or in situations where they can be used for palliative symptom relief. The stent, in this case, allowed for preparation of her colon for a full colonoscopy as well as a colon resection. Perhaps the greatest benefit, especially for elderly patients, is the ability to turn an emergent operation into an elective operation. In addition, avoidance of a colostomy is primary goal of therapy, as a stoma can be very difficult for a geriatric patient to manage, especially if there are dexterity issues. A stoma can mean a loss of the ability to live independently. Stent placement in the upper rectum and sigmoid colon is overall well tolerated but does entail risks of perforation, recurrent obstruction, and migration.

This case study demonstrates the use of chemotherapeutic agents that have been shown to be well tolerated in the geriatric population, such as capecitabine and bevacizumab. For this patient, this regimen was chosen to avoid the toxicities associated with oxaliplatin and irinotecan use, which can be debilitating in the geriatric population. Additionally, while this patient could potentially be a candidate for intraperitoneal chemotherapy and cytoreduction, the morbidity of such an operation is much higher than elective resections, which is not congruent with her goals of care given her current excellent quality of life and lack of symptoms. Balancing toxicities, morbidities, and disease symptoms is paramount in approaching the care of elderly cancer patients, and thorough discussion with patients and their family members should be encouraged to allow for shared decision making and identification of a treatment plan with which all are comfortable.

Epidemiology

Incidence in Geriatric Patients

Colorectal cancer is the fourth most common cancer and the second leading cause of cancer-related mortality in the USA, behind lung cancer [6]. In 2017, an estimated 135,000 new cases of colorectal cancer were diagnosed with over 70% occurring in patients over the age of 65 and more than 10% occurring in patients over age 80 [4, 7]. Age is a well-known and established risk factor for colorectal cancer with the vast majority of cases occurring in patients over the age of 50. The incidence of colorectal cancer continues to increase each decade thereafter without any indication of downtrends or plateaus [8].

While colorectal cancer rates in patients over age 50 are generally decreasing, most likely due to increased utilization of screening tests, the growing population of elderly patients as a whole ensures no shortage of patients with colorectal cancer [7]. In Italy, there was an increase in patients over age 74 having treatment for colorectal cancer during a three-decade span and the number of patients over 80 years old who had treatment doubled [9]. It is encouraging to note that during that time, more elderly patients were being offered resection without changes in palliative or emergency surgeries [9]. This suggests physicians were offering standard of care surgery to more elderly patients than ever before, though they still are behind the curve compared to younger patients.

While elderly patients can have heritable colorectal cancer syndromes, the likelihood of this is small. Familial Adenomatous Polyposis typically presents in the first three decades of life and the average age of presentation of Lynch syndrome, also known as Hereditary Non-polyposis Colorectal Cancer (HNPCC), is under 50 years old. What is important to know is that patients with Lynch Syndrome have five to seven times the risk of metachronous tumors [10]. Thus, elderly patients with a personal history of colorectal cancer and appropriate previous treatment, perhaps before genetic evaluations were routine or well understood, could be presenting with a metachronous cancer that may be associated with a heritable condition. The other main relevance for elderly patients is to inform younger family members of their diagnosis as changes in screening recommendations may be appropriate for those younger family members.

Inflammatory bowel disease (IBD) is another well-known risk factor for colorectal cancer development. Traditionally, duration of inflammation and the extent of inflammatory disease are both predictors of cancer risk [11]. However, IBD is increasingly more often diagnosed in older patients and may be associated with an earlier development of colitis-associated colorectal cancer [12]. Elderly patients with a previous history of colitis should be assessed and followed closely, even if the colitis is quiescent.

Survival in Geriatric Patients

Despite significant advances in the treatment of colorectal cancer in the last few decades, including surgical techniques and systemic medical therapies, it is unclear if older adults are reaping the same benefit as younger patients. While some studies report that long-term survival of very old patients is comparable to that of younger patients, other studies demonstrate that survival in older adults after colorectal cancer is decreased [13–15]. The reason for these discrepancies is unclear, though likely multifactorial. Aside from tumor related features, elderly patients less often undergo screening procedures, and when cancer is found, less frequently have surgery [13, 16]. Regarding adjuvant treatment after surgery, older adults are less likely to be referred to medical oncology, are less likely to receive chemotherapy, or be given the standard of care regimen, and their treatment is likely to be discontinued early compared to younger adults [4, 16, 17].

Competing causes of mortality may be another cause for discrepancies in survival; elderly patients are more likely to have significant comorbidities that are risk factors for poor outcomes after surgery [17, 18]. In a systematic review of surgery for colorectal cancer in elderly patients, the primary finding was that overall survival was reduced for elderly patients; however, for cancer specific survival, age-related differences were much less striking, suggesting that the difference in overall survival between elderly and younger patients cannot be explained in terms of cancer deaths alone and the impact of other noncancer causes of mortality is significant [19]. In one Japanese study evaluating age and comorbidities on colorectal cancer survival, the authors found that diseases other than colorectal cancer influence overall survival more for patients over age 75 who had curative surgery [17]. This was again shown in a Dutch study of colorectal cancer patients that demonstrated conditional relative survival, which reduces the impact of age-related differences in survival, was similar in all age groups and that postoperative complications were a more probable cause of mortality [15]. When 90-day mortality was excluded, long-term disease-free survival up to 10 years after colorectal cancer treatment was unchanged in a cohort of elderly German patients, yet they continued to show decreased overall survival [14]. Interestingly, when considering disease-specific survival or recurrence rates, the authors found no relationship to age, suggesting that the increased mortality of geriatric patients is related to concerns other than their colorectal cancer [14].

These studies suggest that for elderly patients, the first year after colorectal cancer surgery and treatment may be the most critical as the stress of surgery and impact from competing comorbidities is significant. Essentially, the patients have the lowest physiologic reserves and are at their most vulnerable during this time. In a study utilizing the California Cancer Registry, patients 80 years or older had high in-hospital mortality, twice the readmission rate of younger cohorts, and high one-year mortality; medical complications, increasing co-morbidities, and cancer stage were predictive of increased mortality [20]. In a study evaluating readmissions after colectomy for colon cancer using the Surveillance, Epidemiology, and End Results (SEER)-Medicare database, age was not found to be predictive of 30-day readmissions but was significantly predictive of one-year mortality (OR 2.70, 95%CI 2.36–3.08) [21]. Dekker et al. (2011) also noted that those factors that predicted 30-mortality, such as comorbidities, emergent surgery, and prolonged hospitalizations, also predicted an increased 1-year mortality [15]. Postoperative pneumonia and cardiovascular complications have been highly associated with increases in postoperative morbidity and mortality in elderly patients [18].

These confounding issues cloud the consideration of long-term outcomes and survival in elderly patients as it becomes incredibly difficult to tease out and isolate any single key contributing factor. These studies suggest that the delayed consequences of surgery continue beyond the time of discharge and significantly affect morbidity and mortality, especially in vulnerable elderly patients. One way to improve outcomes for elderly patients is to identify problems and comorbidities and intervene early to allow the opportunity to control some of these confounding variables and improve overall survival. The data do seem to indicate that when appropriately treated, and when comorbidities are managed and complications are avoided, elderly patients obtain similar oncologic benefit from treatment and experience similar cancer-related outcomes. This suggests that there should be no age cut-off for appropriate treatments and consideration should be given to a more global assessment of these complicated patients.

Screening in Elderly Patients

Screening for colorectal cancer has clearly been demonstrated to have efficacy in reducing the incidence of colorectal cancer as well as cancer-related mortality. There has been controversy, however, related to which screening and surveillance methods are optimal, how frequently the tests should be done, who should undergo testing, and the cost-effectiveness of the various strategies. Thusly, a number of acceptable options are available each with their own benefits and drawbacks. The recommendations of available screening tests and intervals are summarized in Table 1. Fecal Occult Blood Test (FOBT) has been used for decades and has several advantages including cost-effectiveness, ease of administration, and lack of any invasive component. However, blood in the stool can be from any number of alternative causes; it is rather nonspecific for cancer. The positive predictive value of FOBT has been reported to increase with age from 1.6% for those under 60 years of age to 3.6% for those over 70 years of age [22]. Stool DNA screening tests that detect cellular genetic changes associated with colorectal cancer have been recently introduced. These have shown variation in specificity with regard to patient age; for patients younger than 65 years, specificity was 94.0%, compared to 87.1% for those older than 65 [23]. Regardless of age, any positive stool test needs to be followed

Table 1 Summary of colorectal cancer screening recommendations for each major society [24, 122–124]

Screening Test	Interval	US Preventative Services Task Force (2016)	National Comprehensive Cancer Network (2015)	Multi-Society Task Force[a] (2008)	American College of Gastroenterology (2009)
Sensitive guaiac Fecal Occult Blood Test (FOBT)	Every 1 years	Recommended	Recommended	Recommended	Recommended
Fecal Immunogenicity Test (FIT)	Every 1 or 3 years	Recommended	Recommended	Recommended annually	Recommended annually
Stool DNA test	Unknown; Every 1–3 years	Recommended	Recommended	Recommended, interval unknown	Recommended every 3 years
Flexible Sigmoidoscopy	Every 5 years	Recommended	Recommended with or without stool based testing every 5–10 years	Recommended	Recommended
Flexible Sigmoidoscopy plus FIT	Every 10 years with FIT or FOBT every 1 years	Recommended	Recommended with FIT or stool DNA at year 3; repeat 5–10 years	Not recommended	Not recommended
Colonoscopy	Every 10 years	Recommended	Recommended	Recommended	Recommended
CT colonoscopy	Every 5 years	Recommended	Recommended	Recommended	Recommended
Circulating methylated *SEPT9* DNA	Unknown	Not specified	Unavailable for guideline	Unavailable for guideline	Unavailable for guideline

[a]The Multi-Society Task Force included the American Gastroenterological Association, the American Society for Gastrointestinal Endoscopy, the American College of Gastroenterology, the American Cancer society, and the American College of Radiology

with a colonoscopy for localization and biopsy to be sure of the diagnosis [24].

In 2008, the US Preventative Services Task Force first issued age cutoffs for colorectal cancer screening, stating those between 50 and 75 years of age should undergo screening, while the decision to screen adults age 76–85 should be tailored to the individual patient [24]. The USPSTF recommends against screening adults older than 85 years [24]. Elderly patients are more likely to have complications from screening procedures, such as perforation, that can significantly impact the positive benefit of the procedure, especially in the setting of competing comorbidities and limited life expectancies. Approaching screening in elderly patients, or even in those with significant comorbidities, is a matter of balancing risk and benefit and including the patient in the decision-making process.

Clinical Presentation and General Treatment Considerations in Elderly Patients

Often, patients present after having a positive screening test and a colonoscopy that demonstrated a mass, and a biopsy of this confirms the diagnosis. As with any surgical evaluation, a complete history and physical should be performed, with specific attention to obstructive symptoms and subtle signs of anemia [5]. Additional symptoms of colorectal cancer are detailed in Table 2. Global symptoms such as weight loss, anorexia, and pain are often suggestive of advanced disease. Basic evaluation for colorectal cancer patients includes a baseline serum carcinoembryonic antigen (CEA) level, which can be used for prognosis and during the surveillance period to detect recurrence [25]. Preoperative staging should include a computed tomography scan of the chest abdomen and pelvis with intravenous contrast to evaluate for any distant metastases [5, 26]. For rectal cancer, local staging of the pelvis should be performed with a pelvic MRI or endorectal ultrasound [3]. Currently, the 7th Edition of the American Joint Commission on Cancer (AJCC) Cancer Staging Manual is the accepted standard for staging tumors [26]. The 8th edition, which contains additional information on the molecular staging of tumors, is expected to be released in early 2018 [27].

Table 2 Symptoms associated with colorectal cancer. (Adapted from the following: Oliver et al. [125], Hyman [126])

Global symptoms	Right-sided cancers	Left-sided cancers	Rectal cancer
Weight loss	Occult blood mixed in stool	Change in bowel habits, obstruction	Fresh blood
Anorexia	Anemia	Red blood in stool	Mucus discharge
Streptococcus bovis infection			Perineal pain, tenesmus
			Palpable mass

Most patients with colorectal cancer present with nonmetastatic disease (Stage I-III) where surgery is the cornerstone of treatment. Elective surgery for colorectal cancer entails removal of at least a 5 cm margin of bowel proximal and distal to the tumor, removal of any nonviable or compromised bowel, and *en bloc* complete removal of the draining lymph nodes that are located along the vascular supply. Therefore, the location of the tumor (i.e., right, left, rectum) dictates the type of operation needed (i.e., right hemicolectomy, left hemicolectomy, proctectomy) and the vascular supply that is divided as seen Fig. 1. A minimum of 12 lymph nodes has been established as the minimum required to have adequate sensitivity and specificity for determining the pathologic nodal stage of the tumor [5].

Emergency Surgery

Occasionally, patients present more urgently, often with obstructive symptoms due to the tumor decreasing the luminal diameter of the bowel. When this occurs, it is an emergency and can be managed in several ways depending on the location and the extent of the disease. If the tumor

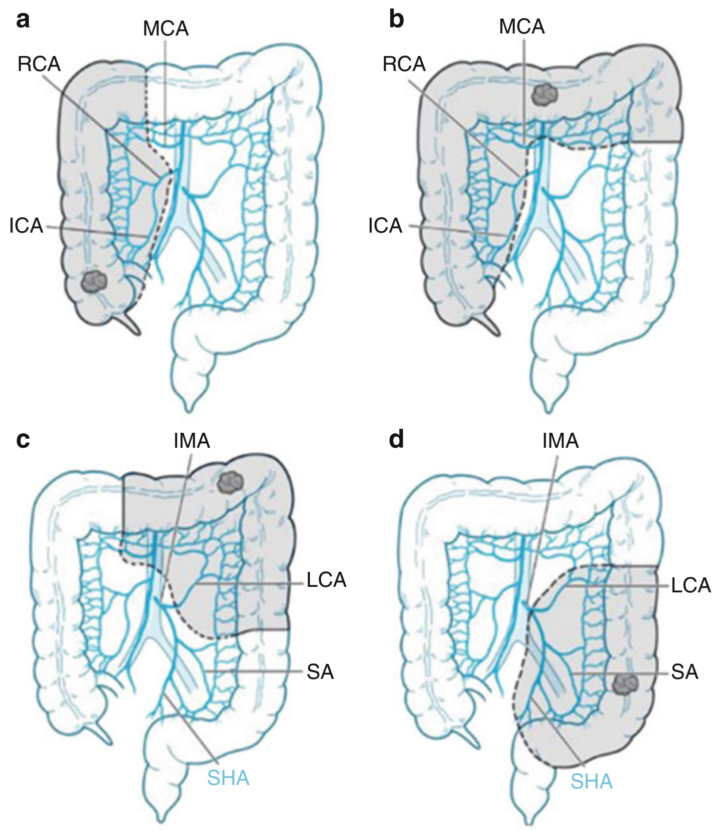

Fig. 1 Schematic drawing of various segmental colon resections, demonstrating the vascular pedicle and mesocolic excision that is performed *en bloc* with colectomy. (**a**) Right hemicolectomy with ligation of Ileocolic Artery (ICA) at its origin and Right Colic Artery (RCA), if present. (**b**) Extended right or transverse colectomy with ligation of ICA, RCA and Middle Colic Artery (MCA). (**c**) Left hemicolectomy with Left Colic Artery (LCA) ligation at its origin off the trunk of the Inferior Mesenteric Artery (IMA). (**d**) Sigmoid colectomy with high ligation of the IMA at its origin off the Aorta. (From Rosenberg and Morris [127])

is in the abdomen without extensive extra-intestinal involvement, then primary resection is indicated to both relieve the obstruction and obtain a diagnosis and staging [5]. If the tumor is in the pelvis or there is significant extra-intestinal involvement or the patient is especially ill, consideration should be given to a proximal diverting ostomy to relieve the obstruction and allow medical optimization prior to any additional treatment. In patients presenting with perforation, either at the tumor site or distant, they should be treated immediately with resection of the perforated area and tumor, if possible, as this is a life-threatening situation [5]. Bleeding from the tumor is another emergency that can occur, though is less common. After appropriate resuscitation, reversal of coagulopathies, and localization of the site of bleeding, surgery is indicated if ongoing control of the bleeding is not obtained. Surgical resection of the primary tumor for either perforation or bleeding should proceed along the same oncologic principles as for elective resection [5]. If the patient is hemodynamically unstable or the tumor cannot be localized, a subtotal colectomy should be considered according to standard oncologic principles described above.

Elderly patients have been noted to present with more advanced disease than their younger cohort, are more likely to have significant co-morbidities, and are more likely to have emergency surgery than their younger cohorts [19, 20, 28]. In a study of colorectal cancer patients over age 80, over 10% required an emergency operation, compared to 5% in those who are younger [18]. Unfortunately, the complication rate of those elderly patients was also elevated at 50% compared to 34% for younger patients [18]. Early mortality in geriatric patients having emergency surgery is also elevated, 36% for those over 80 years in another Germany retrospective review compared to 16% for those under age 80 ($p = 0.03$) [14]. Emergency surgery has also been associated with more advanced tumor stage, another factor that can impact long-term survival [14].

The high rate of emergency surgery among geriatric patients correlates with comorbidities and poor outcomes and is another factor that raises the postoperative mortality rate and lowers the overall survival for these patients [29]. It remains to be seen if more aggressive screening measures in appropriately fit elderly patients might have an impact on reducing the morbidity related to emergency surgery in the oldest of the old. Future studies should be aimed to examine questions such as these.

Metastatic Colorectal Cancer

Elderly patients are just as likely as their younger cohorts to present with metastatic disease, which is found in a fifth of patients at the time of diagnosis. There are many options available for treatment, but the most commonly seen scenario involves colorectal liver metastases. In general, for those patients who are candidates for surgical resection, there is a small survival benefit and chance at durable cure [30]. Encouragingly, there appears to be similar rates of resection for appropriately selected patients. In a German retrospective review, there was no difference between elderly and younger patients in the rates of synchronous resections for the primary tumor and distant metastases (20% vs. 22%, respectively) and no difference in the number of palliative procedures performed in the two age groups either [14]. In a retrospective review of 13 years of experience with surgical treatment of colorectal liver metastases, there was noted to be no difference in postoperative complications between those over age 75 (10% of patients) and those under age 75, though increased preoperative comorbidities were associated with increased complications [31]. It must be noted that these are highly selected patients who had excellent functional status and were good surgical candidates, so limited conclusions should be drawn about the generalizability of these results to the geriatric population as a whole. However, it does appear that for metastasectomy and synchronous primary resection, elderly patients can have good outcomes with surgery, even for metastatic disease.

When patients are not good surgical candidates or their disease is oligometastatic, there are other options available for patients that are significantly less invasive including percutaneous ablative techniques or embolization techniques that can be performed for liver metastases and provide considerable survival benefits for patients. In a randomized trial comparing radiofrequency ablation (RFA) plus systemic chemotherapy to systemic treatment alone, median survival times were comparable between the two groups, but progression-free survival was longer in the RFA plus chemotherapy arm [32]. However, local recurrence after RFA was found to be comparable to surgical resection in two European randomized trials [33]. It is unknown how such treatments are tolerated by elderly patients, though the lower complication rate supports that this may be a useful technique to consider in elderly patients when quality of life would be significantly impaired with surgical treatments [4].

Palliative chemotherapy can give a significant survival benefit, with current optimal therapy resulting in the 1-year relative survival rates more than 50% and median survival nearing 2 years with optimal treatment [7, 30]. The first-line treatment is a combination regimen including 5-flourouricil, leucovorin, and oxaliplatin, known as FOLFOX. Yet little research is available to understand the benefit and tolerability in elderly patients with limited reserves and comorbidities. In a Korean study of well-functioning patients over age 80 with either metastatic colorectal or gastric cancer, dose reductions or delays in FOLFOX regimens were necessary in 7 of 28 patients (25%) due to treatment-related toxicities, primarily hematologic complications [34]. In 50% of the colorectal cancer patients, a partial response was noted and median progression-free survival was 7.3 months (95%CI 0.9–13.7 months) with 1-year survival rates of 43% [34]. Capecitabine, an oral 5-FU prodrug, has similar survival benefit to 5-FU with leucovorin and has been proposed to be preferred and better tolerated than infusional 5-FU [35–37]. The FOCUS2 study evaluated patients who were not candidates for full-dose FOLFOX chemotherapy who then received either 5-FU with leucovorin or capecitabine alone or in combination with a reduced dose of oxaliplatin [38]. Toxicity was greater in the capecitabine arm and survival outcomes were not different for those who received oxaliplatin [38]. Taken together, both studies suggest that when elderly patients are appropriate for oxaliplatin, its use may have benefit, but lower doses for less fit patients may not offer any advantage. Another alternative is 5-FU with leucovorin and irinotecan, known as FOLFIRI, a regimen that is often used for those younger who cannot tolerate oxaliplatin. In patients over age 75 with metastatic disease, FOLFIRI was found to have an increased rate of severe toxicities compared to 5-FU with leucovorin alone, without any improvements in progression-free survival [39].

There are other alternatives that have shown improvements in the tolerability of systemic chemotherapy, including intermittent dosing of oxaliplatin and an infusion rather than bolus administration of 5-FU [4]. Furthermore, targeted agents such as antibodies against the vascular endothelial growth factor (VEGF) receptor and epidermal growth factor receptor (EGFR) antibodies can be reasonably tolerated in older adults. Bevacizumab, a VEGF monoclonal antibody, does have an increased rate of arterial thrombotic events in elderly patients, limiting its use in those over age 75 [4, 40]. Cetuximab and panitumumab are EGFR agents that are well tolerated in older adults without increases in side effects and they offer a survival benefit even when given as monotherapy [4]. Therefore, these are both ideal choices for elderly frail patients with metastatic disease who are candidates.

Concerns for Elective Colorectal Cancer Treatment in Geriatric Patients

For patients presenting with nonmetastatic disease, the primary treatment for colon cancer is surgical, with resection of the involved segment of colon and the corresponding mesentery that contains the draining lymph nodes, regardless of age at the time of presentation [2, 41]. For rectal cancer, standard therapy incudes neoadjuvant chemoradiation for improved local control of the disease, followed by surgical resection following the principles of total mesorectal excision [3, 42]. A flow chart of the treatment algorithms is presented in Fig. 2. We will focus the remainder of this chapter on the discussion of topics that are specific and highly relevant for physicians caring

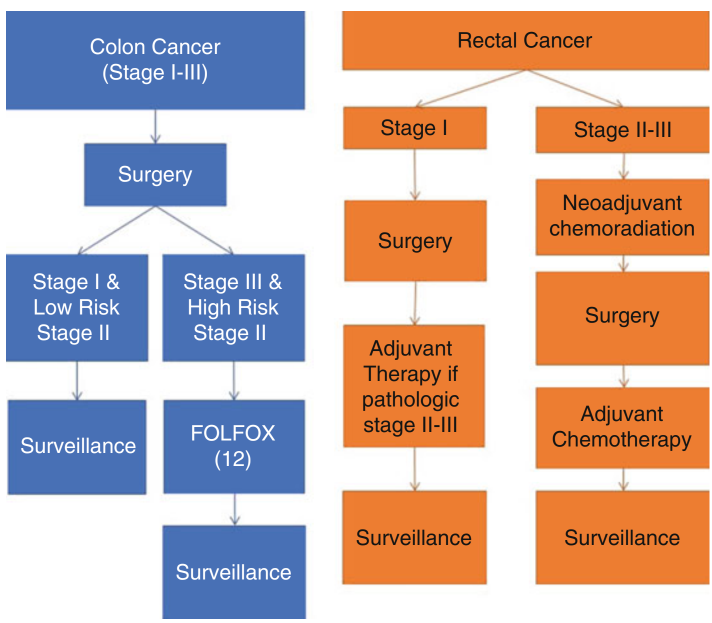

Fig. 2 Schematic diagram of the standard treatment sequencing for colon compared to rectal cancers

for geriatric patients with colorectal cancer, including surgical risk assessment, surgical techniques, and postoperative care. Furthermore, the remainder of the discussion will focus on those patients having elective surgery for colorectal cancer.

Geriatric Surgical Risk Assessment

As patients age, there is a correlational decrease in physiologic and functional reserves that can be markedly pronounced in geriatric patients. These changes leave patients vulnerable when new stressors, such as cancer and surgery, are undertaken. Close consideration of each patient's physiologic standing and comorbidities prior to surgery can allow physicians to intervene with treatment in advance. This might significantly improve outcomes and the trick is learning to identify these patients.

"Frailty" has been proposed as a key feature in some elderly patients that is a risk factor for poor outcomes after surgery [43]. There are several metrics designed to identify frail patients, including the frail phenotype Fried-criteria and the frailty index [44–46]. Regardless of the tool, frailty has been associated with a risk at least three to four times higher for severe complications after surgery [43]. Furthermore, frail patients have lower survival after treatment for colorectal cancer, with five-year survival of 25% for frail patients compared to 66% or normal nonfrail elderly patients [47].

Frailty screening tools use criteria such as weight loss, walking speed, and self-reported exhaustion along with assessment of impairments, such as diseases and disabilities, when evaluating patients. These tools are widely used in research, but little used clinically, given the added time and resources needed to execute them properly (see Table 3). Additionally, these metrics do not identify specific disease processes that would allow interventions to occur before surgery; they are useful for screening and prognosis only. A two-stage approach includes using these metrics to identify frail patients, who then undergo further assessments using the Comprehensive Geriatric Assessment, a multidisciplinary assessment of an individual's functional status, physical performance, comorbidity, medications, cognitive and emotional functioning, nutrition, and social support network [48]. The CGA aims to identify specific issues that may be treated prior to surgery and has been recommended by the International Society of Geriatric Oncology (SIOG) [49]. The National Comprehensive Cancer Network has also issued guidelines on caring for older adults with cancer and has outlined a number of aspects consistent with a comprehensive assessment [50]. Interestingly, in a recently published randomized Norwegian study, such a strategy did not result in improved postoperative complications despite employing rigorous screening and assessments, possibly due to low recruitment goals and an inconsistent application of prehabilitation therapies [51]. Additional studies are in recruitment to understand how such a comprehensive evaluation can identify needs and specific programs to prepare elderly patients prior to surgery [48].

A thorough history and physical exam, performed by any physician, can go a long way to meeting many of the goals of a standard focused geriatric assessment. Such an examination can identify subtle signs and symptoms of diseases, such as cardiac disease and pulmonary

Table 3 Frailty screening tests [44–46]. (ADL = activities of daily living; MI = myocardial infarction; CHF = congestive heart failure; CVA = cerebral vascular accident; DM = diabetes mellitus)

Frailty Phenotype Metrics	Frailty Index Metrics
Grip strength	Help with ADLs (bathing, dressing, eating, grooming, toileting, stairs, shopping, housework, cooking, finances, medications)
Walking time	Weight loss
Weight loss	Self-rating health; change in last year
Physical activity	Activities (walking outside, lifting >10 pounds, perceived effort, grip strength, walking pace)
Exhaustion	Emotional state (depression, happiness, loneliness)
	Comorbidities (MI, CHF, CVA, cancer, DM, hypertension, arthritis, lung disease, obesity)

insufficiency that can be optimized prior to surgery. Particular attention should be paid to examining the heart and cardiac function, including evaluation for signs and symptoms of congestive heart failure, as this is a leading predictor of mortality and nearly 85% of patients over age 80 have some type of cardiac risk factor [18]. For those rare patients who are not taking beta-blockers already and are found to have some evidence of cardiac ischemia, administration of beta-blockers for 1–2 weeks prior to surgery should be considered as this is associated with reductions in cardiac perioperative mortality [52]. Consideration should be given to functional cardiac assessments, including dobutamine stress echocardiography, for those patients with cardiac risk factors or symptoms. The management of cardiac ischemia in the perioperative setting is a topic of significant controversy with much variability in recommendations for types of cardiac stenting used as well as duration and type of antiplatelet therapy. Close collaboration with your interventional cardiologists can help significantly in coordinating the most prudent treatment options for these complex patients to avoid not only an excessive bleeding risk during colorectal surgery but an increased risk of cardiac events in the perioperative period. As of yet, there are limited consensus guidelines as to perioperative management to help guide clinicians [53].

Pulmonary assessment is also of paramount importance in this patient population. After abdominal surgery, there is an expected 15–30% reduction in functional residual capacity [54]. Older patients are more than twice as likely as younger patients to have respiratory complications in the postoperative period [19]. This can have considerable consequences for patients who already have reduced pulmonary function due to comorbidities. Identifying obstructive disease in the preoperative setting allows administration of bronchodilators, mucolytic agents, and possibly antibiotics for acute exacerbations. Furthermore, pulmonary rehabilitation programs can offer considerable benefits in mortality and morbidity reduction [55].

Identifying patients with malnutrition can also be critically important in preoperative risk assessment. Over 5% of patients age 70–80 years old are undernourished, and this may be even higher for patients with an underlying malignancy due to cancer-related cachexia worsening aging-related sarcopenia and anorexia [18, 56]. Malnutrition is a known prognostic indicator for poor outcomes, including anastomotic leak and perioperative mortality [56–58]. Clinical markers of malnutrition can be somewhat misleading. Body Mass Index (BMI) is a well-established metric in the general population, yet is less accurate in elderly patients due to age-related sarcopenia; serum albumin and prealbumin levels are other often used clinical metrics for identifying those at risk. Objective measures, such as the Malnutrition Universal Screening Tool (MUST) or Patient-Generated Subjective Global Assessment (PG-SGA), have more sensitivity and specificity for identifying patients with cancer who are at risk for malnutrition [56, 59]. These objective tests can be difficult to administer and are often timely, limiting their use in clinical practice.

Managing patients clinically who present with significant malnutrition can be difficult clinically as well, even when there is little question of the extent of the nutritional deficit. For those patients with significant malnutrition or critically ill patients, parenteral nutrition before surgery may be beneficial in reducing complications after surgery, yet the optimal duration and type (i.e., immunomodulating diets) of nutritional optimization is unclear [60–62]. Unfortunately, patients with such severe malnutrition are seldom in a situation where surgical care can be significantly delayed and often require emergency procedures that do not allow time for nutritional optimization. However, if delaying surgery is possible in severely malnourished patients, administration of parenteral nutrition for at least 7 days has been shown to reduce postoperative complications [60, 62].

Enhanced Recovery Pathways

Fast-track programs, otherwise known as enhanced recovery after surgery (ERAS), have become an idea that is very much in vogue and can be beneficial to elderly patients. Enhanced recovery programs originated in Denmark and

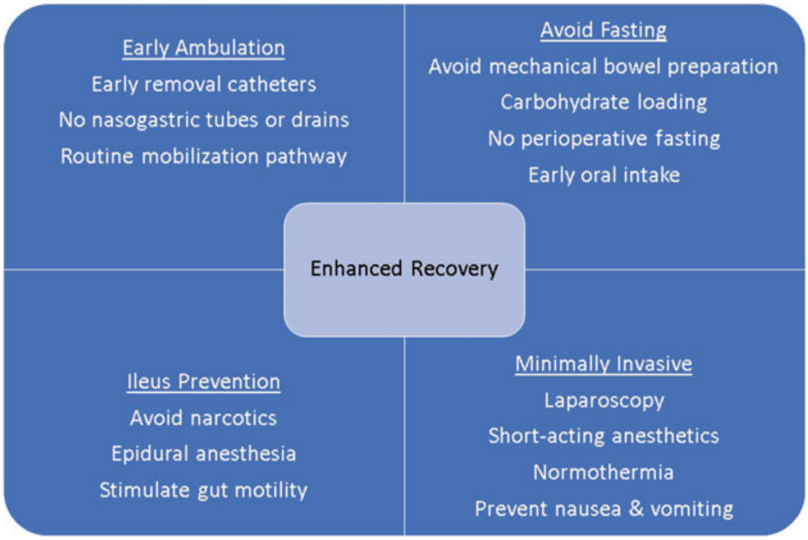

Fig. 3 Diagram outlining possible elements that can be included into an enhanced recovery after surgery (ERAS) pathway

are designed to minimize the stress response of surgery and promote the rapid return of function for the patient [63, 64]. Often, these programs contain many specific strategies, but no two programs are the same as each is tailored to the specific patient population at that institution. Common strategies include avoidance of bowel preparation and minimal fasting, ileus prevention, preference for minimally invasive procedures, early mobilization, and early oral intake after surgery (see Fig. 3) [65]. Such pathways have been shown to reduce complications and the length of hospital stays, without increasing readmissions or mortality after colorectal surgery [66, 67].

For elderly patients, similar benefits may be achieved, though it is not completely understood how well elderly patients with limited mobility might participate in such programs. One study found that only 55% of patients over age 80 were out of bed the day after surgery, compared to 70% for younger patients [68]. Participation in enhanced recovery is important and benefits are noted when patients adhere to at least 70% of the programs elements, with increasing benefits for increasing participation; for those patients who are the highest participators (>90% adherence to protocol), a 25% reduction in morbidity and 50% reduction in mortality was noted [69]. Geriatric patients could stand to gain considerably from these benefits if participation can be encouraged and supported with adequate resources.

Two randomized control studies specifically evaluated ERAS pathways in elderly patients and demonstrated that they did indeed gain benefit from these strategies [70, 71]. Included only patients with colorectal cancer having open surgery who were older than age 70; those following the ERAS protocol received a thoracic epidural with no narcotics, oral liquid diet starting 6 h after surgery, catheter removal by postoperative day 2, normal meals and a carbohydrate drink prior to surgery [71]. Those patients in the ERAS group had faster return of bowel function by 3 days (78 h vs. 49 h, $p < 0.01$), shorter hospital stays by 4 days (9 vs. 13, $p < 0.01$), and 54% fewer complications than the traditional group, significantly in pulmonary and urinary infections as well as heart failure [71]. Furthermore, the ERAS group had significantly fewer episodes of delirium in the postoperative setting (3% vs. 13%, $p < 0.01$), which was associated with a lower level of serum IL-6, a proinflammatory cytokine suspected in the development of postoperative delirium [71, 72]. Wang and colleagues (2012) specifically evaluated patients older than age 65 having laparoscopic surgery for colorectal cancer randomized to either ERAS pathways or traditional care and found similar results with shorter hospital stays by 1 day (6 vs. 7, $p < 0.01$) and fewer complications (5% vs. 21%, $p < 0.01$) [70].

Additional cohort studies have reported mixed results on the rate of overall morbidity and mortality in elderly patients participating in ERAS protocols, though none reported differences in pulmonary complications, suggesting that the risk of aspiration due to early oral intake may be limited [73]. Unfortunately, many of the reports evaluating the utility of ERAS pathways in elderly patients are of only moderate quality, including the randomized studies discussed above, and fail to report on compliance to ERAS elements or confounding comorbidities and frailty that could significantly impact outcomes, especially in elderly patients [73].

Avoidance of narcotics is a central tenant of enhanced recovery pathways. Epidural anesthesia in elderly patients who require a laparotomy can be particularly beneficial as it can minimize or avoid entirely the need for narcotic medications in the postoperative period, which can reduce the risk of respiratory depression and delirium in vulnerable patients. In a randomized controlled trial of patients over age 70 years having major abdominal surgery, those who received a patient-controlled epidural after surgery, rather than patient-controlled intravenous analgesic, had better pain control, improved bowel recovery, and improved mental status during the postoperative period [74]. This is in congruence with many studies from patients of all ages on the benefits of thoracic epidural in the postoperative setting after abdominal surgery summarized in a Cochrane Review, demonstrating that the use of local anesthetic in a thoracic epidural with or without opioids is associated with improvements in bowel recovery, reduced pain scores, and reduced lengths of stay for open surgery [75]. Not only is pain control improved, but respiratory function is not depressed with epidural anesthesia as it often is with narcotic pain medications. Other strategies, such as nonsteroidal anti-inflammatory medications, are another option to minimizing narcotic use; however, the side effects and possible toxicities may limit their use in a population of patients with significant comorbidities.

Use of a mechanical bowel preparation on prolonged fasting prior to colorectal surgery remains an area of ongoing debate without a clear answer. ERAS protocols support the avoidance of mechanical bowel preparations to avoid significant dehydration prior to surgery, and the American Society of Gastroenterology also recommends against the use of magnesium citrate or combination agents for elderly patients and those with renal failure due to risks of dehydration [76]. Concerns of operating on unprepped bowel include spillage and difficulty manipulating the heavy bowel, especially during laparoscopy as well as an inability to perform intraoperative colonoscopy if needed. Mechanical bowel preparation in elderly patients necessitates increased intraoperative fluid requirements that have been independently associated with postoperative complications – for each liter of fluid given, there was a 32% increase in the probability of postoperative complications in one prospective study [69]. Specific studies evaluating the efficacy of mechanical bowel preparation in elderly patients have yet to be conducted, but prudent use of aggressive mechanical bowel regimens is warranted in this vulnerable patient population.

Furthermore, use of a preoperative carbohydrate drink prior to surgery was found to be protective and associated with reductions in postoperative symptoms of 44% – particularly risk of nausea, vomiting, pain, diarrhea, and dizziness [69]. Ultimately, the lack of these inciting symptoms leads to reductions in the rate of wound dehiscence when carbohydrate drinks were given (OR 0.16, 95%CI 0.05–0.50) [69]. While this study is not randomized, there is some significance suggesting that consideration be given to close monitoring and compliance to protocols for these factors. Balancing the risks of a mechanical bowel preparation and carbohydrate loading in this population with the benefits and needs is key to balancing these patients' postoperative complications.

While some have advocated for an Intensive Care Unit (ICU) stay in the immediate postoperative setting for all elderly patients, there are little data regarding this practice. The most frequent complication in the immediate postoperative period is cardiac with 96% of perioperative infarcts detected on electrocardiogram in the first 2 days after surgery, and it is thought that a short, but not too long, stay in the ICU could help detect and treat these complications when they arise [18]. On the contrary, ICU stays, especially for geriatric patients, are associated with reduced mobility and increased delirium and may lead to longer overall hospital stays [77–79]. It has not been our practice to routinely admit geriatric patients to the ICU following elective surgery without a clear indication (i.e., inability to extubate, vasopressor requirement). We would advocate using remote telemetry monitoring for those with cardiac risk factors in an intermediate-care unit or regular hospital ward where patients will be encouraged to participate in ERAS elements.

Minimally Invasive Surgery

The benefits of minimally invasive surgery are extensive and well accepted. Patients are expected to have less pain, shorter hospital stays, quicker recoveries, and fewer complications when colectomy and proctectomy are performed laparoscopically [80]. For colectomy, many studies have demonstrated that the oncologic benefit is the same as open surgery in regards to completeness of resection and lymph node harvest [81–83]. The data on laparoscopic proctectomy for rectal cancer are less clear, and initial studies demonstrated concerns for appropriate circumferential margins, though this did not translate into differences in local recurrence or survival [82]. Robotic surgery, which facilitates surgery in the pelvis and generally has a lower learning curve than laparoscopic proctectomy, has gained considerable enthusiasm in recent years. There is currently a randomized trial exploring the outcomes of laparoscopic and robotic surgery to better understand the differences between the two techniques and the final results have yet to be published [84].

Despite these benefits in outcomes and improvements in recovery, minimally invasive surgery remains underutilized in colorectal resections, with only 29% of colectomies done laparoscopically in 2009 [80]. Not only are elderly patients not offered surgical resection as often as younger patients, they are less likely to have minimally invasive surgery performed when surgery is done [80, 85]. There can be several reasons that surgeons may be reluctant to offer minimally invasive surgery to elderly patients, including longer operative times, risks of pneumoperitoneum in the setting of severe pulmonary and cardiac comorbidities, advanced or bulky disease, and an emergency setting [86]. Despite these, many observational studies have explored the benefit of minimally invasive surgery in the geriatric patient population and reported that for elective surgeries, the risks are acceptable.

In a single-institution study from Italy, patients older than 75 were matched to a younger cohort of patients having elective, nonpalliative surgery for colorectal cancer [87]. There were no differences in rates of conversion to open surgery, use of diverting ileostomies, lymph nodes removed, or operative times between the two groups [87]. The elderly patients had a higher postoperative morbidity rate, 24% compared to 8% in the younger cohort; however, the rates of anastomotic leak were similar in the two groups (2% each) [87]. The elderly patients did have more medical comorbidities (i.e., atrial fibrillation and renal failure) as well as wound infections (6% vs. 2%), likely reflecting underlying poor nutrition and other competing comorbidities that affect outcomes [87]. Noteworthy is that there were no differences in mortality in the study [87]. Again, these results point to comorbidity management as key to having good outcomes in this complex patient population.

Robotic-assisted surgery can have similar benefits for elderly patients, though may be less attractive as the operative time is generally longer than laparoscopic surgery and often patients are positioned in steep Trendelenburg, especially for pelvic surgeries. In a retrospective analysis of patients undergoing elective colectomy using propensity score matching in the National Inpatient Sample (NIS), Juo and colleagues (2014) demonstrated that robotic colectomies were not associated with any additional in-hospital complication rates, mortalities, conversions to open procedures, or decreased routine discharge rates when compared to patients having laparoscopic colectomy [86]. Robotic colectomy did incur a higher overall hospitalization cost than laparoscopic colectomy by nearly US$3000 [86]. The future utility of robotic colectomy and proctectomy will need to be further explored in prospective trials to determine the potential benefit for colon and rectal surgeries, especially in regard to geriatric patients.

Minimally invasive surgery in elderly patients can have concrete benefits, but it is not fully understood how these surgeries affect patient-reported outcomes and quality of life in this population. In another study of elderly patients' health-related quality of life (QOL) following surgery for colorectal cancer, elderly patients over age 70 had a more significant decrease in global QOL at 1 month after surgery when compared to their younger counterparts, most notably in fatigue, sleep disturbances, appetite loss, and dyspnea [88]. These changes can significantly impact elderly patients and their ability to be independent and thus significantly impact their quality of life. Another study found that the use of laparoscopic surgery in elderly patients having colectomy for cancer was associated with maintaining patients' independent living status after surgery more often than when patients had laparotomies [89]. In most cases when treating patients with colorectal cancer, cure of the disease is the ultimate goal, but in elderly patients, quality of life may take precedence over quantity. Understanding how surgical technique impacts patients with multiple comorbidities is important. While laparoscopic and robotic colectomy and proctectomy are complicated procedures, elderly patients should be offered these types of minimally invasive surgery whenever possible, as there are no data to suggest they are harmed and much to support considerable gains from minimally invasive surgery.

The Volume–Outcome Relationship

Much has been made in recent years regarding the association of high volume centers that perform a larger volume of highly specialized and technical procedures [90]. This relationship is true for both colon as well as rectal resections with high volume hospitals having lower 30-day readmissions and 1-year mortality [21]. In an exploration of the Nationwide Inpatient Sample (NIS) database in 1997, patients having surgery for colorectal cancer at a low volume center were more likely to be healthy with no significant comorbidities, have had emergency surgery, and had a higher in-hospital mortality rate (3.7% vs. 2.5%, $p = 0.006$) compared to those patients who had surgery at high volume centers [91]. This difference in mortality was primarily due to differences in age; for patients over age 80, the mortality rate at the highest volume centers was 4.6% compared to 7.3% ($p = 0.04$) at the lowest volume centers [91]. While the absolute difference may seem small, 27 elderly patients would need to be referred to a high-volume center to prevent one death, a manageable number that does not put undue stress on either end of the health-care spectrum and could promote regionalization of care and optimization of outcomes [91]. Interestingly, the relationship of hospital volume did not hold true in the Veterans Affairs (VA) system [16]. The authors were not able to find an association with low volume centers and high-volume centers within the VA system, though it is likely that alternate definitions of volume could alter the reported effect [16].

These findings may be reflective of the complex needs required to care for elderly patients with considerable comorbidities where the advantages of a high-functioning system and network can have considerable advantages. Such a strategy of selective regionalization for elderly patients capitalizes on the available resources at high volume centers to help manage complex comorbidities in the immediate postoperative setting.

Sphincter Sparing Surgery for Rectal Cancer

It is unclear if the anastomotic leak rate in elderly patients is elevated compared to younger patients, or if this is a reflection of more profound underlying diseases and risk factors, such as malnutrition. Marusch et al. (2005) found that in those patients having colorectal surgery for cancer, in patients over age 80, the rate of anastomotic leak that required surgery was not elevated compared to younger patients (2.2% vs. 2.8%), but the rate of anastomotic insufficiency that did not warrant an operation was elevated (0.6% vs. 1.9%) [18]. A large meta-analysis of studies published evaluating outcomes in elderly patients after colorectal surgery did not find evidence of an elevated anastomotic leak rate among elderly patients, even when only rectal cancer studies were included alone [19]. In elderly patients having laparoscopic surgery, no difference in anastomotic leak was noted compared to younger patients [87]. Interestingly, in a retrospective study of patients over age 65 having colorectal surgery utilizing the American College of Surgeon's National Surgical Quality Improvement Program (ACS-NSQIP), increasing age alone was not a risk factor for anastomotic leak [92]. The authors did identify a number of risk factors for anastomotic leak in elderly patients and developed a nomogram to help predict the risk in individual patients and guide clinical decision making [92].

While the anastomotic leak rate is not necessarily elevated in elderly patients due to age alone and patients should be considered for primary anastomosis when appropriate, it is prudent to consider the negative impact on quality of life should a low anastomosis be created in patients who are less mobile [93, 94]. It is well understood that bowel dysfunction after low colorectal anastomoses can severely impact quality of life for patients [95]. Consideration of a permanent ostomy is prudent in these patients, though care of an ostomy can also have an impact, particularly in patients who are partially dependent or have limited dexterity.

While total mesorectal excision and reconstruction after neoadjuvant chemoradiation is the standard of care, in elderly patients with significant comorbidities who are not candidates for a major abdominal operation, local excision of the rectal tumor can be considered. Local transanal excision of early rectal cancers is best considered for those with low tumors (<8 cm from the anal verge), favorable histology, T1 or T2 and N0 status, and lesions of smaller size [96]. Local techniques such as transanal excision or transanal excisional microsurgery have excellent outcomes with morbidity between 4 and 30% and mortality less than 0.5% after surgery, though local recurrence rates of 15% are higher than when standard mesorectal excision is undertaken [97].

Another potential way to minimize the impact of rectal cancer surgery on elderly patients is to consider total neoadjuvant treatment and give all medical treatment up-front prior to surgery, including systemic chemotherapy and standard combined chemoradiation therapy. When induction systemic chemotherapy is given first, followed by combined chemoradiation therapy, 36% of patients were found to have either no evidence of residual tumor on imaging or examination (complete clinical response) or no residual tumor on final pathology after surgery (complete pathologic response) [98]. Such results raise the question of whether patients who have a complete clinical response even need to have surgery to remove the offending organ and this is currently an active area of study and debate. For the appropriately selected patient who is willing to undergo close follow-up and is averse to either a low anastomosis or ostomy, such a strategy can have reasonable outcomes long-term comparable with standard therapy [99].

Colorectal Cancer and Inflammatory Bowel Disease

Inflammatory bowel disease (IBD), both Crohn's Disease (CD) and Ulcerative Colitis (UC), raises the risk of developing colorectal malignancies in subjected patients, though UC is thought to have a higher malignancy risk at 60% greater than the risk of the general population, increasing with severity and duration of UC among other factors [11, 100]. The current standard of care for patients with UC and a new colorectal adenocarcinoma includes a total proctocolectomy (TPC) either with or without an ileal-pouch anal anastomosis (IPAA), a reconstruction to maintain bowel continuity and avoid a permanent ostomy [101]. IPAA can be difficult as patients often have numerous liquid bowel movements every day and continence can be compromised, two factors that become even more concerning when patients' mobility is reduced as they age [102]. Ileostomy is also associated with risks, including dehydration, and can be difficult for older patients with limited dexterity to manage well.

As such, some patients elect to undergo a more limited partial resection of the segment containing malignancy, understanding the future risk of metachronous lesions is unknown, and little data exist outside of single-institution case series to support this practice. Khan et al. (2017) performed a review of patients with UC and colorectal cancer who had surgery using the VA database, which encompasses all 50 states and has long-term outcomes data [103]. The authors identified 59 patients that underwent surgery, of which 25 had partial resection (PR) and 34 had total proctocolectomy [103]. The group that had PR was older with a shorter length of UC, less severe and less extensive UC than those whom had TPC; they also had earlier stage cancers with 24% having no residual disease in the resected specimen after finding adenocarcinoma in the resected polyp and only 5% of the TPC group had such findings [103]. While both groups recovered well after surgery, the majority of those in PR group required additional medical therapy for UC following resection. No patients were diagnosed with metachronous colorectal cancer during the follow-up (median 7 years), though an equal number of patients in each group developed distant recurrence (4% vs. 6%) [103].

As with many decisions about treatment choices for geriatric patients, a balance is warranted when considering the extent of resection for those with UC and colorectal cancer. Data suggest that partial resection is a reasonable alternative for those who have less severe, less extensive UC or might have significant issues related to ileostomy or IPAA. Patients who are candidates for partial resection should also be counseled about the need for close follow-up and the likely need for ongoing treatment of colitis along with additional endoscopic surveillance.

Neoadjuvant and Adjuvant Therapy in the Elderly

While surgical resection remains the cornerstone of colorectal cancer treatments, in many cases additional treatments are given to improve outcomes. Specifically, radiation therapy with radiosensitizing chemotherapy is given for Stage II and Stage III rectal cancer prior to surgery, which has been shown to decrease local recurrence rates in a notoriously difficult to treat disease [2, 104]. Adjuvant systemic cytotoxic chemotherapy is then given after rectal resection surgery. It is also given for colon cancer after colectomy when patients are found to have Stage III disease or Stage II disease with certain high-risk features [3, 5].

Geriatric patients more often do not receive standard treatment than their younger cohorts and are less likely to be given adjuvant and neoadjuvant treatments. In Japan, patients with Stage III colon cancer, only 35% of those over age 75 received adjuvant therapy, in contrast to 70% of those under age 75 [17]. The same trend holds true in the United States, where only 43% of octogenarians with Stage III colon cancer who were eligible for adjuvant chemotherapy after surgery actually received it [105]. Fears of severe side effects and poor tolerance to treatment dominate the decision-making process. The prevailing rationale is that elderly patients have less reserve to tolerate the side effects of neoadjuvant or adjuvant treatments and that the expected benefits are more limited in these patients due to their decreased overall survival from competing comorbidities. Unfortunately, there are little high-quality data to help guide physicians as few geriatric patients are included in clinical trials.

Neoadjuvant Chemoradiation Therapy for Rectal Cancer and Geriatric Patients

Neoadjuvant combined chemoradiation therapy is considered standard treatment for Stage II and Stage III rectal cancer. This should include a 5-FU based agent in radio-sensitizing doses given concurrently with external beam radiation [2].

This strategy has been shown to reduce local recurrence after rectal cancer surgery [104]. Furthermore, these treatments also allow the tumor to regress prior to surgery, known as tumor downstaging, and can potentially impact the type of operation offered to patients [106]. For example, a low rectal cancer that is directly adjacent to the sphincter complex might require an abdominoperineal resection and permanent ostomy, but if tumor regression occurs due to neoadjuvant therapy, then the patient may be a candidate for sphincter-preserving low colorectal anastomosis.

The rate of use of neoadjuvant chemotherapy for rectal cancer in geriatric patients is particularly dismal, despite its well-accepted benefit of reducing local recurrence after surgery and potential for downstaging and sphincter preservation. In one German review, only 14% of eligible rectal cancer patients received neoadjuvant treatment according to guidelines, in comparison to 73% of those under age 80 ($p < 0.01$) [14]. This may be due to issues with elderly patients' ability to tolerate neoadjuvant chemoradiation therapy. In a review of patients age 75 or older having chemoradiation for rectal cancer, 25% required a radiation treatment break and 33% had a dose-reduction, break or discontinuation of concurrent chemotherapy, with only 17% completing therapy without any deviations [107]. Interestingly, these results were consistent whether patients had preoperative or postoperative chemoradiation therapy. This contrasts with an Italian study that found elderly patients who were considered vulnerable were still able to tolerate neoadjuvant chemoradiation at rates similar to fit elderly patients [108]. Therefore, elderly patients should be offered neoadjuvant chemoradiation unless significant contraindications to treatment are noted as they can gain considerable benefit as per younger patients in reducing local recurrence and tumor downstaging.

Adjuvant Chemotherapy and Geriatric Patients

Adjuvant 5-flourouricil (5-FU) chemotherapy has a demonstrated overall survival benefit for Stage III colon and rectal cancer following oncologic resection [109]. It also has been shown beneficial in decreasing recurrence and improving survival for patients with Stage II rectal cancer, even when treated with neoadjuvant therapy and surgical resection [110]. For young patients, oxaliplatin is given in conjunction with 5-FU & leucovorin, known as FOLFOX, as the first line therapy, but oxaliplatin has not shown a survival benefit for elderly patients in previous studies [111, 112].

In a recent large review of octogenarians with Stage III colon cancer using the National Cancer Database in the United States, those who received adjuvant chemotherapy of any kind were younger, more often male, had fewer comorbidities, and in a higher income bracket than those patients who did not receive adjuvant chemotherapy [105]. Furthermore, they were also more likely to have more nodal involvement (N2 disease) [105]. On multivariate analysis, young age, N2 node status, income over US$46,000, and treatment not at comprehensive community care program were independent predictors of receiving adjuvant chemotherapy, and adjuvant therapy was associated with increases in overall survival for octogenarians compared to those who had surgery alone, from 35 months to 62 months median [105]. Even those who were offered chemotherapy but refused, amounting to 28% of those who had surgery alone and representative of physiologically fit patients with minimal comorbidities, had a decreased overall survival at 43 months median [105]. This retrospective review demonstrates that overall five-year survival was improved by 20% with the use of adjuvant chemotherapy in Stage III disease in octogenarians, even though this group had more advanced disease. What is interesting is this study did not account for type of chemotherapy nor any dose-reductions or early cessation and yet significant benefit was still noted [105]. As mentioned above, only half of eligible patients received chemotherapy and considerable improvements in survival could be anticipated if more elderly patients were offered adjuvant therapy.

Oxaliplatin can also be given with capecitabine, an oral prodrug of 5-FU, and offers a survival benefit above 5-FU and leucovorin alone [37, 113]. Oxaliplatin can have significant side effects, the most significant of which is neuropathy, primarily in the hands and feet and can persist for years after finishing treatment and elderly patients have been shown to be more susceptible to this neuropathy than younger patients [114, 115]. When this occurs in elderly patients, it can significantly impact their ability to perform daily tasks, such as self-dressing, and is a risk factor for falls that might warrant institutionalization and negatively impact quality of life [116, 117]. As the benefit of oxaliplatin in elderly patients overall is not well understood, it is not recommended in the routine oncologic adjuvant therapy for patients over age 70 and this decision should be made on an individual basis [50]. It is also no known whether oxaliplatin may be better tolerated in fit, healthy elderly patients, or if 5-FU alone offers a benefit for unfit, less health elderly patients. A randomized controlled trial is currently enrolling patients age 75 or older with Stage III completely resected colon cancer in France to help understand the disease-free survival benefit of various chemotherapy regimens in elderly patients [118].

The utility of adjuvant chemotherapy for rectal cancer, after neoadjuvant therapy and complete surgical resection, is also poorly understood for similar reasons. In retrospective review of patients having treatment for colorectal cancer in Japan, for those over age 75, adjuvant therapy was found to be independently associated with improved DFS for both colon and rectal cancer patients [17]. However, when elderly patients who received FOLFOX were compared to those who received 5-FU with leucovorin alone, adding oxaliplatin did not improve survival for patients over age 73, regardless of nodal status [112]. These studies suggest that there is limited benefit to adding oxaliplatin in older patients, though they do benefit from other adjuvant regimens.

The Comprehensive Geriatric Assessment (CGA), advocated initially for perioperative clinical assessments, can also be applied in the postoperative setting to help risk stratify patients for adjuvant chemotherapy. In a prospective study, patients 75 years or older were administered the CGA and stratified into fit, medium-fit, and unfit categories to receive either standard adjuvant chemotherapy, an adjusted regimen, or best supportive care according to fitness [119]. The authors found that classification into these categories not only correlated with 5-year survival, but those classified as unfit had a significantly greater risk of noncancer related death. This study demonstrated the CGA can help discriminate elderly patients with competing comorbidities who may gain little benefit from adjuvant therapies.

Posttreatment Surveillance

Surveillance after treatment for curative colorectal cancer is multifactorial, including frequent examinations to evaluate for symptoms suggestive of recurrence, blood tests to detect changes in serum biomarkers, cross-sectional imaging to detect asymptomatic recurrences, and repeat endoscopy to look for metachronous polyps or lesions. These recommendations are summarized in Table 4.

For patients with Stage II or Stage III colon or rectal cancer, or for those whom had curative resection of Stage IV disease, ongoing surveillance is indicated. This should include an office visit and examination and serum CEA level every 3–6 months for 2 years, then every 6 months for 5 years. Imaging should include a Computed Tomography scan of chest, abdomen, and pelvis annually for 5 years. Those patients enrolled in high intensity surveillance programs had higher

Table 4 Surveillance after curative treatment for colorectal cancer [2, 3, 120]

Office visit and examination	Every 3–6 months for 2 years Then every 6 months until 5 years
Serum carcinoembryonic antigen (CEA)	Every 3–6 months for 2 years Then every 6 months until 5 years
Computed tomography (CT) Chest, abdomen, and pelvis	Annually for 5 years
Colonoscopy	1 year after preoperative colonoscopy (or 3–6 months after surgery if previous colonoscopy was not complete)

rates of detection of asymptomatic recurrences and underwent curative resections for often [120]. What is not clearly understood is the frequency of liver imaging, which can allow earlier detection of potentially curable metastases, and could be considered for very-high risk patients such as those with N2 disease, prior liver resection, or prior indeterminate liver lesions. For patients with Stage I colorectal cancer, surveillance may be indicated for those with higher-risk features, such as poor histology, lymphovascular invasion, positive margins, transanal excision, or T2 disease [120]. The literature exploring the benefit in Stage I disease is limited and more heterogeneous. Overall, the risk of recurrence in Stage I colon cancer is <5% and the benefit of high-intensity surveillance may be limited, though the rates of salvage are excellent [120]. The National Comprehensive Cancer Network Guidelines do not recommend additional surveillance beyond close interval colonoscopy as described below for either Stage I colon cancer or Stage I rectal cancer patients who underwent oncologically appropriate mesorectal excision and full surgical staging [2, 3].

Colonoscopy is indicated after curative treatment and surgery for colorectal cancer to evaluate for metachronous or local recurrence. The first colonoscopy should be 1 year after surgery or 1 year after the diagnostic complete colonoscopy [121]. Subsequent colonoscopies should be in 3 years and then 5 years, if no additional high-risk lesions are found. Following this, colonoscopy should be at 5-year intervals. For patients with rectal cancer, which has a higher rate of local recurrence, closer surveillance may be indicated. For those patients who did not receive standard of care treatment (i.e., transanal excision of early rectal cancer, no neoadjuvant chemoradiation therapy for Stage II or III, surgery that was not total mesorectal excision), flexible sigmoidoscopy to evaluate the pelvis and anastomosis should be performed every 3–6 months for the first 23 years after surgery in addition to the colonoscopy recommended above for metachronous surveillance as these patients have higher risk of local recurrence [3, 121]. For those patients with rectal cancer who did receive neoadjuvant chemoradiation and appropriate surgical resection, the risk of local recurrence is <5% and the likelihood of detecting curable disease is minimal; therefore, the benefit of more frequent proctoscopy may be more limited and is not in the most recent NCCN guidelines [3].

In all guidelines, surveillance after curative treatment is recommended to continue for 5 years. How this timeline effects elderly patients remains unclear. In elderly patients, this may entail less time as the risks of ongoing interventions (i.e., colonoscopies) should be balanced against the expected survival benefits of detecting recurrences. Furthermore, it should be discussed in advance with elderly patients what their goals would be should recurrence be found. Again, a candid discussion with the patient about expected benefits versus risks should be undertaken.

Conclusions

The outcomes of treatment for colorectal cancer in elderly patients could be similar to that of younger patients if careful selection and appropriate attention to detail is maintained. These patients require special considerations and a thoughtful discussion of the balance between risks and benefits with any treatment options, especially in the setting of significant comorbidities. The impact on quality of life and the possibility of losing independence due to complications or side effects from medications or surgery should be carefully considered.

When surgery is offered, minimally invasive strategies should be utilized to minimize the recovery and morbidity for elderly patients. Enhanced recovery programs should be strongly considered to reduce the stress of surgery and optimize outcomes during the perioperative period. Following surgery, if adjuvant chemotherapy is indicated, it should be strongly considered and many options are available that can offer benefit without long-term consequences. Approaching the management of elderly patients from multiple perspectives, perhaps with the help of a geriatrician, can appropriately frame the problem and help the surgeon and patient understand competing comorbidities.

There does not appear to be any such thing as "too old" for standard treatment, especially surgery, and age alone should not be a criterion for surgery or other treatments. Rather, a global assessment of the patient, including medical comorbidities, functional status, and support system, should be undertaking to understand not only the medical risks of treatment, but the impact complications and poor outcomes may have on a patients' quality of life. Including the patient and family members in the discussion will lead to optimal decision making and a clear understanding of what is in store.

Abstract

Gastric cancer is the fourth most common cancer worldwide and the second leading cause of cancer death, representing a major contributor to the global health cancer burden. In the Western world, gastric cancer has been on the decline overall but remains a significant risk factor in the elderly population. This chapter will review the epidemiology, diagnosis, and treatment of gastric cancer in the elderly. Emphasis will be placed on landmark clinical trials which guide current surgical management and perioperative therapy decision-making. Up-to-date management recommendations from the National Comprehensive Cancer Network (NCCN) and European Society for Medical Oncology (ESMO) will be integrated in the discussion. Special focus will be given to issues relating to advanced age and how these issues impact decision-making for oncologists managing this growing patient population.

Keywords

Gastric cancer · Geriatric surgery · Total gastrectomy · Partial gastrectomy · Subtotal gastrectomy · Frailty · Elderly · Gastric adenocarcinoma

Introduction

Cancer is the second leading cause of death worldwide. In 2015, it is estimated that there were 17.5 million cancer cases worldwide and 8.7 million deaths [1]. During the preceding decade, cancer incidence increased by 33%, with population aging contributing 16% to this incidence [1]. Worldwide, gastric cancer is the fourth most common cancer by incidence and second leading cause of cancer death [2]. In the Western world, gastric cancer has been on the decline overall, but its incidence in the elderly population is increasing [3, 4]. Given its incidence worldwide and its association with aging, gastric cancer is a significant contributor to the global cancer burden and a disease that is critical to understand in the elderly patient population. In this chapter, the focus will be primarily on gastric cancer in the Western patient population, addressing issues specific to the geriatric surgical patient.

Epidemiology

Gastric cancer demonstrates significant global variation. Highest incidences are found in Eastern Asia, Eastern Europe, and South America, with lower rates in the United States and Western

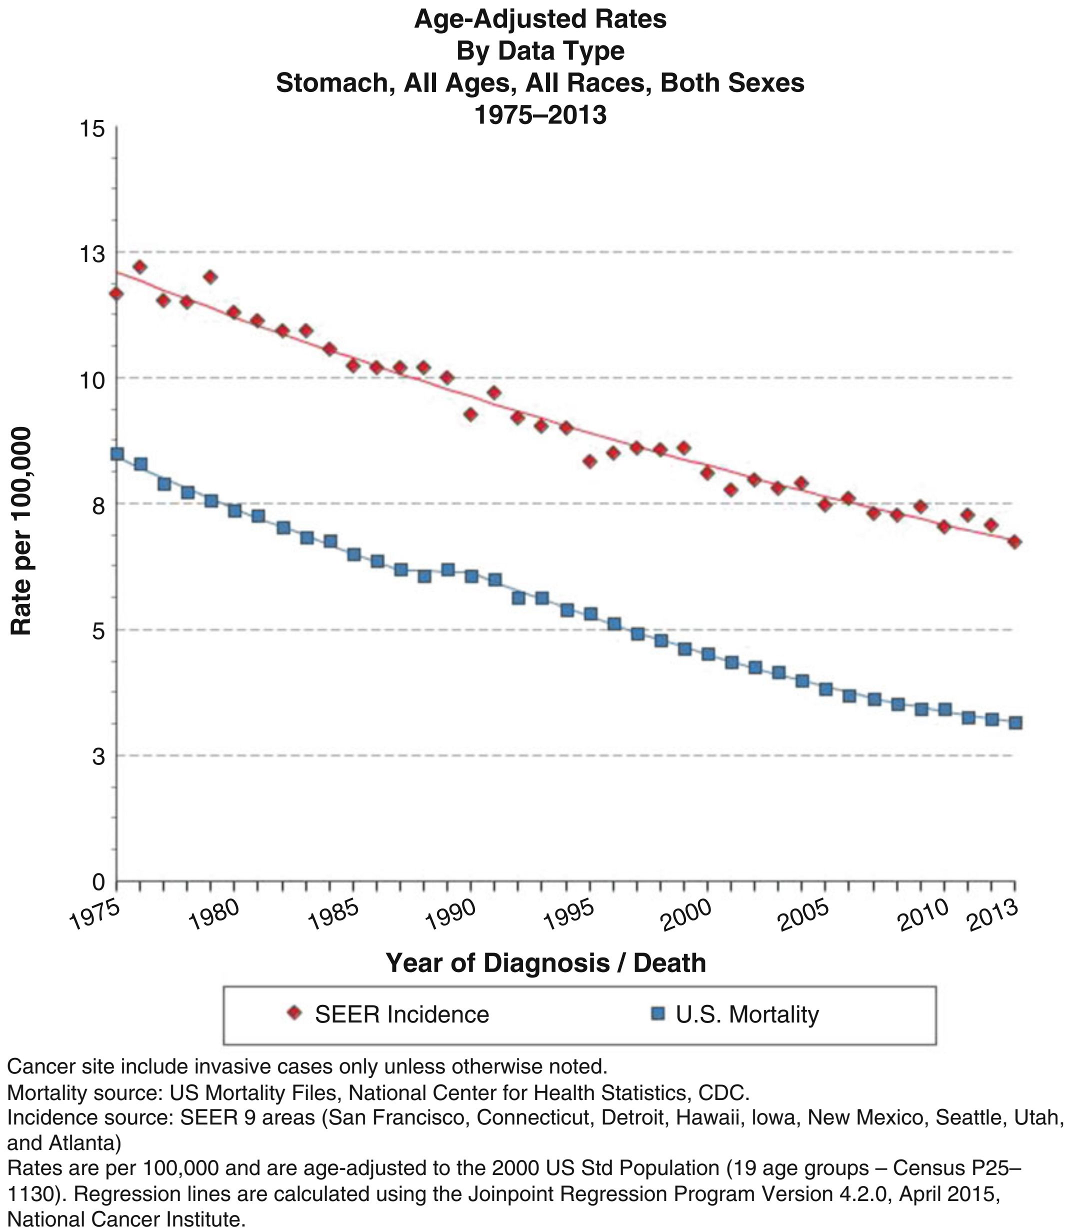

Fig. 1 Age-adjusted rates of gastric cancer incidence and mortality (1975–2013) (https://seer.cancer.gov/faststats/selections.php?#Output)

Europe [5]. Gastric cancer in the United States has seen an overall decline in both incidence and mortality over the past several decades (Fig. 1) [4]. This decline stands in contrast to the early twentieth century, when gastric cancer was the leading cause of cancer mortality in the United States and Europe until the late 1930s. This decline has been attributed in part to the decrease in incidence of infection with *Helicobacter pylori* [6], a known risk factor for more distal gastric cancers. The decline may also be related to the increased use of refrigeration for food storage (and subsequent decreased used of salted and smoked foods).

Though the overall incidence of gastric cancer in the United States has decreased over the past several decades, the relative incidence of proximal gastric cancers has increased. A SEER analysis in the early 1990s demonstrated the rising incidence of adenocarcinoma of the esophagus and gastric cardia [7]. This increase affected white men disproportionately as compared to women and other races, and, ultimately, cardia tumors represented half of all gastric cancer incidence in this group. This change has been attributed in part to the increases in obesity and gastroesophageal reflux disease.

In 2016, it is estimated that the incidence of gastric cancer in the United States will reach 26,370 people, and about 10,730 people will die from this disease [3, 8]. The median age of gastric cancer patients in the United States is 69 years [4]. It is a cancer clearly associated with advancing age (Fig. 2): approximately, six out of ten patients diagnosed with gastric cancer in the United States are at least 65 years of age. While gastric cancer is not in the top 10 cancers in the United States by incidence, it carries a low rate of survival. The overall 5-year survival rate of patients with gastric cancer in the United States is about 29% [9]. Survival also declines with increasing age of incidence (Fig. 3).

Gastric cancer overall affects men more frequently than women, and this predominance persists in the elderly population. In 2016, men will comprise 16,480 of cases and women about 9980 of the projected 26,370 cases of newly diagnosed gastric cancer in the United States [3]. Some have suggested this imbalance is due to differential exposure to environmental carcinogens, while others postulate hormonal causes [10].

Risk Factors

H. pylori infection is one of the most important known causes of gastric cancer, primarily associated with more distal gastric cancers. According to Herrero et al., up to 90% of non-cardia gastric cancer is attributed to *H. pylori* [6]. These gram-negative bacteria have many virulence factors that induce pro-inflammatory, pro-proliferative cell signaling and epithelial damage. Host genetics that produce a heightened pro-inflammatory response in the presence of this bacterium add to the increased risk of transition to gastric cancer [11]. The effects of these pathological phenomena increase the risk of developing gastric adenocarcinoma over time, which makes *H. pylori* a critical risk factor for elderly patients [12]. As the recognition of the role of *H. pylori* in the pathogenesis of peptic ulcer disease and gastric cancer has grown, so too have aggressive efforts to eradicate this pathogen. The decrease of these diseases over the last few decades can likely be attributed to these efforts.

The majority of gastric cancers are considered sporadic. However, approximately 5–10% of gastric cancers are considered to have a familial component, and 3–5% are associated with cancer predisposition syndromes. Gastric cancer is increased in hereditary diffuse gastric cancer, Lynch syndrome, juvenile polyposis syndrome, Peutz-Jeghers syndrome, and familial polyposis syndrome. Because these syndromes are generally associated with early onset of gastric cancer, they are less commonly encountered in the elderly patient and thus are not a focus of this chapter.

Other important risk factors for gastric cancer are obesity and gastroesophageal reflux disease (GERD). In the United States, one in three adults is obese, comprising nearly 78 million adults, as well as 13 million children. Clearly associated with numerous health issues such as hypertension, diabetes, and heart disease, there is a growing recognition of the role of obesity in cancer. Elderly patients are no different: data from the National Health and Nutrition Examination Survey from 2007 to 2010 demonstrated that more than one-third of the adults over the age of 65 were obese [13]. By 2050, the number of elderly patients is expected to double to 88.5 million. Obesity and GERD have been primarily associated with proximal gastric cancers, and this rise in obesity may offset some of the decreases in gastric cancer seen over the past few decades.

Environmental risk factors have also been associated with gastric cancer. Low consumption of fruits and vegetables and high intake of salts, nitrates, and pickled foods have all been implicated [2]. Heavy alcohol use may also be a risk factor for more distal gastric cancers [14]. And, as with many solid tumors, smoking appears to increase the risk for gastric cancer.

Anatomic Classification

Gastric cancers are primarily divided into cardia and non-cardia locations. Non-cardia tumors are sometimes called true gastric tumors, whereas cardia tumors are called gastroesophageal (GE) tumors. The most common classification of gastroesophageal tumors is the Siewert classification [15]. This classification identifies three types:

Type I: center of the tumor located within 1–5 cm above the anatomic GE junction

Type II: center within 1 cm above and 2 cm below the GEJ

Type III: center between 2 and 5 cm below GEJ (may infiltrate the GEJ from below)

All gastric cancers involving the GE junction should be classified by Siewert tumor type. Anatomic classification is important due to significant differences in risk factors, incidence, disease course, and treatment regimens. Consistent with National Comprehensive Cancer Network guidelines, this chapter will focus on the management principles of true gastric cancers, including Siewert type III [16]. Siewert type I and II tumors are more commonly treated according to esophageal cancer guidelines.

In elderly patients, lower or distal third tumors predominate (42–63%), whereas younger patients' incidence ranges from 31 to 44% and middle and upper third tumors predominate [10]. In addition, multiple synchronous gastric cancers are more prevalent in the elderly (8–15%) [10]. These multiple tumors arise predominantly in the distal third of the stomach.

Some have suggested this pattern is related to the higher prevalence of intestinal-type gastric cancer in this age group.

Histologic Classification

Gastric adenocarcinomas are histologically diverse. This diversity has led to a number of classification schemes, including the Lauren and WHO [17, 18]. According to the Lauren classification, gastric carcinomas are characterized as diffuse, intestinal, mixed, or indeterminate types. Diffuse carcinomas are poorly differentiated with the absence of gland formation, whereas intestinal carcinomas are mostly well to moderately differentiated and form glandular structures [2]. Diffuse type tends to spread transmurally, or via lymphatics, whereas intestinal type is more commonly associated with hematogenous spread of metastases.

The intestinal subtype is more common in high-risk and elderly patient populations, and the diffuse type is more common in women and younger patients. Prognosis tends to be less favorable for patients with diffuse-type carcinomas. This subclassification as intestinal or diffuse also has implications for systemic therapy, as intestinal type cancers more frequently overexpress HER2-neu. This implication for therapy has led the NCCN to recommend reporting this histologic subtype in pathologic evaluations [16].

The WHO classification, on the other hand, divides gastric carcinomas into five types: tubular, papillary, mucinous, poorly cohesive, and rare variants. This classification aligns these cancers with classification of other gastrointestinal malignancies [2]. In general, tubular and papillary carcinomas roughly correspond to intestinal type in the Lauren classification, and poorly cohesive (including signet ring types) correspond to diffuse-type carcinomas.

Molecular Classification

Recent significant molecular subtyping work has begun to emerge in the literature [19]. Utilizing The Cancer Genome Atlas, investigators analyzed 295 primary gastric adenocarcinomas and identified four molecular subtypes: EBV-positive tumors, microsatellite instability (MSI), genomically stable, and chromosomal instability. Currently, such subtyping is not part of consensus guidelines for pathologic review from either the National Comprehensive Cancer Network (NCCN) or European Society for Medical Oncology (ESMO) guidelines [5, 16]. However, these efforts hold great promise to better characterize prognosis and target systemic therapies in the future.

NCCN and ESMO guidelines do recommend pathologic evaluation for HER2 positivity [5, 16]. Overexpression of HER2-neu is observed in 10–15% of gastric cancers [5]. Currently, the NCCN recommends assessment of HER2-neu overexpression in patients with inoperable locally advanced, recurrent, or metastatic disease. ESMO guidelines currently recommend assessment of HER2-neu overexpression in patients with metastatic disease (level 1 recommendation).

Presentation and Diagnosis

Gastric cancer remains a challenge clinically. Most patients with early-stage gastric cancer are asymptomatic and therefore remain undiagnosed until a later stage. In countries where the incidence of gastric cancer is high – such as Japan and Korea – screening programs have enabled early detection and overall more favorable outcomes. However, in the United States, due to the low incidence of gastric cancer, widespread endoscopic screening programs have low positive predictive value, and therefore disease is most commonly detected at later symptomatic stages of disease.

Efforts at early detection in Western countries have primarily focused on high-risk patient populations, especially in those with hereditary cancer syndromes associated with an increased risk of gastric cancer. This difficulty in detecting gastric cancer early in Western countries is even more profound in the elderly patient population, where frailty and malnutrition further complicate management decisions.

The most common presenting symptoms may be fairly nonspecific. In a study of 1172 patients with resectable gastric cancer at Memorial Sloan Kettering Cancer Center, the most common presenting symptoms were anorexia, weight loss, pain, and vomiting [20]. These symptoms can also be frequently seen with a number of gastrointestinal conditions, and patients are often treated for presumed benign etiologies before suspicion for underlying malignancy arises. With more advanced disease, other symptoms may occur. Dysphagia may be associated with tumors at the GE junction. Abdominal distention, nausea, and vomiting may also occur secondary to obstructing masses at the distal stomach.

Diagnosis may also follow abnormal laboratory values suspicious for underlying gastric malignancy. Positive fecal occult blood tests or iron deficiency anemia can spur a workup for gastrointestinal bleeding. Though colorectal malignancy is a more common etiology for these abnormalities, frequently an upper endoscopy is often pursued with a lower endoscopy, resulting in a reasonably timely diagnosis of gastric cancer.

Physical examination findings are also often unremarkable, except in very advanced disease. Findings such as Sister Mary Joseph sign (palpable periumbilical node), Virchow's node (palpable left supraclavicular node), and Blumer's shelf (palpable mass on rectal exam) are rarely seen in the modern era.

Endoscopy is the examination of choice for confirming the diagnosis of gastric cancer. Historically, upper GI series with barium was an important component of the initial workup. Barium studies can demonstrate intraluminal mass and irregular rugae, but its sensitivity is low. Currently, upper GI series are primarily used in advanced cancers to assess significance of obstruction. This modality may also be useful for linitis plastica, where a contrast study may show nondistensibility of the stomach. In general, though, upper endoscopy has largely supplanted contrast studies in the initial workup of gastric cancer.

Upper endoscopy has the benefit of direct visualization of the upper digestive tract. Suspicious masses or ulcerations can be directly biopsied. Sensitivity of upper endoscopy for making the diagnosis of gastric cancer has been reported to be as high as 90–96% [21]. Typically, six to eight biopsy specimens with standard-size endoscopy forceps are sufficient to obtain the diagnosis. Cytologic brushings or washings are much less frequently used in the initial workup of a gastric mass.

Workup

Once the diagnosis is made, clinical staging is critical as over 50% of patients will have advanced disease at the time of diagnosis [16]. For these patients, curative resection is not indicated.

Both endoscopic ultrasonography (EUS) and CT imaging of the chest and abdomen are essential modalities for proper preoperative staging; both are recommended by ESMO and NCCN [5, 16]. EUS provides the more accurate tumor (T) and lymph node (N) staging and maybe the proximal extent of disease. EUS discriminates T1–T2 lesions versus T3–T4 at approximately 86% sensitivity according to a recent Cochrane review [22]. Lymph node positivity was 83% sensitive. As nearly 70%–80% of the patients with resectable disease will have involvement of regional lymph nodes, this clinical assessment is critical for applying appropriate treatment modalities and sequencing.

For assessment of distant disease, CT imaging of the chest and abdomen/pelvis is the diagnostic modality of choice. Its sensitivity for T staging is limited (43% to 82%), and its utility in lymph node staging is variable [16]. However, given the high incidence of advanced disease at the time of diagnosis, investigation of distant metastatic disease is mandatory.

PET-CT and MRI are less commonly used for the workup of gastric cancer. Though PET-CT plays an important role in the preoperative management of esophageal and GE junction cancers, its utility is less established for true gastric cancers, given the availability of EUS and high quality CT imaging. In addition, PET-CT has a low detection rate in diffuse and mucinous tumor types due to low tracer accumulation. MRI has been advocated for its ability to detect occult peritoneal disease, but that ability appears to depend on the administering institution.

Currently, it is not recommended by ESMO or NCCN guidelines.

Because of this difficulty in detecting peritoneal disease with conventional imaging methods, diagnostic laparoscopy with cytology has been advocated by some but remains controversial in the workup of gastric cancer. Currently, laparoscopy +/− peritoneal washings carry a level III recommendation (supported by prospective cohort studies) in the current ESMO guidelines for patients with stage IB–III gastric cancer [5], i.e., patients with potentially resectable disease and at least T2 by localized staging. NCCN guidelines recommend laparoscopy with cytology for patients with clinical stage T1b (tumor invades the submucosa) or greater who are considered surgically resectable and who are undergoing preoperative therapy (2B recommendation) [16].

Positive peritoneal cytology, even in the absence of macroscopic peritoneal disease, is classified as M1 disease and carries a poor prognosis. It is also common. In a study of 657 patients at Memorial Sloan Kettering Cancer Center with preoperative assessment of surgically resectable disease, laparoscopy revealed M1 disease in 31% of patients [23]. The strongest preoperative predictors for occult metastatic disease in this study included GE junction/whole stomach tumors and lymphadenopathy. Typically, in patients with macroscopic disease, surgical resection is contraindicated. In patients with positive cytology only, up-front surgical resection should not be pursued except in palliative circumstances. However, in the subset of patients who respond to systemic therapy, the role of surgery is controversial. These patients should be treated in the context of a clinical trial.

Once clinical stage is established, appropriate decisions can then be made for need for or intent of surgical intervention.

Geriatric Assessment

In the elderly patient with locoregional disease being considered for surgical resection, another critical element of the preoperative assessment is fitness for surgery and aligning interventions with patient goals of care.

Geriatric patients present unique challenges in surgical care and cancer treatment. Special consideration must be taken for the individual physiologic reserve and frailty prior to presenting different treatment options. Currently, geriatric patients make up about 50% of the total operations in the United States [24]. This percentage will be expected to increase as the baby boomer population ages. The US Census Bureau anticipates that the baby boomer population (born between 1946 and 1964) is expected to increase from 13% of the total population to at least 20% of the total population by the year 2030 [25]. At that point, nearly one in five US citizens will be age 65 or older [26]. Given the aging of the population, assessment for surgical resection of gastric cancer can be expected to increase, and special approaches must be taken to ensure that patients are appropriately selected for specific treatments and procedures. This includes special assessment tools for those patients carrying a higher risk for increased postoperative morbidity and mortality.

The concept of frailty is multidimensional and incorporates health outcomes including any potential serious adverse effects, like loss of the ability to care for oneself [27]. Frailty has been recognized as a more sensitive and specific predictor of postoperative outcomes in the aging population, particularly in gastric cancer, resulting in the development of several direct and surrogate estimates [28–30]. These estimates have been recommended from various professional organizations and have been shown to assist in decreasing morbidity and mortality when utilized [31–33]. Geriatric frailty is most likely due to a lowered physiologic reserve combined with multiple comorbidities [34]. The concern over physiologic reserve becomes critical when considering an elderly patient for gastrectomy.

These variables, such as the activity level, use of assistive devices, nutritional status, polypharmacy, and cognition, have been individually examined for the association with mortality, length of stay, and/or readmission after surgery [28–30, 35, 36]. In circumstances where surgery reduces nutrient absorption, such as in total gastrectomy, nutrition parameters like albumin and weight loss are of especial importance to postoperative recovery [30, 37].

These are just a few of the many factors that may contribute to or be markers for frailty; the challenge lies in determining the best modalities for frailty measurement and how to use them to maximize improvement preoperatively [38]. In the authors' institution, the combined efforts of surgical and geriatric specialists have created a standardized assessment of patients at high risk for postsurgical complications. Patients over the age of 80, or over 65 with multiple comorbidities, dementia, polypharmacy, weight loss, or visual impairment, are eligible for evaluation in this Perioperative Optimization of Senior Health (POSH) clinic. The majority of the patients seen in this clinic undergo partial or total colectomy, hernia repair, cholecystectomy, or pancreatectomy. Team-based care between surgery, geriatrics, nursing, and anesthesia is focused on risk stratification, then developing a patient-centered optimization plan including planning for post-hospital care. Evaluations and recommendations are evidence based, and they target the gamut of barriers to postoperative recovery: physical function, social planning, mobility and activity, nutrition, cognition, and medication (Fig. 4).

A comprehensive preoperative geriatric assessment allows the team to provide recommendations for perioperative plan in and out of the hospital. These recommendations range from management of comorbidities, reduction of unnecessary medication, nutrition and exercise counseling, sensory augmentation, sleep enhancement strategies, multimodal pain management, planning reorientation strategies and cognitive stimulation, delirium education for prevention, patient activation for preparing for surgery, enlisting social support and family engagement, advance care planning, and anticipating postsurgical discharge needs (Table 1).

Preoperative interventions that can be carried out by the patient, such as improving mobility and nutrition and discontinuing high-risk medications, are also explained to the patient and family. Patients with other diseases or findings of high potential for poor outcomes are referred to the

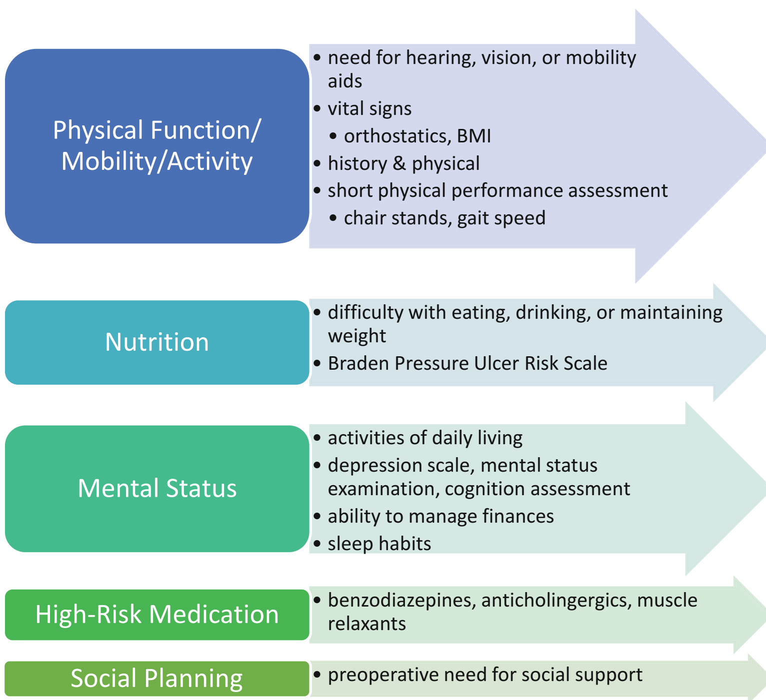

Fig. 4 Frailty-directed preoperative assessment through POSH Clinic. Phone and clinic screening assesses the patient's previous experience with surgery and delirium and reviews family and social history, current living situation, activity level, social support pre- and post-discharge, and advance directives. This screening also aims to identify any difficulties with exhaustion, hearing, vision, nutrition, mobility, sleep, memory, mood, or activities of daily living. Braden Pressure Ulcer Risk Scale [79]

Table 1 American Joint Committee on Cancer (AJCC). TNM Staging Classification for Carcinoma of the Stomach. (7th ed., 2010) (Used with permission of the American Joint Committee on Cancer (AJCC), Chicago, Illinois. Primary Tumor (T)	
TX	Primary tumor cannot be assessed
TO	No evidence of primary tumor
Tis	Carcinoma in situ: intraepithelial tumor without invasion of the lamina propria
T1	Tumor invades lamina propria, muscuiaris mucosae or submucosa
T1a	Tumor invades lamina propria or muscuiaris mucosae
T1b	Tumor invades submucosa
T2	Tumor invades muscuiaris propria[a]
T3	Tumor penetrates subserosal connective tissue without invasion of visceral peritoneum or adjacent structures[b],[c]
T4	Tumor invades serosa (visceral peritoneum) or adjacent structures[b],[c]
T4a	Tumor invades serosa (visceral peritoneum)
T4b	Tumor invades adjacent structures
Regional Lymph Nodes (N)	
NX	Regional lymph node(s) cannot be assessed
NO	No regional lymph node metastasis[d]
N1	Metastasis in 1–2 regional lymph nodes
N2	Metastasis in 3–6 regional lymph nodes
N3	Metastasis in seven or more regional lymph nodes
N3a	Metastasis in 7–15 regional lymph nodes
N3b	Metastasis in 16 or more regional lymph nodes
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis
Histologic Grade (G)	
GX	Grade cannot be assessed
G1	Weil differentiated
G2	Moderately differentiated
G3	Poorly differentiated
G4	Un differentiated

Anatomic	Stage/prognostic		Groups
Stage 0	Tis	N0	M0
Stage IA	T1	N0	M0
Stage IB	T2	N0	M0
	T1	N1	M0
Stage IIA	T3	N0	M0
	T2	N1	M0
	T1	N2	M0
Stage IIB	T4a	N0	M0
	T3	N1	M0
	T2	N2	M0
	T1	N3	M0
Stage IIIA	T4a	N1	M0
	T3	N2	M0
	T2	N3	M0
Stage IIIB	T4b	N0	M0
	T4b	N1	M0
	T4a	N2	M0
	T3	N3	M0
Stage IIIC	T4b	N2	M0
	T4b	N3	M0
	T4a	N3	M0
Stage IV	Any T	Any N	M1

[a]A tumor may penetrate the muscuiaris propria with extension into the gastnocolic or gastrohepatic ligaments, or into the greater or lesser omentum, without perforation of the visceral peritoneum covering these structures. In this case, the tumor is classified T3. If there is perforation of the visceral peritoneum covering the gastric ligaments or the omentum, the tumor should be classified T4

[b]The adjacent structures of the stomach include the spleen, transverse colon, liver, diaphragm, pancreas, abdominal wall, adrenal gland, Kidney, small intestine, and netroperitoneum

[c]Intramural extension to the duodenum or esophagus is classified by the depth of the greatest invasion in any of these sites, including the stomach

[d]A designation of pN0 should be used if all examined lymph nodes are negative, regardless of the total number removed and examined

correct specialist for preoperative evaluation and surgical clearance, as necessary. These evaluations and interventions carry out the POSH clinic's intention to integrate care plans and communications between various providers; reconcile best practices; standardize care; diminish delirium, length of stay, ICU admission, and readmission; and improve rate of and rescue from complications of the patient and caregiver satisfaction and discharge destination.

Gastrectomy for a surgical cure is the optimal goal for gastric cancer treatment but may carry significant morbidity and mortality [39]. In an analysis utilizing the American College of Surgeons (ACS) National Surgical Quality Improvement (NSQIP) database, 23.6% of patients undergoing gastrectomy for gastric cancer suffered serious morbidity and 30-day mortality was 4.1%. Mean age in this patient population was 66 years old, and age was an independent predictor of serious morbidity and 30-day mortality on univariate and multivariate analyses.

As the surgical procedure for treating gastric cancer carries a high risk for morbidity and mortality in a patient population that is often frail and deconditioned, geriatric assessments can be utilized to help refine treatment decisions for these patients. A recent publication demonstrated the utility of a multidimensional frailty score to more accurately predict a 1-year all-cause mortality in elderly patients ($\geq$ 65 years of age) undergoing intermediate-risk or high-risk elective operations than the American Society of Anesthesiologists (ASA) classification [33]. This frailty score was generated on multiple domains: Charlson Comorbidity Index (CCI), dependence in activities of daily living, dependence in instrumental activities of daily living, dementia, risk of delirium, short mid-arm circumference, and malnutrition [33]. Tools such as these hold great promise in better assessing surgical risk and better informing patients considering major surgical procedures.

Comprehensive geriatric assessments (CGAs) have been demonstrated to better assess surgical risk in gastrectomy patients. A recent publication from MD Anderson Cancer Center reported their experience utilizing preoperative geriatric assessments [29]. Patients were assessed on the following variables preoperatively within 30 days: falls within the last month, pain scores (0 vs. $\geq$1), use of assistive devices, activity level of Eastern Cooperative Oncology Group (ECOG) performance status, ASA presurgical fitness score, CCI, polypharmacy ($\geq$5 daily medications), weight loss $\geq$10% in the past 6 months, and albumin level $\leq$ 3.3 g/dL. In this study, they demonstrated that CGA variables such as pain score, ECOG performance status >0, and polypharmacy were independently associated with major morbidity on multivariate analysis in patients undergoing gastrectomy.

CGAs may also help predict long-term complications in patients undergoing gastrectomy. One recent publication investigated whether the Study of Osteoporotic Fractures (SOF) frailty index could predict readmission within 1 year [40]. In their study patients classified preoperatively as “pre-frail and frail” had a readmission rate of 19.1% versus those patients categorized preoperatively as “robust” with a readmission rate of 6.7%.

With the use of the comprehensive geriatric assessments (CGAs), practitioners have the opportunity to identify areas of need and can utilize a multidisciplinary approach to optimize patient outcomes. CGAs hold promise in decreasing in hospital complications as well as anticipating and decreasing complications post-discharge. Specific recommendations have been established by the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society and were recently published [32].

Surgery

Long-term survival in patients with gastric cancer is only achievable with surgical resection. Resection goals include margin-negative resection and appropriate lymphadenectomy. Endoscopic resection may be a suitable alternative for T1a lesions, and this recommendation is supported by ESMO and NCCN guidelines [5, 16]. Lymph node positivity in this group is nearly zero. Endoscopic resection techniques include endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD). Guidelines limit Local Excision to lesions $\leq$2 cm in diameter, well or moderately well differentiated on biopsy, does not exhibit lymphovascular invasion and has clear lateral and deep margins. EMR/ESD should only be performed by experienced endoscopists. The presence of any of these high-risk features after resection should also mandate interval formal gastrectomy and lymphadenectomy.

For stage Ib–III tumors, gastrectomy should be performed. In general, location of tumor dictates resection strategy. Recommended gross luminal margins are 4–5 cm proximally [2, 5, 16]. For diffuse cancers, a margin of 8 cm is advocated

[5]. For this reason, proximal tumors (about 50% of all gastric carcinomas) and midbody tumors (15–30%) require total gastrectomy. More distal tumors (approximately 35% of all gastric carcinomas) may be managed with partial/subtotal gastrectomy. T4 lesions may require en bloc resection of involved structures.

Surgeons should routinely freeze the proximal margin. The surgeon should discretely document completeness of resection:

R0: no residual gross disease and negative microscopic margin
R1: microscopic residual disease only
R2: gross residual disease

Lymphadenectomy

The role of lymphadenectomy in the management of surgically resectable gastric cancer remains controversial. In the current parlance, investigators typically utilize the following classification to describe the extent of lymphadenectomy:

D1: removal of perigastric lymph nodes (within 3 cm of primary tumor)
D2: D1 plus clearance of celiac, common hepatic, splenic, and left gastric lymph nodes
D2+: D2 plus omentectomy, splenectomy, and distal pancreatectomy and clearance of porta hepatis and periaortic lymph nodes.

The Japanese have long advocated at least D2 resection. This recommendation stems from the original report by Kodama et al. in 1981 [41]. In patients undergoing curative attempt resection, a 5-year survival in patients with extensive regional node dissection was 45% compared to 18% in patients undergoing simple resection alone. In node-positive patients, a 5-year survival advantage was maintained at 39% versus 18%. Extensive node dissection included all perigastric lymph nodes (D1) in addition to left gastric artery, common hepatic artery, celiac artery, and splenic artery (D2), including splenic hilum, hepatic pedicle, retropancreatic, mesenteric root, middle colic artery, and para-aortic stations (D2+ or D3).

Though clearly D2 dissection leads to more accurate staging, this technique's contribution to improved survival remains controversial, and these results have not been reproduced reliably in the Western world and widespread adoption has been resisted in Western countries.

The Dutch Gastric Cancer Trial randomized 711 patients with resectable gastric cancer to a D1 dissection versus D2 dissection [42–44]. D2 dissections were performed by nine surgeons trained in D2 dissections by Japanese experts. Morbidity (25% vs. 43%) and mortality (4% vs. 10%) were significantly higher in patients undergoing D2 dissection. Notably, in this study, D2 dissection included distal pancreatectomy and splenectomy. After 11 years, there was no statistical difference in survival (30% vs. 35%, $p = 0.53$). However, a 15-year follow-up ultimately demonstrated a survival difference. A 15-year survival was 21% (82 patients) in D1 versus 29% (92 patients) in D2 patients.

Similarly, the Medical Research Council (MRC) Gastric Cancer Surgical Trial randomized D1 versus D2 resections for patients with resectable gastric cancer [45]. Again, routine pancreaticosplenectomy was routinely included in the D2 resection. There was no difference in a 5-year survival between the two groups (35% vs. 33%).

Finally, the Italian Gastric Cancer Study Group performed a randomized trial of D1 versus D2 resection [46]. Due to the evolution in many centers of abandoning routine pancreaticosplenectomy as part of D2 dissection, this trial did not include routine resection of distal pancreas and spleen, but rather incorporated only when suspected to be directly invaded by gastric cancer. In this study, operative morbidity was similar. Again, there was no difference in a 5-year survival between the two groups (66.5% vs. 64.2%, D1 vs. D2, $p = 0.695$). A subgroup analysis did suggest a possible benefit to D2 dissection in patients with more advanced disease.

These studies have all been somewhat criticized for quality control in the D2 dissection groups. For these reasons, ESMO guidelines do recommend D2 dissection for medically fit patients, and the recommendation is that patients should undergo these procedures in specialized, high-volume centers [5]. Routine pancreatico-splenectomy is no longer advocated.

In the United States, given the technical expertise required to perform routine D2 dissection and the controversy regarding its impact on patient survival (stage migration rather than true impact on survival), NCCN recommends a minimum of 15 nodes evaluated at the time of gastrectomy and the current AJCC staging system supports these guidelines (Tables 1 and 2) [16]. This recommendation is supported by a large analysis by Schwarz et al. [47]. Utilizing the SEER 1973–2000 database to evaluate outcomes from 1377 patients who underwent gastrectomy, these investigators identified a significant cut point in survival for patients with a minimum of more than 15 lymph nodes examined.

As the guidelines state, surgeons should perform "gastrectomy with D1 or a modified D2 lymph node dissection, with a goal of examining at least 15 if not more lymph nodes" [16]. In practice, reliably obtaining >15 lymph nodes requires technical skill beyond a D1 dissection alone, and practitioners performing gastrectomy for gastric cancer should pursue D2 dissection. The NCCN also emphasizes that these dissections should be performed by experienced surgeons in high-volume centers.

Table 2 Perioperative Optimization of Senior Health

Recommended evaluations specific to frailty assessment	Improving postoperative outcomes
Orthostatic vital signs	Communication between all providers and patient/family
Nutritional assessment	Preoperative optimization of physical performance and nutrition, other comorbid conditions
Mental status exam	Use of hearing, vision, and ambulatory aids
Physical performance exam	Limit pre- and postoperative high-risk medications
Medications/substances at high risk for delirium	Pain control with multimodality, nonnarcotic medications
Aids for hearing, vision, ambulation	Sleep cycle optimization

Minimally Invasive Surgery

Over the last decade, minimally invasive approaches to gastrectomy have emerged as a promising technique to decrease morbidity while maintaining important oncologic principles. Several randomized trials in the East have been conducted, but high-quality Western studies are rare and small. For example, an Italian group randomized only 59 patients with resectable, distal gastric cancers [48] to open subtotal gastrectomy ($n = 29$) versus laparoscopic subtotal gastrectomy ($n = 30$). Lymph node retrieval was similar between groups. Operative mortality rates were low overall (two patients vs. one patient). Operative morbidity was similar (27.6% vs. 26.7%). A 5-year overall survival was 55.7% in the open group versus 58.9% in the laparoscopic ($p = \text{NS}$).

Scattered high-volume centers in the United States have begun to demonstrate the feasibility of minimally invasive gastrectomy for gastric cancer. A recent single-institution analysis from Kelly et al. compared outcomes from 87 consecutive patients undergoing laparoscopic gastrectomy to 87 patients undergoing open resection during that same time period [49]. Patients were matched by age, stage, body mass index (BMI), and procedure (subtotal vs. total). Operative time was longer in the laparoscopic group but was associated with less blood loss. Microscopic margin positivity was higher in the laparoscopic group (9% vs. 1%). Lymph node retrieval was similar (median of 20). Postoperatively, laparoscopy was associated with decreased use of narcotics and epidural, decreased minor complications, decreased length of stay, and increased likelihood of receiving adjuvant therapy. Major morbidity and 30-day mortality were similar.

In all likelihood, large robust clinical trials in the United States will be difficult to perform, and reliance upon the experience of these high-volume centers will lead surgeons to an appropriate understanding of the role. Almost certainly, as has been demonstrated in other gastrointestinal oncologic surgeries, minimally invasive techniques, when appropriately applied, provide equivalent oncologic outcomes while providing advantages in postoperative recovery.

However, it is critical to understand that, unlike other high-volume malignancies such as colorectal cancer where oncologic equivalence has been demonstrated with laparoscopic techniques, the challenge of low patient volume is unique to surgeons performing gastrectomy for gastric cancer in the United States. In a recent editorial, Strong points out that in a recent high-quality Eastern report, 42 cases were required before surgeons achieved equivalence with lymph node retrieval, complication rate, and outcomes [50]. In general, she notes that it is likely that 50–60 laparoscopic gastrectomies are necessary to achieve proficiency [51]. For gastric cancer in the United States, few centers can achieve this learning curve and the appropriate strategy for adoption is unclear.

Staging

Following gastrectomy, patients can be assigned a formal pathologic stage.

Overall, outcomes are dictated by pathologic stage. According to contemporary SEER data, 5-year survival outcomes by stage are as follows [9]:

IA – 71%
IB – 57%
IIA – 46%
IIB – 33%
IIIA – 20%
IIIB – 14%
IIIC – 9%
IV – 4%

Outcomes in the Elderly

Stage-by-stage survival rates do not necessarily capture the difficulty of predicting outcomes in elderly patients. Efforts to better understand surgical outcomes in the elderly include nomogram strategies. For instance, the Memorial Sloan Kettering Cancer Center group published a nomogram in 2003 predicting disease-specific survival in patients undergoing surgical resection [52]. Of note, these predicted outcomes did not incorporate the impact of perioperative chemotherapy or radiation therapy, but instead predicted outcomes for patients undergoing complete surgical resection. Predictive factors included age, tumor size, sex, tumor location, Lauren classification, T stage, and the number of positive and negative lymph nodes. In this model, increasing patient age is a potentially more powerful predictor of patient outcome than sex, Lauren classification, tumor size, or tumor location.

Historically, surgical outcomes in the elderly were considered quite poor, and many patients did not undergo attempted resection. In an analysis of an English registry from 1957 to 1981, less than 20% of patients over age 80 years underwent surgical resection and resection rates in 70–79 year olds were still only 25% [53]. Similarly, a Dutch registry analysis from 1982 to 1992 demonstrated resection rates of 54% for 70–79-year-olds versus only 35% for 80+ –year-olds [54]. Over time, as perioperative care has improved and the understanding of geriatric physiology has improved, resection rates have increased and have begun to approach rates in other age cohorts.

In addition, elderly patients may not undergo resections which adhere to recommended oncologic principles, thus potentially compromising their oncologic outcomes. A recent SEER analysis addressed this question for patients ≥65 years old undergoing gastrectomy for gastric cancer [55]. In this analysis, though 61% of the patients undergoing resection were elderly patients, less than 30% of patients in this cohort underwent appropriate lymphadenectomy (≥ 15 lymph nodes examined). Older age was also associated with worse cancer-specific mortality, especially in proximal gastric cancers.

Investigators have also looked at outcomes in octogenarians, sometimes called the super-elderly. In a recent Japanese report, though 80+ –year-olds had significantly more comorbidities (74.7% vs. 49.5%) than a matched 60–69-year-old cohort, postoperative complication rate was equivalent (23.2% for each group) [56]. However, initiation of adjuvant chemotherapy was markedly less

(9.5% versus 29.0%) in the super-elderly group. And finally, disease-specific survival (DSS) was worse for super-elderly patients with stage II and stage III disease.

A recent National Surgical Quality Improvement Program (NSQIP) publication again highlights some of the differences seen between Eastern and Western experiences. Teng et al. evaluated all patients undergoing gastrectomy for malignancy in the 2005–2011 dataset [57]. Octogenarians had higher 30-day mortality (7.2% vs. 2.5%, $p < 0.01$) and higher complication rates despite fewer undergoing total gastrectomy (24.0% vs. 43.2%, $p < 0.01$) and extended lymphadenectomy (10.1% vs. 17.4%, $p < 0.01$). Again, these poorer outcomes in Western series may be related to increased frailty in Western patients or may represent high-volume experience in Eastern countries.

Advances in minimally invasive techniques hold promise for reducing perioperative morbidity for elderly patients undergoing gastrectomy. As mentioned earlier in this chapter, much of this work has been published in the Eastern literature, where gastric cancer is more common. A recent meta-analysis of Eastern studies comparing laparoscopic and open outcomes in elderly patients undergoing gastrectomy showed less intraoperative blood loss, earlier time to first ambulation, earlier oral intake, shorter postoperative hospital stay, and few postoperative complications with no significant difference in lymph node retrieval [58]. Other analyses have demonstrated similar findings [59]. Clearly, these endpoints may be disproportionately influential in a patient population that is more frail and less resilient.

Perioperative Locoregional and Systemic Therapy

Despite advances in preoperative staging, surgical technique, and perioperative care over the past few decades, the majority of patients with a diagnosis of gastric cancer will die from this disease. As stated previously, the overall relative survival rate in the United States is 29%, regardless of stage. In patients with resectable disease, overall survival remains well less than 50%. For this reason, continued progress with locoregional and systemic therapies is critical.

Preoperative Chemoradiation Therapy

Several institutions in the United States have favored preoperative chemoradiation strategies. In a critical pilot study, Lowy et al. reported on the feasibility of a preoperative chemoradiation pilot study [60]. In this study, 24 patients were administered 45 Gy of external beam radiotherapy with concurrent 5-FU with plans for interval surgical resection. Twenty-three patients completed the planned chemoradiotherapy protocol. Nineteen of 23 (83%) patients underwent interval surgical resection. Reported morbidity and operative mortality rates were 32% and 5%, respectively. Fourteen of 19 patients had some pathologic evidence of treatment effect, including two patients with complete pathologic response.

To date, there is no level 1 evidence for the benefit of preoperative chemoradiation therapy in patients with true gastric cancer, only extrapolation from studies in resectable adenocarcinoma of the esophagus, inclusive of gastric cardia tumors. Currently, there is an ongoing randomized trial by the Australasian Gastrointestinal Trials Group evaluating this question (Trial of Preoperative Therapy for Gastric and Esophagogastric Junction Adenocarcinoma [TOPGEAR] trial) (ClinicalTrials.gov Identifier NCT01924819). In this trial, patients are randomized to preoperative chemotherapy, preoperative chemoradiotherapy, surgery and postoperative chemotherapy versus preoperative chemotherapy, and surgery and postoperative chemotherapy. The perioperative chemotherapy regimens include epirubicin + cisplatin +5-fluorouracil (ECF chemotherapy), and the radiotherapy arm includes 45 Gy of radiation in 25 fractions. This trial is currently recruiting and will be an important advance in understanding optimal treatment of patients preoperatively. Currently, preoperative chemoradiation therapy carries a category 2B recommendation by the NCCN for resectable patients with T2 or higher, any N disease [16]. ESMO guidelines do not include preoperative chemoradiation in its recommended treatment algorithms [5].

Adjuvant Chemoradiation Therapy

The landmark Southwest Oncology Group (SWOG) 9008/INT-0116 trial provided level 1 evidence for the benefit of postoperative chemoradiation in patients with resectable gastric or GEJ tumors [61]. In this trial, 556 patients with resected adenocarcinoma of the stomach or GE junction were randomly assigned to surgery plus chemoradiotherapy ($n = 281$) versus surgery alone ($n = 275$). Adjuvant therapy included 5-fluorouracil (FU) and leucovorin (LV) plus 45 Gy of radiation therapy followed by 5-FU/LV. Median overall survival in the surgery-only group was 27 months versus 36 months in the chemoradiotherapy group ($p = 0.005$). Three-year OS (50% vs. 41%) and RFS (48% vs. 31%) were also improved in the chemoradiotherapy group.

This trial has several limitations. It has been criticized for poor standardization of surgical therapy. Though a D2 dissection was recommended, only about 10% received a D2 dissection. Only 36% underwent formal D1 dissection. Thus, the majority of patients (54%) underwent less than a D1 dissection. In addition, only 64% of patients ($n = 181$) completed their planned treatment in the chemoradiotherapy group. Reasons for incomplete treatment included toxicity (17%), patient declined further treatment (8%), disease progression (5%), death (1%), and others (4%). Despite these shortcomings, this trial has established postoperative chemoradiation therapy as an important regimen in patients who have not received preoperative therapy.

It should also be noted that though the Intergroup trial established a role for adjuvant chemoradiation therapy in patients with resected gastric cancer, the toxicity was significant. Currently, regimens typically include infusional fluorouracil or oral capecitabine. In addition, the benefit of adjuvant radiation for patients with T2 disease remains controversial. Finally, the role of adjuvant radiation therapy remains controversial for patients who have undergone D2 dissection. The ongoing phase III Adjuvant Chemoradiotherapy in Stomach Tumors-II (ARTIST-II) trial (ClinicalTrials.gov Identifier NCT01761461) may help answer this question. In this trial, patients with true gastric cancer or GEJ cancers who have undergone at least D2 dissection are randomized to one of the three arms: adjuvant S-1, adjuvant S-1 + oxaliplatin, or adjuvant S-1 + oxaliplatin, then chemoradiation (45 Gy), and then S-1 + oxaliplatin. This trial is currently recruiting.

Currently, the NCCN recommends an adjuvant regimen which includes chemoradiation for all patients who have not undergone preoperative therapy and who have undergone an R1 or R2 resection. In addition, in those patients with no preoperative therapy and an R0 resection, a chemoradiation-based regimen is recommended in T3 or T4, any N patients who have not undergone primary D2 dissection (chemotherapy alone is considered sufficient for these patients) [16]. ESMO guidelines also support adjuvant chemoradiation but similarly note that benefit likely accrues to primarily patients who have undergone incomplete lymph node dissection [5].

Perioperative Therapy

Another critical landmark trial establishing the role of systemic chemotherapy in the management of resected gastric cancer was the MAGIC trial conducted by the British Medical Research Council [62]. In this trial, patients with resectable adenocarcinoma of the stomach, GEJ, and lower esophagus were randomized to either perioperative chemotherapy with surgery ($n = 250$) or surgery alone ($n = 253$). Of note, only 74% of the patients in this trial were true gastric cancers. Chemotherapy consisted of three cycles of preoperative and three cycles of postoperative ECF. Again, in this trial, systemic therapy carried significant toxicity. Only 104 of 250 patients (41.6%) completed all six cycles of perioperative chemotherapy. Primary endpoint was overall survival. A 5-year OS was 36% in the perioperative chemotherapy group and 23% in the surgery-alone group.

This trial has similarly been criticized similarly for surgical technique. As reported, less than one-third of the patients underwent D2 dissection.

Currently, ESMO guidelines consider perioperative chemotherapy the "preferred pathway" for patients with >T1 disease [5]. The NCCN considers perioperative chemotherapy a category 1 recommendation for patients with T2 or higher, any N disease though up-front surgery is still considered an option, along with preoperative chemoradiation (category 2B, previously discussed) [16].

Adjuvant Systemic Therapy

Typically, for patients with resected T1 disease, adjuvant chemotherapy is not offered. There was no benefit demonstrated in a large randomized trial from Japan evaluating adjuvant mitomycin and fluorouracil [63].

In patients with T2 or greater disease, the benefit of postoperative systemic chemotherapy alone is best supported in patients who have undergone D2 dissection. In another important Japanese study, 1059 patients with resected stage II (excluding T1) or stage III disease (all patients underwent extended D2 lymph node dissection) were randomized to postoperative S-1 (an oral fluoropyrimidine) ($n = 529$) versus surgery alone ($n = 530$) [64]. The trial was terminated early due to significant difference in outcomes. A 3-year overall survival was 80% in the S-1 group and 70% in the surgery-only group ($p = 0.002$). Of note, S-1 remains an investigational agent in North America.

Another important trial that has helped frame the role of adjuvant systemic therapy was the CLASSIC trial [65]. This trial was conducted in South Korea, China, and Taiwan. In this trial, which again included only patients undergoing gastrectomy with D2 lymph node dissection, 1035 patients with stage II–IIIb disease were randomized following surgical resection to oral capecitabine and oxaliplatin ($n = 520$) versus surgery alone ($n = 515$). The primary endpoint was a 3-year disease-free survival (DFS). A 3-year DFS was 74% in the surgery plus chemotherapy group versus 59% in the surgery-alone group ($p < 0.0001$).

These two large, high-quality randomized Eastern cooperative group trials have clearly established the benefit of adjuvant systemic chemotherapy in patients with at least T2 disease undergoing resection for gastric cancer. Of note, in patients who do not undergo D2 dissection, current guidelines recommend adjuvant regimens that include radiation therapy [16]. ESMO guidelines also recommend caution in applying these results in Western countries, noting that perioperative chemotherapy regimens remain the preferred strategy, given the increased difficulty for patients to tolerate adjuvant therapy versus neoadjuvant therapy [5]. This issue may be especially notable for elderly patients undergoing gastrectomy.

Clinical Trials in the Elderly

Despite high-level evidence regarding the survival benefits of perioperative therapy for resected gastric cancer, it is well known that elderly patients are underrepresented in clinical trials and the applicability of the results from these trials to the elderly may not be fully known. In an analysis of the participation of elderly patients in clinical trials sponsored by the National Cancer Institute (NCI) from 1997 to 2000, investigators found that the elderly comprised only 32% of participants in phase II and phase III cancer clinical trials, despite comprising 61% of patients with newly diagnosed cancers in the United States [66]. Similarly, in an analysis of patients enrolled in SWOG treatment trials between 1993 and 1996, patients aged 65 years or older represented only 25% of trial participants [67].

In a recent SEER analysis of elderly patients undergoing gastrectomy for gastric cancer, older patients were less likely to undergo recommended radiation therapy [55]. In this analysis, patients older than 65 years of age received indicated adjuvant radiation therapy only 23% of the time. Much of the data regarding strategies for systemic therapies in the elderly come from trials in advanced gastric cancer originating in the Eastern literature.

Xiang et al. assessed the efficacy and safety of oxaliplatin plus oral capecitabine (XELOX) as a first-line regimen in 46 patients aged $\geq$70 years in a recent publication from China [68]. A median of six cycles was administered, and the overall response rate was nearly 50%. The investigators concluded that toxicities were well tolerated: grade 3 toxicities included neutropenia (6.5%), thrombocytopenia (2.2%), nausea (2.2%), vomiting (4.3%), diarrhea (4.3%), and peripheral neuropathy (2.2%). No grade 4 toxicities were reported.

Lee et al. performed a randomized phase II study from Korea on 91 patients comparing oral capecitabine versus S-1 as first-line treatment in elderly patients [69]. In this study, response rates were 27–28%. Toxicities included granulocytopenia, asthenia, anorexia, diarrhea, and hand-foot syndrome. Toxicity rates were similar between groups and less than 10% overall.

In a recent Italian study, Catalano et al. evaluated the efficacy and safety of 43 elderly patients ($\geq$ 70 years) undergoing a modified FOLFOX regimen for advanced gastric cancer [70]. In this phase II study, overall response rate was 35%. Toxicities included grade 3 neutropenia, fatigue, vomiting, and peripheral neuropathy – again, primarily less than 10%. No treatment-related deaths were seen.

A recent meta-analysis from the United Kingdom pooled data from three clinical trials evaluating chemotherapy for patients with locally advanced or metastatic cancer of the esophagus, GEJ, and stomach [71]. Outcomes were compared between patients $\geq$70 years and those younger. In this analysis of 1080 patients, there were no significant differences between the groups in grade 3 or 4 toxicities. Response rates and survival were also not significantly different between groups, and age was not an independent predictor of outcome. However, low performance status did predict worse outcome. This analysis is a compelling challenge to the traditional nihilism associated with treating elderly patients with gastric cancer, based on age alone.

Advanced Disease

Outcomes in patients with metastatic disease are poor, in any age cohort, ranging from 4 to 12 months. However, in patients with advanced disease, systemic chemotherapy has been demonstrated to prolong survival and improve quality of life. This understanding of the potential palliative benefit of systemic chemotherapy is critical when considering therapeutic options for the elderly patient.

The cytotoxic agents which have demonstrated the most activity against advanced gastric cancer include fluoropyrimidines, platinums, taxanes, epirubicin, and irinotecan [2]. Most of the response rates are around 20% with single-agent use. A recent large Cochrane review concluded that combination chemotherapy demonstrates survival benefit over best supportive care (8.3 months vs. 6.7 months) and also compared to single-agent 5-FU [72]. In general, the most commonly used first-line chemotherapy regimen in metastatic gastric cancer is a combination of a fluoropyrimidine with a platinum. The role of triplet regimens is controversial.

As stated previously, systemic chemotherapy for advanced gastric cancer has also been shown to improve quality of life [73]. In an important study conducted in Sweden, investigators randomized 61 patients with advanced gastric cancer to best supportive care versus best supportive care plus systemic chemotherapy (ELF regimen: 5-fluorouracil, leucovorin, and etoposide). Quality of life was evaluated utilizing the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire (EORTC-QLQ)-C30 instrument. In this trial, more patients in the chemotherapy group reported improved or prolonged high quality of life for a minimum of 4 months. A similar difference was noted subjectively by the treating physician evaluation.

Currently, ESMO guidelines recommend doublet or triplet platinum/fluoropyrimidine combinations as first-line therapy for advanced gastric cancer.

Targeted Therapies

To date, trastuzumab and ramucirumab are the only two targeted agents approved for the treatment of advanced gastric cancer.

Overexpression of HER2-neu is observed in 10–15% of gastric cancers [5]. Currently, the NCCN recommends assessment of HER2-neu overexpression in patients with inoperable locally advanced, recurrent, or metastatic disease. ESMO guidelines currently recommend assessment of HER2-neu overexpression in patients with metastatic disease (level 1 recommendation).

These recommendations emerged from the Trastuzumab for Gastric Cancer (ToGA) trial [74]. In this trial, 594 patients with HER2-positive (3+ on immunohistochemistry or FISH-positive) advanced gastric or GEJ cancers were randomized to trastuzumab plus chemotherapy (fluorouracil or capecitabine and cisplatin) versus chemotherapy alone. The majority of patients (>80% in each group) had true gastric cancer. This phase III trial demonstrated statistically significant improvements in response rate, progression-free survival (PFS), and overall survival (OS) (13.8 vs. 11.1 months, $p = 0.046$) with the addition of trastuzumab to systemic chemotherapy [74]. This trial represents one of the first meaningful advances in targeted therapy for advanced gastric cancer.

Ramucirumab, a VEGFR-2 antibody, has demonstrated a survival benefit in two randomized trials as a second-line agent over best supportive care alone [75, 76]. In the REGARD trial, a randomized phase III trial conducted in 29 primarily Western countries, 355 patients with advanced gastric cancer and disease progression on first-line therapy were randomized to ramucirumab versus best supportive care [75]. In this trial, median survival was 5.2 months in the treatment group versus 3.8 months in the placebo group.

In the RAINBOW trial, a randomized phase III trial conducted in 27 countries, 665 patients with advanced gastric cancer who had progressed on first-line therapy were randomized to paclitaxel plus ramucirumab versus paclitaxel alone [76]. Overall survival was significantly longer in the ramucirumab plus paclitaxel group than the paclitaxel group alone (9.6 months vs. 7.4 months).

These trials highlight significant advances being made in personalized treatment strategies and novel agents for patients with advanced gastric cancer. The favorable toxicity profiles of many of these agents are well suited to the geriatric population.

Palliative Surgery

Palliation in advanced gastric cancer may involve resection, bypass, or both. Though partial gastrectomy may be performed with reasonable morbidity, caution should be exercised when considering palliative total gastrectomy. In an analysis of palliative gastrectomy in patients with gastric cancer from Memorial Sloan Kettering Cancer Center, reasons for palliative resection included bleeding (20%), obstruction (43%), pain (29%), unexplained weight loss (4%), and others (4%) [77]. About 20% of these palliative patients underwent total gastrectomy. Of note, patient age > 65 years was an independent predictor of worse outcomes.

Since this important publication, continued advances have been made in nonsurgical strategies for palliation. Patients with bleeding may be palliated by endoscopic or embolization strategies. These strategies include injection therapy, endoscopic clip placement, ablative therapy, or angiographic embolization. External beam radiation therapy may also be effective. Obstruction may be relieved with endoscopic stenting. Pain may be controlled through radiation therapy or pharmacologic means. These other modalities should be explored thoroughly before subjecting the patient to the greater morbidity of surgical resection.

Future Directions

Given the relatively low incidence of gastric cancer in Western countries, it is unlikely that widespread endoscopic screening programs will be adopted. Therefore, earlier detection of gastric cancer remains a challenge. Certainly, the promise of serum biomarkers is an intriguing and less invasive strategy. Noninvasive methods of detection such as protein and nucleic acid tumor markers, circulating tumor cells, and tumor-associated autoantibodies in peripheral blood have shown promise but remain far from widespread clinical application [78].

Though traditional classification systems such as the Lauren and WHO have provided useful prognostic information, they have essentially had little impact in guiding therapeutic decision-making. The promise of a more robust molecular classification, such as the recent efforts by The Cancer Genome Atlas (TCGA) Research Network, will provide molecular insights for better tumor targeting [19].

With these advances, targeted therapies will also be increasingly utilized. As discussed previously, trastuzumab has been shown to improve median overall survival in patients with HER2-positive advanced gastric cancer [74] and is approved as a first-line therapy for patients with HER2-positive advanced gastric cancer. Targeted therapies also hold promise as less toxic alternatives to traditional cytotoxic chemotherapeutics, an especially crucial issue in the elderly population, a population that is more often frail with decreased performance status.

Advances in minimally invasive techniques, including the emergence of robotic technologies, and the more widespread adoption of these techniques will also decrease morbidity associated with surgical resection. In Western countries, increased emphasis on appropriate lymphadenectomy will also be critical for accurate staging and optimal oncologic outcomes.

Finally, in addition to better characterization of tumors and more precise targeting of tumors with systemic therapy, better "targeting" of patients will also be necessary. Gastric cancer is a disease that predominantly impacts the elderly. Strategies for "prehabilitation" and better risk characterization will provide providers and patients with the tools to make better decisions about which patients will benefit from the spectrum of available treatment options.

Conclusion

As the worldwide population continues to age, the global burden of cancer will continue to increase. Though the age-adjusted incidence of gastric cancer has demonstrated an overall decline, the absolute incidence is increasing due to global aging. Appropriate management of elderly patients with gastric cancer will be critical to enhance longevity, optimize quality of life, and decrease the burden that these patients will have on healthcare systems.

Clinical Vignette 1

An 84-year-old physician with a history of an appendectomy and glaucoma, status post corneal transplant, was under endoscopic surveillance for gastritis and mucosal abnormalities over the previous 2 years. His only notable family history was paternal colon cancer at 75 years of age, and he had no personal tobacco or alcohol use history. Biopsies were negative for malignancy as late as 1 month prior to presentation, but on computed tomography (CT) scan, he was found to have antral thickening with corresponding hypermetabolic activity on positron emission tomography (PET). He did endorse early satiety around this time. Further workup with endoscopic ultrasound and biopsy revealed Her2-negative linitis plastica. A D2 total gastrectomy with Roux-en-Y reconstruction was then performed, yielding a diagnosis of signet ring cell carcinoma that was microsatellite stable. It involved the entire stomach and 41 of 42 lymph nodes.

He completed 6 months of adjuvant chemotherapy but 2 months later presented with large bowel obstruction from extrinsic compression of the hepatic flexure (Fig. 5). On laparotomy, a mass in the right upper quadrant adherent to the flexure,

Fig. 5 CT Imaging demonstrates large bowel obstruction at hepatic flexure secondary to recurrent gastric cancer

as well as adhesions and a perforation distal to the initial jejunojejunal anastomosis, was discovered. Peritoneal nodules and ascites were also encountered, the former of which was consistent with metastasis of the original carcinoma. The perforated bowel, also consistent with metastasis on pathologic examination, was resected and the jejunojejunal anastomosis recreated. The mass encroaching on the colon was unable to be resected and was instead bypassed via diverting loop ileostomy.

During this hospital admission, the patient was first referred to palliative care for pain control alone, but on subsequent hospitalizations (for bacteremia from line infection and biliary obstruction requiring percutaneous biliary drain), discussion of hospice care was introduced to him and his family. He went on to complete a further two doses of chemotherapy, and he survived a month and a half after referral to hospice, 5 months after palliative bypass, and 16 months after the initial resection.

This case highlights one of the significant complications of advanced disease in gastric cancer. Peritoneal carcinomatosis is a common site for metastatic disease. Diagnosis and management of malignant bowel obstruction can be a difficult challenge for clinicians, patients, and their families.

Clinical Vignette 2

A frail 73-year-old man with a complex medical history was diagnosed with gastric adenocarcinoma on esophagogastroduodenoscopy (EGD) for hematemesis. He had a history of tissue valve replacements for endocarditis, non-insulin-dependent diabetes, COPD, and iliac aneurysms. He reported previous tobacco and heavy ethanol use.

He required multiple hospitalizations over the next few weeks for repeated hematemesis, severe anemia, poor oral intake, and cachexia. He finally developed aspiration pneumonia bilaterally, and a non-contrasted CT demonstrated a dilated, fluid-filled stomach and esophagus; an 11 cm distal gastric mass extending to the duodenal bulb; lymphadenopathy in the perigastric, porta hepatis, and aortocaval nodes; liver lesions of uncertain character; and pulmonary emboli of unknown chronicity. A contrasted CT further demonstrated thickening of the antrum (Fig. 6).

After a week of conservative management, an upper endoscopy demonstrated benign-appearing lymph nodes that were not biopsied. He was then taken to operating room for palliative laparoscopic loop gastrojejunostomy, placed a few centimeters proximal to the tumor.

Despite a patent anastomosis on swallow study, he failed to demonstrate oral tolerance, and 2 weeks later, he returned to OR for open subtotal gastrectomy with Roux-en-Y gastrojejunostomy. He was staged T3N3bM1 with poorly differentiated signet ring adenocarcinoma, *H. pylori* negative. There were foci of tumor at the distal and omental margins, 24 of 39 lymph nodes were involved, and an excised umbilical hernia sac was also positive for metastatic tumor.

The rest of his prolonged hospital course was notable for pancreatic leak, acute kidney injury, respiratory failure requiring re-intubation, anemia/bleeding on anticoagulation requiring transfusions, catheter and surgical site infections, and pleural effusion requiring thoracenteses. Once

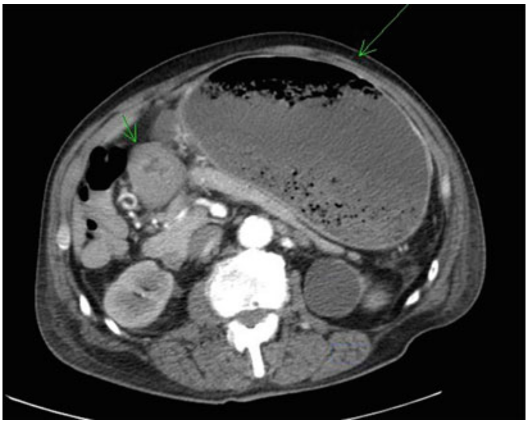

Fig. 6 CT Imaging demonstrates gastric outlet secondary to large gastric antrum malignancy

stabilized 3 weeks after the partial gastrectomy, he was discharged to his local medical oncologist for care.

This case highlights a common problem with gastric cancer in Western countries. Patients frequently present with advanced and symptomatic disease. In this case, the patient presented with gastric outlet obstruction. Despite efforts to palliate this frail, malnourished patient with a lesser operation (from a morbidity standpoint), he ultimately required palliative resection of the tumor.

Esophageal Cancer in the Elderly

48

Manisha Shende and Neha Reddy

Contents

Abstract

Esophageal cancer is the sixth leading cause of cancer-related mortality and the eighth most common cancer worldwide. In 2016, 16,000 new cases of esophageal cancer were diagnosed in the United States. An increasing number of elderly patients are diagnosed with esophageal cancer and subsequently referred for surgical treatment. Operative management of esophageal cancer in the very elderly still remains a subject of controversy. Even with substantial advances in preoperative risk evaluation, surgical technology, intensive care medicine, and nutritional supplementation, the in-hospital mortality and morbidity associated with esophagectomy remains high when compared to other GI malignancies Begg et al. (JAMA 280:1747–1753, 1998). However, recent studies published from high volume centers are showing that carefully selected elderly patients can undergo esophagectomy with postoperative morbidity and mortality rates similar to those of younger patients.

https://doi.org/10.1007/978-3-319-47771-8_62

and history of ongoing nicotine abuse. Preoperative PFTs included FEV1 of 90% predicted and DLCO of 60% predicted. She received neoadjuvant chemotherapy and radiation (45 Gy). Restaging was done with PET scan, diagnostic laparoscopy, and deemed resectable. However, she was very weak and deconditioned and underwent rehabilitation prior to surgery. ECOG score was 2 prior to rehab and 1 afterwards.

Management: She underwent minimally invasive McKeown esophagectomy. She had no surgical complications such as anastomotic leak, bleeding, or recurrent laryngeal nerve injury. She did develop drug resistant pneumonia that required tracheostomy, prolonged ICU stay, and innumerable toilet bronchoscopies. No aspiration could be demonstrated on modified barium esophagram or endoscopy. The conduit was narrow and emptied well. However, she continued to have recurrent pneumonias. She had a hospital stay of 2 months and was still in inpatient rehab 4 months later. CT scan now shows chronic bibasilar fibrotic changes.

This case demonstrates how aspiration and recurrent pneumonia contributes to increased morbidity and potential mortality after an esophagectomy despite careful preoperative evaluation.

Patient 2

Background: 86 year old male was diagnosed with T3 N1 esophageal cancer at an outside institution and treated with definitive chemoradiation. Surgery was not offered due to his advanced age. Unfortunately, 1 year after treatment, at the age of 87, cancer recurred. He was referred for management. He was a healthy man and quite active. Cardiac and pulmonary function testing was within normal limits. Repeat staging showed a T3 tumor.

Management: Patient underwent a minimally invasive Ivor Lewis esophagectomy. Surgery was technically difficult due to extreme fibrotic reaction due to prior radiation. Patient did well but developed a small anastomotic leak which was well contained by the JP drain. He was managed with serial dilations and drain manipulations and leak healed over next 3–4 weeks. Patient had a hospital stay of 3 weeks and was able to be discharged home to a supportive family. His feeding tube was removed at 2 months and patient lived past 90 years of age when he developed malignant pleural effusion and lung metastases.

This case demonstrates that esophagectomy can be accomplished safely in the elderly patient even after radiation treatment, if carefully selected.

Introduction

Esophageal cancer is the sixth leading cause of cancer-related mortality and the eighth most common cancer worldwide. In 2016, 16,000 new cases of esophageal cancer were diagnosed in the United States. It affects 450,000 people worldwide and the incidence is rapidly increasing. Despite trimodality therapy and multidisciplinary approach, the overall 5 year survival ranges from 15% to 25% [1]. Treatment remains challenging and the majority of esophageal cancer cases are diagnosed at advanced stages. Simultaneously, worldwide increase in life expectancy leads to an increased number of elderly patients diagnosed with esophageal cancer and the subsequent referrals for surgical treatment [2]. Based on SEERS database, the median age at diagnosis of esophageal cancer was 67 and most commonly diagnosed among the age group of 65–74 years (Fig. 1) [3].

Squamous-cell carcinoma (SCC) remains the predominant form of esophageal carcinoma worldwide. Countries such as Turkey, northeastern Iran, Kazakhstan, and northern and central China have a very high incidence of esophageal SCC, with more than 100 cases per 100,000 people annually. The incidence of esophageal SCC also remains high in southern and eastern African countries. Tobacco use and alcohol consumption along with low socioeconomic status, poor oral hygiene, and nutritional deficiencies are associated with increased risk of SCC of the esophagus [1].

Over the last few years however, there has been a shift in epidemiology that has been seen in Australia, the UK, the USA, and some western European countries (e.g., Finland, France,

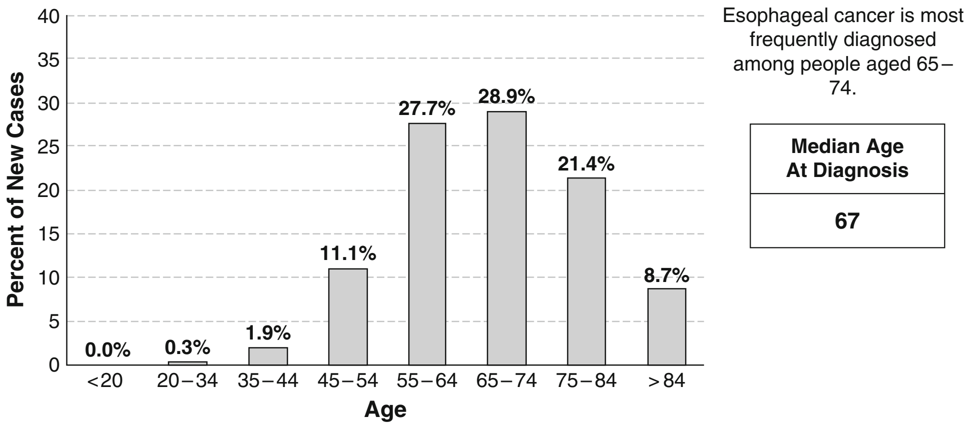

Fig. 1 Percent of new esophageal cancer cases by age group (SEER 18 2009–2013, All Races, Both Sexes)

and the Netherlands), where the incidence of adenocarcinoma now exceeds that of SCC. This major epidemiologic shift is thought to be related to gastroesophageal reflux disease, obesity, and Barrett's esophagus, the dominant risk factors for esophageal adenocarcinoma. The risk of esophageal adenocarcinoma in patients with Barrett's esophagus has been estimated to be in the range of 0.12–0.5% per year. The risk is highest in patients with high-grade dysplasia (HGD) of the esophagus which progresses to adenocarcinoma in 16–59% of patients [1].

According to SEER database, the stages of esophageal cancer at the time of diagnosis are as follows: 20% are localized (confined to the primary site), 31% are regional (spread to regional lymph nodes), 38% have distant spread (metastasis), and 11% are unstaged (Fig. 2). Cancer stage at the time of diagnosis determines treatment options and has a strong correlation to length of survival [4]. Outcomes after treatment of esophageal cancer are suboptimal, with an overall 5-year survival rate of 25.2%; for those in Stage I 94.4%, stage IIa 36%, stage IIb 14.3%, stage III 10%, and stage IV 0% [5].

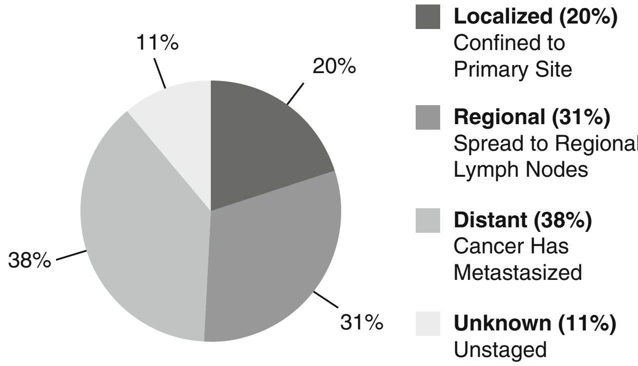
Treatment Options for Esophageal Cancer

Patients with early stage esophageal cancer, staged as T1a lesions, are candidates for endoscopic mucosal resection (EMR) for treatment and potential cure of their disease. T1a lesions have a less than 2% risk of lymph node metastases, making them appropriate candidates for this approach. The incidence of regional lymph node involvement however, increases with the depth of invasion of the cancer; T1b lesions have a reported incidence of 25–30% lymph node involvement. Thus, this group benefits most from surgery with curative intent. Local treatment with EMR in T1b lesions should be considered on a case-by-case basis [6]. Moreover, since the majority of patients present with Stage III cancer, local treatment is a feasible option in only a small number of patients [1, 7].

Operative management of esophageal cancer in the very elderly still remains a subject of controversy. Even with substantial advances in preoperative risk evaluation, surgical technology, intensive care medicine and nutritional supplementation, the in-hospital mortality and morbidity associated with esophagectomy remain high when compared to other GI malignancies [8]. However, recent studies published from high volume centers are showing that carefully selected elderly patients can undergo esophagectomy with postoperative morbidity and mortality rates similar to those of younger patients.

Although there is no well-established cutoff to define a patient as "elderly" for esophageal surgery, 65–75 years has been used for assessing treatment outcome of esophageal cancer in most studies. There are also several studies that examined outcomes in the octogenarians.

Fig. 2 Percent of cases by stage (SEER 18 2006–2012, All Races, Both Sexes by SEER Summary Stage 2000)



Studies examining the relationship of volume and outcome for specific surgical procedures including esophagectomy have demonstrated a consistent improvement in clinical outcomes with increased hospital volumes. High volume center is defined as a hospital doing greater than 20 esophagectomies per year. Analysis of the literature of the last 10 years shows a clear reduction in postoperative mortality with increasing case volumes per year. For a given hospital, an experience of more than 20 esophagectomies per year can lead to a significant reduction of the mortality to 4.9% [9].

It has been demonstrated that when complex surgical oncological procedures are performed in high-volume hospitals (HVHs) with specialty expertise, operative mortality and morbidity is lower [8, 10]. Dimick and colleagues were able to show that pulmonary complications were particularly prevalent at low-volume hospitals (LVHs) [11]. In addition, there is new growing body of evidence to suggest improved patient outcome in high-volume hospitals with specialty expertise irrespective of individual surgeon case volume. Surgeons with appropriate training in esophageal resection may get good results despite lower individual case volumes when a standardized approach is taken in an institution with a high-case volume. In conclusion, to reduce mortality and morbidity of esophagectomy, the procedure should be performed at a high-volume center, by a surgeon who is trained, and where patient care is approached in a multidisciplinary manner. The studies also showed that when complications did occur in HVHs, they were recognized earlier and treated more effectively [12].

There are several different approaches in performing an esophagectomy whether open or minimally invasive: the two main approaches are transhiatal and transthoracic approach. The transthoracic esophagectomy (TTE) approach includes Ivor Lewis esophagectomy, “3-incision” McKeown-type esophagectomy, and lastly, a left thoracotomy or left thoracoabdominal incision. The surgical approach depends on various factors, including the location of the tumor, surgeon preference, and the conduit and route chosen for reconstruction. Large single-institution series have adopted various approaches, but there is no single ideal approach [13].

Visbal and colleagues retrospectively examined 220 consecutive patients from 1992 to 1995 who all underwent an open Ivor Lewis esophagectomy for esophageal cancer. In this study, the operative mortality was 1.4%, and all of the mortalities were secondary to postoperative MI. The overall morbidity was 37.7% and the most common complication being atrial fibrillation at 17.3%, which was followed by pneumonia in 12.3% [5]. Swanson et al. looked at 250 consecutive patients that had undergone a 3-hole esophagectomy. The 30-day mortality was 3.6% (9 patients) with 4 out of 9 patients dying from pneumonia, aspiration, and respiratory failure. The morbidity rate of 33% is similar to the previous study. However, they do report a recurrent laryngeal nerve injury of 14%, which can cause a marked increase in pulmonary problems [14].

Orringer et al. published in 2007 a retrospective analysis of over 2000 transhiatal esophagectomies (THE) performed at a single institution from 1976 to 2006. Orringer observed that the in-hospital mortality, mean blood loss, rate of anastomotic leak, and recurrent nerve injury have significantly decreased overtime. The hospital mortality rate steadily fell as the volume of THE operations increased, averaging 10% from 1978 to 1982 with an average of 23 THE operations annually to 1% since 1998, with more than 100 THE operations annually. Clearly, there has been an evolving refinement in surgical technique and perioperative management of patients undergoing esophageal resection over the years [15].

Lastly, Luketich et al. reported on over 1000 patients who underwent an esophagectomy from 1996 to 2011. MIE-McKeown (neck) was performed in 481 (48%) and MIE-Ivor Lewis (chest) in 530 (52%). The primary approach originally used was a 3-incision McKeown MIE and by 2006 the Ivor Lewis MIE became the preferred approach [16]. In 2002, an additional paper was published from the University of Pittsburgh which specifically looked at mortality and morbidity in 41 patients that were 75 years of age or older [17]. All patients underwent an MIE (neck) from 1997 to 2001 for esophageal cancer. The study showed no increase in incidence of mortality or morbidity in this age group when compared to the younger counterpart.

The overall 30-day mortality, morbidity, and mean age from these studies are listed in Table 1. Mortality rates at high-volume centers ranges from 1% to 3.6%, and mortality rates have improved with time. The reported mortalities are secondary to postoperative MI, progression of respiratory failure, massive aspiration, sepsis, and multiorgan failure from anastomotic leak, ischemic bowel, ischemic conduit, and massive PE. The major morbidity rate, however, is high even at high-volume centers ranging from 17.7% to 37.7%. Major morbidity included in these studies are RLN injury, prolonged respiratory failure, postoperative MI, anastomotic leak, gastric tube necrosis, and chylothorax [5, 14–16].

Each approach to esophagectomy has its own advantages and disadvantages. Patients who underwent THE had shorter duration of surgery and overall less morbidity then compared TTE approach. However, patients that underwent TTE had significantly more lymph nodes resected (improved 5-year disease-free survival, but did not reach statistical significance), better exposure, and safer dissection of the mediastinum [42]. Pulmonary morbidity is increased with TTE approach due to entrance into the chest cavity in addition to the abdominal cavity.

Some recent trials have demonstrated improved survival with neoadjuvant chemoradiotherapy over surgery alone in patients with locally advanced disease. The MAGIC trial randomized 503 patients with gastric or GE junction adenocarcinomas to three cycles each of pre- and postoperative epirubicin/cisplatin/5-FU and surgery alone. There was a significant improvement in overall 5-year survival rate (36% vs. 23%). There were no pathologic complete responders (pCR) in this trial [18]. The low rates of pCRs led to interest in examining the role of radiation combined with chemotherapy in a neoadjuvant fashion. Patients that achieve pathologic complete response consistently achieve increased survival [19]. CALGB trial 9781 randomized patients to two cycles of preoperative cisplatic/5-FU and radiation or to surgery alone. Patients that received neoadjuvant treatment had significantly improved median survival (4.5 vs. 1.8 years) compared with surgery alone [20].

There are several studies looking at differences in outcomes after open versus minimally invasive esophagectomy for the transthoracic approach. Patients who were treated at an academic center or comprehensive cancer facilities were more likely to undergo MIE. Patients who underwent MIE had significantly more lymph nodes examined (15 versus 13; $p = 0.016$) and shorter hospital lengths of stay (10 versus 11 days; $p = 0.046$) but similar resection margin positivity, readmission, and 30-day mortality [21]. MIE was also shown to offer short-term risk reduction in postoperative respiratory complications [22, 23] The TIME trial is the only randomized, prospective, multicenter study comparing traditional transthoracic esophageal resection with minimally invasive resection for esophageal cancer. It was also shown to decrease overall in-hospital incidence of pulmonary infections from 34% to 12%. Thus, MIE can offer a decrease in short-term

Table 1 Outcomes after esophagectomy at four different high-volume centers. Most recent morbidity rates range from 1% to 3.6%; however, the morbidity rates remain high ranging from 17.7% to 37.7%

	Study Date	Surgical Approach	Number of Patients in study	Mean age	Overall 30 day mortality	Morbidity	Anastomotic leak rate	RLN injury	Chylothorax	Gastric Tube Necrosis

and 30-day morbidity from a pulmonary standpoint without significant differences in 30-day mortality when compared to an open esophagectomy [22].

Studies have also looked at outcomes after esophagectomy specifically in the octagenerian group. Elderly patients undergo a more detailed risk assessment prior to surgery given that they may have concomitant cardiovascular and respiratory disease [24]. For example, the inclusion criteria for operating on patients greater than age of 80-years-old were performance status score of 0 or 1, normal cardiac function (abnormal EKG findings or LVEF <55% were considered to have cardiac risk), and acceptable pulmonary function (hx of COPD or FEV < 70% were considered high risk for the surgery) in one study. The study reported a morbidity rate of 25% and a mortality rate of 0%, comparable to that of the younger group [25]. However, other studies without such stringent inclusion criteria reported increase in mortality (8.4 versus 3.8%) and morbidity secondary to nonsurgical complications from cardiovascular and pulmonary disease [13, 26]. Octogenarians were found to have significantly more Stage III disease but received less neoadjuvant therapy than younger counterparts and more likely to undergo transhiatal resection as opposed to transthoracic [27]. Other institutions have showed that patients older than 80 years have age-related increased mortality risk after esophagectomy, independent of comorbidity [28].

Atkins et al. retrospectively looked at records of 379 patients who underwent an esophagectomy at tertiary medical centers between 1996 and 2002. This study was performed to identify prognostic variables that might be used to develop a strategy for optimizing outcomes after esophagectomy. Study concluded that increasing age, anastomotic leak, Charlson comorbidity index of 3, worse swallowing scores, and pneumonia were associated with increased risk of mortality by univariate analysis. However, only age and pneumonia were independently associated with mortality by multivariable analysis. Pneumonia was associated with a 20% incidence of death. Patients with pneumonia had significantly worse deglutition and anastomotic integrity on barium swallow compared to patients without pneumonia. This study has identified pneumonia to be the major factor associated with early death after esophagectomy [29].

The decision whether or not to perform an esophagectomy on an elderly patient with esophageal cancer is often difficult to make and encompasses many immeasurable factors. Although cardiovascular complications are more likely to occur in elderly patients, some authors suggested that advanced age alone should no longer be considered a contraindication to esophageal resection or neoadjuvant therapy in carefully selected patients [24, 43]. Esophagectomy in elderly patients can be performed after an accurate preoperative selection based on evaluation of comorbidities.

The risk of pulmonary complications after esophagectomy is higher than after any other common operation including major lung resection. The reasons for this includes entry into two separate body cavities, disruption of bronchial innervation and lymphatic circulation, placement of reconstructive organ in substernal space, cachexia, RLN injury, and discoordinated deglutition [7].

Pulmonary risk after esophagectomy is predicted on the bases of a number of preoperative factors, including patient age, spirometric values, diffusing capacity, performance status, and diagnosis of COPD [40]. Age and spirometry are objective measurements, and performance status is based on clinical observation which can be easily obtained with brief patient interview. A review of the STS database showed that only 40% of the patients that underwent esophagectomy for cancer had preoperative PFTS. Surgeons need to be encouraged to increase the frequency of ordering PFTS to better risk stratify patients [30]. FEV1 < 65% predicted were associated with prolonged mechanical ventilation and length of stay (LOS) in the ICU and hospital [31].

Geriatric surgery patients have physiologic vulnerability requiring assessment beyond the traditional preoperative evaluation of older adults. In addition to cardiopulmonary testing and comorbidity assessment, frailty and disability are two clinical entities that must be investigated prior to any major surgical resection.

Frailty markers include: advanced age, impaired cognitive function, recent weight loss with BMI $<$ 25, unexplained falls, depression, and anemia. Disability defined as loss of independence in activities of daily living should also be assessed in the office setting. The presence of four or more markers of frailty, dependence in one or more activities, and a high burden of comorbid conditions, was related to 6-month mortality with high sensitivity and specificity [32].

Any preexisting swallowing disorders in the elderly should be teased out in the clinical settings, especially since swallowing disorders are a major cause of pulmonary complications. Bartels et al. developed a composite scoring system to predict the risk of esophagectomy, based on quantitative assessment of preoperatively available physiological parameters. The scoring system was reviewed retrospectively on operated patients and was evaluated prospectively. The study concluded that compromised general status, poor cardiac, hepatic, and respiratory functions are independent predictors of a fatal postoperative course [33].

Intraoperative factors such as increased volume of blood loss, length of operation, use of substernal rather than the posterior mediastinal route for esophageal reconstruction, and the routine use of ventilator support rather than early extubation also have an increase in postop pulmonary complications [41]. Postoperatively, good pain management control (use of epidural analgesia), aggressive pulmonary toileting, and use of bronchoscopy to clear secretions are all important to successfully avoid pulmonary complications [7].

They are high risk for aspiration particularly in the early postoperative period when transient diminished airway protection occurs in 47–67% esophagectomy patients. There should be low threshold for postoperative patients to undergo a formal MBS or fiber-optic endoscopic evaluation of swallowing. Aggressive ongoing therapy with speech is recommended for those patients that do have swallowing abnormalities [29].

More than 50% patients will have incurable disease at diagnosis, either due to advanced disease or poor medical condition [34]. Many modalities of palliation are available for those who cannot undergo an esophagectomy. The goals of palliation are to relieve dysphagia, avoid malnutrition, control pain, and improve quality of life. The palliative treatment that is best suited for the patient is based on the location of the tumor, performance status, and expected survival. Definitive chemoradiotherapy alone may be an acceptable option for patients who have a decent performance status and a contraindication to surgery. A Scandinavian phase III trial of 91 patients randomized between chemoradiation alone or surgery showed no survival difference at median follow-up of almost 52 months [35].

Endoscopic palliative options include placing esophageal stents, laser therapy, and placing feeding tubes. Stents are used extensively to palliate dysphagia because of relatively low cost with wide availability in most institutions. Stents can effectively palliate dysphagia very quickly but are associated with complications such as stent migration, esophageal perforation, aspiration pneumonia, bleeding, and pain. Approximately 30–35% of patients will develop recurrent dysphagia due to tumor over growth or stent migration. In one study of 100 patients who were stented for malignant dysphagia, 85% had immediate relief from dysphagia, 49% had palliation until their death, and 51% required re-intervention [36]. Stents are also useful in the unfortunate patient with fistulous formation to the trachea or surrounding structures. Effective closure of the fistulous opening can be achieved in most patients with an appropriately placed stent [37].

Brachytherapy is another option for palliation of dysphagia. This modality delivers high-dose radiation to the tumor in short periods. The advantages of brachytherapy are that it is cost effective when compared with other modalities and is suitable for frail elderly patients. The disadvantages are the lack of homogenicity in dose distribution of the radiation and approximately 6-week lag time before symptomatic relief of dysphagia is seen [3]. Nonetheless, it offers better long-term control of dysphagia as compared to stenting [38].

Photodynamic therapy, a tissue ablative technique, uses endoscopically delivered light of a specific wavelength to activate a previously administered photosensitizer. Photofrin is quite costly, and it is the most commonly administered photosensitizer. A study of 215 patients showed relief of dysphagia in 85% of patients. Sunburn was the most frequent complication and occurred in 6% of patients [39]. Other complications were perforation, fistula formation, and stricture formation.

Conclusion

Refinement in surgical technique and ICU care has allowed high-volume centers to reduce mortality from esophagectomies to 1–3.6% in the overall population. However, morbidity from the procedure remains high even at centers of excellence. Several studies have shown that complications are diagnosed earlier and treated effectively at high-volume centers compared to low-volume centers. Nonsurgical complications from cardiopulmonary comorbidity contributed to increased mortality and morbidity in the elderly population. Age-associated changes in the cardiovascular, pulmonary, hepatorenal, and endocrine systems lead to a decrease in functional reserve in the older population. Preoperative evaluation in a multidisciplinary team can provide accurate selection of the patients for whom esophagectomy may be feasible at reasonable risk. When the decision of proceeding to an esophagectomy is unclear, the judgment of the multidisciplinary team may be an invaluable opinion to the surgeon. For those patients who are a marginal performance status, we recommend that they undergo for a short-period cardiopulmonary rehabilitation prior to categorizing them as nonsurgical. Many effective palliative options are available for the patient with advanced disease or the inoperable patient.

49 Breast Cancer in Elderly Women

Monica Morrow and Oriana Petruolo

Contents

Abstract

In the setting where breast cancer is the second leading cause of cancer death in American women, and in which the incidence of breast cancer increases with age, herein we review the important issues related to the management of breast cancer in the elderly (defined as those older than 70 years of age), including the impact of age on the value of mammographic screening, the selection of local surgical therapy, the need for adjuvant radiotherapy, the efficacy and toxicity of systemic therapy, and the effect of mortality due to breast cancer in this population.

We conclude that screening mammography in healthy women up to 75–80 years of age appears beneficial, that healthy elderly breast cancer patients should undergo surgery of the primary tumor (excision to negative margins or mastectomy) using standard selection criteria, that sentinel node biopsy is the axillary staging procedure of choice for clinically node-negative women if the finding of nodal metastases would alter treatment, and that axillary dissection remains standard management for patients presenting with clinically evident metastases. We also conclude that good local control is obtained with excision alone and endocrine therapy for T1, estrogen receptor-positive tumors, while radiotherapy should be given for others undergoing breast-conserving therapy.

Introduction

Breast cancer is the most common malignancy in American women aside from skin cancer and the second leading cause of cancer death, exceeded only by lung cancer. It is estimated that there were 231,840 new breast cancer cases diagnosed in the United States in 2015 and 40,290 deaths. In addition to invasive breast cancer, carcinoma in situ (CIS), the earliest form of breast cancer, accounted for about 60,290 new cases in 2015 [1].

The incidence of breast cancer increases with age, and despite competing causes of mortality, breast cancer remains a significant cause of death in elderly women. Cancer is the leading cause of death in those 55–74 years of age and is second only to heart disease in the 75+ age group [2]. As life expectancy increases and the elderly population continues to grow, there will be an increasing number of elderly women diagnosed with breast cancer. Despite the high prevalence of this disease in the elderly, they largely have been excluded or discouraged from participating in clinical trials and often are not given the same therapeutic options as their younger counterparts [2, 3].

The goal of this chapter is to review the important issues related to the management of breast cancer in the elderly. These include age-specific issues regarding the value of mammographic screening, the selection of local surgical therapy, the need for adjuvant radiotherapy, the efficacy and toxicity of systemic therapy, and the effect of mortality due to breast cancer in this population. Because there is no standard definition of "elderly," for the purposes of this chapter, an elderly patient is defined as one older than 70 years of age.

Epidemiology

Breast cancer incidence and mortality increase with age, with the greatest increase observed during the childbearing years. In Western countries, a continued increase in incidence is seen after menopause, whereas in Asian countries, the incidence decreases in elderly women [4, 5]. Approximately one-half of the breast cancers in the United States are diagnosed in women 65 years of age and over. For women in this age group, an age-adjusted incidence rate of 426 cases per 100,000 population was noted in the SEER database [6], compared with 82 cases per 100,000 for women younger than age 65. The age-specific incidence rate for women 85 years of age or older rose to 350 cases per 100,000 population. Although the overall incidence of breast cancer is similar among black women (121.5 cases/100,000 population) and white women (123.6 cases/100,000), differences by age are seen with breast cancer incidence higher among black women <60 years of age but lower among those age 60 years and older compared to white women [7].

Breast cancer incidence rates in the United States increased by 32% from 1980 to 1987 [8]. Since that time, data from the National Program of Cancer Registries (NPCR) and the SEER registries [9] indicate that age-adjusted incidence rates for invasive breast cancer decreased significantly in women 50 years of age and older each year between 1999 and

2003, with the greatest decrease (6.1%) occurring from 2002 to 2003. The largest decreases were seen in women 55–59 years of age (11.3%), 60–64 years (10.6%), and 65–69 years (14.3%). After the sharp decrease from 2002 to 2003, there was no significant change in overall incidence rates in any age group from 2003 to 2007 [10]; however, SEER data showed incidence rates were increasing in women in their 60s and 70s through 2012 [11] (Fig. 1). Rates of in situ breast cancer also stabilized from 1999 to 2003 after increasing by more than 6.6% per year since 1981, with women 50–79 of age years experiencing a significant decrease in incidence during this period [12].

Over the past 25 years, the incidence of in situ carcinoma has increased in association with a decrease in regional disease and a stable metastatic disease rate [8]. Between 1987 and 1997, a decrease in breast cancer mortality was observed in the United States, with a 9% reduction in mortality for those 70–79 years of age. Approximately 50% of this mortality reduction is attributed to screening and 50% to improvements in therapy [13]. Despite the reported decreases in breast cancer mortality, it is important to keep in mind that breast cancer represents the underlying cause of death in 54.5, 37.1, and 30.7% of women aged 60–69, 70–79, and 80+ years, respectively, who are diagnosed with the disease [14].

As in young women, infiltrating ductal carcinoma is the most common histologic tumor type in the elderly, accounting for 77–85% of cases [15, 16]. The relatively favorable subtypes of colloid and papillary carcinoma are observed more frequently in elderly women but still account for less than 10% of mammary carcinomas even in women 85 years of age or older [15–17], whereas inflammatory and medullary carcinoma are seen less commonly in elderly women than in their younger counterparts [16, 17]. Breast cancers in elderly women are more likely to be estrogen receptor positive, and less likely to overexpress HER2, than those in younger women. The proportion of estrogen receptor-positive cancers was 55.9% among women ages 30–34 compared to 85.1% among those ages 80–84 [18].

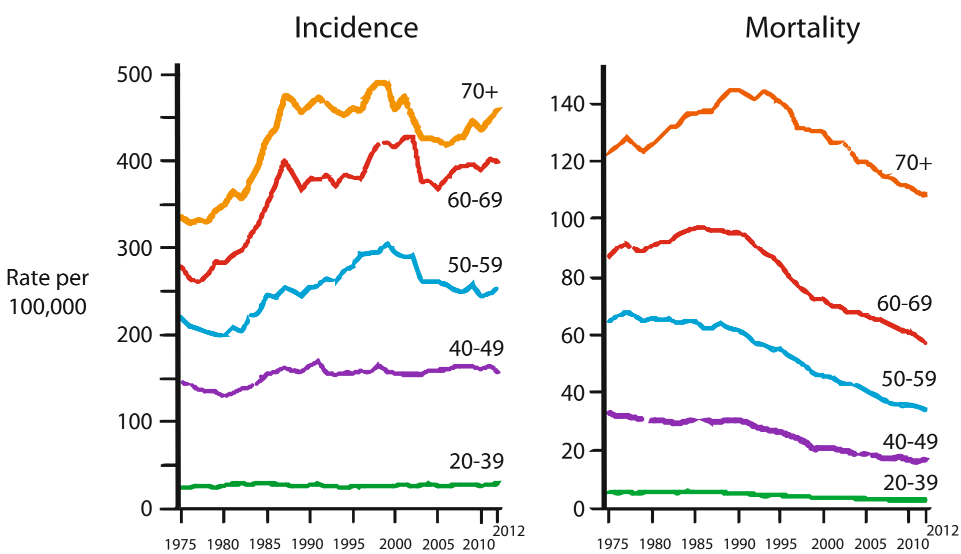

Fig. 1 Incidence and mortality rates of female breast cancer by age from 1975 to 2012. Rates are per 100,000 females and age adjusted to the 2000 US standard population. Incidence rates were adjusted for reporting delay (Republished with permission of John Wiley and Sons Inc, from CA: A Cancer Journal for Clinicians, DeSantis CE et al. Screening

Randomized studies have shown that screening for breast cancer with mammography reduces breast cancer mortality by approximately one-third, especially for women 50–69 years of age at invitation to screening [19–21]. As life expectancy increases, attention has turned to determining an appropriate upper age limit for population-based mammography screening. Current guidelines are vague, indicating that chronological age alone should not be the reason for the cessation of regular screening. Theoretically, screening should be beneficial for women 70 years of age or older, but evidence to support this statement is limited. To date, the only randomized screening trial that included women 70 years of age and older was the Swedish Two-County trial [21]. In this study, 162,981 women 40–74 years of age were randomized to a screening or a control group. A 31% reduction in mortality from breast cancer and a 25% reduction in the rate of stage II or higher cancers were seen in the group invited to screening, and the benefit extended to patients 70–74 years of age.

Van Dijck et al. [22] reported the results of a nonrandomized trial of screening in 6,773 women 68–83 years of age, enrolled during 1977–1978 and followed through 1990. Women from the same birth cohort in a neighboring city without a screening program served as controls. Over the entire study period, the cumulative mortality rate ratio was 0.80 (95% confidence interval [CI], 0.53–1.22) for the screened women; at 9–13 years after the start of screening, it had decreased to 0.53 (95% CI, 0.27–1.04). A subsequent study by Jonsson et al. [23] attempted to evaluate the contribution of screening to decreasing breast cancer mortality in women 70–74 years of age. Breast cancer mortality for both the screened and not-screened groups decreased during the study period, but with a mean screening interval of 22.8 months and a mean follow-up time of 10.1 years, a 24% reduction in breast cancer mortality was estimated in the screened group after adjusting for lead time bias.

In 2000 Smith-Bindman et al. in a study of 690,993 women 66–79 years of age reported that screening mammography was associated with a decreased risk of detecting metastatic breast cancer among elderly women [24]. Taplin et al. [25] retrospectively reviewed data from seven health-care plans dating from 1995 to 1999, comparing women 50 years of age or older who were diagnosed with late-stage (metastatic and/or tumor size $\geq$3 cm; $n = 1{,}347$) or early-stage (control subjects, $n = 1{,}347$) breast cancers. The odds of having late-stage breast cancer were higher among women not undergoing screening (odds ratio [OR] = 2.17, 95% CI, 1.84–2.56; $p < 0.001$); failure to screen was significantly associated with age >75 years (OR = 2.77, 95% CI, 2.10–3.65), as well as lower socioeconomic status.

Mandelblatt et al. [26] used a decision analysis model to determine whether mammographic screening extends life for women 65 years of age and older in the presence and absence of comorbid conditions. Patients were stratified into age groups of 65–69, 70–74, 75–79, 80–84, and 85 years or older. In each age category, women were further stratified into those with average health, those with mild diastolic hypertension, and those with symptomatic congestive heart failure, to determine the effect of comorbid conditions on screening benefit. Screening was found to save lives for elderly women of all ages, although the magnitude of benefit decreased as the severity of the comorbidity increased. For a woman with breast cancer, screening prolonged life 617 days for the woman of average health 65–69 years of age, and 311 days for women in the same age group with congestive heart failure. The prolongations of survival for women older than 85 years in the same health groups were 178 and 126 days, respectively. The cost-effectiveness of annual screening ranged from $13,200 to $34,600 per year of life saved. In comparison, the cost per year of life saved by treating mild to moderate hypertension in the nonelderly is $16,000–$72,000 [26]. These estimates of cost are based on the use of annual screening mammograms. Moskowitz [27] calculated that owing to the longer lead times seen with breast cancer in older women, most of the benefits of screening could be obtained with a 2- to 3-year interval between studies. In a study of women 66–89 years of age, Braithwaite et al. found that biennial versus annual screening was not associated with more adverse tumor characteristics at diagnosis and that the cumulative probability of a false-positive recall was higher among annual than biennial screeners [28].

Boer et al. [29] used a model incorporating the natural history of breast cancer and the known effect of screening to identify the optimum upper age limit for screening. Using a model in which preclinical duration of breast cancer was assumed not to increase after age 65, no upper limit for screening benefit was identified. If the duration of the preclinical phase was "pessimistically" assumed to increase in the elderly, screening up to age 80 was found to be of benefit. In a study of 2,067 million screening exams performed between 1998 and 2000, the overall breast cancer detection rates in the 50–69 and 70–75 age groups were, respectively, 4.2 and 14.2 per 1,000 initially screened women. The referral, biopsy, and detection rates were substantially higher in women 70–75 years of age than in their younger counterparts, and a significant trend toward a smaller tumor size distribution was observed [30]. These findings suggest that mammographic screening is a beneficial technique in the elderly (Table 1) [30].

The U.S. Preventive Services Task Force (USPSTF) changed their guidelines in 2009, recommending that screening mammography in women younger than 50 should be on an individual basis, and biennial screening mammography for women 50–74 years of age [31]. They also noted insufficient evidence regarding the benefits or harms in screening women 75 years or older. The following year, there was a 4% decrease in screening mammography utilization in the Medicare population [32]. Since the publication of these recommendations, results of studies examining changes in screening mammography rates have been mixed [33–35], with some studies showing decreased rates of screening mammography in older women 50–64 [36] and 50–74 [37] years of age, and a continuing decline in rates of screening mammography in women >75 years of age [38, 39]. In the 2016 update of the USPSTF guidelines, it was again noted that the greatest benefit of screening was seen in women 50–74 years of age and that randomized trials including women older than 74 years of age were lacking [40]. A number of studies indicate that breast cancer screening in the elderly, whether by mammography or clinical breast examination, is underutilized. The National Cancer Institute Breast Cancer Screening Consortium [41] reported the results of seven population-based surveys of women 50–74 years of age. In five of the seven studies, the rates of breast screening by mammography and breast examination in the 70–74 years age group were lower than those reported for other ages. This occurred despite the fact that more than 90% of women surveyed had a regular source of medical care.

Table 1 Outcomes of screening in older women

	Age group (years)	
	50–69	70–75
No. of screening exams	1,880,082	187,207
No. of women	18,902	3,429
% Additional imaging	33.9	24.9
% Biopsy	5.1	4.2
Screen detected cancers/1000	4.2	10.3
% In situ	14.8	11.6
% Node neg. (invasive only)	66.3	69.7
Positive predictive value of biopsy	70.0	79.0

Source: Data from Fracheboud et al. [30]

In a prospective cohort study, Malmgren et al. assessed mammography-detected breast cancer in women 75 years of age and older [42]. They found a significant difference in tumor stage between patient- or physician-detected versus mammography-detected cancers; 62% of mammography-detected cancers were stage I, whereas 59% of patient- and physician-detected cancers were stage II and III ($p < 0.001$). Patients with mammography-detected cancer were more likely to have lumpectomies (87%) versus non-mammographically detected cancers (56%) and fewer mastectomies ($p < 0.001$). They also found a significant difference in type of treatment administered ($p < 0.001$), with patients with mammography-detected cancers less frequently having chemotherapy as part of their treatment. With a median follow-up of 6.4 years, when adjusted for age and treatment, mammography detection was significantly associated with decreased breast cancer mortality (hazard ratio [HR] 0.50; 95% CI 0.31–0.82; $p < 0.001$). This supports the potential benefits of continued screening in the elderly age group.

Lack of awareness of breast cancer risk and screening procedures in elderly women contributes to the underutilization of these techniques. Leathar and Roberts [43] identified a lack of knowledge among elderly women about breast cancer, a pessimistic attitude toward disease outcome, and embarrassment about being examined as major barriers to screening. Fox et al. [44] conducted a telephone survey of 724 women 65 years of age and older to assess factors influencing the use of mammography. Only physician recommendation predicted a recent mammogram, with age, race, and health status found to be insignificant factors.

In 2001 data from the state-based Behavioral Risk Factor Surveillance System (BRFSS) and the National Health Interview Survey (NHIS) confirmed that the percentage of women who reported receiving mammography and clinical breast exam within 2 years was lower among older women (56.7% of women 70 years of age and older) compared with younger women (71.1% of women 50–69 years of age). Among both groups, those unable to perform a major activity of daily living were less likely to report receiving mammography within 2 years. Interestingly, most (62.7%) women 70 years of age and older reported having no activity limitation, and only 5.5% reported being unable to perform a major daily activity [45].

In 2007 Field et al. studied women 65 years of age or older when diagnosed with early-stage invasive breast cancer ($n = 1{,}762$). They assessed mammography use during 4 years of follow-up and found that the percentage of women having mammograms after treatment declined significantly during the studied time frame, from 82% in the first year post-treatment to 68.5% in the fourth year of follow-up. Women at higher risk of recurrence (breast conservation without radiation therapy or higher stage) were less likely to have yearly mammograms, as were women without visits to breast cancer surgeons or oncologists, suggesting that underutilization of mammography is a problem for women at all levels of breast cancer risk [46]. Massimino et al. evaluated rates of mammographically detected cancer and benign biopsy rates for follow-up mammograms in elderly breast cancer survivors 80 years of age or older [47]. Four hundred twenty-nine women were included and had a median of four mammograms over a mean 50-month follow-up period. Eighteen women (5.9%) had a local recurrence; 50% detected by mammography alone and 50% by palpation. Of the four contralateral cancers, all were detected mammographically. While the rates of local recurrences and contralateral cancers were low in this subset of patients (0.9%), the risks of mammographic surveillance were minimal, with only a 1.2% benign biopsy rate. These results suggest that annual mammography is not necessary for elderly breast cancer survivors and confirm the need for further studies to determine the most effective follow-up in this population.

Local Therapy of Breast Cancer

What constitutes appropriate local treatment for the elderly woman with breast cancer remains controversial. In the past, when mastectomy was the standard surgical therapy, the major debate in older women centered on dissection of the axillary nodes. The emergence of breast-conserving surgery and sentinel lymph node biopsy as accepted modalities for the local therapy of breast cancer and the development of endocrine therapies such as tamoxifen and the aromatase inhibitors have increased the available options for local treatment in this population. When evaluating therapeutic options, it is important to consider not only the immediate morbidity and mortality of treatment but also the efficacy of the therapy in maintaining local control for the duration of the woman's life. Current options for the local management of breast carcinoma in the elderly include mastectomy, breast-conserving therapy consisting of excision and irradiation, or excision alone, and endocrine therapy.

Mastectomy

Mastectomy remains a common treatment in the elderly patient. A modified radical mastectomy includes removal of breast tissue, the underlying pectoralis fascia, and the axillary lymph nodes. In patients with clinically negative axillary lymph nodes, the modified radical mastectomy has been replaced by total (simple) mastectomy plus sentinel lymph node biopsy, an operative technique that is discussed later in this chapter. The 30-day operative mortality rate of any type of mastectomy is uniformly low, and the procedure is physically well tolerated. Petkke et al. used the National Surgical Quality Improvement Program database from 2005 to 2013 to compare postoperative outcomes in patients older and younger than 80 years of age [48]. They found low rates of morbidity and mortality regardless of age, with a 30-day mortality postmastectomy of 0.3% for those >80 years of age (0.1% for the <80-year-old age group, $p < 0.01$). They observed significantly higher rates of systemic complications such as urinary tract infection and pneumonia in the elderly age group postmastectomy, but these were seen in fewer than 1.5% of patients. In contrast, return to the operating room occurred for 2.3% of patients <80 years of age compared to 2.1% of those ≥80 years of age ($p = 0.57$). Similar results have been noted in other studies, with mortality rates less than 4% commonly observed [49–52]. Davis et al. reported a 3% mortality rate for women 80 years of age or older treated by mastectomy and a 7% incidence of major complications [49]. Hunt et al. in a study of 94 patients reported a complication rate of 20% in elderly patients, but the operative mortality was still only 1% [50]. Wound problems accounted for most of the complications in this series, while Kessler and Seton found cardiovascular and neurologic problems to be the most common cause of postoperative morbidity in their series [51]. Data on the morbidity and mortality of mastectomy in the elderly are summarized in Table 2 [49–56]. In patients with severe comorbidities, mastectomy has been performed using local anesthesia and regional nerve blocks [57]. Mastectomy under local anesthesia alone using the tumescent technique of infiltrating dilute lidocaine with epinephrine (25 ml of 1% lidocaine [250 mg] and 1 ml of 1:1,000 epinephrine [1 mg] in 1 L of Ringer's lactate) via an infusion pump has also been reported [58]. Although mastectomy is an excellent method for obtaining local control of breast cancer with a minimum number of outpatient visits, and although elderly women can undergo the procedure safely, these results are obtained at the expense of cosmesis. Older women are less likely to have a reconstructive procedure postmastectomy compared to younger women [59–61] in spite of studies showing that older age groups do not have significantly higher rates of complications after reconstruction [62, 63]. In et al. examined data from the SEER-Medicare database from 2000 to 2005 on postmastectomy reconstruction rates in women >65 years of age with ductal carcinoma in situ or stage I–II breast cancer. They found that of 19,234 women, only 6% underwent reconstruction and only 2.4% of patients >75 years of age had reconstruction [60]. Oh et al. performed a meta-analysis including 42 studies from eight countries published from 1993 to 2015 evaluating rates of breast reconstruction in women >60 years of age and found a pooled breast reconstruction rate of 6.1% [61]. While it is unclear from these studies whether low reconstruction rates reflect patient preference or the failure of surgeons to discuss the availability of reconstruction with healthy

Table 2 Morbidity and mortality of mastectomy in the elderly

NS not stated

older women, a study from 11 institutions using patient-reported outcomes found that older women reported higher levels of sexual well-being than their younger counterparts after breast reconstruction [62], suggesting quality of life benefits for reconstruction across the spectrum of age.

Breast-Conserving Surgery in the Elderly

Since 1970, multiple prospective randomized trials have compared survival after breast-conserving treatment to survival after mastectomy for stage I and II breast cancer. No survival advantage has been noted for mastectomy. Although most of these trials did not include women older than 70 years of age, the biologic rationale for breast preservation can be extrapolated to the elderly population. Several studies have suggested that elderly women may have a lower rate of breast recurrence after partial mastectomy and radiotherapy than their younger counterparts [64–66]. Fourquet et al. reported a 97% rate of control at 10 years for women older than 55 years of age compared to 85% for women 33–45 years of age and 71% for women 32 years of age or younger in a series of 518 patients [65]. Veronesi et al. [66] and Clark et al. [64] have also reported a decreasing frequency of breast recurrence with increasing age. Some of these differences in local failure rates may be due to a higher incidence of adverse pathologic features, such as an extensive intraductal component or lymphatic invasion in young women, but older women appear to have lower local failure rates even after correction for pathologic features.

In addition, local recurrence rates can be affected by a number of treatment factors, such as the extent of surgical resection, the status of the surgical margin, and the use and duration of adjuvant endocrine therapy. Five years of tamoxifen reduces the relative risk of locoregional recurrence to 0.47 compared to placebo, and the use of aromatase inhibitors alone or in sequence with tamoxifen reduces the relative risk to 0.50–0.83 compared to tamoxifen [67]. Thus, in women treated with breast-conserving therapy, including breast irradiation and endocrine therapy, the incidence of local failure is low, and the small risk of a second surgery is not an appropriate reason to recommend that elderly women routinely undergo mastectomy. The standard contraindications to breast-conserving therapy (Table 3) [68] used to determine the suitability of young women for breast-conserving therapy are applicable in older women as well [68].

High rates of mastectomy in the elderly have been attributed to patient choice. Some studies have indeed shown that breast-conserving therapy is chosen less frequently as age increases [69–71]. In contrast, Bleicher et al. [72] examined the role of age in the surgery decision-making process by surveying 1,279 patients 79 years of age or younger from two SEER program registries. A majority of patients (80.3%) underwent breast-conserving therapy. There were no differences in patient preference for mastectomy on the basis of age, and in a logistic regression analysis, age and comorbidities were not significant predictors of mastectomy use.

The necessity for adjuvant radiotherapy in patients treated with breast conservation is a matter of particular interest in the elderly population. The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) overview of randomized trials included ten trials of post-breast-conserving therapy radiotherapy with a total of 23,500 patients. The main analyses of local recurrence, breast cancer mortality, and overall mortality were stratified by age into five groups (<40, 40–49, 50–59, 60–69, and >70 years of age) [73]. The relative risk of recurrence, comparing those allocated to radiation therapy with those not, was about 0.3 in every trial, corresponding to a 5-year risk of local

Source: American College of Radiology [68] recurrence of 7% in the radiation therapy group versus 26% in the control. The absolute effects of post-breast-conserving surgery radiation therapy on local recurrence were greater in younger than in older women (5-year risk reductions of 22, 16, 12, and 11% for those <50, 50–59, 60–69, and >70 years of age, respectively). The proportional risk reduction for breast cancer mortality was less pronounced than that for local recurrence, with one breast cancer death averted at 15 years for every four local recurrences prevented in year 5. The lower absolute benefit of RT in older women coupled with the long follow-up period needed for mortality reductions to be observed makes it unlikely that RT will have a major impact upon survival in this population [73].

A similar age-related difference in the magnitude of benefit achieved with a boost dose of radiation was demonstrated in a randomized trial by Bartelink et al. [74]. Although the use of a boost resulted in a statistically significant reduction in local recurrence in all age groups, the absolute benefit ranged from 10.4% at 10 years in women <40 years of age to approximately 3% in those older than 60 years of age [74].

Although the value of radiation therapy in the setting of breast-conserving surgery in the general population, and to some extent in elderly patients, has been demonstrated, the argument that older age may be associated with lower rates of recurrence, less aggressive tumor biology, and increased comorbidity has prompted investigation into the need for radiation therapy after breast-conserving surgery in this subgroup of patients. Hughes et al. [75] designed a prospective randomized trial that included 636 women 70 years of age or older who were randomly assigned to receive tamoxifen plus radiation therapy or tamoxifen alone to examine the benefit of radiation therapy in older women with small breast cancers. Eligibility criteria included estrogen receptor-positive clinical stage I (tumor <2 cm, clinically node negative) breast carcinoma treated by lumpectomy. At a median follow-up of 12.6 years, the 10-year rate of locoregional recurrence was 2% in the tamoxifen plus+ radiation therapy group versus 10% in the tamoxifen alone group ($p < 0.001$) [76]. There were no significant differences in the rates of mastectomy, distant metastases, or overall survival between groups [76]. These findings suggest that lumpectomy plus adjuvant tamoxifen is a reasonable treatment choice for women 70 years of age or older with small, estrogen receptor-positive breast cancers. In the PRIME II trial, 1,326 women 65 years of age or older with hormone receptor-positive, node-negative breast cancers <3 cm undergoing breast-conserving surgery and receiving adjuvant endocrine therapy were randomized to either whole breast radiation therapy or no radiation therapy [77]. At a median 5-year follow-up, ipsilateral breast recurrence was 1.3% in the whole breast radiation therapy group and 4.1% in the no radiation therapy group (95% CI 0.2–2.3 and 95% CI 2.4–5.7, respectively). No significant differences in regional recurrences, distant metastases, contralateral breast cancers, new cancers, or 5-year overall survival were seen between groups. These findings mirror those of Hughes et al. [76] discussed above, leading the authors to conclude that in older patients with lower-risk hormone receptor-positive breast cancer, endocrine therapy alone is a safe option.

Practical issues, such as the difficulty in traveling to radiation therapy appointments daily for 6 weeks, play a significant role in the omission of radiation therapy in elderly women, and studies have examined the feasibility of alternative methods of radiation delivery. Hypofractionated whole breast irradiation which allows treatment to be completed in 3–4 weeks rather than the conventional 5–6-week period has been demonstrated in prospective randomized trials to result in local recurrence-free survival and overall survival rates which do not differ significantly from those seen with conventional fractionation (Table 4) [78, 79]. These results support the conclusion that hypofractionation is a safe, more convenient approach for elderly patients requiring radiation therapy. In recent years, hypofractionation has also been used to deliver partial breast irradiation (PBI). PBI is defined as the delivery of radiation to the surgical cavity plus a 1–2 cm margin after breast-conserving surgery. The rationale for PBI is that most local recurrences occur at the primary tumor site or immediately adjacent to it, rather

Table 4 Randomized trials comparing standard and hypofractionated radiotherapy (RT). Long-term follow-up shows no difference in locoregional recurrence rates and no worsening of overall survival rates [78, 79]

Study	Total patients	Median follow-up (years)	RT type[a]	Locoregional recurrence rate[b]	p-value	Overall survival rate[b]	p-value

than elsewhere in the breast. Numerous techniques have been developed to deliver PBI, including interstitial brachytherapy, a single-source balloon catheter brachytherapy, three-dimensional conformal treatment with external beam, and intraoperative treatment (IORT). There are a limited number of studies assessing long-term outcomes after accelerated PBI (APBI). Polgar et al. reported the 10-year results of their single institution trial [80] in which 258 patients with T1N0-1mi breast cancer treated with breast-conserving surgery and axillary dissection were randomized to receive either 50 Gy of whole breast irradiation or PBI with brachytherapy catheters, or electron beam irradiation. At a median follow-up of 10.2 years, the 10-year actuarial local recurrence rate was 5.9% for the APBI group and 5.1% for the WBI group ($p = 0.77$), with no significant difference in overall or disease-free survival. Significantly higher rates of good or excellent cosmetic outcomes were seen in the PBI group, with superior results for those treated with brachytherapy compared to external beam PBI. At William Beaumont Hospital, Wobb et al. conducted a matched-pair analysis comparing 274 patients prospectively followed after treatment with brachytherapy post-breast-conserving surgery to controls treated with WBI matched in a one-to-one ratio [81]. At 10 years, there was no significant difference in the rate of local recurrence–4.2% for APBI and 3.7% for WBI ($p = 0.11$)–or in disease-free survival or overall survival. Long-term outcomes, however, are still limited for most techniques of PBI, and many of the patients selected for PBI were at very low risk for local recurrence in the absence of radiation therapy, raising questions as to whether the favorable outcomes are applicable to a wider spectrum of women with breast cancer. In spite of these concerns, the very brief period of time needed for treatment with PBI (5 days, or on the day of surgery in the case of IORT) makes this an attractive approach for elderly women. Meattini et al. [82] performed a subgroup analysis of the group's previously published phase 3 trial to assess the role of APBI in elderly breast cancer patients. In the initial study, 520 BCS patients with invasive cancer and ductal carcinoma in situ, and a maximum tumor size of 2.5 cm, were randomized to receive either APBI using intensity-modulated radiotherapy technique or conventional whole breast radiation therapy [83].

The subgroup analysis included 117 women 70 years of age or older. Similar to the overall study results, the subgroup analysis showed no significant difference in locoregional recurrence between treatment groups, 3.9% in the WBI group and 1.9% in the APBI group ($p = 0.60$), with no significant difference in disease-free survival. The largest ongoing trial comparing WBI and APBI is the NSABP B39/RTOG 0413 phase III multi-institutional study enrolling patients with ductal carcinoma in situ or stage I–II invasive breast cancer with tumors no larger than 3.0 cm and randomizing to one of several APBI techniques (multi-catheter brachytherapy, balloon catheter, or external beam radiation) or WBI [84]. The results of this study and the long-term results of other randomized studies will provide definitive data on the safety and efficacy of PBI, but existing data indicate that hypofractionated whole breast irradiation and PBI are reasonable options for older women undergoing breast-conserving surgery who do not meet criteria for elimination of radiotherapy or who desire the local control benefit of radiotherapy.

Overall, breast irradiation has been shown to be well tolerated in the elderly population. A tolerance study by Wyckoff et al. demonstrated that radiation dose, duration of therapy, number of treatment interruptions, and toxicities were no different in women older than 65 years of age compared to women less than 65 years of age [85]. When considering whether to omit breast irradiation after limited surgery, it is important to remember that most local failures occur within 6 years of surgery, leaving many elderly women at risk of this occurrence. Irradiation is well tolerated in the elderly population, and chronologic age alone is not an indication for its omission from breast-conserving therapy. However, Schonberg et al. evaluated SEER data from 1992 to 2005 to determine how life expectancy affected treatment for women 80 years of age or older and found that 37% of women with a Charlson Comorbidity Index (CCI) of 3 or greater (72% 5-year mortality) received radiation therapy after breast-conserving surgery although they were unlikely to benefit, indicating a greater need for individualization of therapy [86].

Sentinel Lymph Node Biopsy

The sentinel node is defined as the first lymph node/nodes to receive drainage from a particular cancer and can be identified by lymphatic mapping with a blue dye, a radioactive tracer, or both. Injection of the breast tissue around the tumor, the subareolar space, and the skin overlying the tumor has all successfully been utilized to identify a sentinel node. The success rate for identification of the sentinel node in prospective, multi-institutional studies is greater than 95% and improves with experience [87, 88]. When identified, the sentinel node is an accurate predictor of the status of the remaining nodes in the axilla in more than 90% of cases [87, 89, 90]. In the American College of Surgeons Oncology Group (ACOSOG) Z10 trial, increasing patient age was significantly associated with failure to identify a sentinel node [88], with the failure rate increasing from less than 1% in women less than 50 years of age to 2.7% for those 70 years of age and older ($p = 0.0004$). Others have reported excellent outcomes for sentinel node biopsy in older patients. Gennari et al. reported a sentinel node identification rate of 100% in 241 consecutive patients 70 years of age or older who underwent sentinel node biopsy [91].

In the past, many elderly patients were not offered axillary staging because the complications associated with axillary lymph node dissection were felt to outweigh the potential benefits of the procedure. The sentinel lymph node biopsy technique allows patients with clinically node-negative breast cancer to undergo axillary staging with a significant decrease in morbidity. There are complications associated with the procedure, however. After 6 months of follow-up in the ACOSOG Z10 trial, decreased range of motion was observed in 4% of patients, axillary paresthesias in 9%, and lymphedema in 7%. Although paresthesias were more common in younger women, the incidence of lymphedema increased with age [92]. Thus, it is important to ensure that knowledge of nodal status is important for overall patient management prior to performing a sentinel node biopsy, since excellent outcomes have been reported after observation of the clinically negative axilla in older women.

The International Breast Cancer Study Group conducted a prospective, randomized trial of axillary dissection versus observation in women 60 years of age and older [93]. The median patient age was 74 years, and all patients received tamoxifen. At a median follow-up of 6.6 years, axillary recurrence as a first event was observed in 2% of patients and did not differ between groups. This low rate of axillary failure is particularly noteworthy since most of the study participants did not receive radiotherapy. Differences in quality of life favoring no axillary surgery were present in the first 6–12 months postoperatively, but were minimal with longer follow-up. This study indicates that axillary observation is associated with a low risk of axillary recurrence but that when axillary dissection is necessary, it can be performed with a limited effect on quality of life. The impact of knowledge of axillary nodal status on treatment has been examined, with changes in planned therapy occurring in 14–38% of patients based on knowledge of nodal status [94, 95]. In aggregate, these studies suggest that when knowledge of axillary nodal status will not change therapy, axillary observation is a safe approach. When axillary staging is indicated, sentinel node biopsy is the procedure of choice, and axillary dissection can be safely carried out with acceptable morbidity in patients presenting with clinical nodal involvement and those found to have metastases to the sentinel nodes who are having mastectomy. In clinically node-negative patients undergoing breast-conserving surgery with whole breast irradiation and found to have metastases to 1 or 2 sentinel nodes, 10-year follow-up of the ACOSOG Z0011 trial demonstrated axillary recurrence rates of less than 2% after treatment with sentinel node biopsy alone and no difference in disease-free or overall survival compared to patients randomized to axillary dissection [96], allowing a greater proportion of women to avoid the sequelae of axillary dissection if these results are applied in practice. The morbidity of sentinel node biopsy and axillary dissection is compared in Table 5 [97–99].

Axillary dissection is an effective method for maintaining local control in the axilla with isolated axillary failures seen in only 1–2% of patients after the procedure [100, 101]. Major complications of axillary dissection, including injury or thrombosis of the axillary vein and injury to the motor nerves of the axilla, are uncommon, although significant short- and long-term morbidity are associated with the procedure (Table 5). Of the potential sequelae of the procedure, lymphedema of the arm is potentially associated with the greatest disability. The incidence of lymphedema following axillary dissection ranges from 1.5% to 62.5% [102–105] depending on the definition used, the length of follow-up, the method of detection employed, and the population studied. Several studies have suggested that older age is a risk factor for the development of lymphedema. Pezner et al. [105] noted lymphedema following breast-conserving treatment (including radiation therapy) in 25% of women 60 years of age or older compared to 3 of 46 younger women (7%) ($p = 0.02$). Other studies have failed to identify an association between age and lymphedema [102–104]. Axillary dissection has also been shown to cause pain and decreased upper arm mobility [106], factors that can cause significant functional impairment in women with preexisting limitations due to neurologic disease or arthritis. In patients with microscopic nodal involvement, axillary irradiation is an alternative to dissection to maintain local control [107], but in the presence of clinically evident, histologically confirmed nodal disease, axillary dissection remains the procedure of choice because failure rates after irradiation alone are higher than those seen with surgery in this clinical setting.

Table 5 Comparison of the morbidity of sentinel node biopsy and axillary dissection

Symptom	SN biopsy (%)	Axillary dissection (%)
Pain	8–14	23–72
Paresthesia	2–9	24–85
Decreased range of motion	0–6	18–27
Lymphedema	1–11	7–69

Primary Endocrine Therapy as an Alternative Local Therapy

Because of concerns regarding the morbidity and mortality of conventional surgical therapy for breast cancer in elderly women with comorbid conditions, considerable attention has been given to the use of tamoxifen as a primary treatment. In 2007, Hind et al. reviewed the evidence from randomized trials comparing primary endocrine therapy to surgery, with or without adjuvant endocrine therapy and/or radiation, in women 70 years of age or older [108]. Seven studies were included in the review, three reporting outcome data on surgery versus primary tamoxifen, and four analyzing surgery plus endocrine therapy versus primary tamoxifen. Only one study selected patients on the basis of estrogen receptor status. When comparing surgery alone to primary endocrine therapy, no significant difference in overall survival between interventions (HR 0.98, 95% CI, 0.74–1.30, $p = 0.9$) was noted. One trial [109] reported adequate summary data to show a significant difference in progression-free survival (PFS) favoring surgery (HR 0.55, 95% CI, 0.39–0.77, $p = 0.0006$). In the three trials comparing surgery plus adjuvant endocrine therapy to primary endocrine therapy [110–112], there was a nonsignificant trend in favor of surgery plus endocrine therapy (HR 0.86, 95% CI, 0.73–1.00, $p = 0.06$). Only one trial [111] reported adequate data on PFS to calculate a significant difference favoring surgery plus endocrine therapy (HR 0.65, 95% CI, 0.53–0.81, $p = 0.0001$), and two trials [110, 111] showed a significant decrease in local recurrence favoring surgery plus endocrine therapy (HR 0.28, 95% CI, 0.23–0.35, $p < 0.00001$). These results are summarized in Table 6 [108]. The results of this review are based on a limited number of small studies of variable methodological quality, with significant heterogeneity among studies. Nonetheless, this review demonstrates that primary endocrine therapy is inferior to surgery plus endocrine therapy for the local control of breast cancer in estrogen receptor unselected, medically fit older women, independent of the type of surgery (mastectomy or wide excision alone). The meta-analysis showed no significant difference in overall survival between the two treatments, although one trial showed a small but significant survival advantage for surgery with adjuvant endocrine therapy where follow-up was extended to 13 years [110]. These results suggest that primary endocrine therapy should only be offered to women with estrogen receptor-positive tumors who are not surgical candidates or who refuse surgery. In a cohort of women with reduced life expectancy due to significant comorbid disease, primary endocrine therapy may be an appropriate treatment choice. The ESTEEM trial (Endocrine +/− Surgical Therapy for Elderly Women with Mammary Cancer), a national trial in the United Kingdom, was designed to evaluate selection criteria for the use

Table 6 Primary endocrine therapy for breast cancer

HR hazard ratio; *EORTC* European Organization for Research and Treatment of Cancer; *CRC* Cancer Research Campaign; *GRETA* Italian Cooperative Group of primary endocrine therapy and hopefully clarify the indications for its use [108]. The trial included patients 75 years of age and older with operable estrogen receptor-positive breast cancer randomized to primary endocrine therapy with anastrozole or surgery and adjuvant anastrozole. Unfortunately, these questions were not answered, as the trial closed early due to failure to recruit, an issue that has been seen with several other studies attempting to address management controversies in this age group [113].

Systemic Therapy

The majority of older women have hormone receptor-positive breast cancers and will receive adjuvant endocrine therapy.

Tamoxifen is well established as an effective endocrine therapy for postmenopausal, estrogen receptor-positive women with node-positive or node-negative breast cancer. The 2005 update of the meta-analysis by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) [114] demonstrated that only for estrogen receptor-positive disease, adjuvant tamoxifen reduced the annual breast cancer death rate by 31% in all age groups (50, 50–69, and >70 years) and that the absolute risk reduction after 5 years of tamoxifen was found to be similar for younger and older women [114]. The EBCTCG found similar results in a meta-analysis assessing the relevance of breast cancer hormone receptors on the efficacy of tamoxifen [115], which showed that even in marginally estrogen receptor-positive disease (10–19 fmol/mg cytosol protein), there was a substantial recurrence reduction (rate ratio 0.67 [SE 0.08]) in estrogen receptor-positive disease which was independent of progesterone receptor status, age, nodal status, or use of chemotherapy.

Adjuvant therapy with tamoxifen for 5 years was the standard of care for women with early-stage, endocrine-responsive breast cancer for many years [114]. However, the partial estrogen agonistic activity of tamoxifen and other selective estrogen receptor modulators (SERMs) increases the risk of endometrial cancer and thromboembolic events [116]. Aromatase inhibitors (AIs) are an alternate form of endocrine therapy that profoundly reduce the already low-circulating endogenous levels of estrogens in postmenopausal women by blocking the synthesis of estrogens in non-ovarian tissues, including breast tissue [117]. AIs have been shown to prolong disease-free survival compared to tamoxifen. The EBCTCG conducted a meta-analysis of randomized trials comparing AIs to tamoxifen in early breast cancer [118] and demonstrated that in a comparison of 5 years of AI versus 5 years of tamoxifen, recurrence rate ratios were better for AIs during years 0–1 after surgery (recurrence rate ratio 0.64, 95% CI 0.52–0.78) and years 2–4 (recurrence rate ratio 0.80, 95% CI 0.68–0.93) with no significant differences after 5 years. The 10-year breast cancer mortality with AIs was 12.1% compared to 14.2% with tamoxifen ($2p = 0.009$). In an aggregate evaluation of all comparisons of AIs versus tamoxifen, including switching strategies between tamoxifen and AI in sequence, recurrence rate ratios significantly favored AIs during periods when treatments differed (recurrence rate ratio 0.70, 95% CI 0.64–0.77) and breast cancer mortality was reduced for all time periods combined compared to treatment with tamoxifen alone (recurrence rate ratio 0.86; 95% CI 0.80–0.94; $2p = 0.0005$) [118]. However, the side effect profiles of the AIs and tamoxifen differ, with AIs being associated with an increased risk of osteoporosis, bone fractures, and musculoskeletal complaints; and tamoxifen with an increased incidence of venous thrombosis, endometrial cancer, and cataracts. Crivellari et al. [119] investigated whether the observed effects of letrozole compared to tamoxifen identified in the Breast International Group (BIG) 1–98 trial differed by age to determine whether treatment recommendations should be modified for elderly patients. In the elderly, letrozole significantly improved disease-free survival and was effective in reducing relapses, including distant metastases, when compared to tamoxifen; even though no convincing differences were observed in thromboembolic or cardiac events in the elderly group, data in the older (64–75 years of age) cohort indicated that thromboembolic events appeared more common with tamoxifen, and cardiac events appeared more common with letrozole. Letrozole was also associated with a higher incidence of bone fractures, independent of age [119]. In an update of the BIG 1-98 trial at 8 years median follow-up, letrozole monotherapy continued to show significantly better disease-free survival, overall survival, distant recurrence-free interval, and breast cancer-free interval than tamoxifen, whether by inverse probability of censoring weighting or by intention-to-treat analysis [120]. They found that sequential treatments involving tamoxifen and letrozole did not improve outcome compared with letrozole monotherapy and concluded that use of a sequence might be a reasonable option for patients with risk factors or treatment intolerability that make letrozole contraindicated. The choice between an AI and tamoxifen in the individual patient is often made on the basis of preexisting conditions, such as the presence of significant osteoporosis or a history of deep venous thrombosis, which would influence the risk/benefit ratio of one of the drugs. A follow-up study by Chirgwin et al. assessing adherence to tamoxifen and letrozole in the BIG 1-98 cohort found that older age and sequential treatments were both associated with decreased adherence to treatment, leading to reduced disease-free survival [121]. This should be taken into account during patient education and in developing an optimal treatment regimen.

There is considerable controversy regarding the use of adjuvant chemotherapy in elderly women. The EBCTCG overview [114] only included about 1,200 older women in trials of chemotherapy versus no chemotherapy, making it difficult to draw firm conclusions about efficacy, although the proportional reductions in recurrence and death were smaller in older women than in their younger counterparts. A retrospective review of randomized trial data indicated similar reductions in breast cancer mortality from regimens containing more versus less chemotherapy in older and younger women, but toxicity, including treatment-related mortality, was higher among older women [122]. Chemotherapy is an appropriate treatment for many elderly patients with early breast cancer, but its use requires careful consideration of life expectancy, comorbidity, functional status, and other factors. Unlike endocrine therapy, toxicity can be substantial with a major effect on functional status. Hospitalization rates of 13–24% in women older than 65 years of age receiving various common adjuvant chemotherapy combinations were reported in one retrospective study [123]. For healthy elderly women with hormone receptor-negative tumors and life expectancies of at least 5 years, chemotherapy should be considered for node-positive patients and high-risk node-negative patients. In an effort to reduce the toxicity of treatment, Muss et al. compared the efficacy of oral capecitabine in patients older than 65 years of age to standard chemotherapy (cyclophosphamide, methotrexate, fluorouracil [CMF] or doxorubicin, and cyclophosphamide) and demonstrated that capecitabine was inferior to standard therapy [124]. Similarly, von Minckwitz et al. conducted a randomized study comparing epirubicin, cyclophosphamide (EC), or CMF versus nab-paclitaxel plus capecitabine for non-frail elderly patients [125]. At a median follow-up of 22.8 months, they found no survival differences; however, they noted a significantly more frequent discontinuation of treatment with nab-paclitaxel.

Systemic therapy includes endocrine therapy, chemotherapy, and, more recently, HER2 directed therapy. Trastuzumab combined with chemotherapy significantly improves survival in HER2 positive patients compared to treatment with chemotherapy alone [126, 127]. Cardiac toxicity, reversible in most cases, is a major side effect of trastuzumab, and its incidence increases with age and anthracycline use [128]. Elderly patients with HER2 positive tumors at high risk for recurrence should be considered for non-anthracycline trastuzumab-containing regimens such as docetaxel, carboplatin, and trastuzumab (TCH) if cardiac toxicity is a concern [129]. In a further attempt at reducing toxicity in lower-risk patients, a single-arm trial with one-third of enrolled patients 60 years of age and older examined the use of trastuzumab and weekly paclitaxel in predominantly stage I HER2 positive breast cancer and reported a 2% risk of recurrence at 4 years median follow-up, and a low rate of adverse events [130].

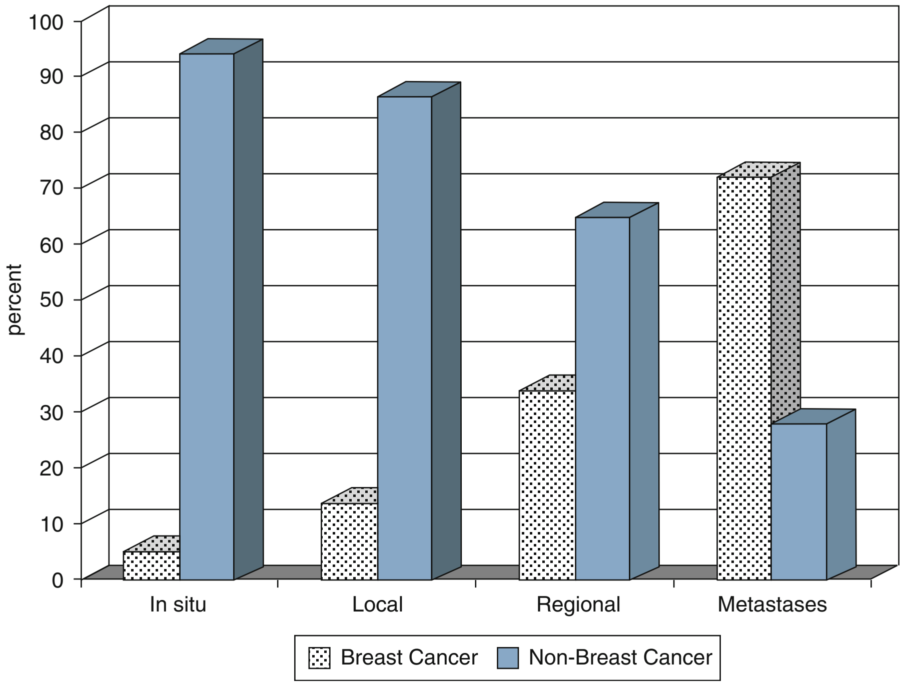

Fig. 2 Causes of death (breast cancer vs non-breast cancer) by stage at diagnosis in women aged 70 years and older at diagnosis (From Schairer et al. [132])

The decision to use adjuvant systemic therapy in elderly women must take into consideration coexisting morbidities and functional status; these may affect a woman's ability to tolerate breast cancer treatment and may decrease survival, regardless of age. The effects of comorbidity on survival can be reliably estimated from mathematical models that are publicly available [131]. This is important in view of the fact that non-breast cancer causes of death are substantial in women 70 years of age and older, even in those with axillary nodal metastases [132] (Fig. 2).

Additional clinical trials are needed to answer questions concerning the risks and benefits of adjuvant therapy in elders.

Breast Cancer Survival and Patterns of Care in the Elderly

In spite of having more biologically favorable tumors, older age at breast cancer diagnosis has been associated with significantly worse breast cancer-specific survival. Chen et al. studied 133,057 women diagnosed with breast cancer between 2004 and 2008 and reported to the Surveillance, Epidemiology, and End Results (SEER) registry [133], including 32,147 70 years of age and older. In multivariate analysis, age over 60 years was an independent predictor of poor prognosis with an HR of 1.46 (95% CI 1.37–1.56, $p < 0.0001$) for death due to breast cancer compared to patients less than 40 years of age. This finding has been confirmed in other studies [18, 134]. Even among women with stage I breast cancer, the adjusted HR for death from breast cancer among those 90 years of age and older was 2.6 compared to those 67–69 years of age [135]. A number of studies suggest that age-related undertreatment may account for the seeming paradox of more favorable biology and poorer survival.

Owusu et al. [136] investigated whether the observed age-related disparities in breast cancer survival were related to differences in treatment received by evaluating 659 women 65 years of age or older with early breast cancer. Women older than 75 years of age were less likely to receive axillary lymph node dissection, radiotherapy, definitive primary therapy, chemotherapy, and guideline-specified therapy. In patients receiving guideline-specified therapy, no age-related differences in breast cancer-specific survival were noted, but 5-year breast cancer-specific survival for those >75 years of age who did not receive guideline-specified therapy was 83% compared to 95% and 94% for those 75 years of age or younger who did and did not receive guideline-specified therapy, respectively. Findings from this study indicated that as many as 66% of women >75 years of age and 45% of women 65–75 years of age received less than guideline-specified therapy. Van de Water et al. retrospectively analyzed patients with early-stage breast cancer from the Netherlands Cancer Registry either less than 65 years of age, or 75 years of age or more, to assess adherence to treatment guidelines for breast and axillary surgery, radiotherapy, chemotherapy, and endocrine therapy in the two age groups [137]. They also found that patients 75 years of age and older were less frequently treated in concordance with guidelines compared to those <65 years of age (55.6% versus 62%, respectively, $p < 0.001$) but did not demonstrate an association with adherence to the guidelines and overall survival in either age group.

Healthy Versus Frail Elderly Patients

Almost 30% of all invasive breast carcinomas occur in women older than 70 years of age [138]. By the year 2030, an even larger portion of breast cancer patients will be 65 years of age or older, and many will be affected by comorbid conditions. In a study of 184 women 65 years of age or older with newly diagnosed, nonmetastatic breast cancer, approximately 1 in 5 declined and/or died within 12 months of breast cancer diagnosis. In multivariable analysis, an increasing score on the vulnerable Elders Survey and having a high school education or less were independent predictors of functional decline or death [139]. These results emphasize the importance of distinguishing healthy from frail elderly patients and the need for clinical tools that guide clinicians when planning care. The following principles have been proposed for the management of frail elderly women. The benefit of screening mammography in these patients is questionable, and a clinical breast exam is likely to identify breast cancers that warrant intervention. Endocrine therapy may be a reasonable primary therapy in older, frail women with hormone receptor-positive lesions. For estrogen receptor-negative and progesterone receptor-negative lesions, excision of the primary tumor may be adequate. Adjuvant endocrine therapy may be appropriate in frail elders with high-risk hormone receptor-positive breast cancer; chemotherapy is rarely indicated regardless of tumor status. The majority of frail elders with metastases will have hormone receptor-positive breast cancers, and endocrine therapy should be considered; those with receptor-negative tumors may be treated with single-agent chemotherapy or supportive care measures. Oncologists need to acquire the skills to appropriately identify frail elders so that they select appropriate therapies that will minimize toxicity and maintain quality of life.

Finally, when considering healthy elderly breast cancer patients, the data included above suggest that compliance with evidence-based recommendations for definitive locoregional treatment, usually defined as breast surgery with evaluation of the axillary lymph nodes and radiation therapy in patients undergoing breast-conserving procedures, is warranted. Tailoring of these recommendations based upon studies specific to elderly patients may include elimination of sentinel node biopsy when results will not change adjuvant therapy recommendations, and omission of radiotherapy in patients with stage I, estrogen receptor-positive cancers receiving endocrine therapy. Standard guidelines for adjuvant systemic therapy, including chemotherapy, should also be utilized in this group [140].

Conclusion

The important issues regarding breast cancer management in the elderly (defined as those older than 70 years of age) are the impact of age on the value of mammographic screening, the selection of local surgical therapy, the need for adjuvant radiotherapy, the efficacy and toxicity of systemic therapy, and the effect of mortality due to breast cancer in this population.

Here we conclude that screening mammography, while not indicated in frail elders, appears beneficial in healthy women up to 75–80 years of age and that healthy elderly breast cancer patients should undergo surgery of the primary tumor (excision to negative margins or mastectomy) using standard selection criteria. We also conclude that sentinel node biopsy is the axillary staging procedure of choice for clinically node-negative women if the finding of nodal metastases would alter treatment, that axillary dissection remains standard management for patients presenting with clinically evident metastases, and that good local control is obtained with excision alone and endocrine therapy for T1, estrogen receptor-positive tumors (while radiotherapy should be given for others undergoing breast-conserving therapy).

Regarding breast cancer management for frail elders, primary endocrine therapy (tamoxifen or an aromatase inhibitor) is the appropriate management of hormone receptor-positive breast cancer. In the rare frail elderly patient with a hormone receptor-negative tumor, excision alone may be the appropriate therapy.

Case Study

Background

An 80-year-old wheelchair-confined diabetic female is s/p right above the knee amputation after failed bypass grafting, and s/p 2 myocardial infarctions, most recently 3 years ago. She is not felt to be a candidate for revascularization. Her ejection fraction is 20%. She has occasional chest pain at rest. She also has an 80 packs per year smoking history, moderately severe arthritis, and mild dementia. She is managed by an endocrinologist, a cardiologist, her family doctor, and a rheumatologist. Her family doctor obtains a screening mammogram which demonstrates a 1.0 cm spiculated mass in the upper outer quadrant of the right breast. Breast exam is normal and there is no adenopathy.

Management

This patient is highly unlikely to have her life prolonged by the detection of this cancer prior to the development of a palpable mass. Ideally, she would never have had a screening mammogram. Since she did, optimal management would include obtaining an ultrasound (US) to see if the mass is visible by US. If yes, an US-guided core biopsy would be far more comfortable for the patient than lying prone, with her breast in compression, for a stereotactic biopsy. The core biopsy demonstrates a grade II, strongly estrogen receptor- and progesterone receptor-positive, HER2 negative infiltrating ductal cancer. This patient is an appropriate candidate for primary endocrine therapy with tamoxifen or an aromatase inhibitor. Although removal of the primary tumor optimizes local control, in her case this would entail localization prior to surgery, which would require her cooperation, as would a procedure done under local anesthesia. Her cardiopulmonary status places her at significant risk for general anesthesia. There is no indication for sentinel node biopsy since the identification of nodal metastases would not change her management. She should be followed with clinical breast exam. If a palpable mass develops in the breast, then surgical excision is warranted.

Abstract
Small bowel obstructions may occur in patients of any age; however, the underlying cause and management may differ in the elderly population.

Keywords
Small bowel obstruction · Elderly · Hernias · Adhesions · Strangulation · Large bowel obstruction · Frailty · Biologic barriers · Nasogastric decompression · Malignant obstruction · Lysis of adhesions

Case Study 1

An 82-year-old female presents to the emergency department with acute onset of right lower quadrant abdominal pain, nausea, and vomiting beginning 8 h prior to presentation. She notes the pain began as nagging, but has steadily worsened. She states she has no significant surgical history. Medical history is significant for hypertension and hyperlipidemia. Her white blood cell count is 16,000, while her creatinine is elevated to 1.6 from her baseline of 0.7. Physical examination demonstrates a distended abdomen with rebound and guarding, as well as an incarcerated hernia in the right femoral canal.

Background

In the elderly patient presenting with obstructive symptoms, and no previous surgical history, the cause of obstruction is likely either from malignancy or hernia. Physical examination may reveal the inciting herniation, though many patients will undergo CT of the abdomen and pelvis in the emergency department. Physicians should take particular attention to look for incarcerated femoral/obturator hernias in the elderly, female patient. The patient's worsening pain, peritoneal signs, and elevated white blood cell count are likely signs of possible strangulation and require emergent surgical intervention.

Management

Nasogastric decompression should be initiated due to the patient's significant symptoms. Fluid resuscitation and correction of electrolyte abnormalities should be initiated after initial assessment of the patient. If physical examination did not reveal the source of obstruction, then CT imaging is warranted. In this patient, the biggest concern is strangulated bowel, considering the examination and laboratory findings. The patient will require emergent surgery after appropriate resuscitation.

Case Study 2

A 76-year-old male presents with a 2-day history of worsening nausea, vomiting, and abdominal distention. He states the symptoms began suddenly, but have slowly worsened. He began vomiting prior to coming to the emergency department. His last bowel movement was 2 days ago and most recently passed flatus in the early morning. He notes a past medical history of type 2 diabetes, hypertension, and a surgical history significant for an open right hemicolectomy 10 years prior for a colonic neoplasm, which required no further treatment. He is distended, tympanic to percussion, and tender on palpation diffusely, but has no rebound or guarding on abdominal exam. A CBC sent by the emergency department physician demonstrates a WBC count of 10.

Background

Adhesions remain the most common cause of small bowel obstruction in the elderly patient, despite increased risk of obstruction from other etiologies. In this patient with prior open surgery, obstruction secondary to adhesions should be considered. A full history, physical, and diagnostic testing will likely reveal the cause.

Management

This patient should undergo imaging to aid in diagnosing the cause of his obstruction. Fluid resuscitation and nasogastric decompression will be the first steps toward managing this patient's obstruction, as he currently does not show signs that would point toward urgent need for operative intervention. CT will likely reveal a discrete transition point, and in many cases NG tube decompression may be potentially curative.

Introduction

Small bowel obstruction (SBO) is a common surgical entity that can occur at any patient age. Although the general principles of diagnosis and treatment of SBO has remained consistent across all age groups, recent shifts in both incidence and etiology among patients of more advanced years now requires focused treatment considerations [1]. Historically, the classical dilemmas associated with management of SBO has remained steadfast for the elderly and include (1) differentiating strangulated from nonstrangulated SBO, (2) delineating ileus from SBO, and (3) determining optimal duration of nonoperative management for partial SBO. Indeed, a better understanding and approach to these clinical scenarios is especially pertinent for the elderly due to their increased risk for perioperative morbidity and mortality [2].

No current data suggests much change in the primary etiologies of SBO, which remain adhesions, neoplasms, and hernias [2, 3]. Likewise, standard operative management still includes an "open" exploratory approach along with adhesiolysis, herniorraphy, enteric bypass, and/or bowel resection. Importantly, advances in clinical imaging (e.g., multidetector computed tomography or MDCT) and biotechnology now provide more effective modalities for accurate detection as well as preventative measures for reducing recurrence of SBO following major abdominal surgery, ultimately leading to better patient management and outcome.

This chapter will focus on fundamentals for approaching the assessment and management of SBO in the geriatric population. Operative versus nonoperative management in the elderly will be addressed. This review will also highlight the important pathophysiology of adhesion formation and resultant SBO as well as current data supporting patient selection and minimally invasive approaches for the treatment of this disease. Moreover, operative intervention and developments in preventative measures, e.g., biological barriers, will be discussed. Throughout, an algorithmic, evidence-based approach for the evaluation and appropriate therapeutic management will be emphasized.

Epidemiology

Geriatric persons are now the largest growing segment of our population, with the number of persons 65 years of age and older more than doubling by the middle of this century, to approximately 80 million [4]. What remains problematic is accurately determining the incidence of SBO among this cohort. Previously, patient statistics were derived from population-based samples, primarily through national hospital-based discharge registries predicated upon imprecise coding schema for SBO, now seemingly more standardized in the International Classification of Diseases (ICD-10 CM) [5]. Therefore, current data likely reflect an underestimation of this escalating clinical problem.

Nevertheless, recent trends in aging have shown that patients 65 years of age and older make up 38% of all hospital discharges accounting for nearly 43% of in-patient care days. These rising figures remain in accord with overall age-adjusted national rates of hospitalization for intestinal obstruction occurring in 44.8 per 10,000 [4]. Similarly, census data based upon National Health Statistics, published in 2011, reported an increasing rise in intestinal obstruction with advancing age (Fig. 1) [6].

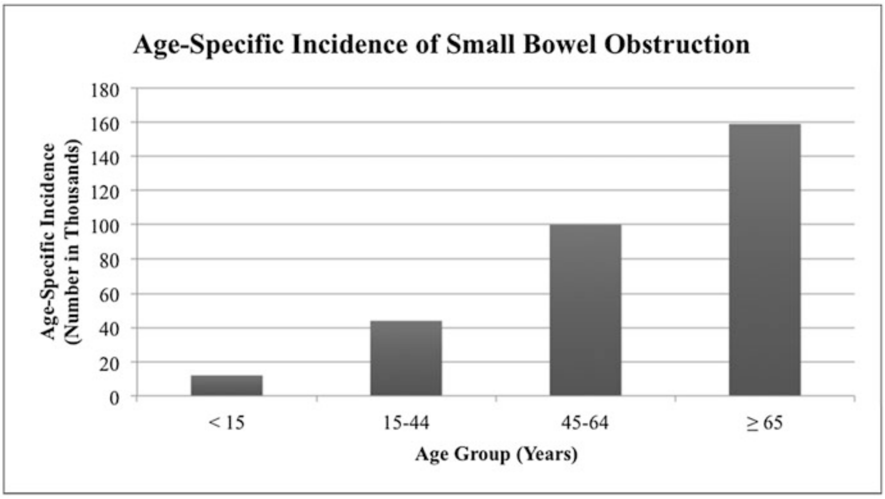

Fig. 1 Age-specific incidence of small bowel obstruction (From the National Center for Health Statistics, 2010)

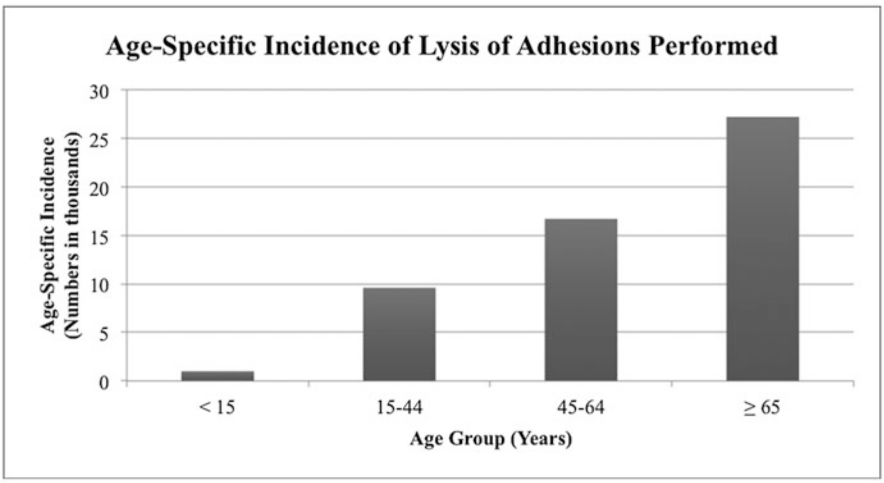

Fig. 2 Age-specific incidence of patients that underwent lysis of adhesions (From the National Center for Health Statistics, 2010)

Moreover, as small bowel obstruction increases with age, so also does the rate of reported operative procedures (lysis of adhesions, only) performed on elderly patients (Fig. 2), as well as a small increase in length of stay (Fig. 3) [6]. However, more concerning is the age-specific mortality rate due to vascular disorders and obstruction of the intestines (without hernia) derived from the National Center for Health Statistics, demonstrating age-specific increase in death rates, especially among individuals over age 75 (Fig. 4) [7].

Etiology-Specific Considerations in the Elderly

To predict the etiology of SBO and direct its treatment, it is first useful to classify SBO using several defining characteristics. Upon initial presentation, the degree of luminal obstruction should be described as either partial or complete. Equally important is *where* along the axis of the small bowel does the obstruction occur (e.g., proximal, mid, or distal). Underscoring the

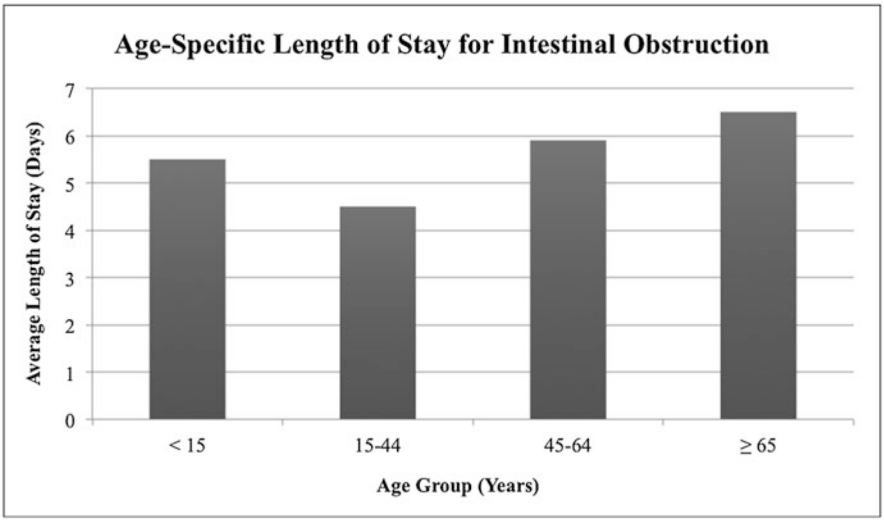

Fig. 3 Age-specific length of hospital stay for patients with admitting diagnosis of intestinal obstruction (From the National Center for Health Statistics, 2010)

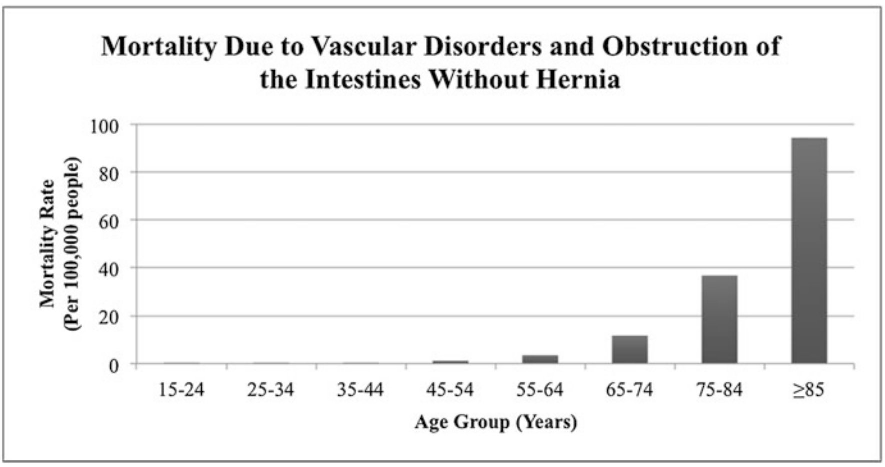

Fig. 4 Age-specific mortality rates of patients with diagnosis of "vascular disorder and obstruction of the intestines without hernia" (From the National Center for Health Statistics, 2007)

importance of these descriptors is the clinical scenario of the worrisome "closed"-loop obstruction where two areas of complete obstruction prevent axial flow of intestinal contents from the involved bowel loop in either direction. Similarly, structures causing obstruction can also be classified by their anatomic location as they relate to the perpendicular axis of the bowel. These structures may be either extrinsic and/or intrinsic to the bowel wall [8–10], both capable of comprising the entire lumen. Table 1 depicts some of the more common etiologies for SBO, keeping in mind that increasing age is a risk factor for most [11].

By definition, mechanical bowel obstruction is an abnormal decrease in the caliber of the involved bowel such that the passage of liquid or solid intestinal contents is impeded. In the majority of cases, SBO starts out as a simple mechanical obstruction with adequate blood supply to the intestinal wall such that the bowel remains viable. However, SBO can progress to strangulation where local bowel ischemia occurs either by direct compression of the affected segment by the obstructing lesion or by extreme dilation and increased pressure in the bowel just proximal to the obstruction, leading to mesenteric occlusion and diminished vascular perfusion.

Table 1 Common etiologies of small bowel obstruction in the elderly

Extrinsic causes
Postoperative adhesions
Hernias Inguinal, femoral, obturator, umbilical, ventral, internal
Malignancy Mass effect, peritoneal metastases
Volvulus
Intrinsic causes
IBD Crohn's disease, ulcerative colitis
Small bowel malignancy Primary, metastatic
Radiation enteritis/stricture
Bowel wall abscess/hematoma
Intraluminal obstruction
Gallstones
Fecal impaction
Bezoars
Foreign bodies

By comparison, the etiology and pathophysiology of large bowel obstruction (LBO) is considerably different from those of SBO, due to the mostly retroperitoneal nature of the large bowel, its relatively short mesentery, along with the competency of the ileocecal valve. Indeed, both types of obstruction occur frequently in the elderly, but nearly 80% of intestinal obstruction involves the small bowel, the predominant cause of obstruction in the elderly being due to adhesions from prior abdominal surgery [12]. Thus, emphasis of this chapter will focus on the pathophysiology, management, and measures to prevent intra-abdominal adhesions. Figure 5 illustrates the incidence of the three most common causes of SBO in the elderly – postoperative adhesions, neoplasms, and hernias – again all have increasing prevalence in the elderly population [10].

Adhesions

More than 90% of abdominal adhesions develop after surgery [13, 14]. The formation of adhesive bands following surgical manipulation is a dynamic process that can occur within several days after surgically traumatized tissues appose one another. Under normal circumstances, following nonsurgical traumatic injury, an inflammatory

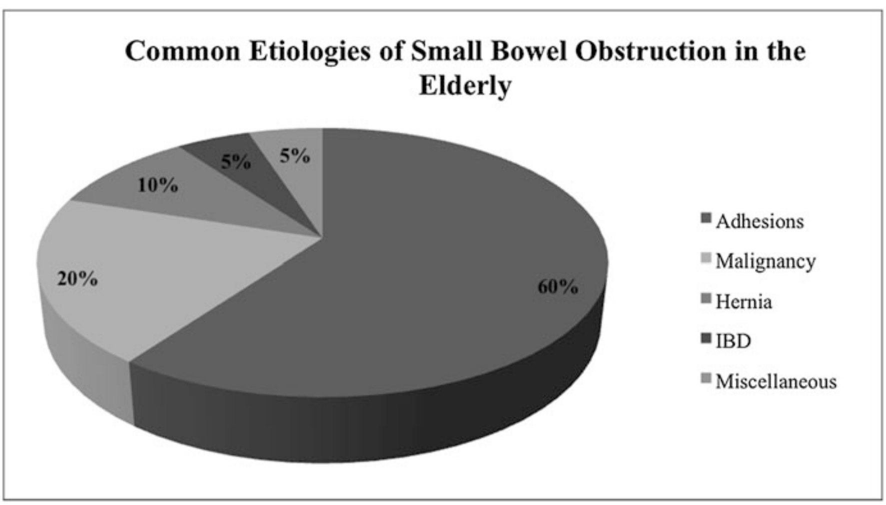

Fig. 5 Percentages of the most common causes of small bowel obstruction in the elderly

response ensues with recruitment and release of proinflammatory cells and cytokines (e.g., interleukin-1) along with activation of the coagulation cascade resulting in the deposition of a fibrinous matrix between apposing tissue surfaces. This fibrin matrix consists primarily of polymorphonuclear cells (PMNs), macrophages, eosinophils, red blood cells, platelets, and tissue debris encased within fibrinous strands. In most cases, such an early fibrin matrix is temporary and undergoes fibrinolysis following activation of tissue plasminogen. Degradation occurs within 72 h leading to tissue remodeling and repairs as mesothelial and mesenchymal cells proliferate to restore peritoneal defects. This process occurs 4–5 days after tissue injury preventing permanent attachment of adjacent tissue surfaces. In contrast, following surgically induced trauma, these involved tissues become ischemic from reduced blood flow resulting in suppression of fibrinolytic activity. With an absence of fibrin degradation (days 5 through 7), the fibrinous matrix now matures into an adhesive band from continued deposition of collagen and organization by fibroblasts. Over time, these adhesive bands represent a well-organized composition of connective tissues containing arterioles, venules, capillaries, and nerve fibers.

Remarkably, postoperative adhesions account for approximately 60% of all cases of intestinal obstruction in the elderly since many patients by the age of 65 have already undergone some form of abdominal surgery [15]. Whereby, the remaining causes of adhesions are typically secondary to inflammatory processes: such as pelvic inflammatory disease, diverticulitis, tuberculosis, and peritonitis.

The onset of adhesion-associated SBO may occur from several days up to 65 years from the initial operation. However, most SBOs develop earlier on during this interval period with reported median times to occurrence between 1.5 and 5.0 years [16–18]. Interestingly, the incidence of SBO after abdominal surgery appears to decrease over time; however, the cumulative risk remains substantial over the increasing lifetime of the patient. Nieuwenhuijzen et al. reported on a series of 234 patients who underwent colectomy and found that 11% of patients developed SBO within the first postoperative year and 30% within the first 10 years [19]. Similarly, a series from Norway demonstrated a 9% cumulative incidence of SBO after colorectal resection over 5 years [20]. Associated procedure-related formation of adhesions typically results after colorectal procedures, appendectomies, as well as multiple prior abdominal surgeries (including adhesiolysis for SBO) each accounting for 20–25% occurrence of adhesive SBO. Gynecologic procedures comprise the remaining 10–15% [18, 21, 22]. These procedures have been found to lead to the formation of single and multiple matted adhesive bands. Interestingly, vascular procedures have also been found to contribute substantially to the occurrence of adhesive SBO [23–25]. Therefore, not surprisingly, more than half of all adhesions causing SBO typically involves the ileum and occur within the pelvis. Moreover, in a recent Mayo Clinic series report, 48% of adhesion-associated SBO resulted from only single bands, whereas nearly 40% were multiple, among these 10% were categorized as dense [16]. In part, these findings clearly support adopting a less traumatic surgical approach (e.g., laparoscopy) in the treatment of certain diseases.

Malignancy

Neoplasms represent the second most common cause of SBO and are responsible for nearly 20% of intestinal obstruction in the elderly. Malignant obstruction occurs by the following mechanism (s): (1) via direct tumor extension causing extrinsic compression of bowel, (2) bulky lymphatic metastases which impinge on adjacent bowel, (3) and, more commonly, peritoneal implants (e.g., carcinomatosis), typically ovarian in origin, leading to a large burden of peritoneal disease and SBO [10]. While typically caused by benign lesions, acute SBO due to intussusception may result from malignancy, most commonly carcinomatosis, and in rare instances carcinoids, lymphoma, or metastatic melanoma [26]. Of greatest concern in these patients are the risk of a potentially palliative procedure and the needs for further treatment of malignancy. Decision to operate on these patients should be considered carefully, identifying potential risk factors that could lead to higher morbidity and short-term mortality [27].

Hernia

The third most common etiology found in the geriatric population is derived from hernias, which accounts for the remaining 10% of cases of SBO. Clinically, hernias are more often associated with bowel strangulation than adhesive bands: these include ventral, umbilical, incisional, inguinal, and internal hernias [8]. In addition, there are certain hernias that occur more frequently in the elderly, also requiring special consideration if a diagnosis of hernia-associated small bowel obstruction is suspected; these include femoral and obturator hernias. There is a well-known preponderance of femoral hernias among female patients; therefore, a high incidence of suspicion is warranted and femoral hernias should never be overlooked. By comparison, obturator hernias, however less common, should also be considered in the aging population with chronic disease, also more prevalent in the elderly and often associated with bowel strangulation [10].

Other miscellaneous causes of small bowel obstruction (10%) in older patients include inflammatory disease processes, such as Crohn disease, diverticulitis, and radiation-induced colitis. Moreover, gallstone ileus, which is rare in the general population, is more common in the elderly and can lead to SBO. Volvulus, bezoars (particularly in edentulous patients with prior gastrectomy), foreign bodies, fecal impaction, intestinal wall hematomas from blunt traumas (i.e., traumatic falls), and intestinal wall abscesses are also potential causes of small bowel obstruction in the elderly. Clinicians must be aware of these possibilities when differentiating an underlying cause for small bowel obstruction.

Moreover, as minimally invasive techniques become a larger part of our diagnostic and treatment armamentarium, application of these techniques is likewise expanding in the elderly due to the potential advantages for reduced morbidity. However, with these changes, new etiologic subclasses of iatrogenic causes of SBO are now being reported with increasing frequency. For example, endoscopically placed foreign objects, such as percutaneous endoscopic gastrostomy tubes and endoscopic retrograde cholangiopancreatography (ERCP) stents, can become dislodged and lead to luminal obstruction [28–33]. Similarly, SBO after laparoscopic procedures is well established [34]. Hernias can occur in trocar sites as well as through peritoneal defects created during laparoscopic procedures [35, 36]. Although postoperative adhesions are less likely, they also can occur. Because of the different etiologies of obstruction after laparoscopy, the general approach to SBO after laparoscopy may differ from that after laparotomy. One recent report examining a series of patients with early postoperative SBO after laparoscopy found that all patients eventually required surgical intervention [37].

Pathophysiology of SBO and Evaluation

Mechanical small bowel obstruction (e.g., adhesion, neoplasia, and hernia) is accompanied by proximal intestinal distension, which is a result of the accumulation of normal gastrointestinal secretions and gas above the obstructed segment. Initially, hyperperistalsis of the bowel is stimulated from intestinal distension leading to frequent loose bowel movements distal to the point of obstruction. Typically, this occurs in the early onset both in partial and complete obstruction. Paradoxically, presentation of frequent bowel movements in the elderly has been found to contribute to high rates of misdiagnosis, delayed treatment, and resultant increased morbidity and mortality [38–40].

As the distension becomes more severe, intraluminal hydrostatic pressures increase leading to the compression of the intestinal mucosal villus lymphatics. This results in the hindrance of lymphatic flow and development of bowel wall lymphedema. Consequently, the venules of the capillaries become congested from the increased hydrostatic pressure at the level of the capillary bed. Resultant fluids accumulate in the lumen as luminal pressures exceed 20 cm H_2O, thereby inhibiting absorption and stimulating secretions of salt and water into the lumen, proximal to the obstruction. Moreover, other causes of accumulation of intraluminal fluid may include (1) release of endocrine and paracrine substances, (2) changes in mesenteric circulation, (3) luminal release of bacterial toxins, and (4) excess release of prostaglandins. These may all contribute to promoting small bowel epithelial secretion, therefore, inhibiting absorption [38–40]. As a result, loss of intravascular fluid into the bowel manifests clinically as dehydration and hypovolemia. Consequently, prolonged dehydration can result in oliguria, azotemia, hemoconcentration, and eventually hypotension and hypovolemic shock. Furthermore, congested loops of bowel may twist upon themselves and accompanying mesentery resulting in vascular occlusion. In turn, bowel ischemia and necrosis develop, and if untreated, perforation, peritonitis, and sepsis may occur.

In general, the pathophysiologic changes that occur in small bowel obstruction are similar between the nongeriatric and geriatric patient population. However, and very importantly, as a result of inherent comorbidities found in the elderly, any delay in diagnosis may negatively impact on patient outcome with mortality exceeding 20% [11].

Clinical Features of SBO in the Elderly

Symptoms of SBO are primarily determined by the anatomic level and degree of obstruction. These include nausea and emesis, abdominal distension, abdominal pain, and obstipation (lack of passage of stool or flatus). Proximal SBO is characterized by frequent vomiting of bilious material and dehydration early in the course of disease with relatively little abdominal distension. With distal SBO, swallowed air and gastrointestinal secretions leads first to small bowel and abdominal distension. Only later do patients develop vomiting, usually after bacterial overgrowth has resulted in a feculent character to the enteric content. Partial obstruction is accompanied by continued, though potentially diminished, passage of flatus or stool. Early complete obstruction may also be accompanied by seemingly normal bowel movements, but eventually obstipation occurs.

Strangulation is notoriously difficult to detect reliably. Classic signs include fever, tachycardia, hypotension, and severe pain or focal tenderness, which are especially unreliable in the elderly, whereby the inflammatory response may be muted. Similarly, an elevated white blood cell (WBC) count may be absent in the elderly patient. From a previous Mayo Clinic series, strangulation was present in 13% of patients operated for SBO and was most commonly seen with the etiologies of hernia and small bowel volvulus [16]. Only 52% of patients with strangulation had an elevated WBC count, and the mean WBC count for patients with strangulation was just 2,000 cells/mm higher than that observed for patients with simple obstruction [3].

Diagnostic Considerations for the Elderly

Symptoms of SBO are common presenting complaints of elderly patients. The differential diagnosis for abdominal pain, nausea, and vomiting includes gastroenteritis, food poisoning, pancreatitis, biliary colic, porphyria, diabetic ketoacidosis, intestinal ischemia, constipation, paralytic ileus, and intestinal pseudo-obstruction. Compounding this problem in the elderly are age-related concurrent comorbidities that have been shown in a recent large retrospective study to be attributed to misdiagnosis, delay in surgical evaluation, and increased mortality [41]. Among these diagnoses, SBO is fairly common. In a review of ER visits to a regional trauma center by patients over 65 years of age, 12% of patients presenting with nontraumatic abdominal pain were ultimately found to have SBO [42]. Patients should be asked about any history of abdominal surgery or SBO, and during the physical examination, evidence of abdominal wall hernias should be vigilantly elicited. Laboratory values that can aid in the diagnosis and management of these patients include a complete blood count (CBC), basic metabolic profile, and serum amylase. As the classic signs of strangulation are often absent in the elderly, a leukocytosis, elevated hematocrit, and blood urea nitrogen (BUN) levels are often seen as a consequence of dehydration. Serum bicarbonate may be elevated because of loss of chloride-rich emesis and as part of a contraction alkalosis. These findings indicate a significant fluid deficit, which should be aggressively corrected upon initial presentation.

Diagnostic imaging is an important part of the evaluation of every patient with suspected SBO. Supine and upright abdomen and upright PA chest films are typically all that is required to confirm the diagnosis of complete SBO and to plan its treatment. Dilation of small bowel, paucity of colon and rectal gas, and air-fluid levels suggest complete SBO. Forty-eight percent of patients with proven SBO will have abdominal plain films that are consistent with SBO [16]. This, of course, means that almost half of patients with SBO have equivocal or even normal plain films, with residual colonic or rectal gas.

When these films are not diagnostic of complete SBO, the decision has traditionally been to rely on the clinical examination and serial plain films. In our experience, other CT scans has been useful in equivocal cases as an early diagnostic test and alters management in up to 20% of patients [43, 44]. Some centers have reported high accuracy of CT in identifying strangulation obstruction. A prospective evaluation of CT in 60 patients with high-grade SBO (with a 48% strangulation rate) showed that CT had 100% sensitivity and 61% specificity for detecting bowel ischemia [45]. The CT findings consistent with strangulation included bowel thickening and a high attenuation bowel wall on nonenhanced CT and abnormal bowel wall enhancement and mesenteric fluid on enhanced CT. A similar series of 100 patients from different institutions found a sensitivity of 83% and a specificity of 93% [46]. In contradistinction to these studies, several studies have compared CT with plain radiography and have found only modest differences in the overall accuracy of these tests when evaluating the grade of obstruction [47, 48]. CT also is helpful in patients with closed-loop obstructions and patients who swallow little air and thus have a gasless proximal bowel, as these problems are difficult to detect on plain films.

CT scans are more likely to demonstrate the cause of SBO, particularly when the obstruction is not secondary to adhesions. Current generation multidetector computed tomography or MDCT now permit high-quality reformatted images to be obtained in multiple planes which facilitate identification of the transition point and other findings in SBO: presence of a high degree of SBO and abnormal vascular course around the transition zone. Ultimately, MDCT may result in a paradigm shift toward earlier cross-sectional imaging in the elderly by its inherent ability to better predict the necessity for emergent surgery (i.e., ischemia) in the elderly when SBO is caused by adhesions [49, 50].

Less commonly used diagnostic imaging modalities in the acute setting include ultrasonography and MRI [51–55]. In the more subacute and chronic setting in patients with an intermittent or partial SBO, enteroclysis (small bowel enema) and small bowel follow-through may be useful [56, 57]. The passage of water-soluble oral contrast into the cecum within 4 h after CT or small bowel follow-through remains highly predictive of nonsurgical resolution of SBO [58, 59]. Interestingly, there have also been two randomized controlled trials examining whether water-soluble contrast speeds the resolution of partial SBO. Assalia et al. found a therapeutic benefit in terms of a shorter hospital stay in those patients receiving oral contrast with SBO from a variety of etiologies, whereas Feigin et al. reported no therapeutic benefit in patients with postoperative SBO [60, 61].

A special case of the diagnostic dilemma between SBO and paralytic ileus may occur during the early postoperative period. At 1–6 weeks after abdominal surgery, inflammatory adhesion can be thick and highly vascular. For these reasons, the morbidity of reoperation can be considerable. Because these early adhesions are also in a fluid state of constant remodeling, there is also a good chance of resolution of even high-grade partial obstructions without surgical intervention. It therefore becomes even more critical to define the degree of obstruction in these patients to avoid the higher morbidity of reoperation. In such circumstances, MDCT scanning may prove more beneficial for accurately distinguishing these equivocal cases [49, 50]. In very selected cases, when persistent partial SBO is a problem, endoscopic placement of a long intestinal tube may prove to be therapeutic and allow for a high-quality small bowel contrast study that more clearly characterizes the site of partial obstruction.

Initial Treatment

The traditional adage of "never let the sun set or rise on a small bowel obstruction," in part, underscores the severity of this diagnosis, particularly in the elderly [16]. Recently, however, this has been largely modified by a multifactorial assessment and approach that first considers the physiologic abnormality that has occurred since the onset of the SBO (i.e., hemodynamic status), type of SBO (partial, complete, strangulated), and patient comorbidities/performance status.

Even the patient who clearly has a complete bowel obstruction benefits from initial nonsurgical measures including proximal decompression, aggressive fluid resuscitation, and correction of electrolyte abnormalities. A Foley catheter is critical in the elderly to assess organ perfusion and fluid status. Generally, a nasogastric tube is adequate to decompress the gastrointestinal (GI) tract, but in some patients in whom a prolonged course of nonoperative management is contemplated, as for early postoperative SBO or the patient with multiple previous laparotomies or known severe adhesions, a long nasogastric (Miller–Abbott without mercury) tube may be considered.

Patients with complete SBO or with obvious signs of strangulation should be expeditiously resuscitated and then brought to the operating room. This strategy particularly applies to patients in whom the etiology is thought unlikely due to adhesions or neoplasm. However, most patients admitted for an SBO do not fall into this category. Two-thirds to three-fourths of patients with partial (primarily adhesive) SBO can be treated conservatively, with resolution of their acute episode [62–65]. In patients with a partial SBO, the duration of medical therapy continues to be a debated issue. Recent series examining this question have consistently shown that partial SBOs that ultimately resolve generally do so within 24–72 h. Delays beyond 48 h have been associated with increased morbidity in some series, whereas others have shown no increased morbidity with even longer delays [65, 66].

The potential arguments against maintaining a nonoperative approach are that the diagnosis of strangulation is inaccurate and the duration of medical treatment may be proportional to the incidence of strangulation or need for bowel resection and the subsequent higher incidence of complications [67]. These concerns are particularly relevant in elderly patients. Adhesive SBO requiring surgery in elderly patients ultimately requires bowel resection in up to 50% of cases, whereas only 8% of patients of all ages required bowel resection in the Mayo Clinic series [16, 68]. In that series, among patients in whom strangulation was found, delays of more than 4 h from presentation to surgery were associated with higher morbidity rates. Much emphasized is the importance of the underlying etiology when determining the mortality risk of delayed surgical intervention [16]. Data from the Mayo Clinic series showed that in the case of obstruction due to hernia, the time from presentation to operation was directly related to the mortality rate, but this relation with mortality did not exist for SBO caused by adhesions or malignancy.

A selective approach may be more appropriate in the elderly patient with SBO. The immediate strategy should be determined by consideration of (1) the evidence for current bowel ischemia, (2) the presumed etiology of the SBO, and (3) degree of obstruction. Patients with two or more signs of strangulation, radiographic signs of complete SBO, or both are operated on as soon as possible after adequate resuscitation. Nasogastric decompression and serial examinations are then planned for those in whom an adhesive, partial SBO is likely. For those in whom the diagnosis of SBO is unclear or the etiology is in question, CT is performed. The longer-term strategy in patients initially treated nonoperatively

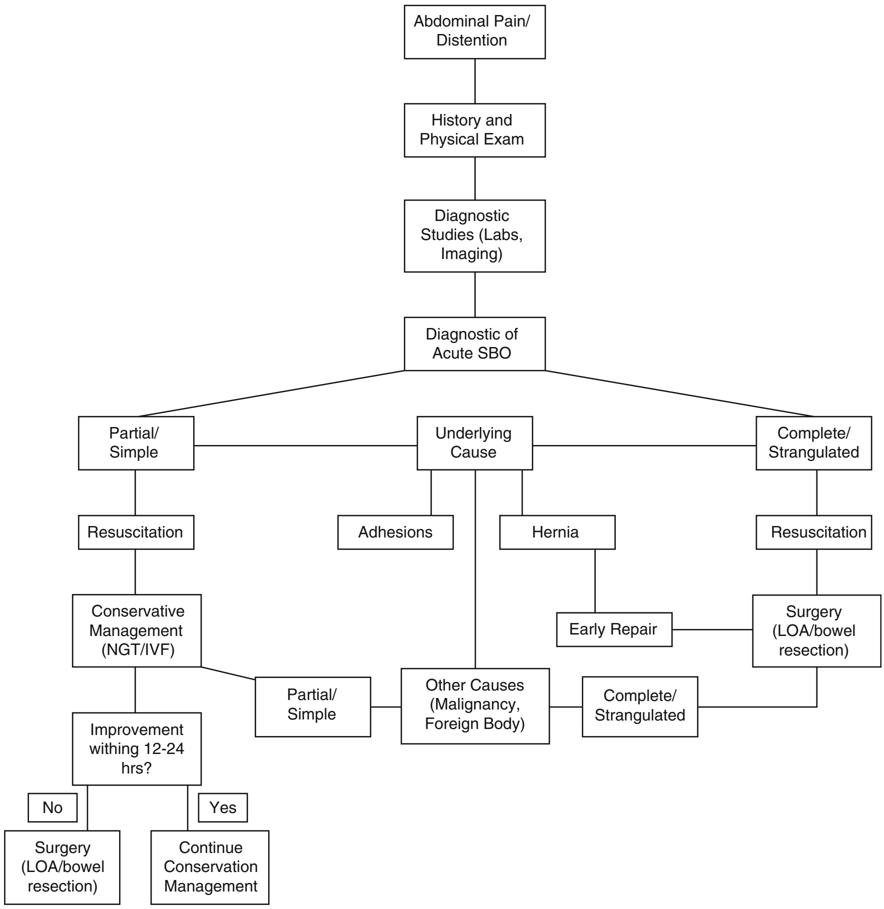

Fig. 6 Recommended algorithm for the management of small bowel obstruction in the elderly. *SBO* small bowel obstruction, *LOA* lysis of adhesions, *SBR* small bowel resection, *LBR* large bowel resection, *IVF* intravenous fluids, *NGT* nasogastric tube, *IBD* inflammatory bowel disease

should include both the above factors as well as [3] the likelihood of intraoperative and postoperative complications. These factors should be weighed against the likelihood of success using continued nonsurgical management. Figure 6 shows our diagnostic and treatment algorithm for patients with SBO.

Surgical Treatment: General Principles

Preoperative antibiotic coverage to cover enteric organisms, as per SCIP guidelines, should be administered, as a number of cases involve bowel resection or inadvertent enterotomy [69]. Although elderly patients are more likely to have underlying cardiovascular disease, increasing the risk of a perioperative cardiac event, invasive monitoring devices are rarely required. Hypotension upon induction of anesthesia should be avoided by attention to adequate preoperative fluid resuscitation often requiring 3–4 L of intravenous isotonic crystalloid. The surgical adage, “rush to resuscitate, then operate,” must always be remembered in the elderly patient with SBO.

Open approach remains the standard of care for treatment of SBO in the elderly; however, use of laparoscopy has increased in frequency over the last decade [70]. Laparotomy should be performed through a midline approach with at least part of the initial incision over virgin/scarless skin, if possible. Entry through the fascia is done with extreme care, avoiding the use of cautery, as transmitted heat can injure underlying bowel. Adhesions are usually stronger than the junctions between the small bowel muscle layer and the muscularis propria and submucosa, and this seems particularly true in the elderly patient. Sharp dissection with scissors or knife should therefore be performed to avoid seromuscular injuries. We generally lyse adhesions from the anterior abdominal wall first and then proceed to run the small bowel lysing adhesions as we progress from the ligament of Treitz to the terminal ileum.

While running the bowel, the etiology of the SBO and local bowel viability are assessed. The commonly available parameters include bowel color, peristalsis, and mesenteric pulsations. Although clearly viable and clearly nonviable extremes are easy to identify, many gradations of color are difficult to judge, and assessment of ultimate viability is prone to error. Adjuncts to these methods continue to include Doppler flow probe assessment of mesenteric and antimesenteric blood flow, intravenous fluorescein perfusion, and electromyography (EMG) [71–73]. Although these methods have their advocates, none has consistently been shown to have higher accuracy than "clinical judgment" using visual and manual inspection. Our general strategy is to resect questionable bowel, if possible. If resection would result in less than 4–5 ft of clearly viable intestine, questionable segments with the highest likelihood of viability should be left in situ with a planned "second-look" reoperation within 24–48 h.

To allow abdominal wall closure, frequently the bowel must be decompressed. This can be achieved with a long nasogastric tube, but we favor gentle retrograde milking of the intestine toward the duodenum with fluid evacuation via a nasogastric tube. To minimize excessive distension and the risk of serosal tears, this process is first started in the mid-jejunum. The proximal jejunal segment is then evacuated of luminal content. The process is then repeated starting progressively more distally on the bowel. Prior to closing the abdomen, the bowel loops should be laid back in the abdomen in gentle folds. Some have advocated the use of long intestinal tubes to act as stents, particularly in the patient with recurrent SBO or pervasive adhesions [74]. Another option gaining popularity is the application of hyaluronidase-containing films to inhibit adhesion formation [75]. Clinical trial data (see section "Biological Barriers") demonstrate safety and potential efficacy for reducing adhesions and adhesion-associated SBO.

Laparoscopic Treatment of SBO

Laparoscopic surgery has theoretical advantages over open surgery including decreased postoperative pain, reduced wound complications, decreased respiratory complications, and shorter hospital stay. These advantages are particularly attractive in elderly patients and have led to a decreased threshold for elderly patients seeking surgical management by a minimally invasive approach. Recent reports of SBO management with favorable outcomes using a laparoscopic approach have been documented [76]. The challenge of laparoscopic treatment for SBO rests not in the diagnostic efficiency, which is between 60% and 100%, but the therapeutic efficacy, which is generally low (40–88%). Not surprisingly, the conversion rate to laparotomy has been reported to be as high as 52% [77–81].

Several factors make laparoscopic treatment of SBO difficult and have prevented many surgeons from adopting this approach to SBO. Most significant is the concern for the physiologic effects of laparoscopy on the elderly patient's cardiovascular system [82]. Insufflation may decrease excursion of the diaphragm, leading to elevated peak airway pressures, and decreased pulmonary compliance and vital capacity. Increased abdominal pressure may also decrease venous return to the heart, elevating systemic vascular resistance and mean arterial pressures. This increased abdominal pressure may also decrease renal and hepatic perfusion. Lastly, insufflation can worsen gastroesophageal reflux in an elderly patient with weakened lower esophageal sphincter, increasing risk of aspiration, especially in Trendelenburg position [82].

Additionally, exposure with laparoscopy can be problematic because of diffuse adhesions to the anterior abdominal wall and because distended bowel may have already increased the intra-abdominal pressure and decreased the volume of pneumoperitoneum that can be achieved. Therefore, it is generally best to use an open insertion technique and to select an initial insertion site remote from previous scars. In a case with concern for extensive adhesions, we recommend open, trocar insertion technique at Palmer's Point (left upper quadrant, 3 cm below the coastal margin in the mid-clavicular line). We typically do not recommend insufflation and creation of pneumoperitoneum by Veress needle approach in the setting of SBO. Bowel distension should be minimized by preoperative nasogastric decompression, and in selected cases using a long intestinal tube prior to attempting laparoscopic treatment. Perhaps the most common reason for reluctance to use laparoscopy for SBO is a concern that treatment may require an extensive adhesiolysis or resection that is problematic to achieve laparoscopically. Therefore, proper patient selection is paramount before choosing a minimally invasive approach. A recent Medline, Embase, Cochrane review from 1980 to 2007 identified predictive factors for a successful laparoscopic adhesiolysis, which includes two previous laparotomies, adhesions associated with appendectomy, single adhesive band, early <24 h laparoscopic management from onset of symptoms, no peritonitis, and surgical expertise [78]. Despite the aforementioned concerns, the number of laparoscopically managed SBOs has increased over time. An analysis of the National Surgical Quality Improvement Program (NSQIP) database demonstrated an increase in laparoscopic management from 17.2% in 2006 to 28.7% in 2013 [70].

The laparoscopic approach is particularly attractive for adhesive SBOs where there is a single adhesive band. Conventional laparotomy is recommended for malignant SBOs and hernia-related SBOs, where there is a high rate of strangulation. The general principles of the laparoscopic approach are similar to those of the open approach. Adhesions are dissected sharply, and after adhesiolysis, the bowel is inspected from the ileocecal valve to the ligament of Treitz.

Although one-half to two-thirds of patients may be managed laparoscopically, one must anticipate a high conversion rate to open laparotomy. A study by Bailey et al. compared SBOs treated in two surgical units, one with a special interest in laparoscopy [83]. The laparoscopy unit attempted laparoscopic treatment in 80% of SBOs, and among those cases, they completed treatment laparoscopically in 56%. The laparoscopically treated patients left the hospital 5 days earlier than the open procedure patients, but they also had a higher rate of unplanned reoperation (14% vs. 5%). The safety and efficacy of diagnostic laparoscopy for SBO appears well established from retrospective studies, whereas laparoscopic adhesiolysis requires careful patient selection and laparoscopic surgical expertise, using an operative plan that includes converting to an open approach if extensive adhesions or nonadhesive causes are encountered. Ultimately, prospective randomized trials assessing all clinically relevant outcomes are needed.

Nonoperative Management

In many cases of SBO due to malignancy, surgery may be high risk, and often for palliative relief. Risk of performing a surgical procedure in these patients may outweigh the benefits. Placement of self-expandable metal stent (SEMS) has become a viable alternative cases of malignant gastric outlet obstruction or large bowel obstruction, and its use is being investigated for management of malignant SBO [84, 85]. Small prospective studies have been performed describing three different techniques: (1) through-the-scope insertion with colonoscope, (2) through-the-overtube using double balloon/single balloon/spiral enteroscopy, and (3) withdrawal-reinsertion using double balloon enteroscopy [86–90]. Most publications regarding this topic are case series or reports, though with favorable outcomes with regard to morbidity and relief of symptoms. Decision to employ this strategy requires attention to patient selection, as some patients will have more than one site of obstruction, in particular those with peritoneal metastases. However, there may be significant benefits toward this tactic in select patients including shorter hospital stay, decreased cost, lower short-term mortality, and early continuation of chemotherapy [91].

Outcomes of Treatment of SBO

Most studies of the outcomes of treatment of SBO have centered on traditional surgical outcomes, such as perioperative mortality, survival, and post-operative complications. Increased age is a risk factor for mortality from SBO (Fig. 4). Perioperative mortality is also related to the etiology of the SBO. For example, SBO from malignancy has an in-hospital mortality of 21% and a median survival of 6 months, compared to a 4–5% mortality risk for hernia and adhesive etiologies. Similarly, a large prospective experience by Miner et al. showed that the potential benefits of palliative surgery are minimized by the inherent morbidity (29%) and mortality (11%) of these procedures [92]. Of note, delay from symptom onset to presentation is not generally related to mortality risk except in the case of hernias, where there is also a higher risk of strangulation; overall, in-hospital morbidity is 30% but is increased in patients with strangulation to 60%.

As adhesions represent the most common cause of SBO in the elderly, identifying pertinent risk factors for adverse outcome following surgery for adhesion-associated SBO may provide the clinician with important information for stratifying the risk-to-benefit ratio for clinical decision making especially in the more concerning elderly population. A recent VA National Surgical Quality Improvement Program developed a morbidity and mortality risk index assessment based on a cumulative score that predicts the probability of an adverse outcome [93]. Not surprisingly, the odds of mortality in a patient 70–79 years of age are increased by a factor of 1.855 compared to a patient younger than 50 years. Similarly, better outcomes are associated with adhesiolysis only, compared to bowel resection.

Attempts were also made to ascertain the longevity of treatment of SBO, specifically, for patients treated nonsurgically, the likelihood and timing of recurrence, and how this compares to patients treated surgically. These questions were largely addressed from a statewide longitudinal population-based outcome analysis derived from 32,583 hospitalized patients (mean age 63 years) admitted with a diagnosis of SBO (index admission). From this study, Foster et al. showed that in California, from data derived from patients hospitalized in 1997, SBO was primarily managed non-operatively in 76% of these patients. Of the patients that underwent operative management (24%), there was a longer length of stay, lower mortality rate, fewer SBO readmissions, and longer time to readmission. In general, patients who did not have operations were usually older and with more comorbidities. However, regardless of the treatment, 81% of patients had no subsequent SBO requiring readmission over the 5-year study follow-up period [63]. Similarly, Landercasper et al. retrospectively reviewed 309 consecutive patients with SBO and followed them for recurrence [57, 94]. The SBOs recurred in 34% by 4 years and in 42% by 10 years. Those who were operated on had a lower recurrence rate (29%) than those who were treated non-operatively (53%). Among those who had surgery, recurrences differed by etiology: malignant (56%), adhesive (28%), and hernia (0%). In this study, the number of prior obstructive episodes was not a risk factor for recurrence. However, Fevang et al. retrospectively studied 500 patients with adhesive-associated SBO (ASBO) for up to 40 years for recurrence [58, 95]. They found that the cumulative recurrence rate for patients operated once for ASBO was 18% after 10 years and 29% at 30 years. The likelihood of a recurrent ASBO was highest within 5 years after the previous one, but a considerable risk was still present 10–20 years after an ASBO episode.

In addition to recurrence risk, treatment choice affects the cost of care and utilization of health-care resources. The costs of caring for patients with SBO are considerable. From a Swedish study, 60% of all bowel obstructions were due to adhesions, 65% of them required more than a

1-day hospital stay, and 45% of these required surgery. Calculating direct costs and extrapolating these data, $13 million are spent on adhesive SBO in Sweden (a country of 8.5 million population) annually [96]. In many cases, treatment choice is determined solely by the initial clinical presentation. Either the decision to undergo surgery occurs early or an initial short duration of medical management results in rapid clinical improvement and resolution of the SBO. However, in patients with high-grade partial obstruction likely due to adhesions, an early decision to treat surgically is likely to have a favorable clinical outcome but may result in a longer hospital stay and higher cost of care compared to a nonsurgical approach. As one might expect, retrospective analysis of patients treated medically and surgically show that surgically treated patients have clinical outcomes similar to those treated medically but with longer lengths of stay [17]. The additional costs of care in patients ultimately treated surgically may be as much as eight times higher than nonsurgically treated patients. This differential makes tests with improved diagnostic accuracy, such as CT or MDCT, more cost-effective for questionable partial SBO [97].

Preoperative frailty scores have been more recently used as a predictor of postoperative morbidity and mortality in various surgical specialties [98–100]. Commonly used markers, such as the American Society of Anesthesiology (ASA) score and the Lee and Eagle Criteria, are either subjective estimates or evaluate only one organ system, leaving outcomes in the elderly difficult to predict [101]. For this reason, frailty scores may act as a surrogate marker of an elderly patient's physiologic reserve and vulnerability. One such example, Makary et al. prospectively measured frailty in 594 patients presenting for elective surgery. Their score was composed of five validated criteria including shrinking (weight loss), decreased strength (weakness), exhaustion, low physical activity, and slowed walking speed. Frailty score improved the power of the previously mentioned indices to predict surgical complications and discharge to nursing facility [101]. A systematic review of 23 studies assessing various instruments for measuring frailty (mean age range 75–87 years), demonstrated associations between these markers and 30-day, 90-day, and 1-year mortality, as well as postoperative complications and length of stay [98]. When planning operative intervention for SBO, frailty is an important predictor of the potential for postoperative morbidity and mortality that should be considered in the decision-making process.

Biological Barriers

Barriers are biosynthetic membranes or gels that have been shown to be effective in decreasing surgically induced adhesions. One of the first prototypes successful in reducing postoperative adhesions in humans was Interceed®, which was composed of modified oxidized regenerated cellulose. This particular barrier was found to be applicable following gynecologic procedures; however, its efficacy in general surgical procedures is unknown [102]. Another type of biological barrier is expanded polytetrafluoroethylene (PTFE). This was shown to prevent pelvic adhesions. However, PTFE was not cost-effective or bioabsorbable and required a large piece of material and suturing to keep it in place for adhesion prevention.

To date, the most efficacious barrier is a hyaluronan and carboxymethylcellulose bioresorbable membrane called Seprafilm®. The mechanism of action of adhesion prevention is believed to occur by one of the components known as sodium hyaluronate. It is believed to improve peritoneal healing by increasing the proliferation of mesothelial cells and facilitating their detachment and migration, leading to the restoration of the mesothelial lining within the abdomen. It is also thought to increase the fibrinolytic response of mesothelial cells, aiding in adhesion prevention.

Seprafilm® is typically prepared as a membranous sheet that is applied over potential sites of adhesion formation (e.g., traumatized tissue), prior to closure following an abdominal surgical procedure. Placement of the membrane requires that the peritoneal cavity, as well as the instruments and gloves used to handle the barrier, be as

dry as possible. Approximately, 1–2 cm of the membrane should be exposed from its holder prior to application. When entering the abdominal cavity, the membrane can be curved or slightly folded to facilitate placement over the desired area. To ensure adequate adherence to the tissue, a dry instrument or gloved hand can be used to gently press down on the membrane. Seprafilm® should be sufficiently placed over the margins of the incision or surgically traumatized tissue and overlapped to achieve sufficient coverage. Importantly, a bowel anastomosis should not be wrapped with Seprafilm®, as this practice has been associated with adverse events. Seprafilm® slowly resorbs within 7 days of placement and is fully excreted by 28 days.

Seprafilm® was evaluated in a number of prospectively, randomized, controlled, multicenter studies and consistently demonstrated overall safety (Table 2) [103–108]. The larger clinical trials did show a significant reduction in the formation of adhesions and adhesion-associated SBO (Table 3) [103–109]. Still other trials have demonstrated limited efficacy while confirming its safety [110]. These barriers potentially provide an excellent form of adjunctive therapy for preventing postoperative adhesions, the number one cause of SBO, not only in the elderly but also in the general population.

Conclusion

Small bowel obstruction is a common pathological process that can occur in any patient population. Its effects, however, are devastating in the elderly and warrants prompt appropriate management. Utilization of a thorough clinical history, physical examination, and investigative studies provide the necessary information to determine a diagnosis and direct the next step in treatment. Immediate aggressive resuscitation is required with monitoring of hemodynamic parameters especially in older patients because of their limited physiologic reserve and comorbidities.

Based on the type of SBO, a trial of conservative management may be initiated or definitive surgery may be performed. Either the standard laparotomy or laparoscopic surgical technique may be used dependent on surgeon experience, patient stability, or underlying cause, with further consideration for patient comorbidities. Recent developments of biosynthetic products have made a positive impact in the management of SBO that help in the prevention of surgically induced adhesions in the elderly.

Abstract

Mesenteric ischemia is a condition that can be fatal if not diagnosed early and treated efficiently. The acute form of mesenteric ischemia can present with pain out of proportion of abdominal findings by exam and is usually due to an acute embolus to the superior mesenteric artery. The chronic form of mesenteric ischemia tends to be indolent and presents with postprandial pain and significant weight loss over a long period of time. Accurate diagnosis of chronic

mesenteric ischemia is important to avoid the continuum to acute mesenteric ischemia which has an extremely high mortality. Common risk factors are cardiac arrhythmias, age, and systemic atherosclerosis. In any patient suspected of having chronic mesenteric ischemia, CT angiogram can be diagnostic. A third form of mesenteric ischemia is nonocclusive venous mesenteric ischemia which is usually associated with elderly patients in congestive heart failure or with other intra-abdominal pathologies. That condition if diagnosed appropriately can be managed with anticoagulation and close monitoring.

Standard treatment for chronic and acute mesenteric ischemia is open surgical procedure with embolectomy for an embolus and a bypass either antegrade or retrograde for the chronic form of atherosclerotic mesenteric ischemia. Percutaneous stenting of the SMA has yielded excellent short-term results and in very acute or high-risk patients. The long-term results of superior mesenteric artery stenting are not as good as surgical bypass, and some investigators feel that close monitoring of the stent is required and in many cases only used as a bridge until the patient medically stabilizes. Early diagnostic suspicion and appropriate treatment has a significant impact in good outcomes.

Mesenteric Ischemia Vignettes

Case Study: SMV Thrombosis

A 51-year-old male with no PMH presents with 6 days of increasing abdominal pain. He states on Sunday evening he was at a wake and started noticing epigastric abdominal pain that was aching but not severe at the time. Over the next day, the pain increased and began radiating to his back. The pain was sometimes worsened with eating but not always. It is, however, always worsened by movement/activity. Tylenol did not relieve his symptoms. He had no nausea, vomiting, or hematochezia and no recent weight loss, fever, chills, or night sweats. He additionally denies recent chest pain or shortness of breath. He went to see his primary care physician on Tuesday and was given omeprazole, which he took Tuesday night and Wednesday morning. On Wednesday, he was switched to pantoprazole, which he took on Wednesday evening and Thursday morning. Due to no relief on pain by either omeprazole or pantoprazole, he stopped taking them Thursday night. He was scheduled to see a cardiologist on Friday; however, the pain had increased to 9/10 and was so great that patient was in tears when trying to move, so he came to the emergency department instead.

In the emergency department, vitals were stable, and labs were significant only for hgb of 17.7 (hct 51.3%). Chest X-ray showed mild bilateral atelectasis without acute pulmonary process. EKG was unremarkable. CT body/pelvis with contrast showed complete occlusion of the SMV with fat stranding at the root of the mesentery. He was given fluids and started on Heparin gtt.

Management

The patient was admitted to the hospital and started on a heparin drip. A coagulopathy workup was sent to the lab. Serial abdominal exams were performed. He improved over the course of his hospital stay, and no surgical intervention was offered. By discharge, his pain had resolved and he was tolerating an oral diet. He was discharged on oral anticoagulation therapy.

Case Study: Mesenteric Ischemia

A 42-year-old female presented to clinic with a 3-month history of pain associated with eating and 30 pound weight loss. Three months prior to presentation in our clinic, she had suffered from significant vomiting and abdominal pain. She had a CT at an outside hospital which revealed an isolated aneurysm of the superior mesenteric artery. She underwent resection and interposition grafting at the other institution. On repeat imaging at our institution, she was found to have an occluded interposition graft.

Management

The patient was admitted to the hospital and taken for a diagnostic angiogram. This confirmed the previous diagnosis of occluded SMA interposition graft. She was also found to have a severely disease celiac artery at its origin with a patent common hepatic artery but non-visualized splenic artery. She was brought to the operating room a few weeks later for bypass grafting. She underwent re-operative exploratory laparotomy with bypass grafting from the aorta to the common hepatic artery with greater saphenous vein. The SMA was unable to be safely dissected due to scar tissue. She did well postoperatively and is now tolerating an oral diet and has regained a normal BMI.

Case Study: Mesenteric Ischemia

A 60-year-old male with a history of CAD status post CABG, PAD s/p left BKA, and hypertension presented to the emergency department with acute onset of severe abdominal pain. Patient described this as severe, crampy, and worse with activity. Initially, he thought it was due to constipation and took laxative but without resolution of symptoms. In the emergency room, he had a CT scan which showed portal venous gas and severe stenoses of the celiac and SMA without complete occlusion.

Management

The patient was taken to the operating room for diagnostic laparoscopy and diagnostic angiogram with possible interventions. Laparoscopy revealed a dead right colon. Angiogram showed severe stenosis of the celiac and SMA. It was then decided to stent the SMA with a covered, balloon expandable stent. Exploratory laparotomy was performed, and the right colon was resected and bowel left in discontinuity. The patient was brought back to the operating room 2 days later for a second look. At that point, the remaining bowel looked healthy, and a good Doppler signal was obtained at the base of the mesentery. The bowel was re-anastomosed, and the abdomen was closed in the standard fashion.

Epidemiology

The frequency of atherosclerosis of the mesenteric vessels increases with age and is found in 20% of patients over 65 years old in North America. In a population study of all patients undergoing autopsy or operation in Malmo, Sweden, 12.9% of patients were found to have fatal acute mesenteric ischemia. Chronic mesenteric ischemia accounts for approximately 5% of mesenteric ischemic conditions. On the other hand, acute mesenteric ischemia (AMI) is more common and has a devastating outcome.

The risk factors for acute mesenteric ischemia are all related to advanced age. They include low cardiac output due to congestive heart failure, cardiac arrhythmias, valvular disease, atherosclerosis, and intra-abdominal malignancy.

Anatomy

Understanding the gut blood supply and extensive collaterals is critical to understanding the cause(s) of acute and chronic mesenteric ischemia.

The gastrointestinal tract derives its blood supply from the celiac, superior mesenteric, and inferior mesenteric arteries (Fig. 1). The celiac axis branches into the common hepatic, left gastric, and splenic arteries. The common hepatic artery gives off the gastroduodenal artery which terminate in functional anastomoses to the anterior and inferior pancreaticoduodenal arteries from the superior mesenteric artery. The SMA arises from the aorta just distal to the celiac access. The SMA gives rise to the aforementioned inferior pancreaticoduodenal branches, the middle colic artery, right colic artery, ileal branches, and ileocolic artery. The middle colic artery comes off the proximal SMA and supplies the transverse colon. It also communicates directly with branches of the IMA. The ileocolic artery is the terminal branch of the SMA and supplies the terminal ileum, cecum, and ascending colon. The IMA is the most distal and

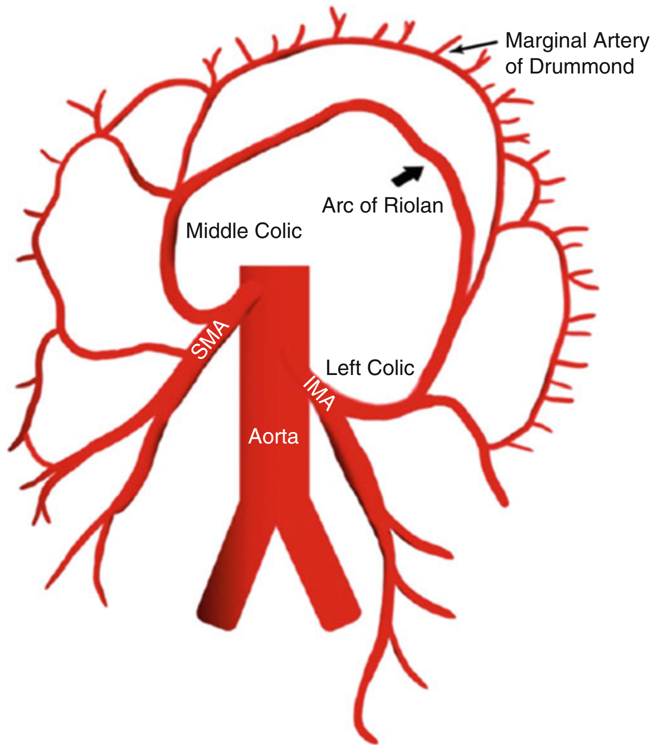

Fig. 1 Drawing demonstrating collateral pathways between superior mesenteric artery (SMA) and inferior mesenteric artery (IMA)

smallest of the mesenteric arteries and is also a ventral branch of the aorta. It arises approximately 6–7 cm below the SMA, which corresponds to the L3 level of the vertebra. It supplies the hindgut, which includes the distal transverse colon, descending colon, sigmoid colon and rectum. The left colic artery communicates with the SMA via the marginal artery.

To understand the pathophysiology of mesenteric ischemia, it is important to understand the anatomic collateral pathways. For collateral circulation between the celiac axis and the SMA, the principle pathways are the gastroduodenal and pancreaticoduodenal arteries. Unusual anatomic variations can also provide collateral flow, such as a replaced right hepatic artery or a pancreatic or middle colic artery originating from the CA. In addition, there is an infrequent but well-recognized collateral pathway known as the arc of Buhler, which represents a direct collateral pathway between the CA and the SMA. This is thought to be due to a persistence of an embryonic ventral segmental artery.

There are three major and consequential anastomotic pathways between the SMA and the IMA, the most significant of which is the marginal artery of Drummond. This artery runs within the mesentery of the colon and gives rise to the vasa recta. It receives branches from the ileocolic, right colic, middle colic, and the left colic arteries. It usually runs close to the mesenteric border of the colon. Normally, this artery is not particularly large; but with occlusion of the SMA, it can enlarge significantly. The arc of Riolan also lies within the mesentery but is much closer to its base. This collateral connects the middle and left colic arteries. The final potential collateral pathway between the SMA and IMA is the meandering or wandering mesenteric artery. Occasionally, this is markedly hypertrophied arc of Riolan, and other times, there is a distinct anastomotic pathway between the SMA and IMA (Fig. 1). The IMA can be collateralized not only by the MSA but also by the lumbar branches of the aorta as well as the hypogastric arteries.

The venous drainage of the gut is principally via the splenic vein for the foregut, the superior mesenteric vein for the hindgut, and the inferior mesenteric vein for the hindgut. These vessels all drain into the portal vein and hence through the liver.

Mesenteric blood vessels are highly reactive, and accordingly, mesenteric blood flow can fluctuate between 10% and 35% of cardiac output. They react to a large variety of endogenous cytokines and exogenous medications. The GI tract requires varying amounts of blood flow based on the metabolic needs of the gut during fasting and fed states. At rest, the mesenteric flow is low due to high resistance with low diastolic flow with flow reversal, which is typical of high-resistance beds. In the fed state, there is both systolic and continuous diastolic flow.

Imaging/Diagnosis

Radiographic imaging plays an increasingly significant role in the diagnosis of mesenteric ischemia. Plain radiographs are commonly used to exclude other causes of the acute abdomen such as bowel obstruction or a perforated viscus. As an early diagnostic aid in acute mesenteric ischemia, plain radiographs lack sensitivity, being reported as normal in up to 25% of cases involving acute mesenteric ischemia. Unfortunately, definitive plain radiographic findings of acute mesenteric ischemia are those associated with progressive loss of tissue integrity, such as pneumatosis and portal venous air and with a much poorer prognosis at this stage.

Duplex ultrasound of the mesenteric vessels is noninvasive and does not require administration of nephrotoxic contrast agents. Its utilization has primarily been in the diagnosis of CMI. As with all duplex examination, this modality is operator-dependent. An optimal patient setting, such as a thin patient with minimal bowel gas, is required to achieve quality results. Duplex ultrasonography accurately identifies high-grade stenoses of the celiac artery and SMA. In patient thought to have CMI, the reported technical adequacy approaches 100%. Studies from Dartmouth and the Oregon Health Sciences University attempted to established duplex criteria for the diagnosis of splanchnic artery stenosis and occlusion. Based on repeat studies, they have determined the peak systolic velocity (PSV) and end diastolic velocity (EDV) that correlates with a significant degree of stenosis. For the SMA, a PSV of >275 cm/s correlated with a > 70% angiographic stenosis with sensitivity of 92% and specificity of 96%. An EDV of >45 cm/s correlated with a > 50% angiographic stenosis with sensitivity of 90% and specificity 91%. For the celiac artery, a PSV of >200 cm/s suggests a stenosis of >70% with sensitivity of 90% and specificity of 91%. Retrograde hepatic artery flow is 100% predictive of a severe celiac artery stenosis or occlusion. Celiac EDV >55 cm/s indicates a stenosis of >50% with sensitivity of 93% and specificity of 100%.

Catheter angiography has long been the gold standard in delineating mesenteric arterial anatomy. However, as the availably of multidetector helical CT scan as spread, the ability to rapidly acquire high-quality CT angiographic images has made this modality the study of choice when evaluating a patient with possible mesenteric ischemia. A significant amount of information can be obtained about the central arterial and venous circulation with CT angiography. Accurate timing of contrast injection and fine slices (0.5–1.5 mm) through the upper abdomen usually provides excellent visualization of the celiac artery and SMA distributions. Other causes of abdominal pathology can also be assessed with CT. Nonspecific findings for bowel ischemia or infarction may include mesenteric stranding, bowel wall edema, or even air within the bowel wall or mesenteric vessels. The exact timing of intravenous contrast administration is tailored to the specified clinical question; usually, a non-contrasted study is performed first to establish a baseline of the appearance of the bowel wall. The tradition as of “positive” oral contrast agents detracts from image quality, and most visceral computed tomography angiography (CTA) protocols recommend the use of a “negative” oral contrast agent, such as water, given before the scan. The negative contrast agent prevents image artifact from pooled areas of high opacification within the intestinal tract and actually enhances the ability to see bowel wall enhancement (or lack thereof) in the late arterial phase of the contrast bolus. Three-dimensional reconstructions may be generated from the raw CT data set, yielding a spatially oriented image that allows for the clinician to evaluate the diseased segments from different perspectives. Some protocols may offer the use of biphasic scanning, a technique borrowed from standard pancreatic and liver studies. A delayed set of images are acquired approximately 1 min after the administration of IV contrast to obtain portal venous phase imaging.

Magnetic resonance angiography (MRA) provides excellent evaluation of the splanchnic vessels. MRI/MRA is noninvasive and avoids the risk of allergic reaction with iodinated contrast agents. There are several caveats to the use of MRI/MRA, such as avoidance of patients with ferrous-containing implants and concern for gadolinium-induced nephrogenic systemic fibrosis (NSF) in patients with impaired renal function. Anatomic imaging of the visceral vessels relies on contrast-enhanced MRI techniques; noncontrast three-dimensional phase contrast MRA identifies on 66% of angiographic stenoses and crates some false-positive results. The most common error of visceral MRA is overestimation of the stenosis. This weakness may result from the relatively poor spatial resolution of MRA. Even on the best systems, resolution is limited to 1 mm^3. Gadolinium-enhanced MRA currently does not provide sufficient resolution to show distal emboli non-occlusive, low-flow states, small vessel occlusion, or vasculitis. One study evaluated 14 patients with CMI; three-dimensional contrast-enhanced MRA had a sensitivity of 100% and a specificity of 87% in the overall detection of 50% or greater stenosis. In a similar, more recent study by Carlos et al., two blinded observers reviewed gadolinium-enhanced MRA studies and compared them with conventional angiography in 26 patients suspected to have CMI. The overall accuracies for the detection of 50% or greater stenosis or occlusion in the celiac artery, SMA, or IMA were 95% and 97%. Secondary signs of mesenteric ischemia, such as fat or bowel wall thickening, which are routinely delineated by CT, are more difficult to assess with MRI. In general, the anatomic evaluation of the mesenteric arteries is limited to the proximal celiac artery and SMA only, and the evaluation of SMA branches or IMA is limited by the spatial resolution of MRI techniques. MRA is not routinely the first imaging study to obtain in the setting of AMI because of time delay. The utility of MRA in CMI depends on the quality of the instrumentation, the sophistication of the software, and the skill of the interpreting radiologist, especially when other modalities are available.

Finally, catheter-based arteriography is a time-tested modality offers superbly detailed images of the visceral arterial tree, and venous patency may also be assessed on delayed images. Due to the time urgency in the treatment of AMI, as well as the burgeoning availability of CTA, the use of catheter angiography prior to laparotomy is now distinctly uncommon. In the setting of CMI, diagnostic angiography may be combined with therapeutic intervention in selected candidates. To document stenosis of the origins of the SMA and celiac axes, lateral views are best. Usually, involvement of at least two mesenteric vessels is required to diagnose symptomatic CMI. It is unusual for a patient to be symptomatic from occlusion of only one vessel. Additional evidence of chronic ischemia is evidenced by hypertrophy of collateral pathways, including the marginal artery of Drummond and the arc of Riolan (Fig. 2). Relative drawbacks of this technique include the need for arterial instrumentation and administration of nephrotoxic contrast agents.

Arterial Mesenteric Ischemia

Acute Pathology

Acute arterial insufficiency to the small bowel results from occlusion of the superior mesenteric artery. This represents the most dramatic and lethal form of mesenteric ischemia. Stoney found that about half of acute SMA occlusions are due to embolic phenomenon, most of which have cardiac origin (Fig. 2). These emboli generally occur in the setting of cardiac arrhythmias, particularly atrial

Fig. 2 Sagittal CTA reconstruction of cardiac embolus in mid-SMA (red arrow) in patient with AMI

fibrillation or following acute myocardial infarction. The can also stem from valve-associated thrombi especially in the inadequately anticoagulated patient with mechanical valve replacement. The vast majority of emboli lodge distal to the SMA origin just beyond the middle colic artery as the SMA begins to taper. In approximately 20% of cases, patients with SMA emboli will also have emboli to other vascular beds.

Patients with acute mesenteric ischemia will have the pathognomonic, "pain out of portion to physical exam." They also usually have elevated white blood cell counts and lactate levels.

Approximately 25% of acute mesenteric ischemic events are due to thrombosis of a preexisting atherosclerotic lesion (Figs. 3, and 4). Although these patients may present acutely, on questioning they generally give a history of chronic mesenteric ischemia symptoms. These lesions occur at the SMA origin, not distally as with embolic disease.

Fig. 3 Sagittal 3D reconstruction of patient with atherosclerotic obstruction proximal SMA (arrow) in patient with CMI

Fig. 4 Drawing of surgical exposure of proximal SMA at root of mesentery. Notice distal embolectomy (first insert) and closure transverse arteriotomy (second insert)

Nonocclusive mesenteric ischemia (NOMI) is a low-flow state in the setting of preexisting atherosclerotic lesions. This ischemia is often unveiled by the administration of vasoconstrictive agents in the setting of septic or cardiogenic shock. NOMI should be thought of as a rule-out diagnosis in that it is relatively uncommon. It is a relatively lethal diagnosis with a mortality rate of about 70%; this is mostly due to the underlying clinical condition that precipitates it. Treatment of NOMI requires diagnosis and treatment of the underlying pathology. Low-flow states result in peripheral hypoxemia and paradoxical splanchnic vasospasm, thereby precipitating intestinal ischemia. Angiotensin and vasopressin have been found to play an important role in the instigation of this ischemic state.

Chronic Pathology

Chronic mesenteric ischemia (CMI) is a "rule-out" diagnosis for chronic abdominal pain. However, the incidence is increasing due to the overall aging population and so to have the number of surgical interventions for this malady. CMI is more common in late middle-aged smokers; 60% of the afflicted are female which is a contradistinction from other vascular diseases where the majority of patients are male. Atherosclerosis in the SMA is a relatively common phenomenon; despite this, clinically significant mesenteric stenosis is relatively rare. In fact, autopsy series have found that up to two third of patients have a significant SMA lesion.

A history of a patient with CMI must include the pathognomonic of postprandial pain. Patients will usually describe dull pain that begins 1–2 h after a meal. This postprandial pain is what is often called "food fear." CMI patients frequently present with significant weight loss.

Ischemic Colitis

Ischemic colitis is the result of decreased perfusion to the colon. Because of the collateral pathways that exist between the SMA, the IMA, and the hypogastric arteries, this problem is uncommon in patients with well-developed collaterals. Patients are susceptible to this problem when they have had surgically ligated collaterals from prior colon surgery or congenitally absent arteries. The marginal artery of Drummond is absent in approximately 5% of the population.

Venous Mesenteric Ischemia

Mesenteric venous thrombosis is the least common form of mesenteric ischemia, accounting for 5–15% of cases. It is divided into acute and chronic presentations in which the cutoff is 4 weeks of symptoms. The etiology of mesenteric venous thrombosis is divided into either primary or secondary. Primary thrombosis is spontaneous and idiopathic and is not associated with any other disease process or hypercoagulable state. Secondary venous thrombosis is associated with hypercoagulability, malignancy, cirrhosis, splenomegaly, intra-abdominal infection, trauma, and pancreatitis. Hypercoagulable states associated with thrombosis included protein C and S deficiency, antithrombin III deficiency, polycythemia vera, thrombocytosis, sickle cell disease, factor V Leiden mutation, and others.

Mesenteric venous thrombosis is generally not as severe as arterial thrombosis in symptomatology. These patients generally present with several days to weeks of diffuse, nonspecific, and often intermittent abdominal pain. Physical exam findings are vague, but most commonly they have abdominal distension. These patients rarely have peritonitis, since it is only present with advanced cases with bowel infarction.

CT is the most sensitive test for mesenteric venous thrombosis. MRI and ultrasound have also been used. Once the diagnosis is made, therapeutic anticoagulation should be started. Unlike arterial ischemia, thrombectomy has not been shown to have proven benefit except in select cases. Generally, chronic, lifelong anticoagulation is recommended in patients that survive the initial episodes. Obviously, any patient with peritonitis should be explored emergently and dead bowel should be resected.

Nonocclusive Mesenteric Ischemia

The cause of nonocclusive mesenteric ischemia is usually a low-flow state in the setting of preexisting atherosclerotic lesions and then coupled with the administration of vasoconstricting medications or digitalis. Low-flow states are generally cardiogenic shock or sepsis.

Treatment

Preoperative Planning

Preoperative planning for mesenteric revascularization is similar to that of other major revascularization procedures. Patients should be evaluated to coronary and cerebrovascular disease. They require the same basic workup as other surgical candidates. A major difference for these patients is that they are generally nutritionally debilitated. They are generally hypovolemic, dehydrated, and anemic. It is generally recommended that these patients have invasive arterial blood pressure monitoring during the procedure as they may be particularly sensitive to episodes of hypotension.

Open Surgery

Once the diagnosis of acute mesenteric ischemia has been made, prompt exploration and revascularization are essential. Open exploration remains the gold standard. The first critical step is to examine the bowel for viability and to surgically resolve the cause of the ischemia. Preoperative imaging should determine if it is CMI or others. Bowel ischemia is determined by visual inspection. Direct signs of bowel ischemia are a dull, ashen gray color, absence of the normal glistening sheen, and lack of peristalsis. Adjunctive maneuvers that can help determine viability include Doppler signals along the antimesenteric border, intravenous fluorescein, and use of a Wood's lamp. In catastrophic cases when the extent of ischemia is too great and any remaining bowel would not be enough to sustain life, it is reasonable to close the laparotomy without restoration of blood flow. In all other cases, it is essential to proceed with revascularization prior to bowel resection because bowel that appears dusky may, in fact, be resuscitated with adequate blood supply. Once blood flow is restored, any dead bowel should be resected, and the patient should be left open to return for a second look exploration.

Embolectomy

SMA exposure for embolectomy begins with retraction of the transverse colon cephalad, while the small bowel and its mesentery are retracted inferiorly. The SMA can be found by tracing the middle colic artery to its junction with the SMA (Fig. 5). A vessel loop is passed around the proximal SMA and the middle colic and jejunal branches for distal control. If direct repair is planned after embolectomy, a transverse incision is made to avoid narrowing the SMA on closure. If the vessel itself seems diseased, then a longitudinal incision is made with a plan to patch the vessel prior to blood flow restored. Proximal embolectomy is performed with a 3 or 4 French (F) Fogarty catheter. The catheter should be passed until pulsatile inflow is achieved. Gentle distal embolectomy is then performed, usually with a 2 or 3 (F) catheter. Preoperative clinical assessment along with imaging should indicate if the patient has acute ischemia on top of CMI or embolic acute mesenteric ischemia. The mortality for acute mesenteric ischemia is around 70%. Factors such as age, delay to surgery from presentation, level of adhesions, and amount of small and large bowel involvement, significantly affect the perioperative mortality. This catastrophic presentation of acute mesenteric ischemia differs significantly from the perioperative mortality of CMI which is 10–20%.

Bypass

Mesenteric bypasses can be categorized as either antegrade or retrograde. Antegrade bypasses are

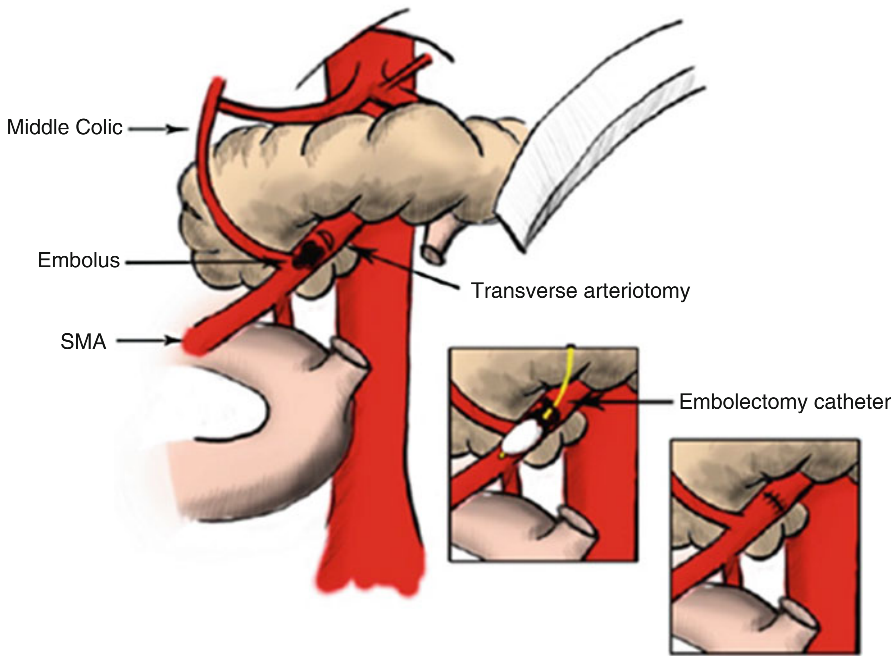

Fig. 5 Sagittal CTA 3D reconstruction in patient with embolus to SMA (arrow) of cardiac source

usually from the supraceliac/thoracic aorta which is an excellent site for inflow because it is generally spared from atherosclerotic disease. Either autologous or synthetic conduit can be used with equal efficacy and no data showing superior of one material over the other. Of course, if any concern for contamination is present, then using autologous vein graft is mandatory.

Exposure of the supraceliac aorta is typically performed through a midline incision or alternatively through bilateral subcostal incisions. The left lobe of the liver is mobilized by dividing the left triangular ligament and retracting the left lobe of the liver inferior and to the right. At this juncture, it is vital that a nasogastric tube is placed in order to identify and protect the esophagus during mobilization and clamping. The gastrohepatic omentum is divided, and the lesser sac is entered. The right crus of the diaphragm is divided with electrocautery. The celiac axis and SMA are then skeletonized. If possible, multilevel (hepatic and SMA) reconstruction should be performed for optimal outcomes and patency. With multilevel reconstruction, there is a better chance of long-term benefit; in case one of the bypasses thrombosis, collateral flow may prevent symptomatic recurrence. If possible, it is preferable to place a side-biting clamp on the aorta. Occasionally, it may be technically necessary to completely cross-clamp the supraceliac aorta; in these cases, the proximal anastomosis can usually be completed in less than 20 min, and the ischemic time is usually well tolerated. Most surgeons will perform the SMA anastomosis to the proximal SMA anterior to the pancreas, but it can also be tunneled retropancreatic and sewn to the SMA at the point distal to where it passes through the uncinate process of the pancreas.

A retrograde bypass is indicated when the supraceliac aorta is not suitable for the proximal anastomosis, i.e., it is aneurysmal or is atherosclerotic. It may also be scarred in from prior surgery, or the patient may not tolerate a supraceliac clamp. In these situations, retrograde bypass from the infrarenal aorta or the iliac vessels can be performed. By mobilizing the ligament of Treitz, the proximal SMA can be isolated below the inferior border of the pancreas at the base of the small bowel mesentery. The proximal anastomosis to the aorta or the right common iliac artery

Fig. 6 Lateral arteriography demonstrating long proximal SMA stenosis. Notice wire in SMA

is performed in an end-to-side fashion. The graft is brought in a gentle curve to the SMA which can then be sewn in end-to-side fashion. It is imperative to review the gentle curve with restoration of the small bowel to the abdominal cavity to avoid kinking of the conduit (Fig. 6).

Overall, the perioperative mortality for mesenteric revascularization for chronic disease is around 6%. Primary patency at 5 years is almost 90% whether performing retrograde or antegrade bypass, and there is no known patency difference for synthetic or autologous conduit. Overall patient survival is 75–80% at 3 years which is acceptable for this disease-burdened population.

Endarterectomy

Transaortic mesenteric endarterectomy is a useful technique for occlusive disease that is limited to the origins of the visceral vessels. Endarterectomy can be advantageous in that it resects the occlusive lesion; it is anatomic revascularization and avoids the turbulent flow that plagues grafts, and it is autogenous. The visceral aorta can be exposed through a midline or a thoracoabdominal incision. This procedure is generally reserved for patients with a "coral reef" aorta as it necessitates aortic cross clamping at the supraceliac aorta.

Exposure of the visceral aorta by midline incision is accomplished with left-sided medial visceral rotation. The splenic flexure is mobilized as well as the descending colon by dividing the peritoneal attachments. The spleen and pancreas are mobilized medially, and the left renal vein is identified and dissected free from the hilum to the cava. In order to retract the vein inferiorly, the adrenal and lumbar branches can be ligated. The left crus of the diaphragm is divided, and the distal thoracic aorta is thus exposed. Distal control is obtained in the infrarenal aorta. Finally, the mesenteric vessels are dissected out until disease free segments are found. After systemic heparinization, clamps are placed, and an aortotomy is created. Generally, gentle eversion endarterectomy is sufficient to treat ostial disease. If the SMA is diseased beyond the origin, it is beneficial to make a separate arteriotomy and vein patch angioplasty.

Endovascular

Percutaneous revascularization is a useful alternative to open reconstruction in patients with intestinal angina. In a retrospective comparison between open and endovascular revascularization, symptom relief and long-term patency were better achieved with open surgery, but the complication rate was also significantly higher in this group. Therefore, a full evaluation of the patient's health status and life expectancy should be considered when deciding the best approach.

Angioplasty and stenting of the mesenteric vessels follow similar rules as that of any other vessel. Ideal lesions are short, non-calcified and not caused by lesions that are not care by extrinsic compression (Figs. 5, 6, and 7). One major difference in SMA angioplasty is that approach is generally easier from left brachial access due to the acute angle of the artery. Purely endovascular techniques cannot be used in the acute setting when a thorough evaluation of bowel viability is mandated. In malnourished patients, this approach should be initially considered even if there is a complete occlusion. Modern endovascular techniques can many times cross totally occluded SMA.

Fig. 7 Repeat lateral intra procedure arteriography demonstrating full deployment of SMA stent and restoration of blood flow

This approach becomes an effective bridge to eventual formal revascularization.

Retrograde open mesenteric stenting (ROMS) is another viable option for a hybrid approach to this disease process. This technique still requires laparotomy for exposure and assessment of bowel integrity. In this modality, the SMA distal to the occlusion or one of the branches are punctures and recanalization is undertaken. One retrospective review found this to be an especially helpful alternative when percutaneous antegrade mesenteric stenting is unsuccessful. The mortality of ROMS is still 20% at 1 year, and primary patency was reported to be 83%.

Conclusion

Patient history is vital to distinguish between acute or acute on chronic pathology and can dictate surgical management. “Pain out of proportion to exam” is a key clinical finding for patient suffering acute mesenteric ischemia and should raise high suspicion. While atherosclerosis of the mesenteric vessels is quite common, mesenteric ischemia remains rare. Exploration via laparotomy is mandatory in any patient with peritonitic signs and suspicion for mesenteric ischemia.

Abstract
The normal physiology of the stomach and duodenum undergoes several changes as patients increase in age. Patients become more susceptible to *H. pylori* infection and the complications related to it, such as peptic ulcer disease, gastric volvulus, and gastric polyps. In addition, patients develop more comorbidities as they age, causing the impact of their disease and complications to be greater. Due to the changes of aging, patients require special perioperative considerations that involve the entire care team. Medical and surgical therapies must be tailored for the elderly patient.

Peptic ulcer disease · Peptic bleeding · Duodenal diverticula · Gastric volvulus · Gastroparesis

Case #1

Background

An 81-year-old Caucasian female with kyphosis arrives to the emergency department complaining of acute abdominal pain and chest pain for the last 3 h. She has associated retching and recently vomited a small amount of rust-colored blood. She denies any other symptoms, but her family affirms that she has some difficulty swallowing tough meats and breads for the past year, as well as heartburn. She has a history of scoliosis that has not required any interventions, as well as hypertension. She underwent a laparoscopic cholecystectomy approximately 10 years ago. Her current medications are hydrochlorothiazide and over-the-counter Tums. She has mild tachycardia with a heart rate of 103 but otherwise is not in distress. While examining her, she begins to have small amounts of emesis, which are bloody.

Management

An acute abdominal series is ordered which shows a large gastric bubble within the lower chest, consistent with a paraesophageal hernia. A CT scan is ordered and is concerning for an incarcerated paraesophageal hernia with gastric volvulus and impending ischemia. The patient remains stable. Nasogastric tube placement is attempted, but it will not pass beyond 35 cm.

An EGD is performed which shows a large hiatal hernia with retained food and liquid content.

A small area of mucosal ischemia is seen. The patient is prepped and draped for a laparoscopic reduction of paraesophageal hernia with reduction of gastric volvulus, gastropexy and gastrostomy tube placement, and repair of hiatal hernia by cruroplasty.

Case #2

Background

A 65-year-old female presents to her endocrinologist complaining of an increasing frequency of vomiting after meals. She states that she has had a long history of occasional vomiting after eating, but over the last 6 months the frequency has increased. She currently vomits after every meal and has associated bloating. She has tried home remedies and an elimination diet, as well as promethazine. She was unable to tolerate promethazine as it caused her confusion. Her past medical history includes diabetes since age 43, hypertension, peripheral vascular disease, and COPD. She is a current smoker. Her prior surgeries include a hysterectomy and tonsillectomy. She is currently using oral medications only to control her diabetes. On examination, her abdomen is bloated, and her mucous membranes are dry. Her physician orders a hemoglobin A1C and gastric emptying study which reveals that greater than 60% of the ingested meal remained within her stomach after 2 h. Her hemoglobin A1C reveals poor glucose control.

Management

It is recommended that the patient gain better control of her glucose level prior to considering a surgical intervention. She is started on short-acting insulin and commits to keeping a glucose log. Dietary modification is also recommended, with the patient encouraged to avoid high-fiber and high-fat foods, as well as carbonated beverages, and to eat six small meals a day. In addition, she was prescribed ondansetron for symptom control. Prior to leaving the clinic, she was given a bolus to correct her dehydration.

Anatomy and Physiology of the Stomach and Duodenum

The stomach comprises five anatomical regions: the cardia, fundus, body or corpus, antrum, and pylorus. The cardia is contiguous to the lower esophageal sphincter and is the transition between the esophagus and the stomach. The cardia is used to create a reference horizontal plane that delineates the second and third regions of the stomach, the fundus, and the body, respectively. The fundus is located above this horizontal plane. The body is delineated proximally by the horizontal plane at the level of the cardia and distally by the incisura angularis. The incisura angularis is located at the abrupt right angle created by the lesser curvature in the distal portion of the stomach; it marks the transition between the body and the antrum [1]. The pylorus lies at the junction of the stomach and aids with digestion and gastric emptying [2].

The duodenum is divided into four anatomical regions. The first part is the duodenal bulb, which is approximately 5 cm. It attaches to the pylorus and crosses over the common bile duct, portal vein, pancreatic head, and gastroduodenal artery [3]. Beyond this is the second portion of the duodenum, the descending duodenum. The second portion contains concentric folds of mucosa called the Kerckring folds, which are seen on endoscopy. This portion of the duodenum is approximately 10 cm and travels over the right renal vasculature, the inferior vena cava, and to the right of the lumbar vertebrae (L1 and L2). The ampulla of Vater, where the common bile duct and main pancreatic duct join the duodenum, is located here. The third portion of the duodenum is referred to as the transverse duodenum and is also 10 cm in length. It crosses from right to left anterior to the spine, aorta, and inferior vena cava. The superior mesenteric artery and vein travel above this portion of the duodenum and delineate the third portion from the fourth portion, called the ascending portion of the duodenum. This portion is approximately 5 cm long and travels upward and obliquely to the ligament of Treitz, where the bowel becomes intraperitoneal and joins the jejunum [3].

Microscopically, the stomach has four different layers. The external layer or serosa is an extension of the visceral peritoneum that covers the entire stomach. Beneath this is the muscularis propria which is formed by three different layers of muscle: an inner oblique layer, a middle circular layer, and an outer longitudinal layer. The middle muscular layer forms the pylorus at the end of the stomach. The muscularis propria contains many ganglion cells that create a neuronal plexus known as myenteric or Auerbach's plexus. The third layer or submucosa is a firm matrix of collagen and elastin that contains plasma cells, lymphocytes, lymphatics, and blood vessels. Numerous ganglion cells are also located in this layer; they form the submucosal or Meissner's plexus. The gastric lumen is lined by the innermost layer, the gastric mucosa, which is formed by a columnar epithelium that covers a layer of connective tissue (lamina propria) and a thin muscular layer known as the muscularis mucosa. The columnar epithelium invaginates and contains different gastric pits. Each gastric pit opens to four or five different gastric glands [4]. While the entire surface of the stomach is lined with glands, each region has a different function and histology except for mucous cells. Mucous cells are the most common type of gastric cell and are present in the surface throughout the stomach. The mucus and bicarbonate secreted by them create a neutral mucous film that prevents back diffusion of hydrogen ions (H +) from the gastric lumen to the cells. This film is very viscous due to the high concentration of long-chain oligosaccharides. Mucous cells also produce a hydrophobic film of phospholipids that blocks back diffusion of hydrogen ions [5].

The duodenum contains the same four distinct layers; however the retroperitoneal segments are only covered by serosa on the anterior portion. The mucosa has a crypt and villus structure. The villi project into the lumen and contain epithelial cells and lamina propria, with the principal roles of absorption and secretion. Within the submucosa of the duodenum are Brunner glands that secrete mucus and bicarbonate into the lumen to neutralize the gastric acid as it enters from the stomach [3].

Gastric glands can be classified as oxyntic or antral based on the main type of cell present. Oxyntic glands are present in the proximal stomach (fundus and body), while antral glands are found in the distal stomach (antrum). Oxyntic glands produce pepsin and gastric acid. The main component of oxyntic glands are parietal cells. These cells contain multiple mitochondria that generate the energy required for acid secretion. The apical membrane of parietal cells contains the H+/K+-ATPase pump, responsible for gastric acid secretion. Parietal cells are mainly present in the proximal stomach (fundus and the body) [1]. Chief cells are located at the base of the oxyntic glands. They store pepsinogen inside intracytoplasmic granules that are secreted shortly after eating. This effect is mediated by acetylcholine. Pepsinogen is converted to pepsin in the gastric lumen; it breaks down ingested proteins into smaller peptides. Pepsin has optimal activity at pH 2.5, but if the intraluminal pH rises above 5, pepsin becomes deactivated [6]. The body of the stomach also contains enterochromaffin-like cells (ECL) that express histidine decarboxylase. ECL cells secrete histamine in response to acetylcholine release during the cephalic or vagal phase of gastric secretion. Histamine is also secreted in response to gastric distention, a response mediated by gastrin. Histamine induces the release of gastric acid by parietal cells [4].

The major function of antral glands is to produce gastrin [7]. G cells are the major component of antral glands and are also located in the duodenum [3]. They secrete gastrin in response to gastric distention, vagal stimulation, or with increase of the intraluminal concentration of peptides and amino acids. Gastrin increases the secretion of gastric acid and pepsinogen. It also induces cell growth and differentiation of parietal cells. D cells release somatostatin into the bloodstream when the concentration of gastric acid increases. The primary location of these cells is the antrum, but the body of the stomach and the duodenum also has D cells. Somatostatin inhibits the secretion of gastric acid, histamine, and gastrin [6].

The duodenum produces and secretes cholecystokinin (CCK) within the I cells, which causes contraction and emptying of the gallbladder, increased bile flow, and relaxation of the sphincter of Oddi, as well as stimulating pancreatic enzyme secretion. This is directly stimulated by amino or fatty acids. Secretin is produced in the S cells of the duodenum and causes the release of water and bicarbonate from the pancreas. It is released when there is low intraluminal pH, fatty acids, and bile salts [3]. The K cells of the duodenum release gastric inhibitory peptide in response to glucose, fat, protein, and adrenergic stimulation. It inhibits the gastric acid and pepsin production and stimulates the secretion of insulin [3]. The enteroendocrine cells of the duodenum secrete motilin in response to alkalinization of the duodenum; motilin causes stimulation of the migrating myoelectric complex and promotes GI motility. Finally, neurotensin and glucagon are secreted in small part by the duodenum. Neurotensin is produced in response to fat and stimulates bicarbonate secretion from the pancreas and GI motility. Glucagon is released in states of hypoglycemia and promotes glycogenolysis, lipolysis, gluconeogenesis, and ketogenesis [3].

Effect of Age on Physiology

Gastric and duodenal diseases are influenced by age. The surgeon caring for elderly patients has to understand that not only comorbidities influence the clinical scenario; aging affects the normal physiology, histology, and pathology of the stomach and duodenum. The major changes in physiology and histology associated with normal aging are:

1. Gastric motility. Aging is associated with normal gastric emptying of liquids but slower gastric emptying with solid foods. In healthy subjects the presence of nutrients in the small intestine decreases antral contractions, increases the pyloric tone, and induces relaxation of the gastric fundus. These responses are mediated by different hormones, but cholecystokinin (CCK) is most responsible for this response. The plasma concentrations of CCK are persistently elevated in older patients before and after meals. As a consequence, they experience decreased appetite and slower gastric emptying [8]. The decrease in gastric motility can influence drug absorption. This is one of the reasons older patients have more side effects as compared to younger patients [9].
2. Bicarbonate secretion. Aging decreases both the basal and induced secretion of bicarbonate in the stomach which decreases acid neutralization in elderly patients [8].
3. Mucous. The quality of the mucus in the stomach decreases with age; this effect is independent of *Helicobacter pylori* infection and any medication. The total number of mucous secreting cells decreases after *H. pylori* infection [9].
4. Prostaglandin (PG) synthesis. The main types of PGs identified in the gastric mucosa are PGE2 and PGI2 and lesser amounts of PGF2 and PGD2 [5]. Mucous cells release PGE2 and PGI2 on epithelial injury. Both molecules increase the mucosal blood flow and induce the release of mucous and bicarbonate secretion. The mucus and bicarbonate create a pre-epithelial barrier that keeps the pH neutral [6]. Gastric biopsies from elderly patients show a decrease in PGE2 and PGF2 levels [10].
5. Pepsin. Studies evaluating the secretory function of the stomach have indicated that pepsin secretion decreases in elderly subjects [11].
6. *H. pylori* infection prevalence. The prevalence of *H. pylori* infection increases with age, with rates up to 80% in patients older than 80 years. Chronic infection with *H. pylori* induces atrophic gastritis, causing hypochlorhydria. Aside from *H. pylori* status, current evidence suggests that gastric acid secretion is not influenced by aging [12].
7. Changes in gastric mucosa. A recent histopathology database study showed an age-dependent change in gastric mucosa over a lifetime. While the majority of these are

caused by *H. pylori* infection, reactive gastropathy is the second most common change in gastric mucosa. This is likely caused by the cumulative effect of exposure to damaging factors over an individual's lifetime, such as NSAIDS [13]. There is no evidence that mucosal blood flow changes in older healthy patients.

8. Decreased number of Brunner's glands. The number of Brunner's glands in the duodenum is decreased, which may cause impaired ability of the duodenum to neutralize the acid secretions from the stomach. It may also affect the activation of pancreatic enzymes that are dependent on a certain pH. Of note, this may also affect drug solubility [14].

Perioperative Considerations in the Elderly Patient

The aging population means that an increasing number of operations will be performed in the elderly patient population. Special perioperative considerations should be taken to improve outcomes in this growing patient population. Efforts to improve geriatric surgical outcomes must involve the entire surgical team, pre- and postoperatively. Strong consideration should be made to consulting geriatric medicine if available as a resource.

1. Risk assessment. Thoughtful care of the geriatric patient starts with an understanding of the specific risks associated with surgical intervention, in particular emergency surgery. This allows the surgeon to have informed conversations with the patient and family pre- and postoperatively and to align the care of the patient with their wishes. Acute kidney injury, ASA class IV or higher, and a Charlson score of 4 or higher are significantly predictive of 30-day mortality [15]. Although initially developed in internal medicine patients and used among oncology patients, the Charlson score takes into consideration comorbid conditions of elderly patients and has been shown to be useful in the surgical setting [15, 16]. The impact of a surgical intervention on an elderly patient extends beyond 30 days, with ASA class IV or higher, Charlson score of 4 or higher, BMI <18.5 kg/m^2, and a low serum albumin being predictive of 1 year mortality. BMI >30 kg/m^2 was protective against death [15].
2. Analgesia. Due to the higher sensitivity to narcotics in elderly patients, a multimodal and balanced use of pain control agents is recommended, including local or topical anesthetics, acetaminophen, NSAIDs (with PPI prophylaxis for stomach protection), and other nontraditional pain management agents such as gabapentin or ketamine. Peripheral nerve blocks and spinal or epidural anesthesia may be considered [17]. These modalities can be particularly useful in managing the pain associated with abdominal incisions.
3. Postoperative delirium. Rapid treatment of the underlying disease state, dehydration, and infection helps prevent or improve delirium, as well as normalization of the patient by providing eye glasses, hearing aids, daytime activities to encourage wakefulness, and a normal sleep-wake cycle [17]. If feasible, minimize nighttime interruptions such as lab draws and vital signs. In addition, encouraging family members or familiar caretakers to stay with the patient will normalize the environment and help orient the patient.
4. Fluid resuscitation. Elderly patients are more susceptible to dehydration but also have reduced total body water volume, as well as reduced glomerular filtration rate and reduced ability to concentrate urine, making them more susceptible to fluid retention and volume overload. Cautious and thoughtful fluid resuscitation using chloride-restricted IV fluids and small colloid boluses results in better outcomes in the elderly [17].
5. Aggressive pulmonary toilet. Incentive spirometry, early mobilization, and upright position are helpful in the elderly population [17].
6. Posthospital care. Every effort should be made to return patients to independent care, as research suggests that many elderly patients are discharged to post-acute care facilities

when they are functionally independent and without postoperative complications [18]. Being placed in a post-acute care setting may be associated with worse outcomes [19].

Peptic Ulcer Disease

Epidemiology

The number of admissions, operations, and mortalities related to peptic ulcer disease (PUD) has generally decreased; however, the proportion of patients older than 65 years admitted for duodenal or gastric ulcer complications is increasing [20]. The first clinical manifestation of PUD is an acute abdomen in up to 50% of elderly patients [21]. Acute upper gastrointestinal (GI) bleeding related to PUD is more frequent in elderly patients [22, 23].

Pathophysiology

PUD results from multiple factors that either injure the mucosal barrier in the stomach and duodenum or increase the production of gastric acid. In the healthy gastric mucosa, the mucus and bicarbonate form a hydrophobic pre-epithelial barrier that prevents backflow of H+ and maintains a neutral pH even with an increased intraluminal concentration of gastric acid [6]. Mucosal injury occurs regularly but is repaired by the mucosal defense system. Cells in the gastric mucosa are replaced continuously, so that the epithelium is renewed every 2–4 days. The normal response after epithelium damage is migration of healthy cells from the gastric pits to denuded areas of the basement membrane, as well as an increase in the release of mucus by damaged cells and the release of plasma by the mucosal vessels. When mucus and plasma mix, they create a mucoid cap that protects the denuded area. Although the basement membrane is highly sensitive to gastric acid, the mucoid cap prevents further damage because it has a neutral pH. This response is dependent on mucosal blood flow. Sensory afferent nerve endings in the mucosa release calcitonin gene-related peptide (CGRP) if the gastric mucosa gets exposed to gastric acid. CGRP vasodilates mucosal vessels. The increase in blood flow is mediated by nitric oxide. The enhanced blood flow buffers, dilutes, and removes gastric acid. PGs are crucial for this defense because they induce the release of mucus, bicarbonate, and phospholipids from the mucous cells. PGE2 and PGI2 also increase blood flow to the gastric mucosa [5]. True ulcers occur if the insult continues and extends into the muscularis propria.

Classification of Gastric Ulcers

Gastric ulcers are classified according to location and possible physiopathology into four types: Type I are gastric ulcers located in the antrum, typically along the lesser curvature; Type II are gastric ulcers associated with a history of previous or active duodenal ulcer; Type III are prepyloric ulcers; Type IV are ulcers located near the GE junction. While Types II and III are associated with increased acid production, Types I and IV are associated either with malignancy or decreased mucosal defense [24]. Type V are secondary gastric ulcers, such as from NSAID use, and can occur anywhere in the stomach.

Etiology

The main factors that predispose to PUD are as follows:

Helicobacter pylori

This microaerophilic gram-negative spiral bacterium colonizes the pre-epithelial mucous layer of the stomach and is one of the most common human chronic infections worldwide. The transmission is either fecal–oral or oral–oral. Prevalence is influenced by socioeconomic status, ethnicity, and age. Approximately 50% of the world's population is infected; the frequency is higher in developing countries with poor sanitation and household hygiene and with low family income and educational level. In the USA, the prevalence increases with age: less than 10%

before 30 years, 50% around 50 years, and up to 80% in patients older than 80 years [9, 20, 25]. *H. pylori* secretes urease, which produces ammonium, which favors gastric colonization with *H. pylori* and damages epithelial cells. *H. pylori* also produces proteases and phospholipases that affect the efficacy of the mucous-bicarbonate layer. *H. pylori* has a rich catalase activity that blocks the neutrophil response [26]. These bacteria also release toxins that generate a chronic inflammatory response which results in type B atrophic gastritis. Why *H. pylori* induces duodenal inflammation is not fully understood. Some studies suggest that gastric metaplasia in the first portion of the duodenum facilitates *H. pylori* colonization and further inflammation. Other studies posit that antral *H. pylori* infection increases gastric acid secretion because the ammonia produced by *H. pylori* increases the pH to which G cells are exposed and because the population of the D cells decreases with *H. pylori* infection. Duodenal *H. pylori* infection decreases bicarbonate secretion in the duodenal cells [26].

Nonsteroidal Anti-inflammatory Drugs

At least 40% of the patients older than 65 years use NSAIDs. Between 1% and 8% of these patients will require a hospitalization to treat a NSAID-related complication. Duodenal and gastric ulcers develop in 5–8% and 15–20% of patients taking NSAIDs, respectively. Proton pump inhibitors (PPI) or misoprostol decreases the risk of PUD, but only 10–20% of the patients receive prophylaxis [22]. The risk of NSAIDs' toxicity increases with age; the risk of serious GI complications after 1 year of NSAID ingestion is 0.32% in patients older than 65 as compared to 0.039% in younger patients [27]. NSAIDs significantly decrease the production of mucus, bicarbonate, and phospholipids in the stomach and duodenum because these drugs inhibit the activity of COX-1 and COX-2. The final result is a pre-epithelial barrier that cannot prevent H+ backflow. NSAIDs also disrupt mucosal healing because they decrease PG synthesis; therefore the mucoid cap cannot be formed, and the increase in mucosal flow and mucosal regeneration cannot occur. COX-1 inhibition also releases endothelin-1, a potent vasoconstrictor, and for that reason blood flow to the mucosa decreases in patients with mucosal injury induced by NSAIDs [27]. NSAIDs also increase the expression of leukocyte adhesion molecules and neutrophil adherence. Neutrophils cause further damage because they release proteases and reactive oxygen metabolites [5]. The toxic effects of NSAIDs are mainly systemic, but these drugs also induce topical cytotoxic injury in the gastric mucosa because they increase cellular permeability with diffusion of the drugs to mucosal cells [5]. NSAID ingestion and *H. pylori* infection are independent risk factors for PUD, but if both factors coexist, the risk of PUD is synergistically increased [28]. This is particularly likely in elderly patients because both risk factors are more prevalent in older populations [20].

Zollinger–Ellison Syndrome

This syndrome is associated with neuroendocrine tumors that secrete excessive amounts of gastrin into the bloodstream. Gastric acid greatly increases in these patients. Zollinger–Ellison syndrome (ZE syndrome) accounts for 0.1–1% of all peptic ulcers. The diagnosis requires an elevated gastrin (>500 pg/ml) in the presence of an acidic gastric pH (pH <5). In patients with non-diagnostic gastric elevations (>150 but less than 500 pg/ml), a rise of more than 120 pg/ml after the intravenous administration of secretin (0.2 mg/kg) is diagnostic. The tumor can be localized with CT, MRI, endoscopic ultrasound, selective arterial secretin stimulation test, and somatostatin receptor scintigraphy, but surgical exploration of the gastrinoma triangle with intraoperative ultrasound is the best method to localize the tumor. This entity is more common in young patients (mean age 41), but it should be considered in patients with atypical PUD localization (ulcers in the second, third, or fourth portion of the duodenum or jejunum), severe gastroesophageal reflux, diarrhea, PUD refractory to treatment, and recurrent disease in patients without *H. pylori* infection or NSAID ingestion [29].

Smoking

Smoking decreases wound healing, increases the risk of *H. pylori* infection, and is an independent risk factor that predicts failure to antibiotic treatment [30].

Clinical Manifestations of Uncomplicated Peptic Ulcer Disease

The cardinal symptom is epigastric pain without radiation. This pain is frequently described as "burning," "gnawing," or "hunger pain." It is usually exacerbated with fasting and relieved with the ingestion of food or antacids. The presence of symptoms other than pain such as weight loss, anorexia, melena, hematemesis, constant pain, or pain radiating to the back suggests complicated PUD. Differential diagnosis includes dyspepsia, upper GI malignancies, symptomatic cholelithiasis, pancreatitis, and GERD. Elderly patients always require an extensive workup because the risk of malignancy increases with age. The gold standard test to diagnose PUD is an upper endoscopy. Duodenal ulcers typically occur in the first portion of the duodenum; they are usually not associated with malignancy (risk less than 1%). The presence of multiple ulcers or ulcers located beyond the second portion of the duodenum suggests ZE syndrome. Gastric adenocarcinoma exists in up to 5% of the patients with gastric ulcers with gross benign appearance; therefore all gastric ulcers should be biopsied [24].

Medical Treatment for Uncomplicated Peptic Ulcer Disease

The mainstay of treatment is to inhibit gastric acid secretion. This can be achieved with proton pump inhibitors (PPIs) or with histamine H2-receptor antagonists (H2RA or H2 blockers). PPIs are irreversible inhibitors of the H+/K+-ATPase. The recommended therapy for duodenal ulcers is 4–6 weeks with the rate of healing between 80% and 100%. For gastric ulcers the recommended therapy is 8 weeks, and the healing rate is 70 and 85%. In cases of associated hypergastrinemia or NSAID ingestion, the treatment should be continued. H2RAs are reversible inhibitors of the histamine H2-receptor in the membrane of parietal cells. The healing rate is 70–80% in duodenal ulcers and 55–65% in gastric ulcers. The duration of therapy is the same as with PPIs [6]. An alternative in the treatment of PUD is sucralfate. This agent improves mucosal healing by creating a protective barrier in the ulcer, as well as stimulating bicarbonate, mucous, and growth factor release. Misoprostol is a PG analogue that improves ulcer healing; however, it is frequently associated with GI side effects such as diarrhea.

The presence of *H. pylori* infection is associated with a high recurrence rate; in duodenal ulcers the recurrence rate is 95% without *H. pylori* eradication compared to 12% for those patients who receive eradication treatment. The recurrence rate for gastric ulcers without *H. pylori* eradication is 74% vs. 13% after eradication [26]. The two most common techniques to diagnose *H. pylori* infection are urea breath test and gastric biopsy; other tools are rapid urease testing, culture, polymerase chain reaction, antibody testing, and the fecal antigen test. Eradication treatment is always indicated in patients with PUD, complicated or uncomplicated. The current regimens approved by the FDA for the eradication of *H. pylori* are listed in Table 1. The success rate is approximately 80% [31].

Patients with gastric or duodenal ulcers associated with NSAIDs require replacement of the NSAIDs with an alternative pain regimen plus the administration of a PPI. Prophylaxis with misoprostol or PPIs is indicated in elderly patients who cannot stop NSAIDs. With prophylaxis, the incidence of ulceration decreases from 20% to 4.5% [5].

Clinical Manifestations of Complicated Peptic Ulcer Disease

The first clinical manifestation is a complication in 50–60% of elderly patients [27]. Elderly

Table 1 FDA approved regimens for Helicobacter pylori eradication[a]

Regimen	Duration (days)
1. Omeprazole 20 mg b.i.d. + Clarithromycin 500 mg b.i.d. + Amoxicillin 1 g b.i.d.	10
2. Lansoprazole 30 mg b.i.d. + Clarithromycin 500 mg b.i.d. + Amoxicillin 1 g b.i.d.	10
3. Esomeprazole 40 mg q.d. + Clarithromycin 500 mg b.i.d. + Amoxicillin 1 g b.i.d.	10
4. Rabeprazole 20 mg b.i.d. + Clarithromycin 500 mg b.i.d. + Amoxicillin 1 g b.i.d.	7
5. Bismuth 525 mg q.i.d. + Metronidazole 250 mg q.i.d. + Tetracycline 500 mg q.i.d. + Histamine-2 Receptor Antagonists[b]	14

[a]The success rate is around 80%
[b]In this regimen the total duration of Histamine-2 receptor antagonists therapy is 4 weeks

patients frequently have comorbidities that affect their mental status or pain perception (uncompensated diabetes, stroke, dementia) or they are receiving drugs that create or mask PUD (i.e., NSAIDs, narcotics, steroids). The diagnosis is frequently challenging because the normal systemic inflammatory response (fever, leukocytosis) may be absent in elderly patients or may be affected by drugs (steroids, beta-blockers) [21, 23]. PPI, H2RA, and antibiotic therapy for *H. pylori* have decreased the number of elective surgical procedures required for PUD, but the incidence of complications such as perforation or bleeding has not changed significantly over time.

Perforation

Between 2% and 10% of the patients with duodenal ulcers present with a perforated ulcer. Elderly patients frequently present to the emergency room without any history of PUD. The diagnosis is suggested by acute epigastric pain that rapidly becomes generalized. The patient is often diaphoretic and tachycardic; low-grade fever can also occur. The presence of generalized tenderness, positive rebound, and abolished peristalsis is usually evident, but the physical examination in very old or immunocompromised patients can be nonspecific. The diagnosis may be confirmed with chest radiography because 70–80% of the patients have free subdiaphragmatic air. If the physical examination is inconclusive or in the absence of free air, the most useful test is a CT scan of the abdomen and pelvis; this study excludes other diagnoses and is highly sensitive to detect free intra-abdominal air. Although conservative treatment with antibiotics and IV fluids has been described in hemodynamically stable patients with contained perforations, elderly patients usually require surgical treatment. After the initial evaluation, fluid resuscitation is crucial. Elderly patients frequently have cardiovascular comorbidities that require careful management, and external and/or internal monitoring of their hemodynamic status may be useful. Broad spectrum antibiotics should be started on diagnosis. The initial assessment and medical therapy should not delay operation. The most frequent surgical procedure for perforated ulcers is primary closure plus reinforcement with an omental patch. The treatment for perforated ulcers is summarized in Fig. 1.

Primary Closure Reinforced with Omental Patch

The patient is placed in the supine position under general endotracheal anesthesia; a nasogastric tube and Foley catheter are placed. The repair may be approached laparoscopically or via a midline supraumbilical incision. After ruling out other diagnoses, attention is turned to the perforation. If the ulcer is on the posterior wall of the stomach, the gastrocolic ligament is divided to enter the lesser sac. Ulcer biopsies should be sent as gastric cancer can simulate perforated PUD. The defect is closed with a full-thickness single layer of interrupted 3-0 silk or vicryl stitches (Fig. 2). The primary closure is reinforced with omentum

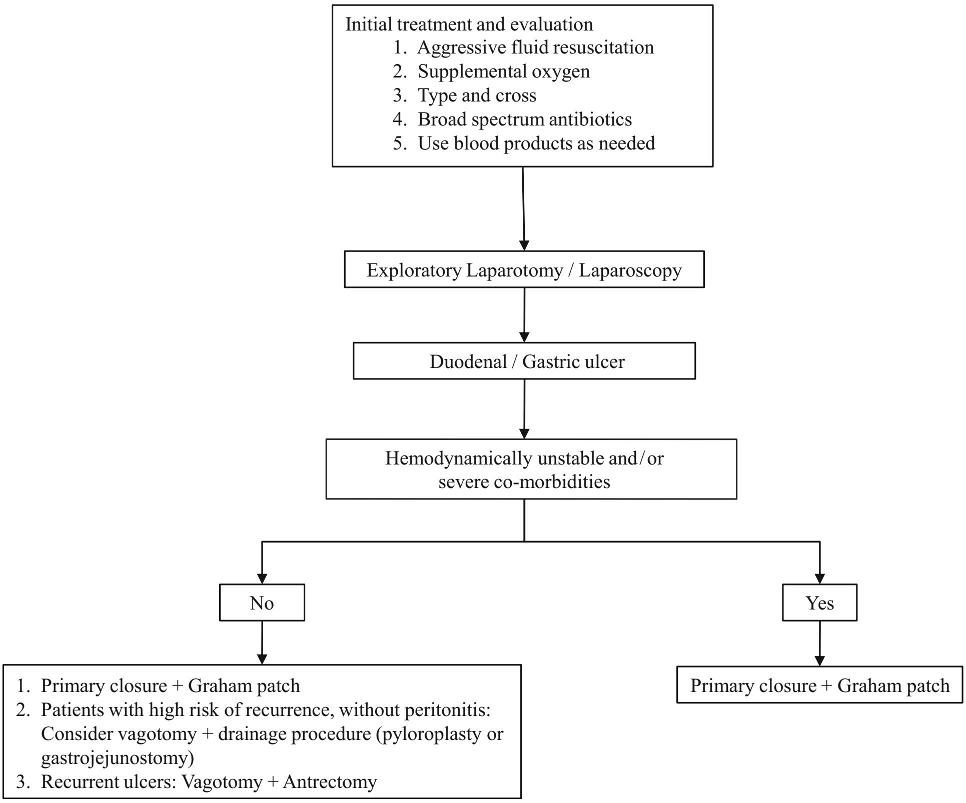

Fig. 1 Algorithm for the management of perforated peptic ulcers in elderly patients

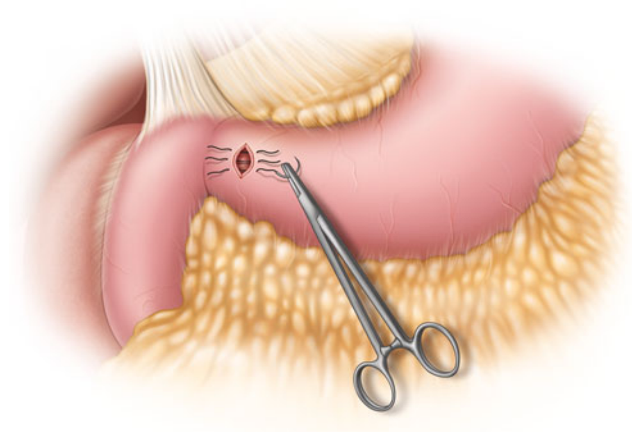
Fig. 2 Primary closure of a perforated ulcer



(omental patch) (Fig. 3). The tails of the sutures are used to hold the omental pedicle, avoiding ischemia, while the sutures are tied (Fig. 4). It is important to avoid vascular injury to the omentum during dissection of the gastrocolic ligament. The abdominal cavity is copiously irrigated.

For duodenal ulcers, after a complete exploration is done, the duodenum is mobilized anteriorly and medially (Kocher maneuver). This maneuver avoids excessive tension on the primary closure. Both the anterior and posterior surfaces are carefully inspected. Routine biopsies are not required

Fig. 3 Reinforcement of the primary closure using an omental patch

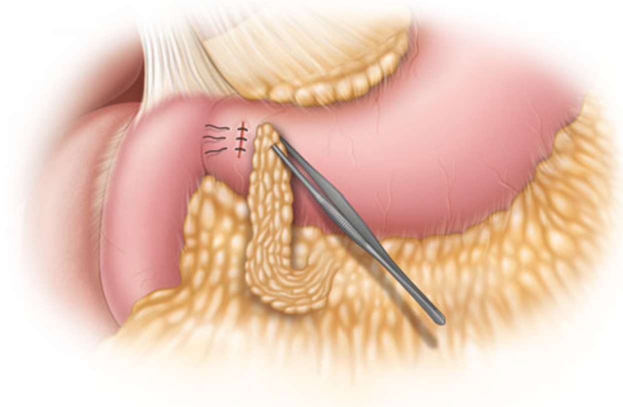


Fig. 4 Final view of the primary repair of a perforated ulcer with an omental patch

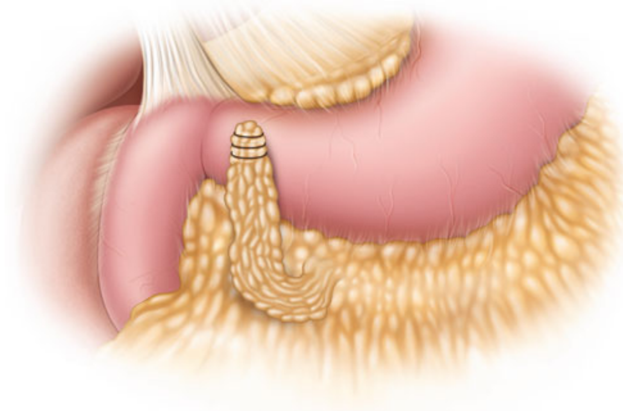

because the risk of malignancy in duodenal ulcers is very low. The duodenal defect is closed following the same principles for a gastric ulcer: interrupted full-thickness sutures reinforced with an omental patch. Duodenal ulcers are associated with more inflammation and defects larger than gastric ulcers, so if a primary closure is not possible, a true omental patch (Graham patch) is used. In this repair the ulcer margins are not approximated, the orifice is only plugged with omentum sutured to the duodenal defect. For very large perforations, a jejunal serosal patch can be used, which involves suturing a loop of jejunum to the perforated ulcer. Drain placement and distal feeding access should be considered based upon the size of the ulcer, difficulty of repair, and patient factors.

Patients are usually extubated unless they have persistent hemodynamic instability and/or if the patient has any respiratory issues. The integrity of the repair is evaluated with an upper GI study using water-soluble contrast, typically 3–7 days after operation. The nasogastric tube is kept to prevent gastric or duodenal distention, and it is removed after there has been an imaging study negative for leak, the output is low, and bowel function has returned. An esophagogastroduodenoscopy is recommended in the postoperative period, typically 6–8 weeks following surgery, to verify healing of the ulcer.

Performing additional procedures that decrease gastric acid secretion is not recommended because elderly patients frequently present with shock and severe comorbidities that require a rapid intervention. Often, these patients have a delay in diagnosis, and generalized peritonitis is found during the laparotomy; therefore, further dissection of the hiatus increases the risk of other complications such as mediastinitis. It is also important to consider that PPIs and *H. pylori* eradication treatment decrease the risk of recurrence.

The morbidity and mortality associated with perforated PUD are between 25–89% and 4–30%, respectively. Risk factors associated with increased morbidity and mortality are age, delay in diagnosis, high ASA score (III and IV), and shock during the operation. Age is crucial because patients older than 65 years have a mortality rate of 37.7% as compared with 1.4% in younger patients. A delay in diagnosis (>24 h) increases the mortality rate in elderly patients. The most common causes of mortality are myocardial infarct, arrhythmias, septic shock, and pneumonia. Resection procedures (i.e., antrectomy) are also associated with more mortality than primary closure in these patients [32].

Bleeding

Bleeding is the most common complication of PUD, which in turn is the most common source of upper GI bleeding. It is seen in 15–20% of the patients [33, 34]. The frequency of acute upper GI bleeding has decreased in general, but the proportion of patients older than 60 years who have bleeding is increasing; recent studies have published that 65% and 25% of the patients are older than 65 and 80 years old, respectively [22, 23]. This trend is a result of increased life expectancy; older patients have more comorbidities that predispose them to PUD (i.e., chronic renal failure, myeloproliferative disorders, portal hypertension) or that require anticoagulation. Elderly patients ingest more NSAIDs either as analgesics or as a preventive measure for other disorders. The most important risk factor to develop GI bleeding is NSAID ingestion. These drugs decrease the mucosal defense to gastric acid and inhibit platelet aggregation by decreasing thromboxane A2 production. The risk is dose dependent, but bleeding also occurs with low aspirin doses (75–325 mg/day) [35]. The risk of bleeding is considerably lower with COX-2 inhibitors as compared with nonselective NSAIDs, but COX-2 inhibitors can induce bleeding when they are combined with anticoagulants, aspirin, or any other NSAIDs [33]. The risk of bleeding significantly increases in patients taking anticoagulants, serotonin reuptake inhibitors, or drugs that prevent platelet aggregation [27]. *H. pylori* infection marginally increases the risk of bleeding; however, concomitant NSAIDs use and *H. pylori* infection significantly increase the risk of bleeding [28].

Symptoms include melena, hematemesis, fatigue, and/or hematochezia. The primary focus during the initial evaluation is assessment of the hemodynamic status. The presence of tachycardia, systolic blood pressure <100 mmHg, postural hypotension, or altered mental status suggests a significant blood loss. The initial goals of resuscitation are to establish a secure airway if needed, to ensure proper oxygenation and ventilation, and to administer IV fluids. It is mandatory to obtain a complete blood count, glucose, blood urea nitrogen, creatinine, electrolytes, INR, type, and crossmatch in all patients. The use of blood products needs to be individualized for each patient; any history of coronary artery disease lowers the threshold for packed red blood cells. Plasma or anticoagulation reversal agents should be considered in any patient with a coagulopathy associated with drugs or comorbidities; however, the risks and benefits should be considered in light of the patient's clinical condition. Once the patient is hemodynamically stable, he or she should be thoroughly examined. In the absence of any other disease, the physical examination of the abdomen is usually unremarkable.

Upper endoscopy is the gold standard in the initial evaluation because it can be diagnostic and therapeutic. Upper endoscopy may identify the source of the bleeding, and bleeding can be stopped using hemoclips, sclerosing agents, epinephrine, thrombin or fibrin glue, or thermal contact with bipolar electrocoagulation, heater probe, or argon plasma. Except for epinephrine, all these techniques can be used either to stop active bleeding or to prevent it in visible vessels. Epinephrine injection can partially control the bleeding before implementation of other techniques. Endoscopic therapy has a low complication rate (0.5%) [36]. The two most common complications are perforation and induced bleeding.

Most bleeding duodenal ulcers are in the posterior wall of the first portion of the duodenum; the bleeding almost always arises from the gastroduodenal artery (GDA) [20]. The most common vessels that bleed in the stomach branch off the inferior branch of the left gastric artery in the lesser curvature [24]. Approximately 20% of the patients will rebleed after endoscopy. For these patients, a second endoscopy is indicated because the success rate is high without significant morbidity; however, if bleeding persists, surgery or interventional radiology intervention is necessary [37]. Interventional radiology can often selectively cannulate and embolize the bleeding vessel.

Another indication for surgery or another intervention is a persistent transfusion requirement, typically considered to be more than 4 units given during a 24-h time span. However, since elderly patients develop coagulopathy more quickly than younger patients and they are at risk of rebleeding when coagulopathic, intervention needs to be considered in elderly patients before four units of blood are required. In addition, ongoing bleeding may aggravate preexisting comorbidities and cause myocardial infarction, renal failure, and stroke. Ulcer size is not considered a surgical indication, but ulcers bigger than 2 cm are associated with an increased risk of rebleeding. If a patient has an ulcer >2 cm and presents with persistent hypotension, surgical treatment should be considered [23].

Adequate platelet aggregation and hemostasis require an intragastric pH >6. Different studies have shown that high doses of PPI decrease the rebleeding rate by 54% and the need for surgery by 41%. The recommended regimens are pantoprazole 80 mg IV bolus followed by 8 mg/h for 3 days or pantoprazole 80 mg IV bolus followed by pantoprazole 40 mg IV every 12 h [38]. Figure 5 summarizes the diagnosis and treatment of bleeding ulcers.

Surgical Treatment of Bleeding Gastric Ulcers

Most gastric ulcers that bleed are type I. The anesthesia, patient's position, and incision are similar to duodenal bleeding ulcers. Treatment depends on the hemodynamic status of the patient. For those with shock, a conservative approach that only aims to control bleeding is recommended. Through an anterior gastrotomy, the ulcer is biopsied and oversewn with figure of eight stitches. The gastrotomy is closed in two layers using the same technique described below for closing bleeding duodenal ulcers. Stable patients with recurrent or large ulcers may require an antrectomy. The gastrocolic ligament is divided to enter the lesser sac; this dissection begins in the middle point between the pylorus and the cardia and is continued distally to the pylorus where the right gastroepiploic vessels are transected. Adhesions between the posterior gastric wall and the pancreas are divided. The gastrohepatic ligament is divided in order to control the inferior branch of the left gastric artery. The proximal and distal margins of this dissection are the incisura angularis and the beginning of the first portion of the duodenum, respectively. The stomach is divided proximally with a gastrointestinal anastomosis (GIA) stapler. The first portion of the duodenum is divided immediately after the pylorus with a stapler. The integrity can be restored with a Billroth I, Billroth II, or a Roux-en-Y gastrojejunostomy. The first option for reconstruction is a gastroduodenostomy, or Billroth I, which requires a complete Kocher maneuver to avoid tension on the anastomosis. The duodenum is mobilized close to the gastric remnant. The anastomosis is done in two layers. The internal layer is a continuous full-thickness layer using a 3-0 absorbable suture reinforced by a second layer of interrupted seromuscular sutures with 3-0 silk (Lembert type). This anastomosis is considered the most physiological reconstruction as the normal transit of the stomach goes to the duodenum; however, alkaline gastritis can occur. Previous scarring can limit the Kocher maneuver and prevent a tension-free anastomosis. The second reconstruction is a Billroth II procedure or gastrojejunostomy, which is preferred in cases with excessive scarring that prevent duodenal mobilization. This side-to-side anastomosis is created between the posterior gastric wall and the anti-mesenteric border of a jejunal limb (10–20 cm distal to the ligament of Treitz). The jejunum is brought up to the stomach, anterior or posterior to the transverse colon

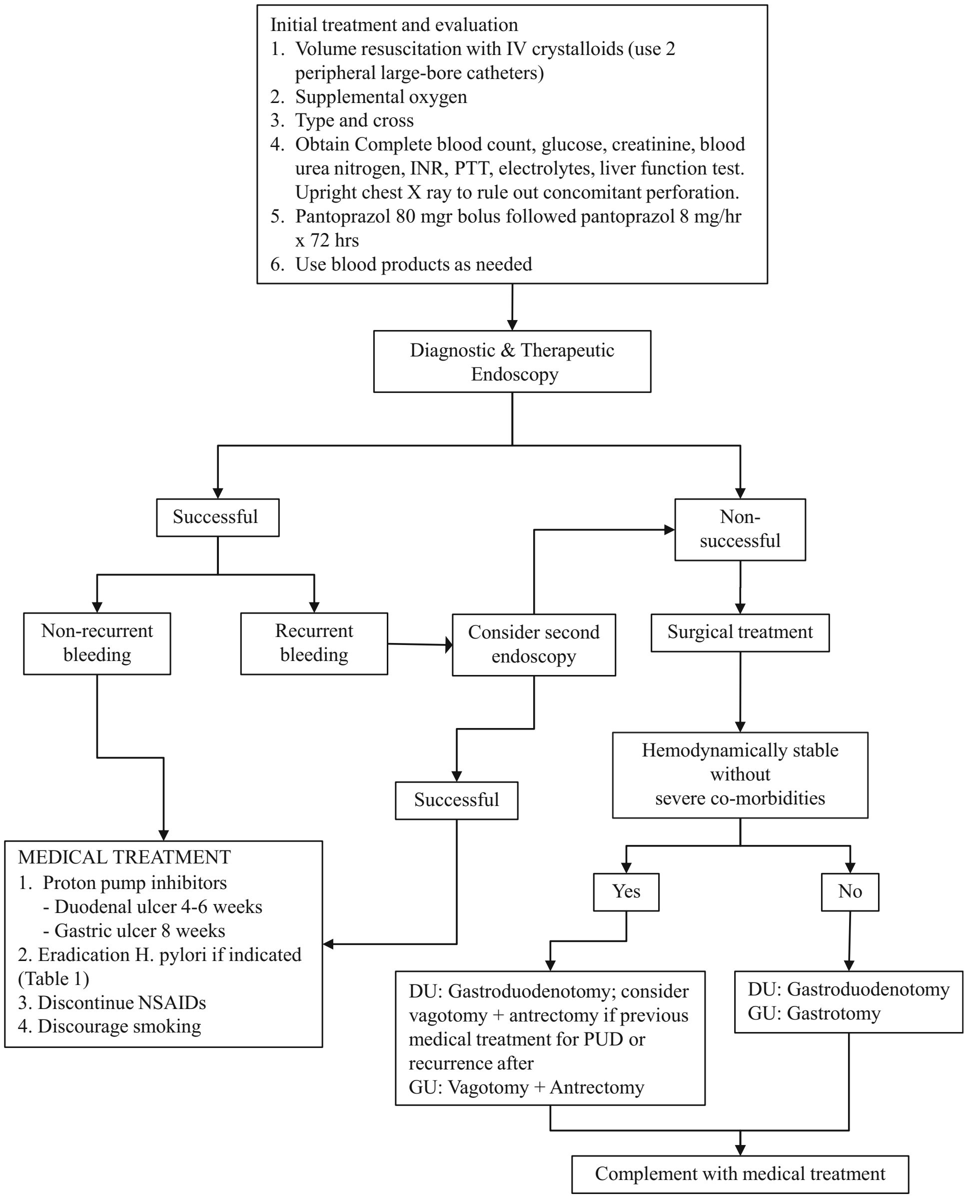

Fig. 5 Algorithm for the management of acute peptic ulcer bleeding in elderly patients

(antecolic or retrocolic, respectively). There is no functional difference in benign diseases. The anastomosis is created with a stapler or manually using the Hofmeister technique. The anastomosis is stapled through a small gastrotomy and enterostomy. The stapler is introduced through these defects, and the anastomosis is created. Both orifices are closed manually with a continuous full-thickness layer reinforced by an interrupted seromuscular layer. The mesenteric defect in the mesocolon is closed with interrupted 3-0 silk stitches in order to avoid internal hernias. The two most common options to restore are Billroth I and II, but both anastomoses predispose patients to alkaline gastritis or reflux; therefore, some surgeons recommend a reconstruction using a Roux-en-Y gastrojejunostomy for benign conditions.

Truncal vagotomy was previously performed in conjunction with a resection but with advances in the medical treatment of ulcer disease and the understanding of *H. pylori* disease is now rarely indicated. It is typically not used in the setting of perforation and is only indicated for patients who bleed on active PPI therapy, have a high risk of recurrent gastric outlet obstruction due to ulcer disease, or for intractable ulcer pain after all medical therapies are exhausted. It should always be combined with a gastric emptying procedure [39].

Surgical Treatment of Bleeding Duodenal Ulcers

The anesthesia, positioning, and incision are the same as for perforated ulcers. A full Kocher maneuver follows an exploratory laparotomy. Profuse bleeding in the first portion of the duodenum can be partially stopped by compressing the duodenal bulb. The pylorus is identified by the palpation of the concentric ring between the stomach and the duodenum or by visual identification of the pyloric vein that crosses anterior to the pylorus (Mayo's vein). Two 3-0 silk sutures are placed in the superior and inferior borders of the anterior surface of the pylorus. A 3-cm longitudinal gastrotomy perpendicular to the pylorus is followed by 3-cm extension toward the duodenum. The most common bleeding vessel is the GDA, which is located in the posterior duodenal wall (Fig. 6). Three stitches are placed to stop bleeding: two initial figure of eight stitches in the superior and inferior margin of the ulcer followed by a third figure of 8 or U-stitch that controls the pancreatic branch of the GDA (Fig. 7). Each suture must be placed carefully to avoid injury to the common bile duct. Once vascular control is achieved, the duodenum and stomach are carefully inspected to rule out any other source of bleeding. The aperture is closed transversely. The internal layer is a full-thickness continuous closure with an absorbable 3-0 suture reinforced by a second layer of interrupted seromuscular stitches using 3-0 silk (Lembert type) (Fig. 8). The closure can be reinforced with omentum, similar to a Graham patch.

This complication has a mortality rate that ranges between 10% and 35% in patients older than 60 years as compared with 10% in younger patients. Bleeding is the most common complication that causes death in PUD. Risk factors that predict high mortality are increased age, severe associated comorbidities, rebleeding, or patients that present with hypotension, shock, or in-hospital bleeding [20, 22, 24].

Gastric Volvulus

Gastric volvulus occurs when the stomach rotates more than 180° and may lead to vascular compromise, ischemia, and perforation, which is life-threatening. This condition has a peak incidence in the fifth decade of life. The volvulus may happen with an intra-abdominal stomach or an intrathoracic stomach within a paraesophageal hernia or due to a congenital or traumatic disruption of the diaphragm [40].

The presentation may be acute or chronic. Acute volvulus often presents with pain and vomiting. Associated hematemesis is a concerning sign, as it suggests mucosal damage due to ischemia. Patients with chronic volvulus often present with difficulty swallowing, mild abdominal pain, and bloating [40]. Diagnosis is typically confirmed acutely with a CT scan or chest X-ray. Chronic volvulus may be diagnosed on an upper GI series.

Treatment of the gastric volvulus depends on the clinical condition of the patient. In a stable patient, gastric decompression with an NGT can be attempted. An EGD may be performed as well to assess the mucosa for ischemia. This may also facilitate placement of the NGT for decompression. If there are no signs of ischemia and the patient is stable, this allows time for operative planning and often facilitates a laparoscopic repair. In the case of an unstable patient or concerns for ischemia, then immediate operative repair should be undertaken. A laparoscopic approach is still recommended if

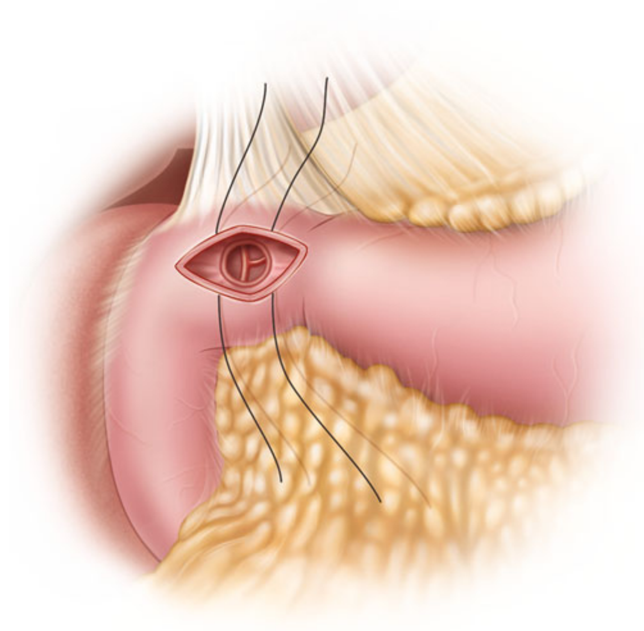

Fig. 6 Bleeding ulcer in the posterior wall of the rst portion of the duodenum

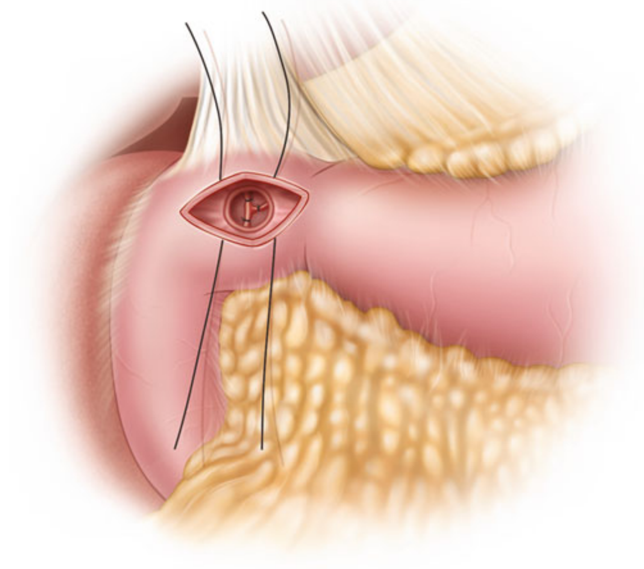

Fig. 7 Hemostasis of the GDA using 3-0 silk stitches

feasible. The aim of the operation is to reduce the volvulus, prevent recurrence, and repair any predisposing factors [40]. In addition, any ischemic tissue will need to be resected and reconstructed. Gastric reduction is accomplished by dividing any adhesions and/or reducing any herniation of the stomach and returning it to its normal anatomical position. Prevention of recurrence often involves pexy of the stomach to the abdominal wall and/or placing a gastrostomy tube to encourage the stomach to adhere to the abdominal wall. These maneuvers do not

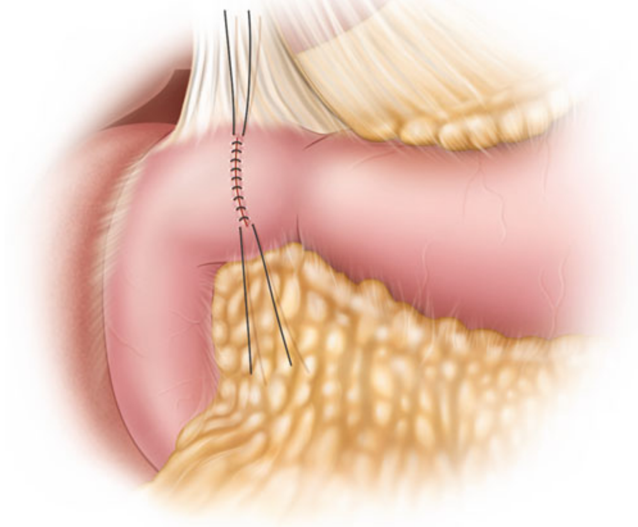

Fig. 8 Primary closure of the duodenotomy

necessarily prevent reherniation of the stomach into the chest but rather may reduce the risk of volvulus. Repairing any predisposing factors includes addressing diaphragmatic or hiatal hernias.

Gastric Outlet Obstruction

Gastric outlet obstruction (GOO) is the result of chronic edema, scarring, and fibrosis of the distal stomach or duodenum. The area proximal to the stenosis becomes chronically dilated; gastric dilation induces gastrin release, which is further aggravating because it increases gastric acid production. The incidence of GOO has declined with the advances in the medical therapy for PUD. GOO accounts for less than 5–8% of all PUD complications. The typical symptoms are early satiety, nausea, vomiting undigested food, heartburn, and weight loss. The most common GOO etiology is malignancy (60–80%); therefore multiple biopsies from the stenosis need to be taken [41]. Only 5–8% of patients with GOO have PUD [34]. Other diagnoses to consider are external duodenal or gastric compression (i.e., pancreatic pseudocysts, tumors) or GOO caused by a large gallstone (Bouveret syndrome), bezoars, or gastroparesis.

The initial evaluation relies on an upper endoscopy with multiple biopsies plus a water-soluble contrast upper GI series. If external compression is suspected, a CT scan is required. The initial treatment is conservative decompression using an NGT, IV infusion of PPIs, and correction of any electrolyte or acid–base disorder. Prokinetics are contraindicated. If *H. pylori* infection is proven, therapy is indicated because some studies report that symptoms improve after *H. pylori* eradication [41]. Nutritional status is also crucial; a liquid diet should be attempted unless the patient cannot tolerate ingestion. Severe GOO requires total parenteral nutrition.

Medical treatment improves GOO obstruction in 50% of the patients [42]. Endoscopic therapy with endoscopic balloon dilation increases the success rate up to 70% [43]. Serial dilations can be attempted in patients with recurrent stenosis, but the failure rate is proportional to the number of dilations attempted. The most common complication is perforation. Although experience with endoscopic stenting for malignancies is increasing, current data on benign disease is limited [44].

Surgical treatment may be indicated if medical therapies fail. The operation depends on the underlying etiology. In cases of GOO caused by recurrent PUD, a truncal vagotomy with antrectomy is indicated. A diverting laparoscopic or open gastrojejunostomy may also be sufficient in other disease states. Chronic gastric obstruction dilates the stomach with subsequent accumulation of food and secretions; this condition predisposes patients to aspiration pneumonia and wound infection due to bacterial overgrowth, so decompressing the stomach with an NGT is indicated before surgery. Duodenal dissection can be difficult in patients with chronic scarring; oversewing the duodenal stump is recommended due to the risk of duodenal stump leak.

Gastric Polyps

Gastric polyps are nodules of tissue, either sessile or pedunculated, which protrude into the gastric lumen [45]. Gastric polyps are seen in 0.5–2% of all endoscopies; most of them are asymptomatic but occasionally gastric polyps can grow, erode, and bleed. Large polyps can produce GOO [46–48]. Several types of gastric polyps can be found, but the three most common in elderly patients are hyperplastic polyps, fundic gland polyps, and adenomatous polyps. Uncommon type of polyps include inflammatory fibroid polyps, xanthomas, Peutz–Jeghers-type hamartomatous polyps, juvenile polyps, gastric polyps associated with Cowden disease, and finally gastric polyps associated with Cronkhite–Canada syndrome [49].

Hyperplastic Polyps

Hyperplastic polyps are the most common variety found during endoscopies in areas where *H. pylori* infection is common [47–49]. The incidence increases with age (mean age of diagnosis is 64–75 years), and they are more prevalent in women. Hyperplastic polyps are usually asymptomatic but are associated with other gastric diseases such as autoimmune gastritis, ZES, antral vascular ectasia, gastric amyloidosis, or cytomegalovirus gastritis [49]. Gastrin plasma levels are higher than controls [45]. The most common location is the antrum followed by the fundus and body. The mean size is 1 cm, although larger hyperplastic polyps have been reported. They are typically an incidental finding during an upper endoscopy. These polyps are usually sessile. The typical histological findings show elongated, dilated, tortuous foveolae lined by mucin-containing epithelium and edema of the lamina propria [48]. The natural history is variable. *H. pylori* eradication is associated with regression [46]. Most hyperplastic polyps are benign and asymptomatic, though a routine biopsy is recommended because final histology reports dysplasia or carcinoma in 1.5–4% of the patients. This risk of malignancy is higher in polyps larger than 2 cm [48, 49].

Fundic Gland Polyps

These polyps are the most common type of benign gastric polyps found in areas with low prevalence of *H. pylori* infection but common use of PPIs. They can be found sporadically or associated with familial adenomatous polyposis at any age, and they are also now recognized as sequelae of long-term PPI use. The most common location is in the fundus. Gastrin values are usually normal [45, 47]. Histology reveals cystic dilated glands lined by parietal and chief cells [48]. When sporadic or associated with PPI use, these polyps can regress spontaneously; routine follow-up is not required because they are ot premalignant [45]. However, when associated with a familial syndrome, surveillance is recommended [50].

Adenomatous Polyps

The incidence of these polyps also increases with age. They are associated with atrophic gastritis and are more prevalent in countries with a high incidence of gastric cancer [48]. The median age of diagnosis is 67 years [46]. The most common location is the antrum, and gastrin levels do not differ from controls. The risk of malignancy is higher in adenomatous polyps than any other gastric polyp, especially if the size is greater than 2 cm (40–50% risk of malignancy) [48]. *H. pylori* eradication does not cause regression. Routine excision is recommended because they may be malignant [46].

Dieulafoy Lesion/Malformation

Dieulafoy lesion is an abnormal submucosal artery associated with a minute mucosal defect frequently associated with bleeding. It causes between 1% and 5.8% of acute nonvariceal upper GI bleeding. The most common location is the stomach followed by the first portion of the duodenum, but they can occur throughout GI tract or in the bronchial tree. The most common location in the stomach is the fundus and body [51]. Histology reveals a submucosal artery that does not undergo the usual ramification within the wall of the stomach or failure to diminish to the minute size of the mucosal capillary vasculature without any inflammation or defect in the mucosa [52]. It is more common in men. The mean age of diagnosis is 63 years, so they are frequently associated with comorbidities. Most patients develop melena and hematemesis along with hemodynamic instability. The treatment follows the same principles described previously for bleeding peptic ulcers; the initial goal is hemodynamic stabilization followed by an upper endoscopy. The same endoscopic techniques described for PUD are used to stop bleeding. The success rate is >90% [53]. In patients who do not respond to endoscopic therapy, local wedge resection of the lesion is indicated.

Gastroparesis

Gastroparesis indicates impaired transit of intraluminal content from the stomach to the duodenum without a mechanical obstruction [54]. It affects 4% of the population.

Etiology

The most common causes of gastroparesis are diabetes, idiopathic, and surgery; however, the most common etiologies in the elderly patient are as follows:

1. Diabetes. Gastroparesis is present in 30% of the patients with type 2 diabetes [55]. Different theories explain this effect. Since gastroparesis is seen in patients with other manifestations of autonomic neuropathy, it is believed that autonomic neuropathy contributes to the development of gastroparesis. Diabetes decreases the number of interstitial Cajal cells, induces smooth muscle fibrosis, and decreases the neurons present in Auerbach's plexus. Hyperglycemia decreases gastric emptying [55]. Diabetes is the most common cause of gastroparesis in elderly patients because diabetes is one of the most common comorbidities seen in this population.

2. Upper GI surgery. Any operation that involves the distal esophagus, stomach, or duodenum can be complicated by delayed gastric emptying. Unfortunately, upper GI malignancies that require surgery are more common in older patients. This complication is also seen in benign diseases; gastroparesis may occur after any operation for PUD or anti-reflux procedures.
3. Neurologic diseases. Parkinson disease and strokes are associated with gastroparesis. Parkinson disease is present in 7% of patients with gastroparesis [55].

4. Drugs. Elderly patients often require drugs that delay gastric emptying such as calcium channel antagonists, L-dopa, opiates, tricyclic antidepressants, and aluminum antacids [54].
5. Other comorbidities. Renal insufficiency, hypothyroidism, previous abdominal radiation, cirrhosis, chronic pancreatitis, and paraneoplastic syndromes can produce gastroparesis.

Clinical Manifestation

The most common symptoms are nausea, vomiting, bloating, early satiety, epigastric pain, and belching. Although in severe gastroparesis the previous symptoms are present with liquid meals, they are more frequent with solid meals. Physical examination usually shows abdominal distention, mild pain, and tympanic percussion in the epigastrium, but in severe cases dehydration is evidenced by tachycardia, orthostatic hypotension, poor skin turgor, and dry mucous membranes. Succussion splash is also present in severe cases. Gastroparesis should be suspected in any patient with predisposing conditions associated with the symptoms previously described. An extensive workup can rule out cancer, dyspepsia, GOO secondary to PUD, pancreatitis, GERD, cyclic vomiting syndrome, chronic pancreatitis, and superior mesenteric or rumination syndromes. An upper GI radiographic study with contrast plus an upper endoscopy is frequently required to rule out any anatomical obstruction. Retained food in the stomach (with proper fasting) without anatomical obstruction increases the probability of gastroparesis. The gold standard for diagnosis is gastric emptying scintigraphy. In this test the patient receives a solid meal (typically scrambled eggs) mixed with technetium-99 sulfur colloid. Gastric emptying is measured after 2, 3, and 4 h. The diagnosis is confirmed if more than 60% of the meal is retained after 2 h or 10% after 4 h [56].

Treatment

The initial goal of therapy is to correct any preexisting dehydration or electrolyte disorders. The medical treatment has different components: dietary recommendations, control of predisposing conditions, and drug therapy. In elderly patients, predisposing conditions are irreversible or difficult to treat. However, good metabolic control and replacement of any drug that delays gastric emptying are required. Meals rich in fiber or fat should be avoided because they delay gastric emptying; carbonated beverages should also be avoided. Frequent small meals are better tolerated than larger meals [55]. Prokinetic drugs such as erythromycin and metoclopramide improve gastric emptying. Different studies have shown that erythromycin is the most potent agent because it activates motilin receptors and increases both antral peristalsis and gastric emptying. Metoclopramide is a benzamide that increases the contraction in the esophagus, fundus, and antrum; it also elevates the lower esophageal sphincter pressure and improves antral–pylorus–duodenal coordination. It is also helpful to control vomiting [57]. However, metoclopramide should be used with caution in the elderly, who may be more likely to experience side effects such as tardive dyskinesia or confusion.

Nausea and vomiting are present in 92% and 84% of the patients, respectively; therefore antiemetics are also indicated. The most useful agents are phenothiazines (prochlorperazine and tiethyperazine). Serotonin 5-HT3 receptor antagonists such as ondansetron may be helpful because they do not affect gastric emptying. Muscarinic M1 receptors antagonists such as scopolamine and H1RA such as promethazine are not recommended because they inhibit gastric emptying [55]. They should also be avoided in the elderly due to their anticholinergic effects.

The role of surgery in gastroparesis is limited to patients with severe gastroparesis that require multiple hospitalizations plus enteral or parenteral nutrition and those patients who fail medical treatment. Surgery relies on the placement of gastric stimulation devices that alter the gastric myenteric neural network and interrupt gastric arrhythmias [58]. Through laparoscopy or open approach, two electrodes are placed 1 cm apart in the muscularis propria along the greater curvature 10 cm proximal to the pylorus. The electrodes are connected to a neurostimulator located in a subcutaneous pocket outside the abdomen [58]. A recent study showed that gastric electrical stimulation produces a good outcome in 70% of the patients, most of whom are able to tolerate oral diets after placement and have a significant increase in the body mass index [58]. In addition, there is a growing role for other therapies, including pyloroplasty, transpyloric stenting, endoscopic pyloromyotomy, and Botox treatment of the pylorus [59]. For patients with refractory symptoms, placement of a palliative gastrostomy or feeding jejunostomy should be considered.

Duodenal Diverticula

Diverticula of the duodenum occur in approximately 5–22% of individuals, typically located along the pancreatic or mesenteric border of the second portion of the duodenum [60]. Often they are asymptomatic but may be diagnosed at the time of a complication, such as inflammation, bleeding, obstruction, or perforation. CT scan is the most useful imaging in the diagnosis of duodenal diverticula. If perforated, management ranges from conservative treatment with antibiotics and percutaneous drainage to a surgical diverticulectomy, with or without duodenal diversion based upon the amount of inflammation and the clinical status of the patient. In the case of a diverticulectomy, a single- or double-layer duodenal closure with placement of drainage tubes is recommended. A patch of omentum over the repair may be considered. Care should be taken to avoid the ampulla of Vater, as diverticula occur commonly around this area [60]. Distal feeding access should be considered at the time of the operation.

Complications After Gastric Surgery

It is not uncommon for elderly patients to develop complications after gastric surgery. Each region has a particular response to food ingestion, which is mediated by the vagus nerve. The proximal stomach is the main reservoir for liquids; and shortly after liquid ingestion there is a decrease in the tone in the fundus, which allows liquid storage. Antral motility is increased by the ingestion of solid meals, and it triturates large particles; only 1–2 mm particles pass through the duodenum. The pylorus controls the transit of food particles to the duodenum and limits alkaline reflux. Any operation that involves the intra-abdominal esophagus, stomach, and duodenum can affect the motor functions of the stomach. The most common postgastrectomy syndromes are as follows:

Dumping Syndrome

This syndrome can present after any vagotomy, drainage procedure, or gastric resection. Between 25% and 50% of the patients have some manifestations related to dumping syndrome. In approximately 10% of the patients, these symptoms are significant. After vagal denervation, the stomach loses the relaxation and accommodation reflexes; therefore, it cannot function as a reservoir. When a drainage procedure is added, gastric emptying cannot be controlled because the size of the particles is no longer regulated [61].

Dumping syndrome can be divided into early and late dumping syndrome. Early dumping syndrome presents within 30 min after food ingestion. This causes diaphoresis, weakness, dizziness, flushing, palpitations, fullness, crampy abdominal pain, nausea, vomiting, and diarrhea. Late dumping is seen 1–3 h after the ingestion of food. The rapid increase of carbohydrate concentration in the intestinal lumen induces a rapid absorption of carbohydrates with subsequent hyperinsulinemia, which then creates reactive hypoglycemia. Clinically, patients present only with vasomotor symptoms and no GI symptoms [61].

The pathophysiology of dumping syndrome is explained by the rapid transit of chyme, fluid shifts from the general circulation to the intestinal lumen, and pooling of the blood supply within the splanchnic circulation. This causes the increased heart rate, vasoconstriction, and elevated plasma norepinephrine levels seen in dumping syndrome. The symptoms are also caused by excessive secretion of gastrointestinal hormones, such as VIP, serotonin, and bradykinin, GLP-1, and norepinephrine levels.

The diagnosis is suspected in patients with a previous gastric surgery. It can be confirmed with a glucose oral challenge test or with gastric emptying scintigraphy. The mainstay of treatment is diet modification: liquids should be ingested 1 h after the ingestion of solids, simple carbohydrates should be avoided, and supplemental fiber is recommended, because it slows gastric emptying. Octreotide or acarbose, as well as antidiarrheal medications such as loperamide and tincture of opium, can help to control symptoms. Surgical therapy is a last resort if all other therapies have failed. If feasible, takedown of the gastrojejunostomy should be performed if the pyloric channel has reopened. If a pyloroplasty was previously performed, performing a longitudinal closure to re-create the original alignment can modify it and slow gastric emptying. Conversion to a

Roux-en-Y gastrojejunostomy may also be helpful [61].

Postvagotomy Diarrhea

The pathophysiology of this condition is unclear; some theories that may explain this complication are denervation of the small intestine, gallbladder, and common bile duct or rapid gastric emptying associated with rapid intestinal transit that leads to malabsorption. The diagnosis should be suspected in every patient with prior gastric surgery and a negative workup that excludes other causes of diarrhea. The initial treatment is dietary modification (avoid lactose and decrease liquid ingestion before meals) and the use of antidiarrheal agents (e.g., loperamide). For refractory untreatable diarrhea, the antiperistaltic interposition of a jejunal limb 100 cm downstream of the gastrojejunostomy may be considered [62].

Gastroparesis or Delayed Gastric Emptying

Gastric surgery is responsible for approximately 10% of all gastroparesis cases [54]. This complication was described previously.

Afferent Loop Syndrome

This is the result of an obstructed afferent limb secondary to stomal edema, kinking, scarring, stricture, adhesions, internal hernias, or cancer. It can occur acutely or chronically. It occurs in 0.3% of the patients that have a Billroth II. The typical manifestations are abdominal pain, nausea, and non-bilious vomiting. If the limb is partially obstructed, the abdominal pain may be relieved by vomiting. In severe cases the chronic obstruction can result in jaundice or pancreatitis. The diagnosis is confirmed with an endoscopy that demonstrates the obstruction. The initial treatment can be endoscopic using balloon dilation, but if it persists the gastrojejunostomy should be converted to a Roux-en-Y gastrojejunostomy. A second option is a Braun enteroenterostomy between the afferent and the efferent limb [63].

Efferent Syndrome

This syndrome results when the efferent limb of the gastrojejunostomy is obstructed. It can be acute or chronic and is manifested as abdominal pain, epigastric distention, and bilious vomiting. Upper endoscopy or an upper GI transit study is typically diagnostic. Possible etiologies are limb kinking, retroanastomotic herniation of the efferent limb, or adhesions. The treatment is surgical, either converting a Billroth II procedure into a Roux-en-Y gastrojejunostomy or revising the initial anastomosis [62].

Duodenal Stump Leak

Dehiscence of the initial duodenal closure after antrectomy is the typical cause of duodenal stump leak. This is more common in the setting of inflammation and scarring in this area but can also be a consequence of an incomplete duodenal mobilization or distal obstruction. It can be avoided with a Kocher maneuver to ensure that the closure is tension-free; however, if the area has fibrosis or acute inflammation, a lateral duodenostomy in the second portion of the duodenum to create a controlled duodenal fistula may be helpful. In a postoperative patient, percutaneous transhepatic duodenal diversion has also been described [64].

Alkaline Gastritis

After a Billroth I, Billroth II, or pyloroplasty, 5–15% of the patients develop gastritis associated with bilious reflux. Patients complain of epigastric pain, nausea, and bilious emesis. The diagnosis is obtained at time of endoscopy that shows gastric inflammation and the presence of bile. The diagnosis can also be made with bile acid scintigraphy. For patients with severe symptoms, the previous anastomosis can be converted to a Roux-en-Y gastrojejunostomy or a Braun enteroenterostomy.

Conclusion

H. pylori infection and NSAID ingestion are the major risk factors for the development of peptic ulcer disease in elderly patients. Unfortunately, an acute complication such as bleeding or perforation will be the first clinical manifestation in 50–60% of patients. Eradication of *H. pylori* decreases the risk of recurrent PUD, especially in light of the fact that elderly patients have worse outcomes than younger patients. Elderly patients are also at unique risk of other complications, such as gastric volvulus, which typically occurs in the setting of a paraesophageal hernia. These can be either chronic or acute, and initial conservative management is recommended once gastric ischemia is ruled out. The geriatric population is also at increased risk of a malignancy arising within adenomatous gastric polyps, and they also suffer with gastroparesis. The most common etiology of gastroparesis is diabetes, and its treatment is very difficult due to the undesirable side effects associated with most antiemetics and prokinetics. It is important to consider the unique risks and treatments required for elderly patients in a multidisciplinary setting.

Benign Disease of the Gallbladder and Pancreas in the Elderly

53

Morgan L. Cox and Alexander Perez

Contents

Abstract

Benign disorders of both the gallbladder and pancreas are important diseases to account for within the elderly population. The incidence of cholelithiasis increases with age, and acute cholecystitis is a common presentation in the elderly. Pancreatic disease including pancreatitis, most likely due to gallstones, is less common in the elderly, compared to the general population. Elderly patients are more likely to present with nonspecific, constitutional symptoms often leading to a delay in diagnosis. However, many of the diagnostic modalities and treatment algorithms essentially remain the same as endoscopic, percutaneous, and surgical interventions are safe and feasible in the elderly population. The higher risk of morbidity and mortality with biliary or pancreatic disease is due to decreased reserve and exacerbation of comorbidities making it critical to identify and optimize the comorbidities of these patients. A multidisciplinary team approach to a focused comprehensive geriatric assessment in the perioperative period helps identify risk factors and informs postoperative management, with improved outcomes.

Introduction

This chapter explores benign biliary and pancreatic disease in patients with advanced age. We will address the varying incidence of these diseases in the elderly compared to their younger counterparts and how they might present differently for medical care. Diagnosis and treatment algorithms are provided for each of the diseases discussed in addition to pitfalls in the treatment of benign biliary or pancreatic disease in the elderly population. Finally, the importance of adequate treatment of comorbidities and the role of specialized multidisciplinary, geriatric teams in perioperative care will be emphasized.

Gallbladder

Cholelithiasis

Cholelithiasis is the presence of gallstones within the gallbladder. The incidence of cholelithiasis increases greatly with age, and therefore, the most common cause of abdominal pain in elderly adults is due to biliary tract stones [1]. In a large autopsy series of elderly patients, about 30% had gallstones present while another 5% had a prior cholecystectomy [2]. In addition to increasing age, risk factors for the development of cholesterol gallstones include obesity, female gender, metabolic syndrome, rapid weight loss, diabetes, gallbladder dysmotility, and a sedentary lifestyle [3, 4].

Cholesterol stones are the most common type of gallstone in the general population including the elderly. These stones are typically yellow in color and consist of 70–80% cholesterol. Calcium bilirubinate stones are the second most common type of gallstone. These are black pigmented stones containing mostly insoluble bilirubin and calcium phosphate with less than 20% cholesterol. Black stones tend to be multiple and are commonly seen in patients with hemolytic anemia. The third type of gallstone is mixed or brown pigmented stones, and these stones typically form due to infection in the biliary tract when bacterial enzymes hydrolyze conjugated bilirubin. Mixed stones are more likely to be radiographically apparent due to the high calcium content. They commonly form de novo in the bile ducts which makes them primary gallstones [5].

Although there is an increased incidence in this population, elderly patients are less likely to present with typical symptoms of biliary disease. Cholelithiasis is most likely to have a silent presentation as most patients remain asymptomatic for decades. Only about 10% of individuals with known cholelithiasis will develop symptoms within 5 years and about 25% within 10 years [4].

Given the indolent course of asymptomatic cholelithiasis that is diagnosed incidentally when investigating a separate disease process, it is recommended that surgery be avoided. The risk of perioperative morbidity and mortality in the elderly outweighs the low incidence of developing symptoms or complications from gallstones.

The most common presenting symptom due to biliary colic or symptomatic cholelithiasis is recurrent abdominal pain. One third of elderly patients who present with symptomatic biliary disease for the first time will have recurrence with nonoperative management [6]. Compared to younger patients, the elderly are more likely to represent with complications of gallstones such as acute cholecystitis (40% versus 18%), gallstone pancreatitis (19% versus 6%), and choledocholithiasis (21% versus 5%) [7].

A prognostic nomogram has been developed by Parmer and colleagues to provide a 2-year risk of developing gallstone-related complications in elderly patients after their first presentation. Factors associated with acute hospitalization included male gender, increased age, fewer comorbid conditions, presentation to emergency department (ED) compared to primary care office, and complicated biliary disease. The 2-year emergent hospitalization rate due to biliary disease was 11.1% [8].

Therefore, due to the increased risk of complications and hospitalization, medical therapy or observation of the elderly patient with symptomatic gallstones is not optimal. Less than 10% of patients are suitable for a nonoperative plan as all of the following criteria must be met: stone <20 mm in diameter, less than four stones, and a functioning gallbladder [4]. Medical treatment consisting of oral dissolution therapy with ursodeoxycholic acid (UDCA) has an unpredictable success rate even within these very select patients.

Given elective or emergent laparoscopic cholecystectomy is safe and effective for cholelithiasis in the elderly population, surgical management of symptomatic cholelithiasis is the preferred option [9, 10]. Elderly patients have a slightly higher risk of postoperative complications and a longer hospital stay compared to younger patients, so the benefits of surgery need to outweigh the risks based on the individual patient's comorbidity profile [4, 11]. The goal of early surgical intervention is to reduce the risk of complications and the development of cholecystitis or cholangitis which can be fatal in the elderly population [12].

Choledocholithiasis

About 10–20% of individuals with gallstones will progress to have common bile duct (CBD) stones which are defined as choledocholithiasis [1]. About 25% of those patients will go on to develop serious complications due to the retained stones. Elderly patients are more susceptible to choledocholithiasis due to an increased diameter of the extrahepatic bile duct; this is thought to be from the fragmentation of longitudinal smooth muscle myocyte bands and connective tissues of the CBD [1]. This dilation of the CBD is age-dependent with an increase of about 0.04 mm per year. Therefore, the upper limit of normal for the diameter of the CBD in an elderly patient should be considered 8.5 mm [13].

Elderly patients with choledocholithiasis are more likely to present with generalized symptoms such as malaise or debility compared to the more characteristic symptoms of biliary disease seen in their younger counterparts. Nausea, emesis, and right upper quadrant or epigastric pain are more typical of patients with CBD stones. Other presentations include biliary colic, jaundice, cholangitis, and pancreatitis. Given the wide range of possible presentations within the elderly population, it is important to perform a timely and thorough workup in order to prevent a delay in diagnosis and the development of acute cholangitis which can be devastating in an elderly patient [1].

Laboratory testing in the elderly patient with abdominal pain should be broad including serum alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase (ALP), fractionated bilirubin, white blood cell count (WBC), hemoglobin, hematocrit, blood urea nitrogen (BUN), and creatinine (Cr). Patients suffering from choledocholithiasis most commonly have elevated ALP in addition to elevated gamma-glutamyltransferase which differentiates an elevated ALP due to bone disease. Liver enzymes can also be elevated in the setting of CBD stones especially with a longer duration of symptoms. An increased WBC is concerning for concomitant acute cholecystitis or cholangitis.

Imaging studies are typically obtained as adjuncts to physical exam and laboratory values in the diagnosis of biliary disease. Transabdominal ultrasound is the most recommended method given it is noninvasive with acceptable sensitivity and specificity. Transabdominal ultrasound actually has an increased sensitivity and accuracy for CBD stones with increasing age [1]. However, magnetic resonance cholangiopancreatography (MRCP) and endoscopic retrograde cholangiopancreatography (ERCP) are the most sensitive in detection of CBD stones. Without direct visualization of a stone, dilation of CBD on imaging is an independent predictor of the presence of a CBD stone [1].

Intravenous fluids and analgesia are the appropriate initial treatment for suspicion of choledocholithiasis. The elderly are believed to have an increased risk of infection and inflammation due to decreased immune competence [14]. Antibiotics should be administered in a timely fashion for those patients with stones complicated by cholangitis, to prevent systemic bacteremia. Allergies as well as declining renal and hepatic function should be considered when selecting antibiotics, analgesia, and dosages.

Pharmacologic choices are complicated further by sarcopenia in elderly patients, making serum creatinine a less sensitive determinant of renal function. Therefore, BUN and glomerular filtration rate should be evaluated as well.

After initial resuscitation and stabilization, the clearance of CBD stones for adequate drainage of the biliary tract is the highest priority. Pharmacological treatment of CBD stones with UDCA is not recommended in the elderly population as it has not been shown to make a difference in stone size or rate of successful duct clearance [1]. The time required for medical treatment, successful or not, puts the patient at risk for infection from persistent obstruction.

ERCP is first-line therapy for choledocholithiasis in all patients including the elderly. Complete extraction of stones from the bile ducts in choledocholithiasis is associated with a longer survival [15]. ERCP has been shown to have an overall complete clearance of CBD stones in over 95% of elderly patients [16]. During ERCP, there are a variety of interventions capable of clearing the CBD and preventing further obstruction including sphincterotomy and papillary balloon dilation [17]. Furthermore, endoscopic biliary stenting with a double-pigtail stent is a safe and feasible therapy following endoscopic sphincterotomy in elderly patients with choledocholithiasis [18]. This is an indicated procedure for patients with three or more common bile duct stones and/or stones greater than 20 mm in size [19].

Rates of post-procedural ERCP complications range 3–10% in elderly patients with no higher incidence due to advanced age [1, 20]. These complications include pancreatitis, hemorrhage, duodenal perforation, and events due to exacerbation of comorbid conditions such as myocardial infarction or stroke. Elderly patients with a concomitant malignancy have been noted to have a higher risk of adverse events following ERCP. Additionally, within the elderly population, those patients greater than 80 years old are more likely to suffer from bleeding, cardiopulmonary events, and death [1].

ERCP with sphincterotomy has a higher risk of peri-procedural bleeding but a lower risk of post-procedural pancreatitis compared to balloon dilation [1]. Therefore, it is recommended that elderly patients on antithrombotic therapy for cardiovascular, cerebrovascular, or peripheral vascular disease undergo papillary balloon dilation preferentially to reduce the risk of procedural bleeding. These patients should also be evaluated for extent of anemia and anticoagulation prior to undergoing a procedure of any kind [1].

As with many other diseases requiring procedural or surgical intervention in the elderly population, there is a higher risk of decompensation from an adverse event due to concomitant comorbidities and decreased functional reserve. Optimization of concurrent medical conditions is imperative in the peri-procedural period including an anesthetic assessment to tailor the sedation approach. A multidisciplinary team approach to a focused comprehensive geriatric assessment can help improve outcomes by providing a geriatric consultation to high-risk patients prior to surgery to identify risk factors preoperatively and manage them postoperatively [21]. With attention to detail, therapeutic ERCP in the elderly patient is safe, effective, and imperative to prevent progression of the disease and overall deterioration [1, 16, 20, 22].

Once endoscopic intervention or advanced imaging has ensured the CBD is clear of stones, definitive treatment with laparoscopic cholecystectomy is indicated to prevent recurrence and subsequent complications. Laparoscopic cholecystectomy has very good results in the elderly population allowing for a shorter length of stay (LOS) and decreased number of postoperative complications compared to an open approach. Alternatively, an open procedure is most commonly planned due to associated pathophysiology from pneumoperitoneum, acid-base disturbances, renal hypoperfusion, or pulmonary physiology leading to an increased anesthetic risk [23].

The importance of extracting CBD stones at the time of surgery for patients who did not have preoperative endoscopic intervention has been well described by Moller and colleagues [24]. Patients who did not undergo measures to remove ductal stones had a 25% chance of suffering postoperative complications including pancreatitis, cholangitis, and jaundice. This risk was decreased to 12.7% in patients who underwent intervention to clear the ducts [24].

Although not as commonly performed as ERCP, a surgical approach to clearance of CBD stones with a common bile duct exploration is considered safe and feasible in the elderly population [25–27]. A laparoscopic approach to CBD exploration carries a morbidity of 30% and a mortality of 3.4% [28]. These are similar results to those described in the general population [29]. Age should not preclude a common bile duct exploration at the time of surgery if the biliary tract was not previously cleared; however, the success rate of stone clearance from the CBD with surgery has been reported as significantly lower within the elderly population, 50% for >65 years old and 90% for <65 years old) [11]. This suggests preoperative clearance of the biliary tract with ERCP followed by definitive treatment with laparoscopic cholecystectomy is the optimal treatment of choledocholithiasis in the elderly population.

Gallstone Ileus

Gallstone ileus is a mechanical small bowel obstruction due to the impaction of a gallstone within the lumen of the intestine via a cholecystoenteric fistula. The most common fistula, accounting for almost 60%, occurs between the gallbladder and duodenum (cholecystoduodenal fistula) [30]. The obstruction most commonly occurs at the ileocecal valve where the stone is unable to pass.

The diagnosis of gallstone ileus is quite rare within the general population but it has a higher propensity to affect females and the elderly. While it causes only 1–4% of all small bowel obstructions, gallstone ileus accounts for 25% of nonstrangulated small bowel obstructions within the elderly population [31]. Overall, mortality is high at 8–18% making early diagnosis critical [32, 33].

Nonspecific history and clinical findings make the diagnosis of gallstone ileus more difficult. Many patients are treated for small bowel obstruction alone leading to a delay in the operative treatment of gallstone ileus. Plain abdominal radiograph is also nonspecific and only suggests intestinal obstruction. Cross-sectional imaging with computed topography (CT) scan is diagnostic with the triad of pneumobilia, small intestine dilation, and a radio-opaque gallstone located within the bowel lumen.

Surgical intervention is required for the treatment of gallstone ileus. However, there is persistent debate over the extent of surgery required. At minimum, an enterotomy with removal of the obstructing stone is necessary, and this is typically performed in an urgent or emergent fashion. Differing opinion suggests completion of the enterolithotomy in addition to cholecystectomy and closure of the fistula tract, known as the one-stage procedure, is required.

Postoperative mortality is lower with only a simple enterolithotomy, 12% versus 17% [32]. However, this leaves the risk of further obstruction if more stones are present within the gallbladder, persistent symptoms due to an inflamed gallbladder, and possibly increased risk of gallbladder cancer [33]. Older literature suggests recurrence of gallstone ileus is only 5% after enterolithotomy alone with 10% of patients having persistent biliary symptoms without recurrence of the ileus [32].

The one-stage procedure results in a longer operative time due to the complexity of the procedure. Although it does offer definitive treatment, it leads to a higher rate of morbidity and mortality. Therefore, this should only be considered in healthier patients with fewer comorbidities and a longer life expectancy leading to less operative risk [31, 33].

Acute Cholecystitis

Symptomatic gallstones progress to acute cholecystitis in 10% of patients [4]. Acute cholecystitis is an acute inflammatory process that occurs in response to an obstruction of the cystic duct by a gallstone. Acute cholecystitis is a very common cause of ED visits in the elderly population [34]. Presenting symptoms most commonly include right upper quadrant abdominal pain, fever, emesis, palpable mass, and jaundice. Up to 12% of elderly patients with acute cholecystitis meet criteria for septic shock upon admission [34].

The workup of the elderly patient with abdominal pain due to suspected biliary disease is similar to that described above for cholelithiasis and choledocholithiasis. Laboratory tests should evaluate for leukocytosis, liver function, renal function, and coagulation status. Imaging typically starts with transabdominal ultrasound given its high sensitivity and specificity for biliary disease and its ability to accurately determine the severity of acute cholecystitis in the elderly population. Severity of disease on imaging can be used to help guide therapy and as a reference for the timing of surgical intervention [35]. Findings such as pericholecystic fluid, wall enhancement, wall thickening (>3 mm), positive sonographic Murphy sign, and a nonmobile stone at the neck of the gallbladder are all consistent with acute cholecystitis. A dilated CBD or elevated ALP and liver enzymes are suggestive of a retained CBD stone and should prompt further evaluation of the biliary tract with either MRCP or ERCP prior to definitive treatment of acute cholecystitis.

Based on the 2007 Tokyo Guidelines, acute cholecystitis is classified into three grades. Elderly age is not a criterion for gauging the severity of acute cholecystitis, but rather it indicates the propensity to progress to a severe form of the disease. Grade I is considered mild with the inflammation limited to the gallbladder and no associated organ dysfunction. Grade II is moderate cholecystitis defined by elevated WBC, significant inflammatory changes on imaging studies, and a duration of symptoms for more than 72 h. Severe acute cholecystitis is considered grade III and involves organ dysfunction. Identifying the grade of acute cholecystitis helps guide treatment options including timing and type of intervention [36].

Treatment of acute biliary disease including cholecystitis requires supportive care including early resuscitation with intravenous fluids, antibiotics, and supportive care in addition to invasive procedures in order to accomplish adequate drainage. Prior to invasive treatment, evaluation should include the severity of disease, the American Society of Anesthesiologists (ASA) score, and the patient's general condition prior to the acute episode especially within the elderly population with multiple comorbidities [37]. Compared to younger patients, the elderly who ultimately undergo cholecystectomy for mild or moderate acute cholecystitis tend to have higher ASA scores and higher serum Cr, and they are more likely to have gangrenous cholecystitis [38].

Given declined functional status and reserve, the majority of elderly patients have a higher propensity to decompensate quickly due to infection or inflammation. Acute cholecystitis is the most common indication for surgery in elderly patients admitted to the intensive care unit (ICU) with severe sepsis. These patients have a high in-hospital mortality of 48% and an additional 1-year mortality of 64%. ICU scoring systems including acute physiology, age, chronic health evaluation (APACHE), simplified acute physiology score (SAPS), and sequential organ failure assessment (SOFA) as well as elevated lactate levels are predictive of increased mortality [39].

Definitively treating these sick, elderly patients with an emergency operation becomes a more difficult decision compared to their younger counterparts. In general, emergency abdominal surgery in the elderly population is more likely to include an open operation with about 26% of laparoscopic procedures being converted to open. These operations still have a relatively high morbidity of 32% and mortality of 14% [40]. Acute cholangitis holds the highest risk of mortality compared to acute cholecystitis and acute pancreatitis [41]. Poor prognostic indicators in elderly patients undergoing an emergent operation include panperitonitis, positive blood cultures, and hypoalbuminemia [42]. On the other hand, relative contraindications to surgery include increased age, myocardial infarction, dementia, diabetes, malignancy, and severe liver disease [41].

Specifically in acute cholecystitis, early surgical intervention with laparoscopic cholecystectomy compared to late surgical intervention results in a decreased length of hospital LOS, but it has no effect on overall complication rate. This has led to early cholecystectomy becoming the gold standard treatment for grades I and II cholecystitis. In addition to systemic illness with hemodynamic instability, serious local inflammation can preclude early cholecystectomy in grade II cholecystitis making early percutaneous or operative drainage recommended with elective cholecystectomy after improvement of the acute inflammatory response [43].

Laparoscopic cholecystectomy is a safe, efficient, and feasible treatment of acute cholecystitis in the elderly population [10, 12, 44–46]. This includes elective, urgent, and emergent cases [9]. Consequently, cholecystectomy should be recommended after the first acute biliary presentation in order to reduce the risk of recurrence in the elderly patient [41].

The literature is conflicting when it comes to the rate of postoperative complications after laparoscopic cholecystectomy in the elderly population. Haltmeier and colleagues evaluated perioperative variables utilizing the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) for over 4,000 elderly patients who underwent laparoscopic cholecystectomy. They found early intervention was associated with a shorter postoperative stay with no increase in postoperative complications or conversion to an open procedure including those with significant comorbidities (ASA < =2 versus ASA>2) [47].

However, other studies have revealed that patients over 80 years old are more likely to have longer LOS and operative times [46]. Additionally, higher ASA scores have been identified as a major risk factor for postoperative complications in extremely elderly patients [10]. Postoperative complications are correlated to the severity of concomitant diseases at the time of diagnosis. Interestingly, patients with fever and leukocytosis have been shown to have better outcomes possibly reflecting the ability to mount a better immunologic response [34].

Although the laparoscopic approach has been deemed safe and feasible in elderly patients, the rate of primary open cholecystectomy remains doubled in the elderly (9%) compared to a younger population (4%) [12]. Evaluation of the surgical approach within an elderly population alone, 47% underwent an open cholecystectomy while 53% had a laparoscopic approach [45]. The conversion rate from laparoscopic to open cholecystectomy is also higher in the elderly ranging from 7% to 36% [12]. The most common reasons for conversion include concern with anatomy, the presence of CBD stones, and a difficult dissection due to severe inflammation [45].

Given the apprehension for surgery due to severe comorbidities and poor functional status in many elderly patients, an alternate treatment option for acute cholecystitis includes percutaneous cholecystostomy tube with antibiotics, analgesia, and interval or delayed cholecystectomy after the resolution of the acute inflammation making the risk of surgery and complications much less [4]. This is recommended for patients with grade III cholecystitis and those patients with less severe acute cholecystitis but a clinical status that precludes an urgent or emergent operation [36, 48].

In fact, those patients who undergo drainage with percutaneous cholecystectomy tube instead of surgery typically have a higher ASA score indicating poor overall health [49]. The mortality rate in patients undergoing percutaneous drainage can be greatly reduced by combining cholecystostomy tube placement with ERCP for common bile duct stones and a subsequent, interval cholecystectomy [50, 51].

Cystic duct stent insertion can be considered as an alternative to percutaneous cholecystostomy tube in elderly patients deemed unfit for surgical intervention. Stenting has been shown to have a 91% success rate with 13% complication rate and 3% mortality rate at 30 days [52]. This procedure can be performed concomitantly during ERCP for clearance of CBD stones.

Unfortunately, patients treated with percutaneous cholecystostomy tube or a delayed cholecystectomy are more likely to have recurrent episodes of cholecystitis, cholangitis, or pancreatitis. Furthermore, cholecystostomy tube is associated with lower rates of definitive treatment, higher mortality, and higher readmission rates in the elderly population [48]. However, those who do subsequently undergo definitive treatment with laparoscopic cholecystectomy have similar rates for conversion to an open procedure at the time of surgery compared to those who had an early cholecystectomy [49]. Therefore, elderly patients treated with percutaneous cholecystostomy tube due to poor clinical status in the acute setting should be recommended for delayed definitive treatment with laparoscopic cholecystectomy at the earliest feasible time.

Pancreas

As a patient ages, overall body composition changes along with functional and morphological changes of the pancreas. Peripheral body composition evolves with an increase in visceral adipose tissue and a decrease in skeletal muscle mass. In addition, insulin-secreting beta cells of the pancreas are reduced in number and function over time [53, 54]. This leads to elevated insulin resistance and an increased incidence of diabetes that is multifactorial in etiology within the elderly population [53, 54].

The morphological changes that occur overtime in the pancreas can be readily seen on imaging studies. It is important that these physiological changes of the pancreas are not confused for pathology. Many of these findings have been well described including a lower position of the pancreas causing the ampulla of Vater to be located below the vertebral level of L3. Calcification of the superior mesenteric artery (SMA) and splenic arteries creates hyperdensities around the pancreas evident on cross-sectional imaging. The width of the pancreatic duct (PD) has been noted to increase significantly with age. For instance, a normal caliber of the PD is 1–3 mm, but this can increase to 1–2 cm in the elderly without any evidence of obstruction. In addition to the increased caliber of the PD, the elderly also have increased linear defects or strictures of the PD due to compression from the SMA, splenic artery, vertebral osteophytes, and local lymph nodes. Ductal ectasia also affects intra- and interlobular ductules to the point some ducts can reach the size of a cyst [55].

Even with these functional and morphological changes of the pancreas over time, the incidence of benign pancreatic disease in the elderly is comparable to the general population.

Pancreatitis

Acute

Pancreatitis is an inflammatory reaction in the pancreatic parenchyma due to an obstruction of secretory function which leads to the activation of pancreatic enzymes and subsequent autodigestion of the tissue. The course of pancreatitis spans in severity from completely benign and self-limiting to multiple system organ failure leading to death [56]. Fortunately, acute pancreatitis is not a common condition diagnosed in the elderly.

As in the general population, there are several different etiologies of acute pancreatitis in the elderly population [57]. However, the incidence of the various etiologies differs with advanced age. Biliary causes remain the most common etiology in both the elderly and general population. With age, there is an increased incidence of cholelithiasis in addition to an increased diameter of the CBD which makes the elderly more susceptible to gallstone pancreatitis [58, 59].

The second most common etiology in the elderly includes unknown or idiopathic causes which differs from alcohol in the general population [56]. Together, biliary stones and unknown etiologies account for about 90% of acute pancreatitis cases in the elderly [57, 60]. Additionally, drug-induced pancreatitis is seen more commonly in the elderly compared to younger patients [57, 60]. This etiology is much more difficult to diagnose requiring the medication to be active at the time of diagnosis, resolution with cessation, and recurrence upon restarting the drug. Medications most commonly incited as inducing pancreatitis include several antibiotics, corticosteroids, diuretics, azathioprine, valproate, and estrogen [60]. A recent case-control study noted a dose-dependent association of polypharmacy and the risk of acute pancreatitis [61]. This is of critical importance within the elderly population given the high incidence of polypharmacy where taking six or more medications is common and puts the patient at highest risk.

Alcohol-induced pancreatitis is less common within the elderly population compared to the general population. It is also a more common cause of chronic pancreatitis. A thorough history still needs to be obtained to rule out this etiology even in the elderly population. Much less common causes of acute pancreatitis in both young and elderly patients include hypertriglyceridemia, hypercalcemia, ischemia, and malignancy.

There is often a delay in diagnosis of acute pancreatitis in the elderly population given its low incidence and nonspecific symptoms upon presentation. Older patients who present with abdominal pain or vague symptoms often undergo a cardiac workup followed by treatment of duodenal or gastric ulcers prior to the diagnosis of pancreatitis [59, 62].

Laboratory values in acute pancreatitis typically reveal an elevated serum amylase and lipase with the lipase level being more specific than amylase. Necrotizing or infectious pancreatitis can have elevated WBC. Elevated total bilirubin and liver enzymes are usually indicative of a biliary cause of acute pancreatitis. Lab evaluation should also include triglyceride and calcium levels as these can cause pancreatitis when severely elevated which affects the proper treatment. Hypoglycemia and a low hemoglobin A1c is a prognostic indicator of patients with frailty and an increased risk of mortality [53]. It is crucial to obtain complete laboratory studies on these patients given their extensive comorbidities and decreased reserve. Early signs of organ dysfunction should be thoroughly investigated.

While age alone is helpful for stratification of severity of acute pancreatitis, several clinical scoring systems have been developed to help determine mortality risk in the setting of acute pancreatitis and critically ill patients [57]. Ranson's criteria are a system specific to pancreatitis which assesses the severity of pancreatitis on admission and within 48 h. This system accounts for age and multiple laboratory values including WBC, blood glucose, lactate dehydrogenase, aspartate aminotransferase, BUN, calcium, oxygen partial pressure, and base deficit. The APACHE III score predicts hospital mortality for all critically ill adults after admission to the ICU which can apply to those with pancreatitis. This system utilizes over 20 variables including age, vital signs, laboratory values, blood gas, primary comorbidity, and the Glasgow Coma Scale in order to risk stratify in-hospital death. Both of these scoring systems can help the clinician assess the severity of acute pancreatitis and the risk of complication and mortality [63].

Imaging for unknown or vague abdominal pain in the elderly typically consists of a contrast-enhanced CT scan of the abdomen and pelvis. A dual phase protocol which includes arterial and portal venous contrast phases is preferred for evaluation of the pancreas. CT imaging findings suggestive of pancreatitis include a change in the density of the pancreatic parenchymal tissue due to local edema and fat stranding in the surrounding retroperitoneal fat. Signs of pancreatic necrosis and the development of pseudocysts also need to be evaluated. Necrotic tissue will not enhance on CT images, and the presence of gas is indicative of infected necrosis. Any associated hemorrhage would be identified as high-attenuation fluid.

Scoring systems based on CT imaging including the Balthazar score within the CT severity index (CTSI) have been developed to help grade acute pancreatitis based on imaging findings. The Balthazar score stratifies pancreatitis as mild (interstitial), intermediate (exudative), or severe (necrotizing) based on the size of the pancreas, inflammatory changes in the pancreas and surrounding fat, fluid collections, and the amount of necrosis present. The CTSI has a similar predictive accuracy to the clinical scoring systems described above. Therefore, CT imaging should not be performed solely for the assessment of severity of acute pancreatitis [64].

At the time of diagnosis, the severity of pancreatitis is much higher in elderly patients leading to an increase in mortality which can be as high as 25% in patients >80 years old [57]. This is most likely due to the comorbidities and fragility of the elderly population [59]. Severe acute pancreatitis defined as pancreatitis with associated organ failure, pancreatic necrosis, pseudocyst, or abscess can increase the mortality to >50% in the elderly population [60].

Interestingly, local complications of acute pancreatitis including abscess, necrosis, and pseudocyst have the same incidence and mortality in the elderly as the general population [65]. However, multisystem organ dysfunction and failure is more common in the elderly. This suggests the higher risk of organ failure as a sequela of acute pancreatitis in the elderly is due to the greater number of comorbidities and frailty [60, 65].

Overall, we can conclude that age and comorbidities contribute to organ failure and mortality while local complications are independent of these factors. This is important in that special attention should be given to the elderly in order to best treat and control comorbid conditions in addition to supportive therapy for acute pancreatitis [66].

Ideal treatment of acute pancreatitis in the general population as well as the elderly requires accurate diagnosis, early supportive care, adequate management of complications and comorbidities, and ultimately the prevention of further episodes [56]. Therefore, the initial treatment of acute pancreatitis in the elderly is consistent with the supportive care we provide to younger patients. This requires intravenous fluid resuscitation, analgesia, and enteral feeding. Antibiotics are reserved for signs of necrosis with infection unless an infectious cause is thought to be the etiology of the acute pancreatitis.

Fluid resuscitation with a balanced crystalloid solution is vitally important and often requires large volumes, on average 2.5–4 L over the first 24 h, in the setting of acute pancreatitis [56]. The patient's respiratory, renal, and cardiac function need to be considered in order to prevent exacerbation of comorbidities which leads to suboptimal outcomes. Pain control is also important and complicated in the elderly population due to high risk of delirium. This can be caused by either uncontrolled pain or overuse of narcotics. Nonnarcotic analgesic agents should be utilized whenever possible.

Enteral feeding should be emphasized in the treatment plan of any patient with acute pancreatitis including the elderly patient. Patients with mild pancreatitis can typically tolerate an oral diet shortly after admission. There is no need to wait for the complete resolution of elevated laboratory values or pain in order to start oral feeds. If the patient is unable to tolerate oral feeds within the first 3–5 days of admission, enteral feeding via a post-pyloric tube should be attempted. Enteral feeding has been shown to be superior to parenteral feeding in the setting of acute pancreatitis [67]. Therefore, total parenteral feeding should be reserved for the rare case where oral and artificial enteral feeds cannot be tolerated for a prolonged period of time [56].

Many studies suggest a diagnosis of acute pancreatitis in the elderly requires an early admission to the ICU given the concern of comorbidities and risk of rapid decompensation [62]. These patients have limited cardiac and respiratory reserve, so treatment of the acute pancreatitis alone can very easily exacerbate coinciding medical conditions, leading to morbidity and mortality. An ICU setting is better equipped to closely and continuously monitor for multiple organ dysfunction in the ill, elderly patient.

Beyond diagnosis and initial supportive care, next steps in treatment should be based on the etiology of pancreatitis. Acute pancreatitis due to biliary causes automatically implies a stone outside of the gallbladder that traveled down the CBD causing obstruction of the pancreatic duct. Clinical course and laboratory values can help determine if a stone is still present causing ongoing obstruction.

For persistent obstruction, the main concern is worsening pancreatitis as well as the risk of cholangitis. In this case, urgent endoscopic intervention to clear the ductal system is indicated even in the elderly population. Advanced endoscopic procedures including ERCP and endoscopic ultrasound (EUS) are not contraindicated in the elderly population as there is no increase in procedure-related complications compared to a younger cohort [68, 69]. Even endoscopic sphincterotomy can be safely performed in the elderly population with comparable success and complication rates similar to the general population [70].

Elderly patients have a lower incidence of post-ERCP pancreatitis compared to the younger population [71, 72]. However, they do have a similar to increased risk of peri-procedural bleeding suggesting hemoglobin, hematocrit, and coagulation studies are important laboratory values to obtain pre-procedure [68]. The risk of perforation during ERCP has been shown to be similar to that in the general population [71].

While endoscopic intervention is safe with a favorable risk profile, the comorbidities, functional status, and metabolism of elderly patients need to be considered when undergoing a procedure, just as they were important in the initial treatment of acute pancreatitis. For instance, lower doses of sedative medications should be administered because elderly patients undergoing ERCP are more likely to experience adverse effects due to prolonged conscious sedation or post-procedural hypotension [72–74].

Once the ductal system is cleared and the current episode of acute pancreatitis steadily improves, definitive therapy for gallstone pancreatitis needs to be considered. Cholecystectomy during the initial hospitalization is the recommended therapy for gallstone pancreatitis in the majority of patients regardless of age [75]. Unfortunately, studies have shown that elderly patients are less likely to undergo cholecystectomy during their initial hospitalization (about 50%) suggesting a hesitation to operate on these older patients with acute gallstone pancreatitis. However, based on readmissions and a subsequent operation within this population, about 40% of these patients would have benefited from early definitive, surgical therapy [75]. Given the acceptable mortality and morbidity associated with laparoscopic surgery, which is less than that of a repeat episode of acute pancreatitis in this age group, laparoscopic cholecystectomy should be offered as definitive treatment with close attention paid to preoperative optimization of comorbidities [57, 62].

Overall, acute pancreatitis has a low incidence in the elderly population with biliary causes being the most likely culprit. Older patients are more likely to suffer from multiple organ dysfunction and failure due to acute pancreatitis. However, this is due to exacerbation of comorbidities and systemic symptoms rather than local complications from the acute pancreatitis. Supportive care with early endoscopic intervention for clearance of the bile ducts is indicated. This should be followed by laparoscopic cholecystectomy during the same hospital admission to prevent further and more serious episodes of acute pancreatitis in the elderly population.

Chronic

Chronic pancreatitis is defined the irreversible sclerosis of the pancreatic gland leading to destruction of the ductal exocrine parenchyma and distortion of the ductal system [76]. Chronic pancreatitis is less common in the elderly compared to younger patients. Alcohol is the most common etiology of chronic pancreatitis regardless of age accounting for about 70% of cases. Idiopathic, obstructive, and biliary causes remain less likely but possible etiologies. Autoimmune pancreatitis with elevated serum levels of gamma globulin has also been diagnosed in the elderly population [76].

These patients typically present with recurrent abdominal pain associated with long-standing alcohol abuse which is also accompanied by smoking in most cases. Pending the duration of chronic pancreatitis, symptoms tend to evolve from abdominal pain to symptoms of pancreatic insufficiency. Elderly patients with chronic pancreatitis can also present with obstructive jaundice due to ductal strictures that developed over time. However, occult malignancy needs to be ruled out.

Cross-sectional imaging of chronic pancreatitis reveals calcifications and atrophy of the parenchyma. Ductal changes include irregular dilation and narrowing of the PD and a tapering of the CBD which can also be seen on ERCP. Acute on chronic exacerbations of pancreatitis might show focal enlargement of the gland with obliteration of the peripancreatic fat. Complications from chronic pancreatitis that might be apparent on imaging include pancreatic pseudocysts, pseudoaneurysms, and splenic vein thrombosis.

Treatment of chronic pancreatitis in the elderly population remains supportive with endoscopic or surgical intervention in refractory patients. While pancreatic operations are being performed more often in the elderly population, chronic pancreatitis as an indication for surgery is decreasing while surgery for cystic tumors is increasing [77].

Chronic pancreatitis is considered a low-risk diagnosis when undergoing a pancreaticoduodenectomy compared to bile duct, duodenal, or ampullary neoplasms after review of the ACS NSQIP [78]. Elderly patients undergoing elective pancreaticoduodenectomy have an expected mortality of <5% suggesting radical pancreatic resection in an elderly population has no increased mortality compared to younger patients [78, 80]. Pancreatic resection can be safely performed utilizing a minimally invasive, robot-assisted technique without increased mortality or morbidity in comparison with a younger population [81].

Postoperative morbidity after pancreatic resection remains high regardless of operative indication, and increased age and preoperative morbidity are independent prognostic indicators of postoperative morbidity [78–80]. Overall, elderly age does not preclude pancreatic resection although there is significant morbidity with poor long-term survival in those patients >80 years which is most likely due to preoperative comorbidities [82, 83].

Conclusions

Overall, benign diseases of both the gallbladder and pancreas occur in the elderly population with biliary disease more common and pancreatic disease less common compared to the general population. However, many of the diagnosis modalities and treatment algorithms essentially remain the same as endoscopic, percutaneous, and surgical interventions are safe and feasible in the elderly.

It is most important to account for and optimize the comorbidities of these patients as exacerbation of coinciding medical conditions is what leads to unfavorable outcomes. A multidisciplinary team approach to a focused, comprehensive geriatric assessment should be a high priority in order to identify risk factors preoperatively and manage them postoperatively to improve outcomes.

Conclusion

Gallstones have an increased incidence in the elderly population with acute cholecystitis as a common presentation. Pancreatitis is less common in the elderly compared to younger patients, and gallstones are the most common etiology followed by unknown or idiopathic causes. Elderly patients are more likely to present with nonspecific, constitutional symptoms. ERCP, percutaneous cholecystostomy tube, and laparoscopic cholecystectomy are safe and feasible procedures in elderly patients. The higher risk of morbidity and mortality with biliary or pancreatic disease is due to decreased reserve and exacerbation of comorbidities.

54 Elderly Donors in Transplantation

Brian Gilmore and Andrew Barbas

Contents

Abstract

The disparity between supply and demand of donor organs remains a major limitation in the field of transplantation. Increased utilization of organs from older donors has significant potential to expand the pool of donor organs; however, utilization of such organs has been limited both in the United States and internationally. Accumulating evidence demonstrates that the use of organs from well-selected older donors produces acceptable patient and graft survival. As donor and recipient selection

criteria are refined, it appears likely that outcomes will continue to improve with time.

Keywords
Organ transplantation · Extended criteria donor · Elderly · Kidney transplantation · Liver transplantation

Cases for Contemplation

1. Kidney donor profile: a 63-year-old male, donation after cardiac death (DCD), history of hypertension, and terminal creatinine of 1.5 with 100 ml/h of urine output prior to death. What additional criteria would help inform the decision to accept a kidney from this donor for transplant? What type of recipient would you prioritize for such a graft?
2. Liver donor profile: an 80-year-old male, no significant past medical history, brain death due to cerebrovascular accident, normal liver function tests, and liver biopsy. What additional criteria would help inform the decision whether to accept the liver from this donor for transplant? What type of recipient would you prioritize for such a graft?

Introduction

Although outcomes of solid organ transplantation are excellent in the modern era, the scarcity of donor organs relative to patients on the waiting list has remained a limitation of the field. The critical organ shortage has led to the increased use of organs from extended criteria donors – particularly organs from older donors.

The effects of aging on organ function are organ specific and highly variable, depending on the severity of comorbid conditions. Although age-dependent dysfunction of an organ must be considered carefully, the majority of available data suggests that appropriately selected older donors can be used routinely with acceptable transplant outcomes.

Demographics

Approximately 100,000 patients in the United States are currently on the kidney transplant waiting list, organized through the United Network for Organ Sharing (UNOS). The average wait time has increased, with 15.7% of patients now having a wait time of more than 5 years, compared to 11.4% in 2005 [1]. This is a continuation of a previous trend, with average wait times increasing from 2.7 to 4.2 years from 1998 to 2008 [2]. In parallel, the age of patients on the waiting list has also increased, with 22.0% of patients being greater than 65 years of age in 2015, compared with 14.5% in 2005. As noted by Hart et al., the number of kidney transplant candidates aged 65 or older is projected to surpass those aged 35–49 years by 2020 [1]. Despite the aging of the recipient population, the use of kidneys from older donors has remained relatively stagnant. In 2005, 5.1% of donors in the United States were older than 65, and this has increased slightly to 7.8% in 2015 [3]. Of these donors older than 65, 66% were deceased donors, and 34% were living donors.

The demographics of the liver transplant waiting list in the United States share some similarities with the kidney transplant waiting list. Approximately 15,000 patients are currently on the waiting list in the United States [4, 5]. The wait time for transplant recipients increased between 2005 and 2015, with 17.2% of patients waiting greater than 1 year in 2005, compared to 21.9% in 2015. The proportion of elderly patients on the waiting list has also increased, with 22.2% of patients being greater than 65 years of age in 2015 compared to 11.7% in 2005. In terms of utilization of older donors, trends appear to be divergent between Europe and the United States. The European Liver Transplant Registry (ELTR) has noted a significant increase in utilization of livers from donors older than 65, from 15% in 1999 up to 29% in 2009 [5–7]. In the United States, however, the utilization of older donors has actually decreased, with only 7.7% of donors being over 65 in 2015 compared with 10.2% in 2005.

Broadly speaking, the increasing wait times for listed individuals and the relatively stagnant utilization of elderly donor organs suggest that the elderly represent an underutilized resource to combat the scarcity of organs.

Renal Transplantation

The binary classification of donor kidneys as either "standard criteria donor" (SCD) or "expanded criteria donor" (ECD) was introduced in 2002 in an effort to identify factors that influence graft failure (Table 1) [8, 9]. By definition, all kidneys from patients 60 years of age and older were categorized as ECD kidneys, despite a wide spectrum of graft outcomes within that heterogeneous cohort. The use of ECD kidneys has increased over time due to a significant literature demonstrating superior outcomes compared to patients who remain on the waiting list [10–14]. This is particularly true in older transplant recipients, where despite comorbidities and advanced age, transplantation has been shown to improve life expectancy relative to remaining on the waiting list. One study of transplant recipients in the UNOS database demonstrated 58% 5-year and 24% 10-year survival among recipients older than 70 [15]. Importantly, despite the increasing use of ECD kidneys, evidence suggests that the most common cause of graft loss in older kidney transplant recipients is recipient death with a functioning graft rather than graft failure [16].

Table 1 Definition of extended criteria donor: Kidney transplantation

Donor characteristic	ECD donor
Age (years)	≥60 or ≥50 plus two risk factors below
Cause of death	CVA
Past medical history	Hypertension
	Cr >1.5 mg/dL

Adapted from Mendizabal, Hsu, and Shaked *Principles and Practice of Geriatric Surgery*, 2011
CVA cerebrovascular accident, *Cr* creatinine

The dichotomous ECD/SCD classification has since been replaced in 2014 with the more granular kidney donor profile index (KDPI), which combines a variety of donor factors to calculate a single number that summarizes the risk of graft failure for a given donor [17]. The KDPI is based on ten donor factors, including donor age, height, weight, race, history of hypertension, history of diabetes, cause of death, serum creatinine, hepatitis C status, and donation after cardiac death (DCD) status. The KDPI ranges from 0% to 100%, with a lower number signifying increased donor quality; it represents the percentile of quality for a given donor kidney in relation to all other deceased donor kidneys recovered in the past year. The overlap between ECD/SCD status and KDPI is significant but not complete, and the transition to KDPI was motivated by a desire to improve prognostication of graft survival beyond the rather crude ECD/SCD designation [17]. The expected half-life of a particular kidney graft strongly correlates with KDPI; for example, kidneys of the highest quality (KDPI of 0–20%) have an estimated half-life of 11.4 years, compared to kidneys of the lowest quality (KDPI >85%), which have an estimated half-life of 5.6 years [18]. The optimal strategy for allocating high KDPI donor kidneys (KDPI >85%) is still under investigation, but most transplant programs favor their use in older recipients who have less life expectancy compared to younger recipients.

Age-Dependent Changes in Kidney Function

The kidney, like most organs, undergoes a progressive decline in function with advancing age. This is distinct from, but can be exacerbated by, the accumulated damage caused by concomitant nephropathy from hypertension, diabetes, and other comorbid conditions [19, 20].

Macroscopically, the kidney undergoes a progressive decrease in overall renal mass [21, 22]. This is predominantly due to a loss of cortical volume with an associated decrease in the number of nephrons. This process is partly compensated until age 50 by an increase in medullary volume which can blunt the overall decrease in renal volume despite declining nephron number [23]. Atherosclerosis, another common finding with aging kidneys, has been shown to accelerate this process [24]. Older kidneys are also known to accumulate both benign cysts and parenchymal scars [19, 25].

Microscopically, kidneys undergo progressive diffuse glomerulosclerosis. This is thought to be due to parenchymal ischemia resulting from arteriosclerosis of the microvasculature [19]. This process results in a decrease in the number of functioning nephrons, producing the gross changes in organ volume described above, and often leads to hypertrophy of the remaining nephrons.

Unlike other organs, kidney function is readily quantified by calculating the estimated glomerular filtration rate (eGFR), a measure of the filtration capacity of the kidney. Although the eGFR for a given individual is variable, there is a predictable decline in eGFR with increasing age [26–28]. This decline is clinically important; even in the absence of diagnosed CKD, the decreased functional reserve significantly increases susceptibility to physiologic insults. Interestingly, the decrease in eGFR seen with aging is not necessarily concordant with the aforementioned macroscopic or microscopic structural changes.

Deceased Donor

The majority of transplanted kidneys continue to come from deceased donors. Indeed, in 2015, 61.8% of the 14,744 kidney transplants done in the United States were deceased donor kidney transplants (DDKT) [3]. Despite the ongoing organ scarcity and large number of patients on the waiting list, it has been estimated that up to 60% of available kidneys from donors older than 65 in the United States are being discarded [13].

Although the use of SCD kidneys is preferred, several studies have demonstrated superior survival among patients receiving ECD kidneys compared with patients who remained on the waiting list, particularly for patients older than 40 years of age [11, 29]. These findings have been confirmed in the setting of high KDPI kidneys where the use of high-risk organs produced the greatest benefit in patients older than 50 years [12].

These observations have significantly impacted allocation policy. In 1999, the Eurotransplant region adopted the Eurotransplant Senior Policy (ESP), in which kidneys from older donors were matched to older recipients [30]. Early data from the ESP found that there was no significant difference in patient survival among older recipients receiving older rather than younger kidneys [31, 32]. More recent data have demonstrated that although outcomes with older grafts are inferior compared to younger grafts, older recipients do derive benefit from early transplantation with older grafts [14]. Comparable outcomes were demonstrated in a 2014 study comparing data from the ESP and the United States [13]. In both Europe and the United States, early transplantation with an ECD graft resulted in improved survival compared with delayed transplantation with a non-ECD kidney. It is noteworthy that many patients in this study, particularly in the United States, died with functioning grafts having never required additional dialysis.

In 2014, the United States adopted the new kidney allocation system (KAS), which requires broader sharing of kidneys with a low KPDI (optimal kidneys) as part of an effort to improve matching of optimal donor organs and recipients with longer life expectancy [33]. The combination of KDPI and the KAS has streamlined the organ allocation process and decision-making regarding the use of what were previously classified as ECD organs. Importantly, the KAS has resulted in a decreased rate of significantly age-mismatched kidney transplantation but has also appeared to decrease utilization of kidneys from donors older than 65 and transplantation in recipients older than 65 [34, 35].

Living Donor

The use of a living donor is favored when possible, as living donor kidney transplantation (LDKT) has superior outcomes in comparison to

DDKT [36–38]. LDKT can also significantly decrease time on the waiting list and eliminate or minimize time on dialysis, which is particularly important for elderly recipients [39]. The percentage of older living donors has been increasing, and this trend can be expected to continue as the general population continues to age [40].

Several single institution studies have found similar patient and graft survival rates between recipients receiving grafts from older and younger living donors [41–43]. In contrast, subsequent studies utilizing large national databases demonstrated somewhat inferior outcomes in patients receiving kidneys from older living donors [44–46]. Despite this observation, additional studies demonstrated that the use of older organs for LDKT was associated with improved outcomes relative to the use of ECD organs for DDKT and similar outcomes to SCD organ use for DDKT [40, 47].

Choice of Older Donors for LDKT

The prospect of LDKT requires careful consideration of the perioperative risks for the older living donor. Although older individuals are generally assumed to have an increased risk of perioperative complications, there are reports of successful living donation from patients as old as 90 years [37, 48]. As such, there are no standardized inclusion/exclusion criteria, although individual institutions have specific internal protocols. However, broadly speaking, an older candidate for kidney donation must have adequate renal function to minimize the risk of renal dysfunction post-nephrectomy and relatively few cardiovascular comorbidities, which could portend serious perioperative complications.

One study of 80,347 living donors found no increase in perioperative mortality among older donors compared to younger donors [49]. Although this study did demonstrate increased long-term mortality among older donors, this cohort had equivalent mortality compared to age-matched non-donors. Additional studies have also demonstrated that perioperative morbidity is not increased in older donors [50, 51]. A 2012 study from a single center in the United Kingdom demonstrated no difference in perioperative complication rates with older patients and similar rates of post-nephrectomy decline in GFR compared with younger patients [50]. Similarly, a 2004 study comparing laparoscopic donor nephrectomy in younger patients and patients older than 60 years found no increase in either perioperative complications or rate of rise in serum creatinine following donor nephrectomy [51].

Encouraging Older Patients to Become Donors

The popularity and feasibility of LDKT are influenced by cultural and economic factors, as well as specific allocation policies [52–54]. Addressing the disparities both within and between countries remains an area of significant research interest, with particular attention being paid to increasing the utilization of paired kidney donation and altruistic kidney donation [55, 56]. Although the optimal policies for facilitating donation from older living donors remain unclear, improved counseling of both potential recipients and potential donors with regard to expected outcomes will ideally increase participation of older donors [57].

Summary

Kidneys from older donors provide significant improvements in mortality and quality of life for patients with end-stage renal disease. Although there is some expected decline in graft survival with utilization of older organs, this is largely outweighed by the benefits of earlier transplantation. In addition, the use of older living donors can significantly improve recipient outcomes with minimal added risk to donors compared with younger candidates.

Liver Transplantation

The first successful liver transplant was performed in 1963 [58]. In the nearly 55 years since that landmark operation, the procedure has become increasingly routine with excellent short- and long-term outcomes. The scarcity of donor organs has motivated attempts to expand the available donor pool, including split liver transplants, living donor liver transplantation, and greater consideration of extended criteria donors, including those from elderly donors. The importance of expanding the number of available organs is of particular importance with regard to liver disease due to the inability to provide life-sustaining organ replacement therapy.

Age-Dependent Changes in Liver Function

In contrast to kidney transplantation, the decision to use elderly livers is confounded by the inability to reliably quantify age-dependent decline in liver function. The biochemical markers used as "liver function tests" such as bilirubin, alanine aminotransferase (ALT), and aspartate aminotransferase (AST) do not consistently change with increasing age [59]. More generally, the decline in liver function and regenerative capacity is difficult to determine and incompletely understood.

The liver appears to be relatively spared from the significant age-dependent structural and functional changes seen with other organs. There is evidence that the liver sustains measurable decreases in both organ volume and effective blood flow in the elderly [60]. Similarly, both hepatic uptake of radioisotopes and elimination of galactose have been found to decrease in older individuals [61, 62]. While these have been interpreted as proxies for regenerative capacity and metabolic ability, there is no clear correlation of these findings with clinically relevant changes [63].

Histologic and electron microscopic examination of rat livers has demonstrated that although hepatocytes increase in size with aging, they decrease in number and sustain a decrease in smooth endoplasmic reticulum content and impaired lysosomal function [64]. There is also evidence that glutathione reductase, a key component of the antioxidant pathways in the liver, is decreased in older organs [65]. Similarly, the hepatocyte content of cytochrome P450 declines substantially in the elderly [66]. Studies have demonstrated that older livers have a decrease in cell cycle activity as well as an increase in autophagy, suggesting that the impairment stems from an inability for the normally quiescent hepatocytes to reenter the cell cycle and proliferate [67]. There is evidence that this impairment is driven by age-dependent shortening of telomeres and decreased numbers of hepatocyte precursor cells [68–72]. Regardless of the underlying mechanism, no currently available clinical tests have been validated for the purpose of assessing the age-related decline in liver function, and there is little evidence demonstrating a clinically relevant deterioration [73–75].

Deceased Donor Liver Transplantation

A number of multi-institutional and international registries have produced high-powered studies evaluating the impact of donor and recipient age. The European Liver Transplant Registry (ELTR), which dates back to 1968, captures approximately 95% of all liver transplants done at 145 sites in Europe. As of 2009, this included more than 93,000 transplants. A 2003 analysis of this registry demonstrated a significantly lower rate of graft survival with the use of livers from donors over 65 compared to those younger than 55 (52% vs. 63% at 5 years) but similar overall patient survival rates [6]. A second analysis of this registry published in 2012 confirmed this difference in graft survival (57% vs. 65% at 5 years), although the rate of graft survival improved for each group over the preceding 10 year period [7]. This study also provided evidence that utilization of organs from octogenarian donors is feasible, though associated with significantly lower 5-year (50% vs. 65%) and 10-year survival (45% vs. 55%).

The decrease in graft survival noted in the ELTR has been corroborated by data from several additional studies. Both a 2006 analysis of 20,023 transplants performed in the United States and a 2015 study examining 20,288 transplants performed in Spain found decreased graft survival with increasing age [76, 77]. An additional retrospective study of 44,756 patients in the OPTN database suggested that this age-dependent decline in graft survival was potentiated by prolonged cold ischemia time [78].

In parallel to the larger studies discussed above, a number of smaller series have been conducted which suggest that neither graft nor patient survival is significantly influenced by donor age, if appropriate recipient selection criteria are applied [79–81]. Although there appears to be an expected decrement in graft survival, the bulk of the available evidence supports the routine use of livers from elderly deceased donors, including organs from octogenarian donors, in appropriately selected patients.

Living Donor Liver Transplantation

Living donor liver transplantation using elderly donors must account for the effects of advanced age on both graft function and the capacity of the remaining liver to regenerate in the donor. With these considerations in mind, the use of an elderly living donor remains an attractive option as it can significantly reduce recipient waitlist time and facilitates an elective procedure for which the recipient can be medically optimized.

In comparison to deceased donor liver transplantation, the majority of studies on living donor liver transplantation come from to a relatively small number of institutions. In 2014, Han et al. published an analysis of the largest patient cohort to date, detailing the outcomes from 604 living donor liver transplants performed in South Korea from 1999 to 2012 [82]. Of the 604 cases, 26 received organs from donors older than 55. This cohort was observed to have a significant decrease in mean graft survival (31.2 months vs. 51.4 months), although 5-year patient survival was not different between groups (79.5% vs. 81.5%) and no patients suffered primary graft nonfunction.

The remainder of the existing literature on outcomes from elderly living donor liver transplant has been inconsistent, with some studies suggesting impaired survival and others demonstrating no difference [74, 83–85]. It does appear that the rate of small-for-size syndrome is increased with the use of older living donor grafts [86, 87]. This finding has been supported by imaging data suggesting slower regeneration of the liver graft in the first month following transplant [72]. In the absence of prospective, large-scale studies, it appears that the use of older living donors is acceptable, provided careful consideration is given during selection of both the donor and recipient.

Prognostic Scoring of Donor Organs

In contrast to kidney transplantation, in liver transplantation, there is no universally accepted definition of “extended criteria donor.” Generally, the term extended criteria donor is used in reference to livers donated after cardiac death, donor livers with significant steatosis, and livers from older donors. Despite the limitations in current knowledge about the effects of aging on the liver, several attempts have been made to develop prognostic scoring systems to guide organ use. In 2010, Feng et al. utilized data from 20,033 transplants performed in the United States to develop a donor risk index (DRI) encompassing eight variables: donor age, donor race, donor height, donor cause of death, donation after cardiac death, partial or split liver graft, geographic allocation, and cold ischemia time [76], Table 2. Of these individual criteria, donor age was most significantly associated with poor outcomes. DRI was found to be predictive of graft survival out to 3 years (81.2% vs. 60.0% for DRI <1 and >2, respectively). In 2012, the DRI was adapted specifically for use in the Eurotransplant region as the Eurotransplant-DRI (ET-DRI) by replacing donor race, donor height, organ location, and cold ischemia time with latest serum gamma-glutamyl transpeptidase, geographic allocation, and rescue allocation [88].

Several additional models have been generated to incorporate both donor and recipient characteristics. One of these is D-MELD, calculated as the product of the donor age and the recipient preoperative MELD (Model for End-Stage Liver Disease) score [89]. Data from the United States

Table 2 Donor risk index: Liver transplantation

Donor factor	Reference donor
Age	<40
<40	
40–50	
50–60	
60–70	
>70	
Cause of death	Trauma

Regional	
National	
Cold time (h)	8 h
Donor risk index	1.0

CVA cerebrovascular accident, *DCD* donation after cardiac death

OPTN suggests worse outcomes with a D-MELD of greater than 1,600, whereas an analysis of patients in the Andalusian Transplant Registry found a preferred cutoff to be a D-MELD of 1,500 [90]. Regardless of the predictive scoring system used, donor age remains one of the dominant factors in predicting outcomes.

Summary

The use of livers from older donors is associated with a higher risk of graft failure, although overall patient survival appears to be similar. Care must be taken during selection of both donors and recipients when considering livers from older donors. In light of a significant ongoing organ shortage, increasing the use of elderly donors appears to be an effective strategy for expanding the donor pool and reducing waitlist morbidity and mortality in liver transplantation.

Improving Utilization of Organs from Older Donors

When compared to organs from younger donors, both kidney and liver grafts are more sensitive to cold ischemia time. A 2004 European study of nearly 3,400 renal transplants found that prolonged cold ischemia time in organs from donors older than 60 was associated with both an increased risk of delayed graft function and ultimately graft loss [91]. Similarly, prolonged cold ischemia time has been associated with both graft nonfunction and diminished recipient survival in livers from older donors [92–94]. Together, these findings strongly support the minimization of cold ischemia time as a strategy to improve recipient outcomes when utilizing organs from older donors. There is no specific cold ischemia threshold for kidney transplantation, while for liver transplantation, a cold ischemia time of greater than 12–15 h is strongly associated with impaired graft and patient outcomes [95, 96].

A novel organ preservation approach that may facilitate the use of organs from older donors is normothermic machine perfusion (NMP). Rather than static storage of organs on ice, in NMP, organs are perfused with an oxygenated nutrient solution at physiologic temperature. This intervention holds promise not just as a method of improving organ preservation but as a platform for rehabilitating organs prior to transplantation. Several recent studies investigating the use of NMP in liver transplantation for organs considered suboptimal due to donor age, graft steatosis, or donation after cardiac death have demonstrated promising results [97, 98].

Current Organ Allocation Policies

Organ transplantation in the United States is governed by the United Network for Organ Sharing (UNOS), which was first established in 1984 as a nonprofit organization to standardize organ allocation. The guiding principle of UNOS is summarized in the “Final Rule,” established by the US Department of Health and Human Services in 2000, which calls for “the equitable allocation of deceased donor organs among potential recipients" [99, 100].

Prior to the implementation of the KAS in 2014, kidney allocation was driven by a combination of recipient waiting time, panel-reactive antibody level (PRA), and degree of HLA matching [99]. The weight given to specific criteria has changed over time, as has the methodology for evaluating donor organs. Notably the designation of donor grafts as either SCD or ECD was replaced following the development of the more granular KPDI system [17]. The introduction of the kidney allocation system in 2014 shifted emphasis to expected life years after transplant in an effort to improve efficiency of utilization of available organs. Although the kidney allocation system has decreased the incidence of significantly age-mismatched transplants, it has also led to an overall decline in utilization of older grafts [34, 35].

Liver allocation in the United States is based on recipient MELD score, which is well validated and has been in use since 2002. However, there is wide geographic disparity in organ availability across the United States [101]. The disparities in organ availability between regions have led to the development of policies such as Share35, which prioritizes sharing of grafts for suitable recipients with a MELD of greater than 35 [102].

Conclusion

Organ scarcity remains an enormous problem for the transplant community. The use of organs from older donors should be routinely considered as data accumulates to demonstrate safety and efficacy in expanding the donor pool. Challenges remain in identifying specific criteria that inform organ performance, and more research is necessary to further elucidate this in elderly donors.

Malignant Diseases of the Gallbladder and Bile Ducts

55

Alex B. Blair, Sandra R. DiBrito, and Mark D. Duncan

Contents

Abstract

Malignant diseases of the gallbladder and biliary tree are challenging cancers in the elderly, often presenting late with poor prognosis. As surgery affords the only cure for gallbladder and biliary cancer, the appropriate selection of patients who may benefit and application of current and disease-specific surgical procedures are paramount. Gallbladder cancer tends to be either an incidental finding after laparoscopic cholecystectomy or an advanced and metastatic cancer with dismal outlook. Gallbladder polyps and porcelain gallbladder

are two particular conditions that warrant attention because of malignant risk. Cholangiocarcinomas include intrahepatic tumors, treated akin to primary hepatic malignancy; Klatskin tumors at or near the bifurcation which require special consideration; and distal bile duct tumors which act as periampullary cancer. Management of each will be elucidated with detailed attention to diagnostic work up and discriminatory testing to guide treatment decisions for the clinician.

Introduction

Case Study Gallbladder Adenocarcinoma

Background

A 69-year-old male with past medical history of hypertension presented with abdominal discomfort and bloating. Laboratory values were unremarkable; however, a right upper quadrant ultrasound was performed revealing a ~2.5 cm lesion suspicious for malignancy. A subsequent cross-sectional computed tomography scan was performed for further evaluation and staging. A diagnosis of gallbladder adenocarcinoma was made based on imaging without confirmatory biopsy.

Management

No additional treatment or imaging was obtained and the patient was taken to the operating suite for resection. Due to concern for possible extension beyond the lamina propria an open approach to cholecystectomy was selected. On frozen section while the margins were negative, suspicion of invasion beyond the muscular layer was confirmed and thus wedge resection of the liver bed was performed. Final pathology revealed a stage T2 N0 M0: 2.6 cm gallbladder adenocarcinoma. The patient had an uneventful stay and was discharged to home on day 6. The patient elected for close observation and did not receive initial adjuvant therapy. Unfortunately, a metastatic lesion was appreciated in the left hepatic lobe at 1 year on routine surveillance imaging. A gemcitabine based regimen was initiated; however, disease progression continued leading to biliary obstruction eventually requiring palliative stenting. Ultimately, the patient succumbed to his disease 2 years following initial diagnosis.

Case Study Perihilar Cholangiocarcinoma

Background

A 76-year-old male without any past medical history presented to urgent care with report of gradual onset dark urine that was not accompanied by pain. Subsequent evaluation demonstrated an elevated bilirubin of 9.3, CA 19–9 of 2241, and a presumed perihilar cholangiocarcinoma extending to segment 5 of the liver on CT imaging. An ERCP with sphincterotomy was performed and adenocarcinoma diagnosis confirmed with brushings and biopsy.

Management

Surgical options were discussed and due to hepatic parenchymal extension a hepatectomy would be necessary. Liver volumetrics suggested 28% volume of the potential remnant thus right portal vein embolization was performed preoperatively. Three weeks later, the patient was taken to the operating suite for resection. An initial diagnostic laparoscopy did not find evidence of metastatic disease and a right trisegmentectomy, bile duct resection, portal lymphadenectomy, cholecystectomy, and Roux-en-Y hepaticojejunostomy reconstruction was performed. Intraoperative frozen sections of the bile duct margins were found to be negative. Final pathology revealed a stage T2b N0 M0: 2.2 cm bile duct adenocarcinoma extending into the liver parenchyma. All margins were negative, no vascular invasion was appreciated, and all lymph nodes were negative for metastatic tumor. The patient went to the ICU for recovery, had an uneventful stay, and was discharged to home on day 7. Close observation versus adjuvant chemotherapy was discussed, and ultimately the patient decided to undergo 2 months of gemcitabine plus oxaliplatin therapy. Adjuvant treatment was tolerated well and at 6 months no evidence of recurrent disease was appreciated on surveillance imaging.

Gallbladder Malignancy

Malignancy of the gallbladder is rare and historically recognized to have a bad prognosis often. Disproportionately impacting elderly patients, females, and particular ethnic groups, gallbladder cancer (GBC) is a challenging disease for the surgeon as it traditionally presents at late stage, is aggressive, and often unresectable. However, with the increased utilization of laparoscopic cholecystectomy for gallstones the incidental diagnoses of early stage cancer have increased. In order to develop a rational treatment strategy, it is imperative to appreciate the risks of radical surgical resection, the limitations of surgical intervention in advanced disease, and the poor efficacy of adjuvant and palliative therapies.

Incidence

Cancer of the gallbladder was first described in 1777 and since that time, survival has not changed appreciably [1]. Despite its rarity, gallbladder adenocarcinoma is the most common malignancy of the biliary tract. It follows a bimodal presentation pattern – either presenting incidentally at the time of laparoscopic cholecystectomy for presumed benign conditions or presenting at late stages with disseminated or invasive disease. Global and national incidence varies greatly by geographic region, gender, and race. For instance, the highest global incidence of GBC is in Chile, where the associated mortality ranges regionally from 8.2 to 12.4 per 100,000 inhabitants. It is the number one cause of cancer-related death in Chilean women, ahead of breast, colon, and lung cancers [2]. Due to this disproportionate incidence, Chile employs an aggressive screening policy recommending sonography yearly from age 35–49 with low threshold for cholecystectomy. Comparatively, the United States has a much lower yearly incidence with 1.4 cases and 0.7 deaths per 100,000 women and 0.8 cases and 0.5 deaths per 100,000 men [3].

In the United States, we note a racial distribution with a 3x higher incidence in American Indian/Alaskan Natives compared to non-Hispanic whites. Across all genders and ethnicities, GBC is a disease of the elderly with a peaked incidence in the 6th decade [4].

Etiology

The etiology of gallbladder adenocarcinoma is not well understood. Several theories center around chronic inflammation caused by gallstones, chronic bacterial infection, or subacute mechanical obstruction of bile outflow. There is a well-known association with primary sclerosing cholangitis (PSC), although the risk of GBC in patients with this disease is only 2% [5]. Historically, infection with typhoid was an important consideration; however, currently the incidence of this infection in the USA is very small and therefore not responsible for many cases. This may be, however, one of the more important associated factors worldwide.

Gallstones are thought to be an underlying concern, with 75–90% of GBC cases occurring concomitantly with cholelithiasis. Clearly, however, few patients with gallstones ever develop malignancy with an estimated rate of only 0.3–3% [4]. On routine examination of pathology specimens following cholecystectomy, Jain et al. reports the incidence of epithelial dysplasia to be 15.7% and carcinoma in situ at 0.6% [6].

A well-defined radiologic finding associated with GBC is the "porcelain gallbladder," referring to calcification in the wall of the gallbladder caused by long-term inflammation (Fig. 1). Recent studies find that patients with porcelain

Fig. 1 Cross-sectional CT scan demonstrates calcification of the gallbladder wall often described as a "porcelain gallbladder"

gallbladder have a 10–15% risk of harboring cancer [7], which is much lower than previously believed. Cholecystectomy is recommended for all medically fit patients.

Pathology and Staging

Adenocarcinoma comprises an overwhelming majority of GBCs (90%), while 4% are squamous/adenosquamous, 3% are neuroendocrine, and 3% other types [8]. It is believed over time that epithelial tissue develops dysplasia which progresses to carcinoma in situ and then invasive cancer [6]. Contrary to popular believe, polyps are rarely part of this dysplastic progression and typically have a negligible chance of malignant transformation [9].

The characteristic appearance of GBC is a thickened gallbladder wall with diffuse inflammation. When advanced in the neck region, obstruction, hydrops of the gallbladder, and invasion into portal vascular and ductal structures may be observed mimicking cholangiocarcinoma [10]. GBC can be separated into infiltrative, nodular, and papillary subtypes, or combinations thereof. Most tumors have at least some infiltrative component, causing wall thickening and induration. Papillary tumors have frond-like projections into the gallbladder lumen. They can become very large, but often have a better prognosis because they are less invasive into the gallbladder wall and liver bed [9]. Regardless of subtype, once the tumor metastasizes, they have the same dismal prognosis. The currently agreed upon staging system is established by the American Joint Committee on Cancer (AJCC) (Table 1).

GBC spreads along lymphatic tracts, hematogenously, with peritoneal implantation, and also through direct invasion (Table 2). The gallbladder is not completely covered in peritoneum. The posterior wall has a fibrous layer of attachment to the liver known as the "cystic plate." This plane of dissection during cholecystectomy is of anatomical importance; surgeons can appreciate the increased ease of direct invasion of the liver without the peritoneal barrier. This route for disease spread is the underlying reason that a simple cholecystectomy is inadequate for most GBCs, particularly those that extend beyond the muscularis layer. The lymphatic drainage pathway of the gallbladder is from cystic to pericholedochal nodes, to retroportal nodes, and ultimately pancreaticoduodenal nodes before reaching the celiac and caval regions. Notably, GBC is not known to ascend to the lymphatics of the proximal porta hepatis.

Presentation and Diagnosis

Clinical Presentation

The classic presentation of symptomatic GBC is an elderly person complaining of right upper quadrant (RUQ) pain, weight loss, anorexia, and in a third of patients, jaundice. The later finding is predictive of more advanced disease (median survival 6 months vs. 16 months in those without jaundice) [11]. Physical exam may demonstrate RUQ tenderness or palpable mass, although this is rare in the absence of advanced disease or concomitant cholelithiasis/cholecystitis. There are no laboratory tumor markers that are very sensitive and specific of GBC; however, CEA and CA 19–9 are often measured and can be trended if elevated.

Although the overall incidence of GBC on a presumed benign cholecystectomy is <1%, nearly half of GBCs are identified in this incidental

Table 2 Patterns of gallbladder malignancy invasion (Data from Boerma EJ, 1994: Towards an oncological resection of gall bladder cancer. Eur J Surg Oncol 20 (5):537–544)

Pathologic finding	Relative incidence (%)
Confined to gallbladder wall	10
Liver invasion	59
Common bile duct infiltration	35
Lymphatic invasion and regional lymphatic metastases	45
Portal vein or hepatic artery invasion	15
Adjacent organ invasion (excluding liver)	40
Perineural invasion	42
Liver metastasis	34
Distant metastasis (excluding liver)	20

fashion after the specimen has been sent to pathology [8]. Some are discovered and noted intraoperatively, allowing the surgeon to change the course of the operation as indicated. Those that are suspected preoperatively tend to be locally advanced (53% of the time) and are found to be disseminated in more than 1/3 of cases [12].

Radiological Evaluation

Ultrasonography is an excellent modality for gallbladder imaging as it is ubiquitous and inexpensive, and several key findings can alert the astute radiologist to the potential presence of malignancy. Discontinuous mucosa, submucosal echo-lucency or heterogeneity, and abnormalities of blood flow in the mucosa help to differentiate benign and malignant disease. Common ultrasonographic findings include a heterogeneous mass replacing all or part of the gallbladder (40–65% of cases), or diffuse thickening of the gallbladder wall (20–30% of cases) [13] (Fig. 2).

Cross-sectional computed tomography (CT) scan can aid in the evaluation of an inconclusive ultrasound exam and is valuable in staging if a malignancy is suspected. Gallbladder carcinoma can be hypodense, hypervascular, and irregular, and this asymmetry and marked enhancement help differentiate malignant from benign processes. In a retrospective analysis of patients at Johns Hopkins Hospital, 66% of patients were

Fig. 2 Coronal view of CT scan reveals a gallbladder mass (circle) later confirmed as stage IIb biliary adenocarcinoma

diagnosed with the correct stage preoperatively on CT scan, which is reflective of prior studies in the literature [14].

On magnetic resonance imaging (MRI), GBC is routinely hypo- to isointense on T1 phase and moderately hyperintense on T2 sequences. It is currently unclear whether MRI can add value to results obtained on CT scan; however, magnetic resonance cholangiopancreatography (MRCP) can be valuable to create a reconstruction of the biliary tree. This is particularly useful in cases that involve the gallbladder infundibulum with invasion into the surrounding cystic duct, common bile duct, or directly into the liver. PET imaging is of limited use in primary diagnosis, as benign inflammation can be interpreted as a false positive [13]. However, PET can be very useful in evaluation for nodal or distant metastasis in later stage disease or disease recurrence. One study found that PET imaging changed the pathway of surgical treatment in 23% of patients who were being preoperatively staged for an initial resection or preparing for a reoperation after incidental cancer was encountered during a laparoscopic resection previously [15].

Treatment

Incidental Discovery

Adenocarcinoma is encountered incidentally in <1% of cholecystectomy specimens on pathologic examination. Nearly 50% are stage T1 in this circumstance [16]. For tumors invading only the lamina propria (T1a), a simple laparoscopic cholecystectomy is sufficient for cure and repeat operation with hepatic wedge-resection is not required. However, for tumors extending into the muscular layer (T1b), the literature has reported a wide range of survival: as low as 50% at 1 year and as high as 75% at 5 years [17]. To err on the side of caution, re-resection of the gallbladder fossa of the liver bed, along with lymph node dissection, is recommended. If there is an intraoperative suspicion of malignancy (palpable, nonmobile mass noted on specimen extraction, enlarged regional nodes), the specimen should be sent for frozen section and the surgeon should prepare for a liver resection and posterior pancreatic nodal dissection if conclusive evidence of cancer is found. If the surgeon does not feel confident performing these maneuvers, data show that closure and referral to a hepatobiliary center for re-operation does not significantly affect survival [18]. Staging workup is recommended postoperatively for all known cases of GBC, regardless of TNM stage.

Single Polyp

Gallbladder polyps are occasionally identified on incidental imaging or cholecystectomy specimens. Unlike polyps of the colon, these are not frequently considered to be precancerous lesions and are most commonly benign cholesterol polyps [9] (Fig. 3). The prevalence of adenocarcinoma is only 0.08% in polypoid lesions and for polyps ≤0.5 cm, no strict follow-up regimen is required. However, in patients with PSC or polyps >1 cm in size, the risk of malignant transformation is elevated particularly in elderly patients and a

Fig. 3 Ultrasound image demonstrates a gallbladder polyp (*arrow*)

cholecystectomy should be performed [9]. In cases where the polyp is between 0.6–1 cm, serial ultrasound imaging can be utilized for follow-up.

A laparoscopic approach is appropriate if the surgeon feels confident in removing the specimen intact, but preoperative consent for liver resection should be obtained if more advanced disease is discovered intraoperatively.

Resection of T2 + Disease

Diagnosed preoperatively on imaging or intraoperatively, tumors stage T2 or T3 (without evidence of distant metastasis) necessitate open cholecystectomy, en-bloc liver resection of segments IVb/V, and regional lymphadenectomy. This aggressive resection increases median survival to 17 months from 9 months [19]. Particular attention should be paid to the cystic duct margin on frozen section, as a positive margin necessitates biliary resection to negative margins. Smaller liver wedge resection is adequate if margins of 1–2 cm are obtained and no radiologic findings were appreciated preoperatively [20]. Studies have failed to demonstrate benefit of more aggressive anatomic liver resection when negative margins are achieved [21].

The benefits of lymphadenectomy have not been clearly demonstrated; however, prognostication is improved with knowledge of nodal status. Regional lymphadenectomy has been a topic of debate in prior years, with most considering dissection of cystic, pericholedochal and hepatoduodenal nodes to be adequate. Yet, the anatomical lymphatic drainage of the gallbladder includes the posterior pancreaticoduodenal nodes and retroportal nodes. Studies of recurrence patterns after surgery support the dissection of these nodal basins, with a goal of harvesting at least 6 nodes to improve prognostication [22, 23]. Unfortunately, evaluation of the SEER database reveals that this is rarely the case with only 5–7% of patients undergoing resection of ≥ 3 nodes [24].

If advanced disease is suspected, staging laparoscopy can be performed to rule out unresectable disease, avoiding laparotomy. Extensive resections for tumors invading the hepatic inflow have not been shown to increase survival, and certainly in the elderly have an increase in morbidity and mortality [25]. If nonregional lymph node or distal metastases are present, palliative resection is not indicated. Additionally, presence of a port-site recurrence following laparoscopic resection is known to be a marker of aggressive disease and overall peritoneal involvement. Despite the previously common practice of resecting port-sites at time of hepatic resection and lymphadenectomy, this is no longer recommended, as there has not been a demonstrable benefit in survival.

Outcomes

GBC has an overall dismal prognosis for nearly every stage with a median survival of 16 months and overall 5-year survival of 20% for patients with *resectable* disease [26]. No significant changes in survival have been noted from 1991 to 2005 [26]. For *unresectable* patients or those who are untreated, median survival is only 2–6 months [27] (Fig. 4). The 5-year survival based on AJCC stage drops precipitously (Table 3).

Adjuvant Therapy

Effective options for chemotherapy and radiotherapy are unfortunately lacking. As 85% of recurrences include distant sites, development of a systemic therapy would greatly improve survival

[26]. A postoperative regimen of mitomycin C and 5-fluorouracil has shown modest improvement of disease-free survival [to 20.3% at 5 years, compared to 11.6% at 5 years with surgery alone ($p = 0.02$)] [28]. Specifically targeting unresectable patients, gemcitabine increased survival to 9.5 months compared to 5-FU (4.5 months) or supportive care (4 months) in a triple-arm randomized controlled trial [29]. Radiotherapy has shown slight improvements in short-term survival, but not at 5 years [30]. This may be attributable to the fact that the disease spreads via multiple avenues, and locoregional radiation does not address distant sites of spread.

Fig. 4 Cross-sectional CT scan reveals invasive stage IV gallbladder malignancy with distant hepatic metastases

Palliation

As GBC is an aggressive disease of the elderly with poor outcomes with or without surgery, palliative care is an important consideration. Proper patient selection for operative management is of concern, as liver resections are not well tolerated by frail patients, and the survival benefit must outweigh the risks of treatment. For symptomatic patients, jaundice caused by obstructive or compressive masses can be managed using biliary stents via ERCP or percutaneous approaches.

Cholangiocarcinoma

Cholangiocarcinoma is a rare group of malignancies arising from the biliary tract epithelium, consisting of three distinct subclasses determined by the location at which they arise in the bile duct: intrahepatic, extrahepatic perihilar, and distal extrahepatic. These three phenotypes have distinct presentations and management. Similar to GBC, outcomes for cholangiocarcinoma have been universally dismal due to its aggressive nature and diagnostic challenges leading to advanced disease on initial presentation. Most patients with unresectable disease live less than a year after diagnosis, dying of disease progression, biliary sepsis, or liver failure. Surgical excision

Table 3 Staging, treatment, and survival for gallbladder malignancy (Used with the permission of the American Joint Committee on Cancer (AJCC), Chicago, Illinois. Stage	AJCC/TNM (7th ed)	Recommended treatment	5 year survival
0	Carcinoma in situ (Tis), N0, M0	Simple cholecystectomy	80–100%
I	Invasion of lamina propria (T1a) or muscular layer (T1b), N0, M0	Simple cholecystectomy (T1a) vs. Cholecystectomy with wedge resection of liver to 1–2 cm margins (T1b)	50–100%
II	Invasion of perimuscular connective tissue without extension beyond serosa (T2), N0, M0	Open en-bloc resection of gallbladder, segments IVb/V, lymphadenectomy	28%
III	Tumor through serosa or into liver or adjacent organs (T3), N0, M0 [IIIA]; or T1–3 with N1 LN [IIIB]	Open en-bloc resection of gallbladder, segments IVb/V, lymphadenectomy, adjuvant chemotherapy considered	8%
IV	Invasion of portal vein or hepatic artery, or two or more extrahepatic organs (T4), N0–1, M0 [IVA]; any N2 LN or metastases [IVB]	Unresectable, adjuvant chemotherapy optional	2–4%

with curative intent is the most effective form of therapy; however, outcomes remain poor.

Incidence

Hepatic and biliary malignancies represent the third most prevalent gastrointestinal malignancy in the United States behind colon and pancreatic cancer [31]. Of these, cholangiocarcinoma represents <3% of all malignant liver tumors [32]. In the United States, cholangiocarcinoma occurs with an average incidence of 1 to 2 cases per 100,000 people with a slight male predominance (1.5:1). Cholangiocarcinoma most frequently presents in the geriatric population with a peak age of diagnosis in the eighth decade of life [33]. Perihilar extrahepatic, or Klatskin tumors (after Klatskin's description in 1965 [34]), are the most prevalent with intrahepatic the least common. Prevalence shows significant variation based on geography with incidences as high as 113 per 100,000 men and 50 per 100,000 women in Asia likely reflecting regional differences in risk factors [35].

Etiology

The etiology of cholangiocarcinoma remains undetermined, although long standing inflammation, biliary stasis, and infection are suggested to play a role. The majority of cholangiocarcinoma is sporadic. There are several established risk factors including advanced age, congenital biliary cystic disease, hepatolithiasis, thorotrast radiographic contrast, and the parasitic hepatobiliary flukes *Clonorchis sinensis* and *Opisthorchis viverini* that inhabit bile ducts predominately in Southeast Asia [35]. The autoimmune disease primary sclerosing cholangitis (PSC) strongly predisposes for cholangiocarcinoma. The lifetime incidence for cholangiocarcinoma among PSC patients ranges from 6% to 36% with most presenting within 2.5 years of their PSC diagnosis [35, 36]. PSC leads to chronic inflammation, proliferation of biliary epithelium, and bile stasis. The risks of inflammatory bowel disease, choledocholithiasis, alcohol abuse, smoking, chronic viral hepatitis, and cirrhosis are less well established [35].

Pathology and Staging

More than 90% of biliary tract cancers are adenocarcinoma with the remainder being squamous cell tumors [36]. Grossly, cholangiocarcinoma is divided into three pathologic classifications: sclerosing, nodular, and papillary. Sclerosing cholangiocarcinoma is the most common pathologic subtype comprising up to 70% of cholangiocarcinomas [33]. They are frequently found at the hilum and grow diffusely along the biliary wall with a corresponding dense desmoplastic reaction and radial tumor infiltration. This allows for perineural and lymphatic spread making local extension into regional lymph nodes and vasculature including hepatic artery, veins, and porta hepatis quite common. Nodular subtypes have firm irregular projections into the lumen of the bile duct. Papillary subtypes, representing less than 10% of cholangiocarcinoma, have a less invasive growth pattern arising from a well-defined stalk and are more often resectable with a more favorable prognosis [36].

Klatskin and Distal Extrahepatic Cholangiocarcinoma

The AJCC staging system for cholangiocarcinoma divides the disease to its locational subtypes accounting for extension of disease, nodal involvement, and distal metastases (Tables 4, 5, and 6). Alternative staging systems, including the Bismuth-Corlette system and Memorial Sloan Kettering Cancer Center classification, can further assist in predicting local resectability and need for hepatic resection. The Bismuth-Corlette system provides anatomic classification based on tumor location and duct infiltration: Type I are confined to the common hepatic duct below the level of bifurcation. Type II involve the hepatic duct confluence without involvement of secondary intrahepatic ducts. Type IIIa and IIIb involve the bifurcation but also extend into the right and left secondary intrahepatic ducts, respectively. Type IV tumors

involve both the right and left secondary intrahepatic ducts [37]. The Memorial Sloan Kettering Cancer Center (MSKCC) classification for hilar cholangiocarcinoma similarly assesses local tumor extent while also assessing portal vein and hepatic lobar atrophy [38].

Intrahepatic Cholangiocarcinoma

Staging for intrahepatic cholangiocarcinoma in the AJCC is based on the number of intrahepatic lesions, presence or absence of vascular invasion, lymph node, and distal metastases (Table 6). The overall median 3- and 5-year survival is 31% and 18%, respectively. In the absence of nodal involvement or distant intrahepatic metastases, 3- and 5-year survival is somewhat better at 40% and 25% [39, 40].

Presentation and Diagnosis

Klatskin and Distal Extrahepatic Cholangiocarcinoma

The most common presentation for extrahepatic cholangiocarcinoma is painless jaundice due to biliary obstruction. Pruritus, abdominal pain, anorexia, fatigue, acholic stools, dark urine, and weight loss may also be present. Apart from potential jaundice, the physical exam is predominately normal. In uncommon cases a palpable gallbladder, Courvoisier's sign may be appreciated. Laboratory evidence of biliary obstruction such as elevated alkaline phosphatase, elevated g-glutamyl transferase, hyperbilirubinemia, or bilirubinuria may also be present. Tumor markers such as CA125, CA19–9, and CEA can be

elevated in cholangiocarcinoma, and higher levels are associated with advanced tumor stage predicting a worse overall survival [36]. These markers, however, are nonspecific as they also increase with other gastrointestinal and gynecologic neoplasms, as well as in benign extrahepatic obstruction [32].

Ultrasonography can identify large hilar tumors but is not the optimal form of imaging for operative planning and has low sensitivity in identifying metastases. CT allows for better understanding of the extent of the disease process; it can demonstrate the level of biliary obstruction or the presence or absence of local vascular invasion or lymph node involvement, and can show distal metastasis that would preclude resection. Klatskin tumors cause biliary dilation of the intrahepatic tree, while distal biliary disease has dilatation of both intrahepatic and extrahepatic ducts as well as the gallbladder (Fig. 5).

Magnetic resonance cholangiopancreatography (MRCP) best defines biliary anatomy. MRCP allows noninvasive three-dimensional reconstruction of ductal anatomy and can accurately identify the level and cause of biliary obstruction while also assessing the extent of bile duct invasion, vessel encasement, and adjacent liver extension [41]. Contrast enhancement is imperative for operative planning in both MRCP and CT to asses both vascular invasion as well as possible anomalous hepatic flow. Endoscopic retrograde cholangiography (ERCP) is an invasive approach that allows visualization of ductal anatomy with the ability to obtain brushing or biopsy specimen. However, ERCP should be used selectively due to risks of pancreatitis and cholangitis. Endoscopic ultrasound scan (EUS) is becoming more commonly utilized due to the ability to evaluate the biliary tract without instrumentation thus avoiding the potential for biliary sepsis. EUS can also assess the level of obstruction, vascular involvement, or regional lymph nodes and provides the ability to sample nodes with fine needle aspiration (FNA) or core needle biopsy. Needle biopsy can often be nondiagnostic due to the desmoplastic nature of this disease and technical challenges of tissue sampling.

Fig. 5 Endoscopic retrograde cholangiopancreatography imaging demonstrates filling of proximal biliary tree with narrowed common bile duct secondary to compressive distal cholangiocarcinoma

Intrahepatic Cholangiocarcinoma

Intrahepatic cholangiocarcinoma typically presents as an incidental hepatic lesion (Fig. 6). Obstructive jaundice is rare and the majority of patients are asymptomatic. Liver function changes may be present as well as weight loss, early satiety, and anorexia. Contrast enhanced CT or MRI imaging is necessary to determine the extent of disease spread, the size, number and location of lesions, vascular invasion, and anatomy. Imaging also can assess for cirrhosis, portal hypertension, and ascites that may affect treatment decision-making.

Treatment

Margin negative resection for cholangiocarcinoma is the only treatment strategy with a potential for cure. Preoperative evaluation is critical to review patient performance status, extent of comorbidities, nutrition status, and hepatic function. The patient presenting with biliary sepsis should undergo biliary stenting to relieve cholestasis. Stenting can also be utilized in cases of marked hyperbilirubinemia and jaundice as a temporizing drainage maneuver while awaiting scheduled surgery. However, biliary instrumentation and manipulation can predispose to infection

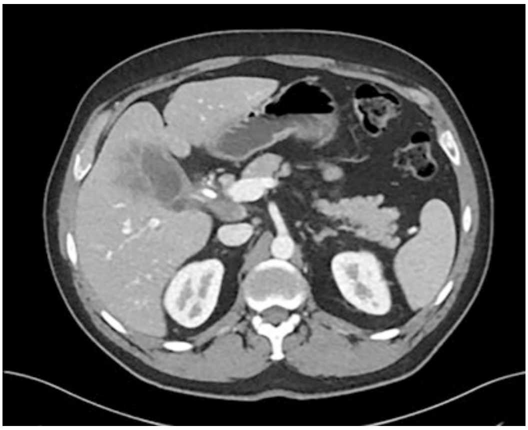

Fig. 6 Cross-sectional CT scan image demonstrates intrahepatic cholangiocarcinoma involving segment 4 of the liver

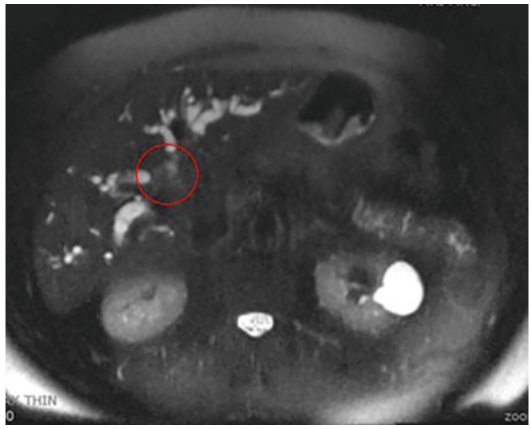

Fig. 7 T2 weighted MRI imaging demonstrates a Klatskin's tumor (*circle*) at the hepatic duct confluence

and prolonged postoperative hospitalization. Additionally, localized inflammatory effects of stenting can feasibly complicate the determination of tumor extent at the time of resection. Therefore, it is preferable, when feasible, to go directly to surgery avoiding stenting in operative candidates.

Patients without locally unresectable disease or metastasis should undergo surgical exploration. Unfortunately, more than half of such patients explored are found to have peritoneal implants, hepatic metastasis, or locally advanced disease precluding a complete resection. Due to the poor predictive value of preoperative staging for surgical resectability, diagnostic laparoscopy, which can identify two third of radiographically occult metastasis, can be utilized to spare laparotomy [42].

Surgical Resection of Klatskin Tumor

The extent of surgical resection for Klatskin is dictated by the location and local extension of disease (Fig. 7). Outcomes have improved with the adoption of more aggressive surgical approaches including extended hepatectomy and portal vein resection. Portal vein embolization (PVE) may be used as an adjunct measure. Preoperative imaging and staging are imperative for surgical planning. Perihilar tumors involving the proximal common duct without proximal involvement of the intrahepatic ducts (Bismuth type I and II) nor vascular involvement are candidates for local tumor excision. The distal bile duct is isolated to the level of the pancreas and divided with intraoperative frozen section to ensure negative margins. The duct is then dissected from hepatic artery medially and portal vein posteriorly with portal caval lymphatics also removed en bloc. At this point a top down approach cholecystectomy is performed. Proximal hilar exposure is accomplished with individual dissection of the right and left bile ducts. Extent of tumor extension is identified and ducts are ligated proximal to the tumor individually with frozen sections to ensure negative margins. A Roux-en-Y reconstruction is performed with individual anastomoses to each duct. If tumor involves the right or left intrahepatic ducts (Bismuth type IIIa or IIIb), respective right or left hepatic lobectomy should also be performed. Frequently, caudate lobectomy is required due to direct extension into the caudate. Tumor invasion of the contralateral or bilateral hepatic arteries, secondary biliary radicals, or extensive portal vein involvement prevents successful resection [43]. The remnant liver following resection must have adequate arterial inflow and venous drainage in at least two contiguous hepatic segments.

Surgical Resection of Distal Extrahepatic Cholangiocarcinoma

Distal bile duct tumors are more often resectable than the perihilar and intrahepatic counterparts. Pancreaticodudoenectomy is required, removing the pancreatic head, proximal duodenum, gallbladder, and bile duct. Identification of tumor extent is imperative and frozen margin of the proximal bile duct should be assessed. Bile duct excision alone is not recommended due to worse lymph node clearance, a lower likelihood of having curative margins, and poorer survival [44].

Surgical Resection of Intrahepatic Cholangiocarcinoma

As with Klatskin's tumors, successful hepatectomy for intrahepatic cholangiocarcinoma must maintain functionally adequate remnant liver. Therefore, initial preoperative assessment must address general liver function. Chronic liver disease or portal hypertension precludes resection. Selective ipsilateral PVE can enable more extensive resections than possible previously by inducing compensatory hypertrophy of the future remnant and should be considered if remnant volume is expected to be less than 30% [45]. Furthermore, PVE is pertinent for patients in which an extended right hepatectomy is anticipated due to the frequent inadequacy of remaining left lateral and caudate volumes [46]. In cirrhotic patients, a larger remnant is essential. Additional criteria for unresectability include tumor extension to bilateral secondary branches of hilar structures, portal vein, hepatic artery, and bile ducts.

Transplantation

In highly selected patients, orthotopic liver transplant (OLT) may be considered for unresectable cholangiocarcinoma. The rates of long-term survival for cholangiocarcinoma associated with PSC are dismal, even following surgical resection, due to frequently multicentric disease and underlying liver dysfunction. Thus, OLT has been pursued particularly for this cohort. The Mayo Clinic has developed a neoadjuvant chemotherapy followed by transplantation protocol for unresectable hilar cholangiocarcinoma or hilar cholangiocarcinoma with PSC. Eligibility criteria include a tissue diagnosis of cholangiocarcinoma, disease above the level of the cystic duct, radial dimension of <3 cm without intrahepatic or extrahepatic metastasis, and absence of prior radiation therapy. Patients must also have adequate performance status. A regimen of 5 fluorouracil, external beam radiation, and iridium 192 brachytherapy is given with Capecitabine added for 2 of every 3 weeks until the day of transplantation. With this protocol, 5-year survival rates of approximately 70% have been reported [47]. Despite these promising results, transplantation remains recommended only in selected patients in specialized centers.

Chemoradiation Therapy

Radiation in the adjuvant setting may provide local disease control and slow overall disease progression. Prospective data are limited although survival benefits have been suggested with utilization in the adjuvant setting compared to controls. Outcomes for unresectable disease treated with radiation have remained poor, with little improvement in disease-free survival. The data for chemotherapy utilization in cholangiocarcinoma are similarly limited. Systemic chemotherapy regimens most commonly consist of a combination of gemcitabine with a platinum agent with modest improvements reported in survival and quality of life compared with best supportive care [46].

Outcomes

Murakami et al. reported a series of 127 patients with cholangiocarcinoma (21 intrahepatic, 50 perihilar and 56 distal) who underwent surgical resection. Overall 1-, 3-, and 5-year survival rates for the entire cohort were 80%, 51%, and 40%, respectively [48]. Complete R0 surgical extirpation remains the best chance for long-term survival, with positive margins associated with a 13% 5-year survival compared to 49% following R0 resection [48]. An additional large single institution series reported median survivals following R0 resected intrahepatic, perihilar, and distal tumors of 80, 30, and 25 months with 5-year survivals of 63%, 30%, and 27%, respectively [44]. Concomitant hepatic resection, histologically negative margins, lymph node status, and well-differentiated tumor histology are all associated with improved outcome after resection.

Operative mortality for perihilar and intrahepatic cholangiocarcinoma is not insignificant and reported at rates of 6–8% with morbidity as high as 70% [36, 44, 49]. The greatest risk factors for recurrence are positive margins and lymph node metastasis [49]. Unfortunately, most cholangiocarcinomas present as unresectable disease. Untreated, survival of these patients is short with a median survival between 3 and 8 months, with patients most frequently succumbing to hepatic failure and cholangitis [32].

Unresectable Disease/Palliation

Less than half of cholangiocarcinomas are resectable on presentation and of patients proceeding to the operating room, 40–50% are found to be unresectable [36]. Palliative biliary drainage may be the only therapeutic possibility. Surgical bypass for patients deemed unresectable preoperatively should not be pursued due to lack of survival benefit and the associated surgical morbidity and mortality. For these patients, percutaneous placement of expandable metal stents or drainage catheters for proximal disease and endoscopic placement for distal can be provided. Stent occlusion is not uncommon and thus self-expanding metal stents are preferred. If determined to be unresectable intraoperatively, however, surgical bypass by Roux-en-Y hepaticojejunostomy has been associated with fewer episodes of cholangitis and improved patency compared to stenting [50].

Palliative chemotherapy treatment can be offered to unresectable individuals, but response rates are disappointing with median survival remaining only 6–12 months [32, 51]. Gemcitabine and cisplatin has shown benefit over 5FU-based chemotherapy or supportive care alone [46]. No randomized data are available to assess the benefit of adding radiation to palliative chemotherapy.

Unresectable cholangiocarcinoma without evidence of metastatic disease in patients who are not candidates for liver transplantation may benefit from photodynamic therapy (PDT). PDT utilizes an intravenous photosensitizing agent which accumulates in tumor cells and is activated during cholangiography by induction of a specific wavelength of light that activates the accumulated agent leading to formation of oxygen free radicals and tumor cell destruction [46]. PDT may lead to marginal improvements in cholestasis and quality of life [46].

Conclusion

GBC and cholangiocarcinoma are uncommon and aggressive malignancies predominately affecting the elderly. Complete surgical extirpation by resection or rarely transplantation remains the only current potential curative treatment; however, outcomes remain dismal and palliation may be the goal of therapy. At present, our armamentarium against this condition is predominantly limited to wide resection. With the advent of molecular medicine and immunotherapeutic approaches to cancer, we hope to see improvements in disease-free and overall survival in the future.

Benign Colorectal Disease in the Elderly

56

Walter E. Pofahl and Mark L. Manwaring

Contents

Abstract

Benign colorectal diseases are a cause of many quality of life impairments for patients. With aging of the population, physicians are likely to encounter more affected patients in the years to come. Constipation, especially prevalent among older patients, has many downstream effects and, with these, may create significant morbidity and expense for patients. Chronic straining and pelvic floor weakness may result in rectal prolapse that usually can be corrected with an appropriate surgical intervention. With antibiotic use, there is risk of *Clostridium difficile* infection which may complicate recovery from a host of conditions seen in elderly patients. Only in fulminant cases is surgery typically required. Colonic volvulus is an unusual cause of large bowel obstruction in the United States; however, its frequency too increases with patient age. Mortality may result from incorrect diagnosis or failure to intervene promptly. Fecal incontinence is disabling for a

Case Study

Background

A 59-year-old female with chronic straining constipation since her teen years presents with a bulge in the anal area for the past 6 weeks. She has a small amount of blood on the toilet paper, mucous discharge, and has noted difficulty getting clean after bowel movements. She does not have pain but does note a “pressure” sensation at the times she has prolapse with an intermittent urge to defecate, but when she toilets, she finds there is only some mucus to pass. For many years, her constipation was untreated but she has begun taking stool softeners and occasional milk of magnesia. Her past medical history is significant for basal cell skin carcinoma, excised last year, and thyroid cancer treated with resection and hypercholesterolemia. Her past surgical history is significant for a laparoscopic total abdominal hysterectomy for dysfunctional uterine bleeding at age 39. She is gravida 3, para 3. Her current medications include Synthroid and lovastatin.

On physical exam, she is a healthy-appearing overweight, middle-aged woman. Abdominal exam is benign. There is a well-healed small Pfannenstiel incision. On digital rectal examination, she has normal anal tone, and there is a broad-based rectocele that is prominent on Valsalva. A mass is palpable against the tip of the examining finger. Proctosigmoidoscopic examination shows infolding of the rectal wall anteriorly with ulceration along the fold. There is some hard stool in her rectal vault. Examination while sitting on the commode shows full-thickness prolapse upon straining on the toilet.

Management

Anal physiology (including anal manometry, EMG, and transrectal ultrasound) is not needed for evaluation of the patient’s condition. Left untreated, full-thickness rectal prolapse would likely progress and dilate the anal sphincters resulting in compromised continence. Chronic constipation and loss of supporting tissue integrity have allowed for folding of the rectal wall, and ulceration sometimes progresses from recurrent trauma as in solitary rectal ulcer syndrome. Defecography or dynamic MRI may be done to confirm the degree of internal intussusception and to evaluate the size/severity of the rectocele, presence of an enterocele, or vaginal prolapse. Colonic transit time using a sitz marker test can be used to categorize her chronic constipation though this would probably not change the management given her age and her limited use of osmotic laxatives. Since rectopexy alone may worsen the patient’s constipation, a laparoscopic (or robotic) rectopexy with sigmoid resection would be the treatment of choice. Properly done, this will correct the internal and early external prolapse and prevent sequela of sphincter dysfunction while avoiding constipation exacerbation. Were the patient to be without constipation symptoms, a rectopexy alone with suture or mesh may be preferred. Though there is interest in anterior mesh approaches for rectal prolapse as this may avoid the denervation of the rectum resulting from lateral stalk division, posterior rectopexy with mesh or suture are most commonly employed. Vaginal/uterine prolapse if present can be treated with cooperation of urogynecologist by sacral colpopexy or other needed intervention.

Introduction

The incidence of benign medical and surgical diseases of the colon and rectum increases with age [1]. Although constipation, fecal incontinence, and several other associated benign conditions increase in frequency with aging, a paucity of information exists regarding the normal aging effect on gastrointestinal pathophysiology. Studies documenting anatomic, physiologic, and pathologic changes that occur in the aging colon have not been definitive, and many studies have reported conflicting results. Mucosal atrophy, atrophy of circular muscles, thickening of longitudinal muscles (taeniae coli), increased elastin deposition, and atherosclerosis are several of the changes seen in the aging bowel [3]. These changes may factor into the development of several disease states (i.e., diverticular disease and angiodysplasia). Medications affect gastrointestinal function, and many have constipation as a side effect. Preexisting diseases (cardiac, pulmonary, renal, neurologic, psychiatric) may affect colonic motility directly or secondarily. Advanced age is a risk factor for the development of infectious processes such as *Clostridium difficile* infection. Comorbidities and age limit physiologic reserve in the elderly, making operative risks higher. These differences make early diagnosis and treatment crucial to good outcomes. In this chapter, we address benign colorectal diseases frequently encountered in the elderly patient and which may increase as the population ages. Diseases equally common to both young and old persons, such as hemorrhoids and fissures, are not discussed.

Constipation and Pelvic Floor Dysfunction

Difficult or infrequent passage of stool and other bowel symptoms that define constipation are common complaints in the United States (Table 1). The frequency of constipation increases with age, and it is more common in women, blacks, and persons of lower socioeconomic status and family educational status [4–6]. The overall prevalence of reported constipation in the elderly Western population is probably 20–33% but differs according to the source of the sample [5, 7–9]. The incidence of constipation is approximately 12% in the ambulatory geriatric population vs. 41% in acute-care facilities and more than 80% in geriatric nursing homes and extended-care facilities (compared to about 16% in the general population). Elderly women are about 50% more likely to report symptoms of constipation than elderly men [7, 8]. Further, studies indicate large variation in bowel habits and frequent use of laxatives in as many as 30–50% of the elderly population [10–12]. Subjective complaints of constipation and laxative use increase with age, but true epidemiologic data suggest that clinical constipation does not [13]. Although complaints of constipation increase in those over age 65, about 80–90% of subjects over age 60 report at least one bowel movement per day [10, 11]. Although there may be normal physiologic aging of the colon and rectum, asymptomatic geriatric patients do not seem to differ significantly from their younger cohorts.

Table 1 Rome III criteria for functional constipation (Adapted from: Shih DQ, Kwan LY. All Roads Lead to Rome: Update on Rome III Criteria and New Treatment Options)

At least two or more of (during at least 25% of defecations)	And
Straining	Loose stools are rarely present without the use of laxatives
Lumpy or hard stools	Insufficient criteria for irritable bowel syndrome
Sensation of incomplete evacuation	
Sensation of anorectal obstruction/blockage	
Manual maneuvers to facilitate defecations	
Fewer than three defecations per week	

Stool transit through the colon is affected by stool consistency and by underlying large bowel motility. Both of these characteristics can be altered both positively and negatively by medications. Stool content and therefore its physical properties are altered by dietary factors – primarily fluid and fiber. Inadequate fluid intake may decrease the fecal bulk causing decreased intraluminal pressures in the colon, which in turn may decrease the number of propagating motor complexes generated [13]. The role of fiber has been debated, but current aggregate data suggests wheat fiber does increase stool weight and frequency and decreases transit times [14].

Polypharmacy, common in the elderly, places this group at particular risk for compromised colonic motility [15]. Anticholinergics, tricyclic antidepressants, beta-blockers, and calcium channel blockers are commonly implicated. Over-the-counter medications, such as aluminum and calcium antacids and laxatives, may also contribute to patients' symptoms. Chronic medical diseases such as hypothyroidism, diabetes, scleroderma, multiple sclerosis, and Parkinson's disease can result in decreased colonic motility. Psychiatric conditions (depression and dementia) have been associated with constipation, which may be behaviorally related [4]. Inability to ambulate to the restroom because of arthritis, for example, or ignoring the call to defecate because of dementia may contribute to symptoms of fecal impaction, constipation, and the development of a megarectum [4, 11]. Constipation is probably not a normal consequence of aging but is associated with and possibly caused by the immobility, chronic illnesses, and increased neuropsychiatric problems of the elderly population.

Patients with constipation can be separated into three groups: The first and by far the largest group of patients are those with normal transit or functional constipation. These patients complain of hard, dry stools that are difficult to evacuate and should be treated with lifestyle manipulation: increased fiber, increased fluid, and exercise or with osmotic laxatives for refractory symptoms. The second group, more likely to present at younger ages, are patients who have slow transit or colonic inertia. These patients have minimal to no motility of their colon and rarely have spontaneous bowel movements. Many of these patients report going for days and occasionally weeks without bowel function. Patients with colonic inertia commonly report a long history of laxative use and abuse. Chronic laxative use, particularly with the anthracene laxatives, can cause degeneration of the myoneural chains and may impede motility irreversibly over time [16]. The final group are the patients with anorectal dysfunction or pelvic floor abnormalities that prevent evacuation and result in clinical constipation. The pelvic floor abnormality can be identified with colonic transit marker studies, cinedefecography, and dynamic MRI. These patients have normal transit to the sigmoid colon but are unable to evacuate their rectums easily, even if they have a soft stool. Within this group are patients with rectal intussusception, pelvic organ prolapse, rectocele, and obstructed defecation (nonrelaxing puborectalis or anismus). In rectal intussusception, the rectum folds in onto itself and may act as a valve that prevents normal emptying. Symptoms vary from mild constipation with rectal pressure to severe constipation with rectal pain and a "plugging" sensation. Incomplete evacuation and discharge of mucus and blood per rectum are frequent complaints. Rectal intussusception may be identified as a component of pelvic organ prolapse. The etiology of outlet obstruction is unclear, although dysfunction and discoordination of the pelvic floor muscles are the most common explanation. In patients with chronic fecal impaction, the rectal capacity increases over time and rectal sensation becomes blunted. These patients cannot feel the urge to defecate until a fecal bolus is too large to pass. These patients often report the need to use digital maneuvers, suppositories, or enemas to evacuate to their satisfaction.

Patients with complaints of severe constipation should be completely evaluated. Initially, a history and physical examination are performed. A detailed medication list, including all over-the-counter medications, is imperative. A diet and defecation diary is helpful to attempt to define the extent of the problem. The American Gastroenterological Association consensus guideline recommends that most patients with severe constipation have a complete blood count, serum glucose, calcium and creatinine, and thyroid-stimulating hormone levels checked [17].

A digital rectal examination should be done to exclude low rectal carcinomas, anal strictures, and other anorectal abnormalities. Contrast studies or colonoscopy should be performed to rule out obstructing colonic lesions, particularly if the symptoms of constipation are recent or associated with bleeding, mucus, or altered stool caliber.

Table 2 Traditional obstructive defecation treatment algorithm (Adapted from Schwartz [107])

Presenting symptoms:				
Constipation, incomplete evacuation, rectal pressure, need for digital maneuvers				
Workup: defecography, sitz marker study, balloon expulsion test				
Defecography	Nonrelaxing PR	Nonrelaxing PR	Internal intussusception	Internal intussusception
Colonic transit	Normal	+ Outlet obstruction	+ Outlet obstruction	+ Outlet obstruction
Balloon expulsion	Normal	Unable to expel	Normal	Unable to expel
Treatment	**Bulking agents**	**Psychological evaluation**	**Fiber/stool liquification if mild, consider rectopexy**	**Psychological evaluation**
	Stool softeners	**Biofeedback**		**Biofeedback**

Defecography, endoscopy, sitz marker testing, and/or manometry can help guide the clinician in determining cause and treatment. (Table 2) On proctosigmoidoscopic examination, the typical patient with significant intussusception often has an erythematous anterior rectal wall approximately 5–8 cm from the mucocutaneous junction. Patients with solitary rectal ulcer syndrome frequently have more severe symptoms of straining, passage of bloody mucus per rectum, and incomplete evacuation, and the rectal ulcer appears as a heaped-up lesion in the anterior midline 5–8 cm from the mucocutaneous junction. This lesion is often palpable and may be mistaken for a rectal carcinoma. Biopsy is important to exclude malignancy and reveals cystic proliferation of fibroblasts and muscle hypertrophy in the lamina propria, epithelial hyperplasia, colitis cystica profunda, or excess mucosal collagen [18].

Several tests are available for assessment of constipation and can aid in creating a strategy for management although it is not uncommon that patient's complaints and concerns do not correlate well with colonic and anorectal physiologic tests. Colonic transit time is a simple radiographic test which helps assess the bowel motility and can identify patients with colonic inertia or outlet obstruction. Patients are placed on a high-fiber diet and taken off all laxatives and enemas for several days prior to testing. A capsule with 24 radiopaque markers is given to the patient to take orally on day 0. A plain radiograph is obtained on the third and fifth days. The markers are counted, and their location should be noted. The presence of more than 10% of the markers on the fifth day is considered to be an abnormal study. It is important to ensure that the patient took the capsule, did not take laxatives, and did not have abnormal bowel function (i.e., diarrhea) during the study period, as these possibilities may give a false normal examination. Patients with colonic inertia have markers scattered diffusely throughout the colon that remain through the fifth day. In patients with rectal intussusception or outlet obstruction, the markers move through the colon and are held up in the rectosigmoid region. Total colonic transit times in healthy asymptomatic elderly subjects show no change with aging but are prolonged in healthy elderly subjects who report symptoms of constipation [19, 20].

There are clearly cause and effect relationships in both directions between pelvic floor disorders and constipation. Commonly chronic straining behavior results in structural changes over time of the anorectal anatomic relationships. Often, however, anatomic alterations can exacerbate difficulties with evacuation. Physical examination, though important, is of limited value in evaluation of the pelvic floor as it misses a significant number of rectoceles, enteroceles, sigmoidoceles, and cystoceles [21]. Cinedefecography may identify patients with severe rectal intussusception or rectal prolapse and can identify patients with significant rectoceles and enteroceles if vaginal contrast is used. This test is done by placing a thickened barium paste in the rectosigmoid to simulate a bowel movement. The patient is then placed on a commode and asked to evacuate the paste while radiographs are obtained. In a normal test, the rectosigmoid remains stable along the presacral space, and the puborectalis is seen to relax as the patient passes the contrast bolus. With an abnormal test, the rectosigmoid may fall away from its attachments to the presacral space, and the proximal rectum is seen to infold (intussuscept). Internal intussusception of the rectum can block the rectal outlet, resulting in incomplete evacuation of the rectal contrast. With severe straining, the intussusception may worsen, and occasionally the entire rectum is seen prolapsing through the anorectal ring (Fig. 1).

One of the shortcomings of defecography is the utilization of ionizing radiation. MRI is noninvasive, does not use ionizing radiation, has a larger field of view, has improved soft tissue contrast, and has multiplanar capability. Dynamic MR imaging has been used to assess the complex pelvic anatomy and changes in these structures during attempts at evacuation. Older methods had long acquisition times (6–12 s) which did not allow for real-time evaluation. Newer techniques have near real-time continuous imaging and can be performed in less than 2 min [22, 23]. Dynamic radiologic examinations of the endopelvis may reveal multicompartmental dysfunction [24]. Segregation of the pelvic floor into posterior, middle, and anterior compartments, however, is artificial because these structures are closely interrelated [25]. Pelvic organ prolapse can be detected and characterized using dynamic MR imaging but cinedefecography is more sensitive in detecting parietal alterations [26].

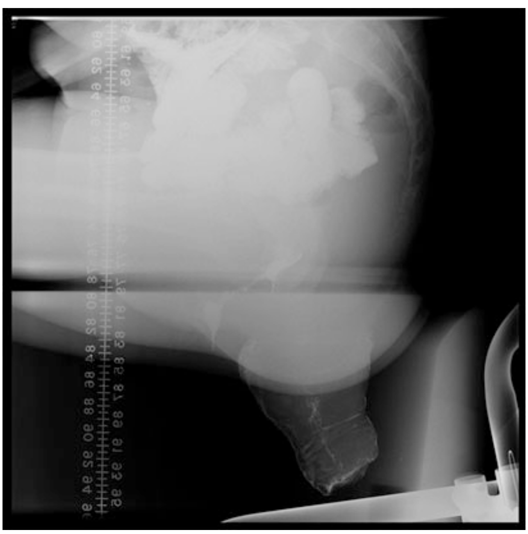

Fig. 1 Defecography showing full-thickness prolapse (Image provided by Manwaring ML)

Anal manometry has limited value in the workup of constipation in the elderly. In select cases, anal manometry, rectal anal inhibitory reflex, minimal sensory rectal volume, and balloon expulsion may identify patients with megarectum and patients with nonrelaxing puborectalis muscle. These tests require specialized manometric instruments and can be done utilizing a capillary perfusion system or microballoon system. These systems measure the pressures within the anal canal and test the function of the anal sphincter mechanism. Anal sensation is tested by inserting a rectal balloon just above the anal sphincter and insufflating increasing amounts of air until the patient notes sensation. Patients with megarectums require large amounts of distension before any sensation is noted. The rectoanal inhibitory reflex is absent in patients with megarectum who require large volumes to induce the inhibitory reflex. A rectal examination performed on an "unprepped" patient with megarectum may reveal a rectum full of stool. The inability to expel the rectal balloon is tested by asking the patient to evacuate a rectal balloon filled with 60 cc of air in the privacy of the bathroom. If patients have an outlet obstruction and the puborectalis muscle does not relax properly, they have difficulty doing this simple task. The inability to relax the puborectalis muscle and evacuate the contrast on cinedefecography helps confirm the diagnosis.

Treatment of constipation in the younger population is generally medical, and treatment of the elderly constipated patient is no different. A trial of dietary fiber and increased fluid intake should be initially instituted once a malignancy has been ruled out. The daily recommended fiber intake is 20–35 g daily, even in the elderly [27]. By adding approximately 5 g of fiber per week until the goal is met, the excessive gas and bloating that occurs with high-fiber diets can be minimized [28]. A bowel evacuation routine is often helpful for those patients with outlet obstruction. The patient is instructed to take bulk-forming agents daily and to use a glycerin suppository or tap water enema at the same time daily. To maximize the effect of the gastrocolic reflex, patients are encouraged to perform this evacuation routine upon wakening in the morning and approximately 15–20 min after drinking a warm beverage. Biofeedback has had some success in the treatment of pelvic floor outlet obstruction but requires a motivated patient [29, 30]. Surgical intervention is rarely indicated for older patients with constipation. A total colectomy with ileorectal anastomosis has been successful in the treatment of severe colonic inertia without small bowel dysmotility if there is no element of outlet obstruction. However, this operation should be reserved for the younger, medically stable patient. Other patients with colonic inertia are probably best treated by accepting the need for continuous laxative use.

Treatment of patients with rectal intussusception is primarily medical. Surgery should be limited to patients who are incapacitated because of the pressure or who have a persistent solitary rectal ulcer after intensive medical therapy. Surgery involves low anterior resection or retrorectal sacral fixation of the mobile rectum. Many patients have persistent postoperative symptoms of constipation and difficulty emptying. Patients with symptoms of nonrelaxing puborectalis or colonic inertia must have these symptoms addressed and treated preoperatively to have a successful surgical result [31]. Patients with pelvic organ prolapse, enterocele, and cystocele combined with intussusception (Fig. 1) may benefit from a combined procedure. Women with severe symptomatic rectal intussusception and pelvic organ prolapse may benefit from a multidisciplinary approach including urology and gynecology. The decision for surgical intervention for pelvic organ prolapse should not be determined by age alone [32] (Fig. 2).

Rectal Prolapse

The most severe abnormality of the pelvic floor is rectal prolapse. Rectal prolapse can be partial thickness (mucosal) or full thickness (complete extrusion of the rectum through the anal canal) (Fig. 3). Patients with these conditions often complain of rectal pressure, mucous discharge, and rectal bleeding. Most patients also report fecal incontinence, while a lesser number have chronic constipation [33]. The prevalence of this condition increases with age and is associated with female gender and neurologic or psychiatric comorbidities [34, 35]. Given that other significant medical comorbidities also increase in incidence with age, patients with rectal prolapse often have other medical problems [36, 37]. Once the

Fig. 3 Full-thickness rectal prolapse

prolapse begins to occur, patients complain more of the incontinence and rectal bleeding than of constipation [38]. Often patients attribute their anorectal findings to prolapsing hemorrhoids, but direct questioning often confirms that the patient's rectum protrudes with bowel movements (especially with straining) and occasionally when assuming an upright position. Manual reduction of the prolapsed tissue by the patient or their caretakers is common. The symptoms of prolapse can be quite debilitating and at times render a frail patient to remain in bed to avoid prolapse.

Examination typically reveals a lax anal sphincter and prolapsing rectum. Circumferentially oriented folds are seen on the mucosal surface of full-thickness rectal prolapse, whereas radial grooves are common in prolapsing hemorrhoids and may be seen in mucosal prolapse. Incarceration or strangulation of the prolapsed rectum is uncommon but can occur if there is preserved anal sphincter tone or if the prolapsed segment has become extremely edematous. Proctosigmoidoscopy classically demonstrates an erythematous, edematous circumferential region (the "leading edge") approximately 5–8 cm from the dentate line. Asking patients to strain to evacuation their rectum may allow visualization of the prolapse by the examiner. Reproduction of the prolapse sometimes necessitates a patient sitting on a commode and recreating the force used to defecate and is often unsuccessful in lateral or prone positions. If the prolapse cannot be demonstrated in the office setting, defecography or dynamic MRI may be done to demonstrate the redundant internal prolapsing rectum.

A complete evaluation is best performed with colonoscopy to rule out a tumor as a lead point of the rectal prolapse. A solitary rectal ulcer, discussed in the previous section, is seen at the leading edge of the prolapsing rectum in 10–15% of cases [39]. Biopsy of the ulcer should be done to provide a definitive diagnosis. Although not always necessary, rectal prolapse may be demonstrated on defecography as well (Fig. 1). These ancillary studies have the advantage of demonstrating associated pathology such as cystocele, enterocele, and/or vaginal prolapse. The anal sphincter may be assessed using anal manometry and electromyography although the results typically show extremely low rest and squeeze effort. However, with a clearly established diagnosis of rectal prolapse, these studies rarely change the treatment approach [39]. Unilateral and bilateral neurogenic injury may result from chronic stretching of the pudendal nerve. Stretch injury may also be a direct result of repeated trauma to the anal sphincter by the prolapsing rectum. Preoperative motility studies with colonic transit times should be done in patients with complaints of severe constipation to identify a group of patients with colonic inertia and prolapse who may require more extensive resection [40].

Although more than 100 operations have been cited as forms of treatment for rectal prolapse, the two general approaches are transabdominal or perineal. Abdominal rectopexy with or without sigmoid resection is the procedure of choice in patients who have an acceptable surgical risk [39, 41] and can usually be completed using a minimally invasive approach. The American Society of Colon and Rectal Surgeons has developed practice parameters for the management of rectal prolapse as summarized in Table 3 [39]. The rectum can be anchored to the sacrum in two ways – with direct suture or prosthetic mesh placement. Complete encirclement of the rectum with a band of mesh (Ripstein procedure) has been largely abandoned due to problems with stenosis and obstruction at the level of the mesh and mesh erosion. This has been modified to leave the anterior bowel

Table 3 Practice parameters for the management of rectal prolapse (Adapted from: Varma et al. [39] (Table 3: summary of ASCRS practice parameters for treatment of rectal prolapse)

Recommendation	Evidence
The initial evaluation of a patient with rectal prolapse should include a complete history and physical examination	+++
Additional tests such as defecography, colonoscopy, barium enema, and urodynamics can be used selectively to define the diagnosis and identify other important pathology	++++
Physiologic testing may be useful to assess functional disorders associated with rectal prolapse, such as constipation or fecal incontinence	+
Although many patients who present with rectal prolapse are older and have multiple comorbidities, there is little nonoperative treatment available for symptomatic rectal prolapse	+
In patients with acceptable risk, procedures incorporating transabdominal rectal fixation are typically the treatment of choice for the treatment of rectal prolapse	+++
Rectopexy is a key component in the abdominal approach to rectal prolapse	+++
Sigmoid resection may be added to rectopexy in patients with prolapse and preoperative constipation, but it is not necessary in those without constipation	++++
Division of the lateral stalks during rectal dissection may worsen symptoms of constipation postoperatively, but it is associated with decreased recurrence rates	++
The Ripstein procedure with fixation of mesh from the anterior rectal wall to the sacral promontory after posterior mobilization may be used for treatment of rectal prolapse, but it is associated with higher morbidity	+++
A modified Wells procedure using a variety of foreign materials for posterior fixation of the rectum may be used for treatment of rectal prolapse	++
The ventral mesh rectopexy reduces constipation by avoiding posterolateral mobilization of the rectum and produces results similar to other abdominal approaches	++
The use of anterior resection alone to treat rectal prolapse is associated with high recurrence rates and significant operative and postoperative morbidity; it should not be considered as a first-line treatment	++++
A minimally invasive approach to rectal prolapse by experienced surgeons compares favorably with an open repair	++++
Patients with a short, full-thickness rectal prolapse can be treated with mucosal sleeve resection; but for longer prolapse, it is associated with a higher recurrence rate compared with abdominal approaches	+++
Patients with a full-thickness rectal prolapse who are not candidates for an abdominal operation may be treated with a perineal rectosigmoidectomy but are susceptible to higher recurrence rates in comparison with abdominal approaches	+++

++ Weak recommendation based on moderate-quality evidence
+++ Strong recommendation based on low-quality evidence
++++ Strong recommendation based on moderate-quality evidence

wall free [42, 43], a posterior mesh rectopexy in the manner of Wells [44], which can be done laparoscopically having a low recurrence rate but does impart a risk of constipation. Mesorectum is largely interposed between the rectum and mesh, minimizing mesh contact with the bowel wall itself and leaving the anterior rectum free to expand avoiding obstruction problems.

Low anterior resection may improve the bowel habits of patients who complain of preoperative constipation in whom a markedly redundant distal colon is found [40, 45] but without rectopexy is associated with recurrent prolapse; therefore, suture rectopexy should be performed at the same operation [39] if a resection is being performed. Resection rectopexy is the best treatment for patients with preexisting constipation as it may improve the constipation symptoms and nonresection procedures typically worsen constipation (Fig. 4). Placement of prosthetic mesh is avoided in conjunction with resection because of the risk and morbidities of mesh infection. Anterior mesh rectopexy is the newest approach and is likely associated with less postoperative constipation. There are limited long-term data, and mesh in the rectovaginal septum can be problematic.

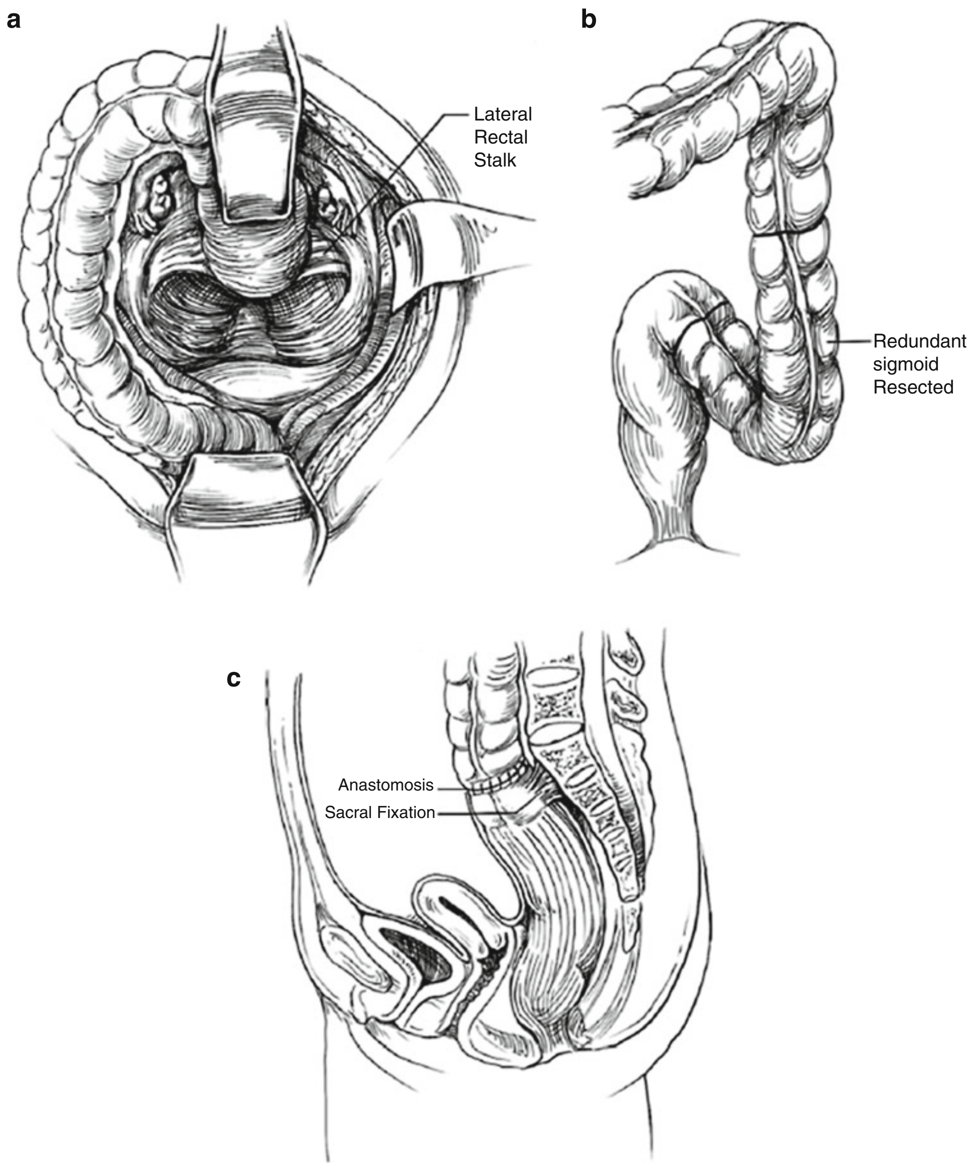

Fig. 4 Resection rectopexy [2]

Whether or not this procedure can be used in full-thickness external prolapse has not yet been determined.

Laparoscopic and robotic approaches have been developed for all the transabdominal procedures for rectal prolapse [39]. The functional and recurrence rates are similar to analogous procedures done open [46–52]. The benefits of minimally invasive approaches are reduced hospital stay, lower narcotic pain requirements, earlier return of bowel function, and reduced wound complications [33, 39, 41], and they have become the standard approach in many practices. Robotic approaches add cost and operative time but allow for enhanced visualization and facilitate suturing deep in the pelvis [53].

Perineal operations are generally reserved for patients who require a regional anesthetic approach or have unfavorable abdominal conditions that increase the risk of an abdominal approach. Postoperative complication rates may be slightly higher for abdominal procedures; long-term results are more favorable (recurrence rate and functional outcome). Laparoscopic recurrence rates increase over time with both the perineal and abdominal approaches [35, 54]. Thiersch wire or other synthetic material is used to encircle the anal canal to prevent rectal prolapse. The encircling material prevents the rectum from prolapsing through the anal canal. The anal encirclement procedures do not treat the underlying condition, and the symptoms of rectal intussusception persist in most patients. It is not uncommon for patients to require laxatives and enemas for fecal evacuation after anal encirclement, as the synthetic material acts as an obstruction to defecation. Because wire erosion, breakage, infection, and fecal impaction complications are common, anal encirclement as a primary treatment for rectal prolapse is generally reserved for moribund patients with limited life expectancy. This procedure is mostly of historic interest and is now rarely performed given the minimal morbidity of both laparoscopic rectopexy and perineal proctosigmoidectomy. However, this procedure with a biological material as an adjunct to perineal proctosigmoidectomy has recently been reported [55].

A mucosal sleeve resection, also called Delorme procedure, can also be used in short, full-thickness rectal prolapse [39] and for mucosal prolapse. This procedure is not a full-thickness rectal resection, but rather the redundant rectal mucosa is stripped circumferentially. The remaining, redundant outer rectal wall is then plicated with a series of circumferential sutures which then allows the mucosal edges to be reapproximated. Although there are concerns for recurrence [56] based on the, limitations of mucosectomy with imbrication of the rectal wall alone, a recent study found that the Delorme procedure could be done with minimal morbidity, a short hospital stay, and a recurrence rate of only 14.5% at a mean of 31 months. The authors found that the recurrence rate was relatively low in patients under 50 (8%) and felt that this procedure may be reasonably be offered to younger patients [38].

Perineal proctosigmoidectomy, first described in 1889 by Mikulicz [57], has been modified and popularized by others [36, 58] (Fig. 5). It can be performed under regional anesthesia in either prone jackknife or lithotomy position. The redundant rectum and portion of sigmoid colon can be easily removed via the anal incision. Resection and anastomosis can be performed with sutures or surgical staplers. Addition of a posterior levator repair described by Prasad et al. re-creates the anatomic anorectal angle and may help patients gain fecal control postoperatively [58]. Minimal pain and little physiologic alteration are associated with this procedure, and most patients can be discharged from the hospital within 24–48 h. The recurrence rate of a perineal proctosigmoidectomy is related to the length of follow-up and ranges from 0% to 22% [36, 37, 39, 58–61].

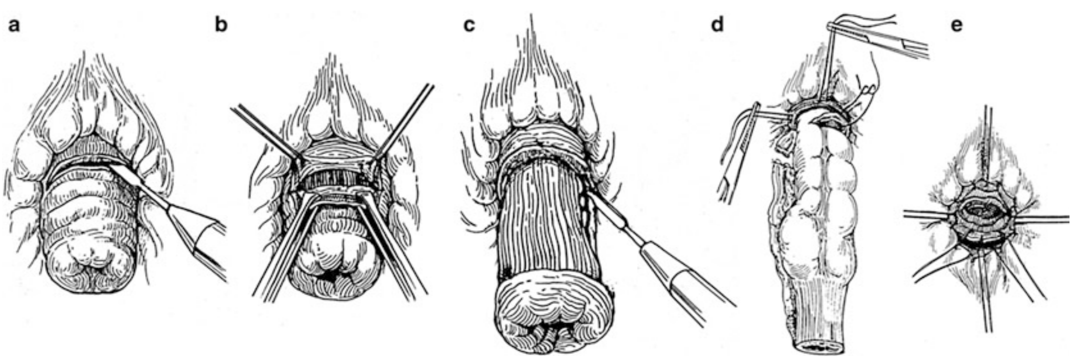

Fig. 5 Perineal proctosigmoidectomy (The ASCRS textbook of colon and rectal surgery, publisher Springer 2007, Chap. 47, Fig. 47.3)

Colonic Pseudo-obstruction

Colonic pseudo-obstruction (CPO) is relatively rare with an annual incidence estimated at 100 cases per 100,000 inpatient hospitalizations per year. It occurs in patients with a mean age of about 65 years but is rare in young patients [62]. It generally follows an inciting event of trauma, surgery, or other medical illness and results in colonic distention without mechanical obstruction [62]. Altered parasympathetic activity, dysregulation of stretch receptors, and compromised smooth muscle activity in the colonic wall have been implicated as causative factors [63–65] resulting in progressive dilation of the colonic wall. When the cecum reaches 10–12 cm in diameter, risk of ischemia and perforation increases, and decompressive treatment is generally recommended [66]. Without decompression, progression to necrosis and perforation may occur with tension increasing proportionally to the radius according to the law of Laplace. Medical therapy initially is directed at eliminating physiologic stress from the inciting event while maintaining decompression. Acetylcholinesterase inhibitors such as neostigmine can be used as treatment of the distention, but this is less effective than endoscopic therapy [67]. Although colectomy with ileostomy should be performed promptly when there is colonic necrosis, surgically treated patients have significantly more morbidity and mortality than medically managed cohorts. This is likely related to the fact that CPO often occurs in comorbid elderly patients who tolerate operative intervention poorly.

Stercoral Ulceration and Perforation

Stercoral perforation is caused by pressure necrosis from fecal mass effect on the wall of the colon and primarily affects the left colon and rectum. Though constipation is present as a chronic condition in a majority of patients suffering from the condition, it is a relatively uncommon but serious complication. Stercoral perforation accounts for just 3% of colonic perforations. The median age of patients suffering from this condition has been reported to be 62 years of age [68]. Diagnostic features include an antimesenteric round or ovoid defect in the colon more than 1 cm in size associated with fecalomas present protruding through the bowel wall. Microscopic findings include chronic inflammation and pressure necrosis or ulceration [68]. Use of NSAIDs, narcotics, sedative medications, and other medications such as aluminum hydroxide containing antacids has been reported in patients suffering these conditions [69]. Treatment should be preventative with osmotic laxatives to avoid fecal impaction, but when presenting with perforation, patients are treated with resection and diverting colostomy.

Clostridium difficile Infection

Clostridium difficile infection (CDI) is caused by a gram-negative, spore-forming bacteria that are frequently a normal intestinal luminal inhabitant. Alterations in gut microflora, typically through antibiotic use, can lead to clostridium overgrowth [70–72]. The production of two exotoxins (A and B) leads to the clinical illness associated with CDI. *Clostridium difficile* infection is an increasing source of community and healthcare-associated infection. It is estimated that there were 450,000 *Clostridium difficile* infections and 29,000 resultant deaths in 2011 alone [73], an incidence more than double that in 2000 [72, 74, 75]. Community-associated infections account for one-third of cases; healthcare-associated infections are evenly divided among community onset, nursing home onset, and hospital onset infections [74]. The mortality associated with CDI is 2.5–5 times greater than expected [72, 76]. Risk factors for CDI include advanced age, antibiotic use, hospitalization, or residence in a skilled nursing facility [70, 72, 75, 77]. CDI results in a significant healthcare and economic burden. The cost associated with this infection is estimated to range from $8900 to $30,000 for hospitalized patients [78]. This is an annual economic burden of $1.5–$3 billion per year [75, 79].

The diagnosis and treatment of CDI are outlined in a set of practice parameters published by the American Society of Colon and Rectal Surgeons [71] (Table 4). Diagnosis is based on

Table 4 Practice parameters for the management of *Clostridium difficile* infection (Adapted from Steele et al. [71]). (Table 4: summary of ASCRS practice parameters for management of *C. difficile* infection)

Recommendation	Evidence
In a patient in whom CDI is suspected, a disease-specific history should be performed, emphasizing symptoms, risk factors, underlying comorbidities, and signs of advanced disease	+++
Patients should be thoroughly evaluated to determine the severity of CDI, such as the presence of peritonitis and/or multisystem organ failure	+++
Endoscopic and radiologic evaluation may be performed to help determine the diagnosis and extent of disease	++
Diagnosis of CDI typically includes laboratory testing	+++++
Infection control measures should be implemented for hospitalized patients with *C. difficile* colitis	+++
Once CDI is diagnosed, the associated antibiotics should be stopped as soon as possible, as clinically indicated	+++
Metronidazole and vancomycin are acceptable first-line agents for an initial bout of CDI, with selection normally based on severity	++++
Surgery for *C. difficile* colitis should typically be reserved for patients with severe colitis that fails to improve with medical therapy, for generalized peritonitis, or for rare cases of colonic perforation	+++
Subtotal colectomy with ileostomy is typically the operative procedure of choice for *C. difficile* colitis	+++
Diverting loop ileostomy with colonic lavage may be an alternative to total abdominal colectomy for treatment of severe *C. difficile* colitis	+

+ Weak recommendation based on low-quality evidence
++ Weak recommendation based on moderate-quality evidence
+++ Strong recommendation based on low-quality evidence

+++++ Strong recommendation based on high-quality evidence
CDI Clostridium difficile infection

testing to document CDI in symptomatic patients. The gold standard is toxigenic culture of *C. difficile* organism followed by cell cytotoxicity assay [79, 80]. Unfortunately, this is time-consuming and difficult to perform. Nuclear acid amplification testing for *C. difficile* toxin genes using polymerase chain reaction or loop-mediated isothermal amplification now provides accurate, rapid diagnosis in symptomatic patients [70, 71, 79, 80]. However, the sensitivity of these assays can result in false positives in asymptomatic patients. Once the diagnosis is established, infection control measures should be implemented and inciting antibiotics discontinued. Treatment with oral metronidazole or oral vancomycin should be instituted. A 10–14-day treatment course will cure CDI in greater than 90% of patients with mild to moderate CDI [70–72, 77, 79]. Vancomycin is more effective in the treatment of severe disease with cure rates of 90% or greater [70–72, 77, 79]. Vancomycin can also be administered as an enema in patients unable to tolerate oral intake or as an adjunct.

Fulminant CDI does not have a clear definition, and only a small proportion of patients with CDI require operation [71]. In the absence of perforation, other indications for colectomy may include underlying inflammatory bowel disease, need for vasoactive agents, ongoing sepsis, and multisystem organ failure. Although there has been interest in lesser procedures, the procedure of choice remains total abdominal colectomy with ileostomy [71, 81, 82]. A large meta-analysis of 31 series documented a 30-day mortality rate of 40% following emergency colectomy [82]. This has prompted a reexamination of the traditional surgical approach. There has been interest in diverting loop ileostomy with distal lavage as an alternative to total abdominal colectomy [71, 83]. However, results of this initial trial have not been replicated. Recurrent CDI refractory to antibiotic therapy is effectively treated with fecal transplant.

In summary, CDI in elderly should be promptly treated with medical therapy outlined above. Of particular importance for frail patients, the decision to perform a colectomy and ileostomy is ideally made early, before sequelae of fulminant sepsis and multisystem organ failure have occurred. Limited reserve in this subgroup of patients makes them especially prone to morbidity and mortality.

Volvulus

Colonic volvulus occurs when an air-filled segment of colon twists about its mesentery. In the United States, colonic volvulus is an unusual cause of intestinal obstruction and accounts for approximately <5% of colonic obstructions [84]. In contrast, the rate of colonic volvulus as a source of large bowel obstruction is reported to be as high as 50% in Africa, the Middle East, and South America [85]. The high incidence of sigmoid volvulus has been attributed to the high-fiber diets in those regions. Chagas' disease, which causes megacolon, may play a role in the development of sigmoid volvulus, particularly in countries where the disease is common [86]. In North America, the incidence increases over the age of 50 years. Sigmoid volvulus and cecal volvulus account for the vast majority of cases of large bowel volvulus [84, 87, 88] [84]. Sigmoid volvulus (Fig. 6) is more common in elderly males, African Americans, nursing home residents, and patients with chronic constipation, diabetes, and neuropsychiatric disorders [84, 87, 88]. Patients with cecal volvulus tend to be younger and have a female predominance [84, 89]. The American Society of Colon and Rectal Surgeons has developed clinical practice guidelines that are summarized in Table 5 [89].

Fig. 6 Abdominal X-ray film of sigmoid volvulus, ASCRS Textbook of Colon and Rectal Surgery, 2011 [2]

Patients with volvulus usually present with abdominal distention, obstipation, and pain. Peritoneal irritation on physical examination, fever, or an elevated white blood cell count indicates ischemic or gangrenous bowel. Plain abdominal radiographs may show an inverted, U-shaped, air-filled bowel loop ("bent inner tube"), with a dense line running toward the point of torsion (Fig. 7a). This radiologic finding is highly suggestive of sigmoid volvulus. Conventional radiographs are less accurate in the diagnosis of cecal volvulus [88–90]. Although water-soluble contrast studies can assist with establishing the diagnosis (Fig. 7b), contrast-enhanced computed tomography is the diagnostic study of choice when plain radiographs do not establish the diagnosis [89]. When used in conjunction with plain radiographs, computed tomography is accurate in >90% cases in establishing the diagnosis of cecal and sigmoid volvulus [90, 91].

In patients with suspected sigmoid volvulus, if peritonitis is not present, sigmoidoscopy (flexible or rigid) should be performed to the point of obstruction. The volvulus can often be reduced by traversing the point of obstruction with the endoscope. A release of gas and liquid follows successful detorsion. A soft tube should be left in place traversing the area for several days to allow for decompression prior to definitive management. The success rate with this technique is good, and reduction of the volvulus can be expected with approximately 75% of attempts [89]. Endoscopy also allows for examination of the mucosa to inspect for ischemic changes. Evidence of mucosal ischemia, bloody discharge, or unsuccessful detorsion indicates strangulation and possibly gangrene. If the patient has signs of peritonitis or if gangrene is suspected, contrast study and tube decompression should not be attempted, and the patient should undergo emergency exploration. When cecal volvulus is suspected, attempts at endoscopic reduction are not recommended; these patients should undergo abdominal exploration and surgical treatment [88, 89].

Following endoscopic reduction, sigmoid colectomy is indicated to prevent recurrence.

Table 5 Summary of clinical practice guidelines for management of colonic volvulus (Adapted from Vogel et al. [89]). (Table 5: summary of ASCRS practice parameters for management of colonic volvulus)

Recommendation	Evidence
Initial evaluation should include a focused history and physical examination, complete blood cell count, serum electrolytes, and renal function assessment	+++
Diagnostic imaging is initial plain abdominal radiographs and often includes confirmatory imaging with contrast enema or CT imaging	+++
Rigid or flexible endoscopy should be performed to assess sigmoid colon viability and to allow initial detorsion and decompression of the colon	+++
Urgent sigmoid resection is generally indicated when endoscopic detorsion of the sigmoid colon is not possible and in cases of nonviable or perforated colon	+++
Sigmoid colectomy should be considered after resolution of the acute phase of sigmoid volvulus to prevent recurrent volvulus	+++
Nonresectional operative procedures, including detorsion alone, sigmoidoplasty, and mesosigmoidoplasty, are inferior to sigmoid colectomy for the prevention of recurrent volvulus	+
Endoscopic fixation of the sigmoid colon may be considered in select patients in whom operative interventions present a prohibitive risk	+
Attempts at endoscopic reduction of cecal volvulus are generally not recommended	+++
In patients with cecal volvulus, resection is required in patients with nonviable or perforated bowel. Resection is also appropriate first-line intervention for patients with viable bowel who are good operative candidates	+++
For cecal volvulus with viable bowel, nonresectional operative procedures may be a suitable alternative to resection	+

+ Weak recommendation based on low-quality evidence

+++ Strong recommendation based on low- or very low-quality evidence
++++ Strong recommendation based on moderate-quality evidence
+++++ Strong recommendation based on high-quality evidence

Recurrence rates after endoscopic reduction have been reported to be as high as 50–60% [88, 92]. Once the volvulus is reduced, medically stable patients should undergo bowel preparation and elective resection. The choice of operation depends on the ability to detorse the sigmoid volvulus preoperatively, the adequacy of the bowel preparation, and the viability of the colon. Emergent of urgent operation due to presence of peritonitis, the inability to endoscopically reduce the sigmoid volvulus, or the presence of ischemia or gangrenous bowel is an indication for resection and colostomy (Hartmann procedure). In cases of cecal volvulus, resection has the lowest risk of recurrence. Unfortunately, there are little data on whether resection with ileostomy is superior to resection with anastomosis in the presence of nonviable bowel [89]. Nonresectional surgical therapy has been described for treatment of sigmoid and cecal volvulus. In general, results are inferior to resectional therapy with little improvement in postoperative death and complication rates [89]. Endoscopic fixation (percutaneous endoscopic colostomy (PEC)) is an option for treating patients with sigmoid volvulus who have prohibitive operative risks [89, 93].

Operative mortality rates for sigmoid volvulus depend upon the urgency of the operation, the presence of gangrene and peritonitis, and presence of comorbidities [84, 94]. For elective resection, death and complication rates of zero and 12%, respectively, have been reported [94]. In contrast, emergency operation was associated with a complication rate of 35% and death rate of 16%. Elderly patients receive particular benefit from minimally invasive approaches to colorectal diseases [95].

Fecal Incontinence

Fecal incontinence is a disabling problem in the elderly and in institutionalized patients [96]. A community-based prevalence study estimated that fecal incontinence affects 2.2% of the general population although the incidence and prevalence are probably underestimated [97]. More than 60% of patients who complain of fecal incontinence are

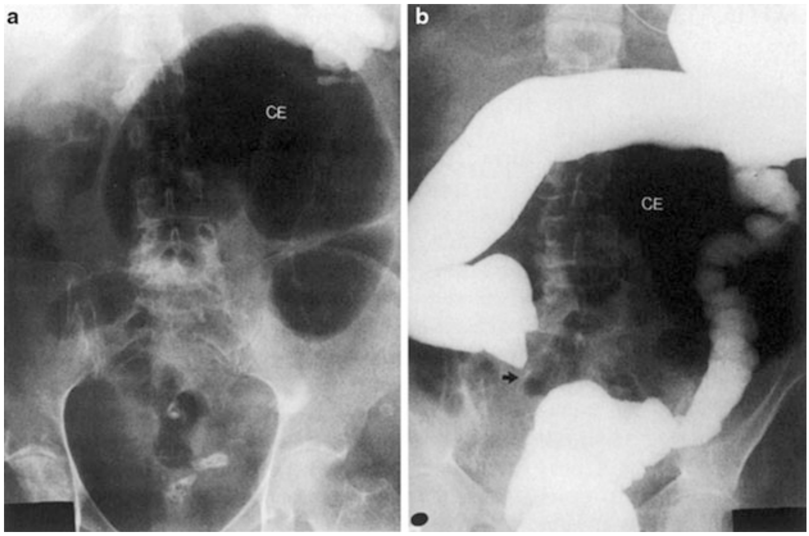

Fig. 7 (**a**) Cecal volvulus, plain radiograph, *CE* cecum. (**b**) Barium enema. *Arrow* indicates the point of obstruction, *CE* cecum [1]

women [97]. In community-based women older than 60, it is estimated that the prevalence varies from 12% to 33% depending on the definition used [98].

Incontinence may be neurogenic, mechanical, mixed, or secondary to other medical conditions. Anal sphincter injuries are the leading cause of mechanical incontinence and are most commonly the result of a midline episiotomy. Fecal incontinence may not occur immediately after the injury, but rather the presentation may be delayed for years. The majority of women with late-onset fecal incontinence have an anatomic sphincter defect [99]. Neurogenic incontinence may be due to central or peripheral denervation of the puborectalis muscle or external anal sphincter. Rectal prolapse or descending perineum syndrome may denervate the sphincter by a stretch injury to the pudendal nerve. Injury to the sphincter mechanism, traumatic or surgical, may lead to fecal incontinence immediately after the injury or during the ensuing years. Decreased anorectal sensation caused by radiotherapy or diabetes mellitus may lead to incontinence as well. Certain physiologic factors have been shown to occur with aging: decreased rectal tone and weakening of the anal sphincter mechanism [100, 101]. The anal sphincter may decrease in strength secondary to loss of muscle mass or neuropathy. These differences are more pronounced in elderly women. It may be due to weakening of connective tissues, possibly from decreased estrogen secretion. Physical limitations and poor general health are other predisposing factors that contribute to fecal incontinence [96, 97]. A common cause of fecal incontinence in the elderly, however, is fecal impaction with overflow incontinence [97]. Systemic diseases such as scleroderma, polymyositis, multiple sclerosis, and diabetes mellitus can be associated with fecal incontinence. Colorectal carcinoma, colonic ischemia, and inflammatory bowel disease may cause symptoms of fecal urgency, and incontinence may be a result of the patient's inability to respond quickly.

On initial evaluation, constipation with overflow incontinence must be ruled out by history and digital rectal examination. A complete colonic evaluation with colonoscopy or contrast enema should be done especially if the symptoms of fecal incontinence have a short history. The anal physiology laboratory can objectively evaluate the anal sphincter mechanism to determine the cause of fecal incontinence and direct treatment. Anal manometry, electromyography, and transrectal ultrasonography can help differentiate neurogenic from mechanical injury to the anal sphincter. Anal manometry assesses the rest and squeeze pressures generated by the anal sphincter. The sphincter length can be determined, and some systems can identify the specific quadrant involved in a sphincter defect. The minimal sensory rectal volume is useful for identifying patients with a very large rectum who do not sense the presence of a large bolus of fecal material in their rectum. Electromyography is used to evaluate the pudendal nerve terminal motor latency. The pudendal nerve innervates the external anal sphincter and the puborectalis muscle. Both muscles are involved in maintaining fecal continence; and denervation of these muscles, represented by prolonged pudendal nerve terminal motor latency, may cause neurogenic incontinence. Transrectal endoluminal ultrasonography has replaced needle electromyography as the preferred method for evaluating the anal sphincter for defects. Using this modality, the puborectalis muscle and the external and internal anal sphincters can be thoroughly evaluated for defects.

Initial treatment may be as simple as dietary alteration (avoidance of milk products and food with high fat content) and a bowel evacuation regimen (bulk-forming agents and glycerin suppositories) [101]. Biofeedback has had some success in patients but requires the understanding and cooperation of the patient [102]. Combined pharmacologic and physical therapy may be more beneficial when combined in appropriate patients [103]. Sacral nerve stimulation (SNS) which was FDA approved for use in the treatment of fecal incontinence in the United States in 2011 has become the most prevalent treatment strategy for fecal incontinence. Implanted electrodes are placed percutaneously adjacent to the S3 nerve root and a generator implanted after a test phase. Pooled data suggests that over three-fourths of patients have at least a 50% improvement in their fecal incontinence symptoms [104]. Application is not precluded by age alone, and though some studies show elderly patients derive a lower success from SNS [105], it is currently the best surgical option available. Anterior sphincter reconstructions with direct muscle repair have had success in the elderly population [106]. Older women undergoing pelvic floor surgery can expect similar results and outcomes as younger patients [32]. A diverting colostomy is rarely necessary for control of the fecal stream in the elderly population. If the rectum is severely damaged by radiation injury, a diverting colostomy is probably the best treatment option for severely incontinent patients.

Conclusion

Benign colorectal conditions are frequently encountered in elderly patients and are usually treatable. A good history and physical examination including office proctoscopy or anoscopy can usually point the clinician to the appropriate needed tests. Directed workup can confirm the diagnosis, and thoughtful intervention usually leads to marked symptom improvement. Though not all conditions can be corrected surgically, an accurate diagnosis with associated counseling directed at minimizing the impact on patient quality of life can ameliorate patient concern and suffering.

Abstract

This chapter deals with diverticular disease and appendicitis in the elderly. Diverticular disease increases in incidence with age and also appears to present with diffuse peritonitis more frequently in the older population. Appendicitis in the elderly accounts for 5–10% of all appendicitis. There is good evidence that the elderly present more frequently in an atypical fashion with both of these diseases compared with their younger counterparts. Furthermore, emergency operations in the elderly are associated with higher mortality and morbidity rates. Appendicitis and diverticulitis have much in common and may share etiologies. High fiber diet and poor hygiene have protective effects on both diseases. Historically, both have been described as starting with local inflammation, having the potential to progress, untreated, to perforating disease. Most nonperforating diverticulitis and appendicitis do not evolve to perforating disease. The incidence of uncomplicated presentation in both diseases is increasing while perforating disease rates remain steady. Uncomplicated appendicitis can be treated nonoperatively with similar success rates as uncomplicated diverticulitis, with similar recurrence rates after nonoperative treatment as well. The major difference is that operative treatment of appendicitis carries significantly lower complication and mortality rates, thus leading surgeons to suggest operation more easily with appendix disease. This chapter attempts to explain these findings.

Diverticulitis · Appendicitis · Nonoperative management · Abscess

Introduction

This chapter deals with diverticular disease and appendicitis in the elderly. Diverticular disease increases in incidence with age and also appears to present with diffuse peritonitis more frequently in old than in young patients. Acute appendicitis in the elderly accounts for 5–10% of all appendicitis, and old patients tend to present more frequently with advanced disease than do young groups. There is good evidence that the elderly present more frequently in an atypical fashion with both of these diseases compared with their younger counterparts. Abdominal pain may be absent or not greatly perceived in older patients. Physiologic responses to stress and infection are also blunted in the elderly. Older patients are burdened with more comorbid conditions and less mental and physical reserves compared with their younger counterparts. Furthermore, it is well known that emergency operations in the elderly are associated with significantly higher mortality and morbidity rates than similar operations on younger patients. Thus, old patients present atypically often with more advanced disease and have higher complication and death rates than the young. Interestingly, appendicitis and diverticulitis have much in common and may share etiologies. A low fiber diet has been implicated with both diseases. Poor hygiene seems to have a protective effect on both diseases. Elevated pressures have been implicated in both diseases, but without definitive studies showing cause. Historically, both have been described as starting with local inflammation, having the potential to progress, untreated, to perforating disease. Over time, many studies have concluded that most nonperforating diverticulitis as well as appendicitis will not evolve to perforating disease. The incidence of uncomplicated presentation in both diseases is increasing (presumably due to increased diagnosis of minimal to moderate disease by CT) while perforating disease rates remain steady. This fact suggests that prior to CT, a significant number of patients with both diseases resolved without medical help or were misdiagnosed and not treated with hospitalization. There is mounting evidence that uncomplicated appendicitis can be treated nonoperatively with similar success rates as uncomplicated diverticulitis. In fact, recurrence rates after nonoperative treatment are similar in both diseases as well. The major difference is that operative treatment of appendicitis carries significantly lower complication and mortality rates, thus leading surgeons to suggest operation more easily with appendix disease. This chapter attempts to explain these findings.

Diverticular Disease

Case Study

MS is a 90-year-old woman with no significant comorbidities who lives by herself at home. She was hospitalized five times over 4 months with unrelenting ischemic colitis of the descending colon diagnosed by multiple CT scans and with endoscopic confirmation. Despite antibiotics and enteral supplementation, she had slow and progressive weight loss and increasing inability to eat. Indication for operation was failure to progress with medical therapy and inability to eat. Her albumin was 2.0 and her prealbumin was 9 and her initial weight was 92 pounds. She underwent a left colectomy with primary anastomosis and protective loop ileostomy. Operative finding, confirmed by pathologic examination, was retroperotineal perforated diverticulitis with contained abscess. Her postoperative course was complicated by ileostomy dysfunction resulting in watery diarrhea which caused dehydration and electrolyte imbalance. She developed a lower extremity deep venous thrombosis and was started on Warfarin after a vena cava filter was placed. After a single 5 mg dose of Warfarin, her INR rose to 10 and she had a spontaneous intra-abdominal bleed requiring transfusion. She was unable to eat due to newly diagnosed, severe esophagitis. This was treated medically and a PEG was placed for enteral nutrition. She was ultimately discharged to an extended care facility 1 month after surgery. She maintained mental acuity throughout her illness and is anxiously awaiting the reversal of her ostomy.

Background

Etiology

Diverticular disease is the fifth most costly digestive disease in the United States [1]. The cause of diverticulosis is unknown. Colonic diverticula are mucosal (and submucosal) herniations through the muscle wall of the colon. The sigmoid colon is affected in 96% of patients, with this area being the only site of diverticulosis in two-thirds of patients [2]. Acute diverticulitis can occur anywhere in the colon and has been reported in the rectum [3, 4]. Diverticula occur at the points of weakness where the blood supply to the mucosa penetrates the bowel wall. Most commonly, they occur between the mesenteric and antimesenteric teniae coli. Less commonly, they occur between the two antimesenteric teniae. Strong epidemiologic evidence suggests that a low fiber diet has a substantial etiologic role in the development of diverticulosis [5–7]. In the United States, the incidence of diverticular disease has increased with decreasing fiber intake [8]. Vegetarians have been found to have a lower incidence of diverticular disease than nonvegetarians [9]. Other studies have confirmed these findings [10–14].

The current speculation is that a diet low in fiber decreases stool bulk. This in turn causes narrowing of the colonic lumen, prolongs intestinal transit time, and increases intraluminal pressures. Painter et al. [15] combined manometry and cineradiography and found that the increased intraluminal pressure may be due to simultaneous contractions of circular muscular bands causing occlusion of short segments of bowel. Contraction rings are thus formed in the sigmoid colon, which produces “segmentation” of these short segments of bowel. Contraction of the muscle wall of these sections can result in intraluminal pressures of 90 mg Hg or more. This pulsion pressure may lead to mucosal herniation along the weak points of the bowel wall, resulting in diverticula. Others have found that the contractile response to eating is exaggerated in people with diverticulosis [16]. Although consistent with the speculation that elevated pressures are particularly significant in combination with or potentiated by low fiber stools, experimentation with colomyotomy showed that decreased muscular activity did not affect intraluminal pressures [17]. Stool bulk may be related to intraluminal pressure only in that stool bulk increases the radius of the colon, thereby decreasing wall tension. Painter et al. suggested that a low fiber diet causes a narrower colonic lumen, which allows the colon to segment more efficiently, increasing the segmental intraluminal pressures [15]. Low fiber diets in rats have been shown to result in diverticulosis in 45% of subjects compared with only 9% in a group fed the highest fiber diet [18]. Further, a large, longitudinal study of males in the United States revealed a relatively straight line correlation between fiber intake and diverticular symptoms [19]. Exercise may also have a protective effect on the development of symptoms from diverticular disease [20].

Colonic dysmotility may contribute to diverticular disease. Abnormally slow wave patterns have been found in patients with symptomatic diverticular disease [21]. Furthermore, patients with symptomatic diverticular disease return to normal motility patterns with ingestion of bran, whereas those with asymptomatic diverticulosis have no change in motility with bran intake [22]. Others have disputed these findings [23]. Colonic transit times can be decreased by adding bran to the diet [24–26], and water-retaining fiber can decrease intraluminal pressure [27]. These findings lead to dietary modifications in attempts to alleviate diverticular symptoms.

One report [28] implicated localized ischemia as a causative factor for antimesenteric free perforation of the colon from diverticulitis. In patients with multiple bilateral pseudodiverticula arranged in a double row about the antimesenteric teniae, the vascular supply to the middle area of the antimesenteric wall is compromised. Careful histologic studies showed that free perforation associated with diverticulitis has the same histologic characteristics as ischemic bowel perforations. It is well known that microvascular changes predisposing to microvascular ischemia occur in the elderly. The more aggressive disease and higher perforation rates found in the elderly [29–32] may be related to this ischemic process. Perhaps this is the reason the elderly have higher free perforation rates when compared with younger patients.

Investigators have also touched on whether an intrinsic change in bowel wall composition is necessary for the development of diverticula. Young people with collagen vascular diseases such as Marfan’s syndrome [33] have been reported with diverticular disease. Several authors have also documented an association of diverticular disease with degenerative disorders such as varicose veins [34], hiatal hernias [35], and arthritis [36]. The most important element with regard to strength of the colon wall is collagen [37]. Collagen fibrils in the left colon become more numerous but smaller in width with age, and this difference is greater with diverticular disease [38]. Similarly, elastin fibrils increase in number but decrease in quality with age [39]. Pace [39] found that colon wall thickness increases with age and is thickest in the distal colon. These factors combined to result in decreased tensile strength and decreased expandability of the aging colon wall [40]. Electron microscopic examination reveals that there is a two times increase in elastin deposition and normal muscle cells in the muscle layer of diverticular diseased colon. The elastin is in a shortened form which may account for the thickened, foreshortened bowel typically found at surgery [41].

The distal sigmoid is the narrowest portion of the colon, and the distal sigmoid narrows with age [42]. The law of Laplace states that wall tension is directly proportional to the pressure times the diameter. Thus, as contractile pressures remain the same and the diameter is decreased, there is an increase in pressure delivered to the bowel wall. A simple example of Laplace's law is inflating a balloon. It is most difficult when there is no air in the balloon and becomes easier as the diameter increases. Similarly, increased pressures are required in the narrower distal sigmoid to propel stool. As the lumen narrows with age, higher pressures are required. This increased stress further damages the colon, causing decreased elasticity and more loss of tensile strength [40]. Comparison studies show that populations with a low incidence of diverticular disease have stronger, more elastic distal colons than industrialized populations [42] presumably due to years of more bulky stools keeping the lumen diameter large. Furthermore, with increasing wall tension pressures, there must be a concomitant decrease in microvascular perfusion [43], possibly adding further weight to the vascular theory of free perforation of diverticulitis [14]. The resulting increased intraluminal pressure causes long-term changes in the bowel wall, including decreased tensile strength, decreased diameter and vascular changes which predispose to diverticular disease and the more frequent perforation seen in the elderly.

Epidemiology

Diverticulosis is an entity particular to the dietary patterns of Western society. There are linear increases in size, number, incidence, and symptoms of diverticula with age [6, 44]. Diverticulae are commonly 5–10 mm in size and can occasionally be greater than 2 cm. Giant diverticula have been described. Diverticulosis occurs in 2–5% of patients less than age 40 and up to one-third of people over age 45. Two-thirds of people over age 85 have radiographic or pathologic evidence of diverticulosis [45]. Deckman and Cheskin [46] cited prevalence in the United States as high as 33% with similar figures in European countries. In comparison, the prevalence in populations with higher per capita fiber intake is much lower. Diverticulosis is uncommon in developing parts of Africa and Asia with rates as low as 1% in Korea [35]. Low incidences have also been found in other, similar populations [47–52].

Independent of age, prevalence is thought to be similar in men and women. However, in a large single institutional series by Rodkey and Welch [53], when sex and age were examined jointly, women over the age of 70 predominated over men by more than 3:1. The reverse was found in patients less than 50 years of age, with more than twice as many men affected as women. This ratio was also substantiated by Ouriel and Schwartz [54], who found a predominance of men in the under-40 age group.

Nonsteroidal anti-inflammatory drugs (NSAIDs) have also been linked to diverticular disease [55], and others have implicated NSAIDs as a potential cause of acute diverticulitis [56–58]. Steroids have been linked to diverticulitis as well. Steroids also mask symptoms of infection which may cause delays in diagnosis with resulting poor prognosis [59–61].

Pathogenesis

Diverticulitis is the inflammatory process that originates within colonic pseudodiverticula. The particular mechanisms of both the local and systemic infections have not been well characterized. It has been hypothesized that diverticulitis constitutes the same endpoint of localized luminal obstruction found with other intra-abdominal visceral inflammatory processes such as appendicitis and cholecystitis [62–64]. Obstruction of the neck of the diverticula, presumably with inspissated stool, creates a closed microenvironment characterized by fluid sequestration, stasis, and bacterial overgrowth. Deitch [65] showed that even in the absence of perforation, obstruction alone is sufficient for bacterial translocation across the intestinal barrier. As the diameter of the diverticulum expands to accommodate the increased intraluminal pressure venous, arterial pressures are overcome. This results in congestion, ischemic necrosis, and perforation. Others cannot find supporting pathologic evidence and suggest that perforation is likely the result of increased intraluminal pressure [46]. Activation of local and systemic inflammatory mediators, in combination with microscopic or macroscopic perforation and soiling of the peritoneum, leads to the clinical manifestations of the disease. The role of localized ischemia was discussed earlier [28].

Atypical, painful, or chronic diverticular disease is a difficult to describe entity. It is described as chronic, intermittent left lower abdominal pain, not usually associated with typical findings of acute inflammation. Motility patterns may be abnormal in this subset of patients [66]. Pain is usually chronic, intermittent, and not associated with acute symptoms. Narrow stools and other changes in bowel habits may result. Attacks may come and go. Symptoms may be confused with irritable bowel syndrome. The diagnosis is difficult, with barium enema showing only diverticulosis and possibly spasm of the sigmoid colon. CAT scan does not reveal acute inflammation and it does not respond to antibiotics or dietary modification. Endoscopic findings are generally nonspecific, although a tortuous colon may be found. Endoscopy may show edema or associated patchy colitis. Treatment is aimed at relieving symptoms. Bulk agents (psyllium seed) and a high fiber diet are usually helpful. Differentiating between irritable bowel syndrome and painful diverticular disease is difficult as symptoms of bloating, distention, and intermittent nonspecific abdominal pain are common. Fortunately, IBS and painful diverticular disease are treated similarly with high fiber diet and symptom control with moderate success. Uncommonly, sigmoid resection is required to produce relief. Appropriate patient selection is paramount in identifying who may respond to operative intervention and those who will not. When well chosen, sigmoid resection will relieve pain in up to 80% of patients [67].

Symptoms

The spectrum of disease produced by diverticula ranges from completely symptom-free to vascular collapse secondary to systemic sepsis from peritonitis. About 10–25% of patients with diverticulosis progress to diverticulitis [68, 69]. Most of these patients never come to surgical attention [68, 69]. A small number, estimated at fewer than 25% of those with diverticulitis, require inpatient management of their disease [70]. Complicated cases involving sepsis, obstruction, fistula formation, or peritonitis constitute approximately 40% of all those admitted. Older patients present more often with complicated disease. The elderly present with diffuse peritonitis up to twice as frequently as younger patients [29, 32].

Typically, patients with diverticulitis seek medical care owing to mild or moderate peritoneal irritation often accompanied by a change in bowel habits. Crampy left lower quadrant pain is also common. Approximately two-thirds of patients complain of constipation or diarrhea [71]. Other associated symptoms may include a palpable mass, abdominal distension, dysuria, excessive flatus, nausea, and vomiting. About 30–40% of patients have occult blood in their stool [2]. Fever and pain are the most consistent indicators of acute disease, occurring 45% of the time. Septic shock with diffuse peritonitis may be the presenting picture. With the presence of a redundant sigmoid colon, suprapubic or right lower quadrant pain may manifest. Occasionally, the diagnosis of appendicitis is the indication for surgical exploration when a redundant sigmoid colon with diverticulitis is found to be the culprit.

Considerable diagnostic overlap exists between diverticulitis and other acute abdominal processes. The spectrum of differential diagnoses range from relatively common urinary tract infections in the elderly to inflammatory bowel disease, colon cancer, closed loop obstruction, and ischemic bowel. These diagnoses and causes of abdominal pain must always be kept in mind during the initial evaluation. Symptoms of diverticular fistulas may lead to an accurate preoperative diagnosis. Pneumaturia and fecaluria are diagnostic of an enteric–vesicular fistula and in the appropriate patients are highly suggestive of a diverticular origin. Similarly, flatus or stool via the vagina leads to common bowel sources. Thigh abscesses, especially those with foul smelling anaerobic pus, may originate from a diverticular abscess with tracking along the psoas muscle onto the skin.

Many investigators have found atypical presentations of diverticular disease in the elderly [29, 72–76]. Wroblewski and Mikulowski [74] noted the absence of typical manifestation of peritonitis in the elderly to be associated with a poor outcome. They also found an absence of abdominal pain in half of their patients with peritonitis. Intra-abdominal abscesses are the most common cause of fever of unknown origin in the elderly [77]. Others noted that elderly patients with intra-abdominal infections have hypothermic temperatures more frequently than young patients. Similarly, old patients have less nausea, vomiting, diarrhea, and fever compared to the young [72]. Acute abdominal pain is more likely to require surgery in the elderly [78, 79]. France et al. [73] examined 12 elderly patients who died of diverticulitis: 75% did not have symptoms typical of their disease, 3 of the 12 did not have abdominal symptoms, and another's symptoms did not warrant further investigation. Generalized peritonitis occurs in up to one-half of old patients [29, 30]. Old patients require operations more frequently, have free perforation more commonly, and have higher mortality rates than young patients [29–32, 80]. Watters et al. [29] attempted to explain this difference. They found that the mean time from the onset of symptoms to hospitalization for old and young patients with generalized diverticular peritonitis was the same. Thus, old patients have peritonitis and free perforation more frequently than the young do, and it is not due to a delay in seeking medical care. This finding suggests that the severity of disease in the elderly is determined early in its course and is independent of the passage of time. Another possible explanation is that symptoms begin later in the course of the disease in the elderly. The former explanation further supports the theory that ischemia is the cause of the more frequent diffuse peritonitis found in the elderly.

Diagnosis

Diverticulitis is usually diagnosed based completely on clinical grounds. This presents a unique problem in the elderly because, as previously shown, they often present atypically and abdominal pain is minimal or absent. A history of known diverticula seen by barium enema or endoscopy often aids the clinician. However, it is unnecessary to have previous knowledge of diverticula in a particular patient, as more elderly patients have diverticula than do not [45]. Useful serologic and hematologic tests include a complete blood count, serum electrolytes, urinalysis, and in the case of suspected ischemic bowel, arterial blood gas measurement for acid base disturbances. WBC can be normal in almost one-half of older patients [81]. Physical examination usually reveals peritoneal irritation to some extent. Mild left lower quadrant tenderness to generalized peritonitis may be found. Rectal examination may reveal a pelvic abscess.

Several diagnostic modalities are helpful for establishing the diagnosis of diverticular disease and assessing the extent of inflammation. In preceding decades, contrast enema was the test of choice for diagnosis. Previous practice parameters of the American Society of Colon and Rectal Surgeons [82] cite a sensitivity of 94%, an accuracy of 77%, and a false-negative rate of 2–15% with water-soluble enemas. Contrast enemas in the setting of diverticular disease have been shown to be less reliable at identifying neoplastic growth compared with colonoscopy [83]. Radiographic findings include intramural or extramural sinus tracts, filling of the abscess cavity, or inferred extramural compression or spasm of the bowel lumen.

Ultrasonography may also provide useful information in the setting of suspected diverticular disease. Investigators have found it to be 84–98% sensitive [84–86]. Ultrasonography can detect abnormal segments of bowel, those with mural thickening, peridiverticular inflammation and abscess, and linear echogenic foci suggestive of fistulous tracts. Unfortunately, this technique is both operator-dependent and limited by the body habitus of the patient. Zielke et al. [86] found that surgical residents were able to accurately diagnose diverticulitis in 84% of patients, with a 16% false negative rate.

Computed tomography (CT) has emerged as the imaging modality of choice for evaluating suspected diverticulitis [87–92]. Though in some studies it is comparable to contrast enema, other investigators have found a clear advantage regarding diagnostic sensitivity and specificity [92]. Hulnick et al. [91] found that CT not only stages the extent of the inflammatory process more accurately, it better differentiates the varying gradations of pericolic inflammation. Furthermore, CT has the distinct advantage over a contrast enema because of its ability to identify both the intraluminal and extraluminal components of diverticular disease. It is also the diagnostic modality of choice for identifying colovesicle and colovaginal fistulas. Findings suggestive of diverticulitis include inflammation of the pericolic fat, thickening of the sigmoid mesocolon, pericolic phlegmon, visualization of colonic diverticula themselves, and thickening of the colonic wall. CT is helpful for demonstrating the manifestations of intra-abdominal abscess, particularly abscesses amenable to percutaneous drainage [88–92]. Despite these modalities, the diagnosis of diverticulitis can be obscure in the elderly [74].

Endoscopic evaluation is reserved until after the acute phase has resolved; it is used mainly to rule out carcinoma. CT colography is a new modality which noninvasively evaluates the contour of the colon lumen. It is especially helpful in cases where, due to stricture or obstruction, a colonoscope cannot traverse the diseased bowel. Colography can ensure the proximal bowel does not harbor unsuspected neoplastic lesions.

Management

Prevention of Symptoms

High fiber diet has been shown to decrease the formation of diverticula in rats [19]. Examination of population based per capita fiber intake reveals less diverticular disease with high average fiber intake [47, 50, 51]. High fiber intake in American males decreases the risk of diverticular symptoms. There is no evidence that increasing fiber intake can cause diverticulae to regress. It follows that high fiber diet should be suggested to decrease the chance of diverticular symptoms. There is no evidence to support the concept of avoiding food particles which can obstruct the neck of diverticulae. Accordingly, avoidance of seeds, nuts, popcorn, etc., has not been shown to cause acute disease. Most physicians suggest a high fiber diet with bulk-producing supplements (psyllium seed) for patients with asymptomatic diverticulosis [93–95]. Fiber has been shown to decrease intraluminal pressures and colonic transit time [27, 96–98]. It also decreases symptoms attributed to diverticular disease [99, 100]. Antispasmodic medications have not been shown to help.

Uncomplicated Diverticulitis

Most acute diverticulitis is treated by primary physicians on an outpatient basis. Those with only mild tenderness, no clinical peritoneal signs, and the ability to achieve satisfactory pain control and tolerate adequate fluids orally may be treated empirically on an outpatient basis [6]. Treatment consists of oral antibiotics covering anaerobic and gram-negative bacteria for at least 7 days and liquid diet until resolution of symptoms. Significant systemic signs of infection including high fever and leukocytosis suggest the need for hospital treatment. Resolution is common. There is no place for outpatient management in the setting of significant concurrent medical disease, immune compromise or in patients those with altered mental status or patients without appropriate supervision.

Immune-compromised patients have a more aggressive disease path, are more likely to present with perforation, and have higher morbidity and mortality rates [60, 101, 102]. Perkins et al. [101] found a 100% failure rate with conservative treatment of immune-compromised patients. Early surgical management is appropriate in this patient population. Due to the aggressive nature of diverticulitis, some have suggested elective sigmoid resection in patients with a single prior attack when they are candidates for organ transplantation with its attendant long-term immune suppression [102]. Patients on continuous peritoneal dialysis represent a special dilemma. CT scanning is usually nondiagnostic and delay in treatment results in poor outcomes. After treatment, very few are able to remain on peritoneal dialysis [103].

Patients who fail outpatient therapy or who present with significant systemic symptoms should be admitted to the hospital. Hospital treatment consists of complete bowel rest and parenteral broad-spectrum antibiotics to cover anaerobic and gram-negative bacteria. Triple-antibiotic or single-agent therapy are both effective. Nasogastric suction is required only with persistent vomiting or evidence of bowel obstruction. Laboratory evaluation includes a complete blood count and urinalysis. CT should be done to confirm the diagnosis, quantify the extent of inflammation, and identify possible complicated diverticular disease. Conservative treatment of acute uncomplicated diverticulitis leads to resolution of symptoms in 70–100% of cases [46, 47, 53, 87, 104]. Oral intake is resumed with disappearance of symptoms. Following hospital discharge, oral antibiotics should be continued for 7–10 days. With complete resolution of the inflammation, patients should have endoscopic or radiographic evaluation of their colon to rule out carcinoma, and they should be started on long-term fiber supplementation. Psyllium seed or hydrophilic colloids have been shown to reduce recurrence by up to 70% [100]. Old studies suggest that one-fourth of patients who recover from their first attack will have further attacks requiring hospitalization [2, 105]. One study with a median 5 year follow-up revealed less than 2% of patients reported more than mild symptoms [106].

Antibiotic treatment of acute uncomplicated diverticulitis is the standard of care. This is despite lack of controlled study. Recent studies questioned this. Chabok [107] conducted a prospective, randomized trial to evaluate whether antibiotics are necessary to treat hospitalized uncomplicated diverticulitis. CT scans were used to ensure diagnosis. Patients were randomized to receive antibiotics or only IV hydration. A small number of patients were placed on antibiotics due to increasing pain. There was no difference between groups regarding complications or surgical procedures. An equal number of patients from both groups were operated on during the follow-up period. There was no difference in hospital length of stay. A recent Cochrane Collaboration agrees with the conclusion that new evidence suggests that antibiotics have no effect on uncomplicated diverticulitis. The Collaboration suggests that more confirmation from future trials is required before clinical guidelines can be changed safely [108].

The goal of elective sigmoid resection is to reduce the potential for re-presentation with complicated disease requiring emergency colon surgery with its attendant increased complication and mortality rates. Emergent surgery often results in Hartmann's resection with temporary ostomy formation. Ostomies formed during emergency operations are not reversed in a significant minority of patients [109]. Over the last decade, there has been a major shift in decision making regarding elective resection and diverticulitis. The natural history of disease is not well known. Past practice parameters from the American College of Gastroenterology, American Society of Colon and Rectal Surgeons, and the European Association of Endoscopic Surgeons have all supported elective resection after 1–2 attacks, especially in younger patients [110–112].

A population based study of first event hospitalized diverticulitis patients [113] showed that only 5% of older patients who did not require emergency surgery at first presentation ultimately required emergent colectomy/colostomy formation. Some have estimated the risk of colostomy after one attack of mild diverticulitis at one in 2,000 patient years of follow-up [114]. A multicenter Kaiser Permanente study [115] followed 3,165 patients admitted with diverticulitis for a mean of 8.9 years. They found a 13.3% recurrence rate in patients treated nonoperatively, one quarter had re-recurrences. Old age was associated with a lower recurrence rate (12.2%). They also noted an increased risk of further attacks with each additional re-recurrence. They believe no patients had colostomies in this group.

These findings have led to a change in the tradition suggestion that patients undergo elective sigmoid resection after 1–3 documented attacks. The frequency and severity of attacks, crescendo attacks, and the medical comorbidities should be considered when deciding to suggest elective sigmoid resection. The number of attacks should not be a major factor in decisions regarding timing of surgery. Most patients with perforating diverticular disease present with such at their first attack [113–118]. As seen above, very few patients require colostomies after initial successful non-operative management. The number of attacks required to suggest elective resection is in dispute at this time. Salem [116] used a Markov model to evaluate the lifetime risk of death and colostomy as well as care costs and quality of life and elective resection for diverticulitis. They conclude that performing colectomy after a fourth attack in 50-year-old patients would result in 0.5% fewer deaths, 0.7% fewer colostomies, and save over $1,000.00 per patient. Using 35-year-old patients in the model resulted in 0.1% fewer deaths, 2% fewer colostomies, and over $5,400.00 saved per patient. Clearly, delaying elective resection appears beneficial to patients and the cost of health care. The severity of disease, as measured by CAT scan during the first attack, may be a predictor of aggressive disease and the future need for operative intervention [119].

Elective resection for diverticulitis results in acceptable results. Thorn et al. [120] followed 75 consecutive elective sigmoid resections for diverticulitis. They found 13% major perioperative complications. Eight percent had recurrent diverticulitis in the follow-up period. Two-thirds of patients classified their results as good or excellent. IBS type symptoms in the preoperative period predicted less successful outcomes. Elective resection after one attack in patients requiring long-term immunosuppression is appropriate to prevent future sepsis. Elective resection may be required if cancer cannot be ruled out [62].

Surgical Technique for Elective Sigmoid Resection

Elective sigmoid resection after resolution of the acute inflammation should include adequate mobilization of the proximal bowel to provide a tension-free anastomosis. The proximal bowel need not be devoid of diverticulosis, but the bowel must be soft, supple, and free of diverticular thickening. Resection should include all thickened, diseased bowel. Splenic flexure mobilization is occasionally required to achieve these goals. Distal resection must include removal of the entire sigmoid to the rectum to significantly reduce recurrent attacks [121]. No diverticula should be left distal to the anastomosis. The site of distal transection should be at the point where the teniae coli are lost, signifying the beginning of the intraperitoneal rectum.

Laparoscopic techniques have evolved significantly in recent years. Laparoscopy has been used in all types of diverticular resections and to drain abscesses drainage not amenable to percutaneous CAT approaches. Laparoscopic colectomy in the elderly is safe and effective as well [122]. Laparoscopy is safe with complicated diverticulitis as well [123]. Laparoscopic surgery is successful in treating fistula disease as well, with laparoscopic colovesicle and colovaginal fistula operations becoming more common [124, 125]. Many studies have showed that laparoscopic approach to this disease is safe and effective and may confer benefits to patients compared with traditional open surgery. Decreased complications, faster recovery of bowel function, and oral intake have been seen in older patients [126, 127]. Pulmonary function is better preserved and a host of stress measurements show less stress is imparted to laparoscopically treated patients compared with open techniques [128]. These benefits have been shown to be enhanced in older patients compared with younger ones [129]. Older patients also enjoy fewer cardiopulmonary complications with laparoscopy [130]. Laparoscopy has allowed more elderly patients to be discharged home rather than rehab facilities compared with open surgery [125, 131]. Finally, Senagore [132] showed a lower direct cost in elderly patients undergoing laparoscopic resection compared with those having open surgery. Practice Parameters published in 2006 by the American Society of Colon and Rectal Surgeons conclude: When a colectomy for diverticular disease is performed, a laparoscopic approach is appropriate in selected patients [133]. More recent Practice Parameters suggest “when expertise is available, the laparoscopic approach to elective colectomy for diverticulitis is preferred” [134].

Robotic Surgery for Diverticulitis

The application of robotic surgery to the treatment of colorectal pathologies has grown in recent years. Most published studies have examined outcomes for oncologic resections. However, there have been reports of its application in the surgical management of diverticulitis. Most of these studies have looked at the feasibility and safety of the technique. In one small series of 24 consecutive patients, Ragupathi [135] demonstrated robotic surgery for recurrent complicated and uncomplicated diverticular disease could be offered to patients with low complication rates and short hospital stay.

On the other hand, Elliott [136] compared their robotic experience in patients with diverticulitis complicated by fistula to the bladder, vagina, or skin with that of patients undergoing laparoscopic resection for the same indications. They found a higher conversion rate, diverting stoma need and longer length of stay in the robotic group, though the retrospective nature of the study and other confounding factors may have influenced these outcomes. Others have described its use in elective reversal of a colostomy after a Hartmann's resection [137]. Much work is still needed to determine whether the application of robotic surgery for the management of diverticular disease is equivalent or superior to the well-established laparoscopic approach. With the growing experience gained by surgeons using this platform, we anticipate its use in diverticular disease will continue to grow in the near future.

Emergent Surgery for Uncomplicated Diverticulitis

Up to one-third of all patients admitted to the hospital require urgent or emergent surgery [2, 45, 46, 56, 106]. Up to one-half of elderly patients present with generalized peritonitis requiring operative intervention [29]. Similarly, more old patients with diverticulitis require urgent or emergent operations compared with younger patients [30]. Most patients requiring urgent or emergent surgery are undergoing their initial episode of diverticulitis [116]. Hinchey et al. [138] described a grading system for acute diverticulitis. Stage I is confined pericolic abscess. Stage II is distant abscess. Stage III is generalized peritonitis caused by rupture of a pericolic or pelvic abscess, "noncommunicating" with bowel lumen because of obliteration of diverticular neck by inflammation. Stage IV is fecal peritonitis caused by free perforation of a diverticulum ("communication"). Emergent surgical treatment aims to relieve sepsis, remove the diseased bowel, minimize mortality and morbidity, and avoid stomas with their concomitant second operation to restore bowel continuity. Options include resection with proximal colostomy and closure of the distal end (Hartmann's procedure), resection with primary anastomosis, laparoscopy with lavage (dealt with later in this chapter), and diversion with drainage alone. The latter plays only a small role today, with only the most ill and unstable patients unable to tolerate removal of the infectious foci. Diversion alone leaves a column of undrained stool above the perforation that can further contribute to the septic process [139, 140].

Hartmann's procedure has been the standard of care for acute diverticulitis surgery for many decades. It consists of removing the affected bowel with proximal end colostomy and closure of distal rectosigmoid stump. Mobilization of the colon should begin in an unaffected area to facilitate entrance into normal planes of dissection. The retroperitoneal structures (ureters and gonadal vessels) can be swept dorsally, elevating the sigmoid colon. Ureteral catheters can be helpful in selected cases due to inflammation causing difficulty with normal anatomic planes [141].

Hartmann's procedure carries significant complication and mortality rates and requires another operation to reverse the colostomy [142]. This has led to the proposal of resection and primary anastomosis for acute noncomplicated disease [95, 135, 139]. Selection is important and should include minimal local sepsis and well-nourished patients. Adding on table lavage of the bowel is an option in patients with proximal solid stool [143]. Adequate diverticular resection requires removal of the distal sigmoid from the rectum when restoring bowel continuity after Hartmann's procedure. Removing the sigmoid from the rectum decreases recurrences of diverticular disease [121]. Furthermore, using the distal sigmoid instead of rectum for the anastomosis was found to be a risk factor in the development of postoperative colocutaneous fistulas [144].

Complicated Diverticular Disease

Complicating factors associated with diverticular disease include abscess formation, free perforation, fistula formation, obstruction, and bleeding. The presentation of complicated diverticular disease occurs in up to one-third of hospitalized patients [87] and more than 50% of the elderly [28]. Bleeding diverticular disease is discussed elsewhere in this text. The vast majority of perforating diverticulitis occurs during the first attack [145, 146]. The incidence of perforating diverticulitis may be increasing [146]. Complicated diverticulitis is associated with significant morbidity and mortality, and the need for operative intervention should be continually reassessed. Treatment of complicated diverticular disease requires accurate diagnosis and staging. The goal of treatment of complicated diverticular disease is to minimize morbidity and mortality, avoid ostomy formation and the number of subsequent operations. To achieve these goals, nonoperative techniques are used to convert complicated disease to medically manageable disease, thereby allowing future elective resection with primary anastomosis.

Hartmann's procedure is associated with high morbidity and mortality rates [141, 147, 148]. The rate of retained colostomy after Hartmann's operation ranges from 5% to 58% [141, 149]. A large review of Hartmann's procedure [109], where diverticulitis was the indication for almost 60% of operations, found a 14% mortality rate and more than 40% of colostomies were not reversed. In a related study [150], a higher than expected mortality rate was found in older patients undergoing colostomy reversal. And in these older patients, only 30% of colostomies created were reversed! Surgeons operating emergently on the elderly need to ensure proper placement and construction of these temporary ostomies, as many of them are permanent to the patient. Furthermore, colostomy closure is associated with significant complication and death rates, especially in the elderly [149]. Eisenstat [151] recorded a lower mortality rate for complicated diverticular disease treated with elective resection than that treated with staged surgical procedures. Avoiding a stoma with its concomitant second operation is a major goal of operative management for complicated diverticular disease. Accurate preoperative diagnosis is helpful, as up to 25% of patients explored for abscess or fistula have a perforated cancer [152].

Abscess formation is the most common complication of acute diverticulitis, occurring in 32–68% of complicated diverticular cases [88–90, 153]. A wide spectrum of presentations may result: small occult abscesses; scrotal, buttock, or thigh abscess; and sepsis due to a large abscess. Diagnosis is best made with CT [89, 154]. Treatment is aimed at relief of the sepsis and treatment of the diverticulitis. Small peri-colic abscesses or phlegmon may be managed conservatively with bowel rest and broad-spectrum intravenous antibiotics [134]. Elective, single-stage sigmoid resection with primary anastomosis can be done with resolution of symptoms. If symptoms worsen or are not alleviated, repeat CT scan with percutaneous drainage of the abscess should be considered. Exploration is reserved for patients whose abscesses are not amenable to percutaneous drainage or who fail conservative management. Primary anastomosis is possible if the proximal and distal bowel is healthy and the perforation is contained, and if a gentle preoperative mechanical preparation has been done [90, 149]. The patient's underlying medical diseases and acute physiologic status must obviously be considered.

Large abscesses, including more distant pelvic abscesses, and smaller ones that do not respond to conservative treatment should be referred quickly for possible percutaneous drainage under CT guidance [155]. Percutaneous drainage of diverticular abscesses is associated with a success rate of 62–100% [155–159]. Following placement of a drainage catheter and aspiration of the pus, repeat radiologic evaluation should be undertaken to assess not only resolution of the abscess cavity but to identify potential fistulous communications to the small or large bowel. In the setting of appropriate drainage, treatment should then progress as for uncomplicated diverticulitis. The catheter may be removed when the drainage stops or when complete collapse of the abscess cavity has been shown by sinography. At discharge, the catheter may also be left in place and removed during subsequent elective sigmoid resection [88]. The presence of a persistent colocutaneous fistula does not preclude elective resection with primary anastomosis [141]. Such a course of treatment allows complicated disease to be transformed nonoperatively to disease that responds to medical treatment, thereby avoiding emergent surgery with stoma formation. Subsequent elective sigmoid resection with primary anastomosis after resolution of inflammation (in about 6 weeks) becomes the only operative intervention required [159]. This has become the standard treatment for diverticulitis complicated by abscess formation.

Another clinical decision which is evolving concerns what to do with a patient who has successfully had a diverticular abscess nonoperatively drained by interventional radiology. Past standard of care required elective sigmoid resection due to small studies. Stabile et al. [88] followed three patients who refused surgery after catheter drainage for large abscesses. One required resection after a repeat diverticulitis attack 7 months later. The second required permanent catheter drainage for recurrent and persistent abscesses. The third died in hospital of sepsis. Ambrosetti [32] suggested that occasional small mesocolic abscesses can be managed without operation, but they stated that pelvic and abdominal abscesses behave aggressively and require surgical treatment. Kaiser [160] found that 41% of patients managed with percutaneous abscess drainage without surgery developed severe sepsis. Conversely, Broderick-Villa [115] found no increase in recurrence rates after abscesses were percutaneously drained and treated without elective operation compared with uncomplicated diverticulitis followed nonoperatively. Others suggest a conservative approach after drainage is appropriate as well [161]. Another study compared uncomplicated diverticulitis and diverticulitis with abscess formation. There was a high initial success rate of nonoperative treatment in both complicated and uncomplicated cases: 92% versus 97%. Readmission occurred more frequently in complicated disease during the first year: 27% versus 11%. Similarly, surgery was performed twice as often in patients who had abscesses: 48% versus 19% at 2 years. Interestingly, more than one-half of abscess patients avoided surgery, with the most common indication for operation being recurrent disease, not complication [162]. Gaetner [163] followed 32 patients who did not have operations, with a mean abscess size of 4.2 cm. Recurrence was 40%, with increasing recurrence rate if the abscess was greater than 5 cm. Devaraj [164] followed 185 abscesses. Sixty percent had recurrent diverticulitis with 40% of these having multiple attacks. One quarter of these patients required urgent surgery and almost one-half re-presented with higher Hinchey scores. They also noticed that larger abscess increased risk of recurrence. With such conflicting data, expectant, nonoperative management has been supported, but future research is needed to better determine the resection criteria in this group of patients [134].

Pelvic abscesses can be drained transrectally and transvaginally in women as well. These techniques have been replaced by CT-guided drainage but should remain in the surgeon's arsenal. If large abscesses cannot be drained adequately or if sepsis does not resolve, operative exploration is required. Gentle preoperative mechanical bowel preparation can be performed in well-selected patients; and with normal proximal and distal bowel, resection and primary anastomosis can be performed safely [149]. The use of Hartmann's procedure is reserved for most other patients. One should remember that restoring bowel continuity after Hartmann's procedure has high morbidity and mortality rates, and a large percentage of "temporary" stomas become permanent [139, 148–150].

Perforating diverticular disease is the most virulent form of this disease. The vast majority of patients with perforating diverticulitis have no previous history of diverticulitis [114–116]. It is important to consider these patients separately from other complicated diverticulitis patients. Perforating diverticulitis has higher operative mortality (12–21% vs. 0–2.6%) compared with nonperforating complicated diverticulitis [53, 118]. Free perforation of diverticulitis generally presents as acute sepsis or an acute abdominal crisis and some degree of shock. It occurs in approximately 10% of complicated cases [88]. More importantly, up to 50% of elderly patients present with diffuse peritonitis [29]. Rapid hydration with correction of electrolyte abnormalities is necessary. Broad-spectrum antibiotics are administered preoperatively. Immunocompromised patients may not exhibit classic abdominal findings. Physical examination and CT scans generally yield the diagnosis. A large number of old patients with peritonitis lack abdominal pain as a finding [74] so a high index of suspicion is required when treating them. Emergent exploration with aspiration of pus, cleansing of fecal material, resection of the diseased bowel, and proximal end colostomy with oversewing of the distal stump (Hartmann's operation) are performed [165–167]. Only rarely are patients so sick that diversion and drainage without resection is appropriate [166, 168]. In fact, one study [139] found higher mortality among patients treated with diversion only compared to those who underwent resection, despite more steroid use and fecal peritonitis in the resection group. The mortality rate associated with fecal peritonitis is as high as 35% [139, 166, 168].

A few important technical aspects of resection must be emphasized. When possible, care should be taken in the face of peritonitis to avoid opening noninfected tissue planes such as the presacral space and the splenic flexure area. These areas are known to invite abscess formation and are best left intact and free from contamination by the infectious process. Ureteral catheters may be employed, as the inflammatory process may obliterate the normal tissue planes and allow the ureters to be drawn into the inflammatory process [169]. The reader is referred to standard surgical textbooks for other technical aspects of sigmoid resection.

Laparoscopic Lavage

As previously discussed in this chapter, resection with or without primary anastomosis is the most common emergent operation performed for acute diverticulitis [170]. There are numerous reasons to avoid ostomy formation. Up to 35% of patients who undergo a Hartmann's procedure for diverticulitis do not have their ostomies reversed [171]. Moreover, colostomy reversal is associated with significant morbidity, including an anastomotic leak rate of 2–20%, and mortality of up to 5% [172]. Because of these problems, some authors have challenged the need for resection in patients with purulent peritonitis resulting from acute diverticulitis [173]. This originates from the observation that during surgery, the perforation is often noted to have self-sealed. Aspiration of the contamination followed by thorough laparoscopic washout of the peritoneal cavity may be all that is needed, thus negating need for sigmoid resection. This would avoid the risks of major laparotomy, stoma creation, and its subsequent reversal.

The laparoscopic lavage technique involves initial exploration to exclude fecal peritonitis, as this typically precludes good outcomes with its use. Most surgeons prefer to leave the omentum over the perforation intact. A four quadrant washout takes place, with thorough irrigation until the effluent is clear. This usually requires somewhere from 10 to 20 L of saline. Some surgeons prefer to suture the perforation closed if identified and others perform a pneumatic test, though these are not standard practice. Most use one or two intra-abdominal drains, with at least one placed in the pelvis. Antibiotics are generally administered for 7 days.

O'Sullivan [173] first published in 1996 a series of eight patients diagnosed at laparoscopy with generalized peritonitis due to acute diverticular disease, all treated successfully with laparoscopic lavage only. Interestingly, the first patient on this series had developed an arrhythmia intraoperatively, which prompted laparoscopic lavage to control the sepsis in expedited fashion, and later observation that recovery was possible without resection. Multiple studies have tried to determine what patient characteristics make this approach successful. The same authors published the results of a prospective multi-institutional series in 2008 [174]. All patients had evidence of peritonitis on exam and radiologic evidence of colonic perforation on CT or CXR. A total of 92 patients treated with laparoscopic lavage were followed for an average of 36 months (12–84 months). Two patients developed pelvic abscesses requiring percutaneous drainage and one returned to the operating room for Hartmann's resection. Mortality was 3% (3/92) and morbidity very low at 4%. However, most of the attention the study generated was based on the fact that no elective resection was needed in any of these patients in the follow-up period.

In the next few years, data became available from numerous nonrandomized studies, mostly retrospective and nonconsecutive. A systematic review from 2010 that included 13 of these publications concluded that laparoscopic peritoneal lavage for patients with peritonitis caused by perforated diverticulitis was an effective and safe treatment that may be preferable to colonic resection [175]. They found a mean hospital stay of 8.5 days (based on data from 11 articles). Mortality was 1.7%, morbidity 10.4%, and stoma rate 1.7%. Failure to control the acute episode was 4.3%. Thirty-eight percent of patients underwent delayed elective resection. There appeared to be a general consensus, from the data available, that laparoscopic peritoneal lavage should not be used for patients with Hinchey grade IV diverticulitis. Other patients who may not benefit from laparoscopic peritoneal lavage included those with pelvic abscess formation.

Subsequently, many European countries provided higher quality data that has allowed for better decision making. In the Netherlands, patients participating in the **LADIES** trial were randomized to laparoscopic lavage versus resection [176]. Preliminary data showed that in patients in which sepsis was not controlled (7/38), the mortality was dangerously high at 42% (3/7), emphasizing the importance of patient selection.

The **DILALA** trial was another prospective randomized multi-institutional trial involving nine surgical departments in Sweden and Denmark between 2010 and 2014 [177]. Here, patients underwent initial laparoscopy to confirm Hinchey III purulent peritonitis, and then were randomized to either laparoscopic lavage versus open Hartmann's resection. Of the 139 patients who underwent diagnostic laparoscopy, 83 Hinchey III patients were randomized. Laparoscopic lavage appeared feasible and safe in the short term. The study drew criticism due to potential bias in patient selection, given the large amount of patients eligible but not included (52 patients with Hinchey III diverticulitis not included). In a 12 month follow-up published in 2016, only three patients in the laparoscopic group had stoma formation [178].

A multicenter prospective randomized trial with 21 participating institutions in Norway and Sweden took place between 2010 and 2014 (**SCANDIV**) [179]. Laparoscopic lavage was performed in 101 patients (no disruption of adhesions, 2 pelvic drains) and 98 underwent colon resection (either Hartmann's resection or primary resection with anastomosis). Although no difference in mortality was observed, laparoscopic lavage did not reduce severe postoperative complications compared to resection. Moreover, the reoperation rate was significantly higher in the laparoscopic lavage group, including both the need for surgery and percutaneous drainage procedures. In addition, four cancers were missed in the laparoscopic lavage arm. **SCANDIV** did not confirm the findings from previous trials.

Similar to **SCANDIV**, Vennis did not demonstrate superiority of laparoscopic lavage for Hinchey III diverticulitis [180]. This prospective randomized trial (**LOLA**) with 34 participating teaching hospitals throughout Belgium, Italy, and the Netherlands had to be closed early due to an increased event rate in the lavage group. Major morbidity or mortality was higher in the lavage group, 16/46 (35%), when compared to the resection group, 7/40 (18%). However, laparoscopic lavage was successful in 52% of patients in long term. Three quarters of the lavage group never had a stoma and at 1 year, 78% were stoma free compared with 71% in the sigmoidectomy group.

Laparoscopic lavage for Hinchey III diverticulitis certainly allows some patients to be treated successfully without stoma (and perhaps never have resection). Patient selection is important and still not adequately determined. In addition to the risk of persistent intra-abdominal sepsis, there is a potential increase in early re-interventions. The long-term fate of the unresected sigmoid colon is also not adequately resolved at this time. All patients who retain their sigmoid colons require colonoscopy to exclude malignancy. In an attempt to answer some of these questions, the **LapLAND** trial is underway in Ireland (Laparoscopic Lavage for Acute Non-faeculant Diverticulitis) [181]. This will be a multi-institutional randomized controlled trial, with a primary endpoint directed at operative and in-hospital mortality and secondary endpoints addressing in-hospital and post-discharge morbidity, rates of stoma formation, and rates of re-presentation with diverticulitis with or without perforation.

Fistula formation occurs in approximately 2% of diverticulitis cases but accounts for up to 22% of patients requiring surgery [149, 166, 182, 183]. Multiple fistulas are uncommon [183]. Fistulas develop when inflammation or abscesses develop in close proximity to adjacent organs. The inflammatory process invades the adjacent normal organs and causes decompression, which spontaneously converts the acute complicated infectious process to controlled, drained, simple diverticulitis. It is diagnosed often on clinical grounds, after the acute inflammation has resolved. Symptoms are usually related to the invaded organ. Diagnostic tests are used to rule out cancer and other diagnoses. Expensive, complex testing is often unnecessary. In general, single-stage resection with primary anastomosis can be performed as the acute inflammation is usually absent.

The bladder is affected most commonly [184, 185]. Symptoms include pneumaturia and fecaluria. Urosepsis can also occur. Diagnosis is made most commonly by the patient's history. CT scan is most accurate for diagnosis, showing air in the un-instrumented bladder and inflammation of the sigmoid colon and dome of the bladder [166]. Contrast enema or endoscopic evaluation is required to rule out colon cancer. Cystoscopy may be performed to rule out a neoplastic process originating in the bladder. In many patients the fistula cannot be demonstrated. Elective sigmoid resection with primary anastomosis is curative [184]. The fistula is pinched off the bladder. A small bladder defect is best treated by Foley catheter drainage for 7–10 days. Large defects should be closed in two layers with absorbable suture and drained by Foley catheter for a similar length of time. Bladder resection should be reserved for malignant disease [185].

Colovaginal fistulas occur most commonly in women who have had a hysterectomy. Diagnosis is simply made by the history, including flatus or stool per vagina. It is confirmed by transvaginal and transanal endoscopy. Air may be heard exiting from the vagina during sigmoidoscopy. Contrast enema or endoscopic evaluation of the colon is required to rule out neoplastic and inflammatory bowel disorders. Patients generally are not septic at the time of presentation and may undergo elective sigmoid resection with primary anastomosis. The vagina can be left open for drainage or may be closed with absorbable sutures and omentum interposed between the vagina and the anastomosis. Other organs, including the uterus, may be involved with the fistulous process. Hysterectomy may be required if the uterus is involved with the infectious process or if a neoplastic process is suspected [186]. Spontaneous colocutaneous fistulization is uncommon and can be treated with resection and primary anastomosis if sepsis is controlled.

Obstruction complicating diverticulitis occurs uncommonly [187]. Repeated episodes of edema, spasm, and inflammation cause a chronically strictured bowel lumen to become narrowed. Acute inflammation can then complete the luminal obstruction. Gentle water-soluble enema or endoscopy by a skilled endoscopist with minimal air insufflation can confirm the diagnosis and exclude a neoplasm. With proper diagnosis and treatment, the inflammation usually resolves and the obstruction abates. This allows it to be treated as uncomplicated diverticulitis with preoperative bowel preparation followed by elective resection and primary anastomosis after complete resolution of inflammation. Emergency operation for obstruction due to diverticulitis generally requires removing the diseased bowel with creation of an end colostomy. The unprepared and dilated proximal bowel often precludes safe primary anastomosis. On-table lavage has been used more frequently in selected cases to allow primary anastomosis [188]. Colonic obstruction due to narrowing from chronic diverticular disease should be treated as malignant obstruction, usually with Hartmann's procedure.

Right-Sided Diverticulitis

Right-sided diverticulitis has a different etiology and pathophysiology and affects a different patient population group compared with left-sided disease. Right-sided diverticula are true diverticula, with all layers of the bowel wall involved with the out pouching. They most commonly affect Far Eastern populations. Presentation mimics appendicitis with right-sided pain and infectious systems. Preoperative diagnosis is uncommon. X-ray findings often suggest neoplastic diseases. Nonoperative treatment is usually effective if accurate diagnosis is made before surgery. Not infrequently, the diagnosis is in doubt at time of operation and right colon resection is performed with a presumed diagnosis of tumor. Resection, diverticulectomy, and inversion of the diverticulum have been reported.

In conclusion, diverticulitis is common in the elderly. Symptoms may be avoided with a high fiber diet and fiber (psyllium) supplement intake. Older patients frequently present atypically and are difficult to accurately diagnose. Diverticulitis appears to be a more virulent disease at initial presentation in the elderly. More than one-half of patients require emergent operation with many having ostomy formation. Ostomies are commonly permanent in these old patients. Goals of treatment include avoidance of ostomy formation and conversion of surgical intervention from emergency to elective, thus decreasing morbidity and mortality. CAT drainage of abscesses allow for safer, elective resection. Laparoscopic lavage may be helpful as well. Most patients who avoid surgery at initial presentation can be managed without subsequent operation. Laparoscopic approaches allow for decreased morbidity, mortality, lower hospital stays, and more frequent discharge to home, and these advantages are more pronounced in the elderly.

Appendicitis

Case Study

JM is an 86-year-old man who presented with urospesis. He lives alone at home and has moderate cardiac disease. CT scan revealed a right pelvic phlegmon. He responded to intravenous antibiotics. He was discharged with the plan of elective laparoscopic appendectomy in the near future. This was done after preoperative colonoscopy was unremarkable. He recovered and was able to be discharged home. Pathology revealed a small carcinoid tumor which had favorable characteristics and was removed completely. No further therapy was suggested.

Many investigators have tried to assign an immune function to the appendix, as it does secrete immunoglobins, but the appendix is an organ whose function is unknown. Certainly, normal life results after its removal. Inflammation and neoplastic transformation are by far the most common afflictions that affect the human appendix. Infectious diseases (typhoid and tuberculosis), regional enteritis, and congenital defects of the appendix are beyond the scope of this chapter. Similarly, neoplasms of the appendix are not addressed. Appendectomy is one of the most common operations performed, with more than 500,000 appendices removed annually in the United States; 5–10% of acute appendicitis occurs in the elderly. Old patients delay presentation, present atypically, and suffer delay in diagnosis and treatment more often than young patients. Perforation is found more frequently in the elderly. Higher mortality rates and prolonged hospital stays result. The following section attempts to explain these findings.

Background

Etiology

Obstruction of the lumen of the appendix has been thought of as the predominant cause of appendicitis, with fecaliths a common cause of the obstruction. After the lumen is obstructed a closed microenvironment is produced, which allows fluid sequestration, stasis, distension, and bacterial overgrowth. Mucosal secretion and bacterial multiplication increase the distension and intraluminal pressure. As the diameter of the lumen expands to accommodate the increased pressure, venous and then arterial pressures are overcome. Ischemia, necrosis, bacterial translocation, and appendiceal perforation result. Interestingly, humans are one of the few animals able to secrete fluid into the lumen of the appendix at pressures high enough to produce necrosis and perforation [189].

Nonperforating appendicitis may have a different pathophysiology compared with perforating appendicitis. Rivera-Chavez [190] suggests that if infection is the major cause of acute appendicitis, isn't it logical to treat it with antibiotics. Most uncomplicated appendicitis resolves with antibiotics alone. If obstruction causes acute appendicitis, then it would be logical to conclude that untreated patients should routinely progress to perforation. This is clearly not the case. Complicated appendicitis was found to occur at similar rates despite varying time to surgery of greater than 12 h [191]. Arnbjornsson [192] measured the intraluminal pressure in patients with acute appendicitis. It was normal in 14/16 with phlegmonous appendicitis and elevated in all three patients with gangrenous appendicitis. They also suggested that enteric bacteria play an important role in pathogenesis of acute appendicitis and obstruction may play a role in perforation. Further an older large Swedish study [193] showed perforated disease occurred at the same rate over 20 years, and was independent of age, while nonperforating disease decreased over the length of the study and was age dependent. More recent study has found a reversal in this decreasing rate of nonperforating appendicitis when CT scanning became more available, again with stable perforating rates [194]. It follows that some patients with nonperforating appendicitis in the pre-CT era resolved without being operated upon, while their more current cohorts are now having an operation due to more accurate CT diagnosing. An autopsy study found about one-third of cadavers showed a diseased appendix [195]. Perforated disease produces significant symptoms which lead virtually all patients to seek medical care. Nonperforating appendicitis produces a varying severity of symptoms, combined with other factors including gender and age, which combine to lead a majority, but not all patients to seek formal medical care or come to operation.

Perforation may occur due to vascular compromise, causing necrosis, usually on an antimesenteric border. There are thought to be many differences in the elderly appendix that predispose it to obstruction and perforation. The appendiceal lumen is small or obliterated, and the blood supply is decreased, predisposing to necrosis; the mucosa is thinned, and there is fatty infiltration of the wall [196]. These changes may lead to increased rupture rates with decreased pressures, thus altering the natural history of appendicitis in the elderly. NSAIDs have been implicated in appendicitis as well. Campbell and DeBeaux [197] found that 37% of patients over the age of 50, with the diagnosis of acute appendicitis, were on NSAIDs compared with only 11% of a similar age group admitted with other emergencies.

Epidemiology

Appendicitis is the most common acute surgical condition of the abdomen. Six to eight percent of the population will suffer from acute appendicitis in their lifetime [198–200]. Life-table analysis estimates that 12% of males and 23% of females have their appendixes surgically removed [199]. Acute appendicitis occurs at all ages but is most frequent during the teenage year [199, 201]. This age peak is thought to result from the peak in lymph tissue in the appendix during these years. The extra lymph tissue presumably narrows the lumen, predisposing it to obstruction and the resulting appendicitis. Males are more commonly affected in young ages, but during later adult life the male/female ratio equals out [202]. Five to ten percent of all acute appendicitis occurs in the elderly [198, 201, 203, 204], and in fact the incidence of acute appendicitis in the elderly is increasing [196, 202, 203]. It may be due to longer life-spans, as Thorbjarnarson and Loehr [196] found that old patients accounted for only 1% of appendicitis between 1932 and 1937, whereas this percentage increased to 6–8% after 1957. Altogether, 1 of 35 women and 1 of 50 men over age 50 years develop acute appendicitis [200]. Furthermore, appendicitis accounted for 2.5–5.0% of all acute abdominal disease in patients over 60–70 years of age [74, 204].

Acute appendicitis is the third most common cause of abdominal pain in the elderly after gallbladder disease and small bowel obstruction [205, 206]. It is the leading source of intra-abdominal abscess, which in turn is the most common cause of fever of unknown origin in the elderly [77]. About 33–50% of the mortality due to acute appendicitis occurs in the elderly [198, 199, 207]. Lowered immune responses to foreign antigens and decreased production of lymphocytes with advancing age limit the older patients' ability to wall off peritoneal inflammation and fight overall infectious events [208, 209]. It has been postulated that changes occur in the appendix as we age, including atrophy of the intraluminal lymphoid tissue and thinning of the appendiceal wall, which render the appendix more susceptible to inflammation. Atherosclerosis diminishes the blood supply narrowing the lumen. Small changes in intraluminal pressure can produce rapid ischemia, gangrene, and perforation at rates much quicker in older persons than the young [210].

Symptoms and Diagnosis

Abdominal pain, fever, and leukocytosis are the hallmarks of acute appendicitis. Distension of the obstructed appendix stimulates visceral afferent nerve fibers, producing vague, dull, mid-abdominal pain. Pain classically begins in the periumbilical area and migrates to the right lower quadrant within hours [189, 211]. This pain is peritoneal in origin and as such is constant and increases with time. Anorexia is common. Vomiting occurs up to 75% of the time. Protracted vomiting and diarrhea should lead the clinician away from the diagnosis. There are many variations in presentation.

Physical examination reveals the site of peritoneal inflammation. Usually tenderness is found at McBurney's point. Rovsing's sign (pain referred to the right lower quadrant with palpation of the left side) indicates localized peritoneal irritation. The appendix may be found anywhere in the abdomen and thus can cause pain during psoas muscle stretch, obturator muscle stretch, rectal examination, or palpation of any abdominal site [211]. Continued irritation results in rebound and referred peritoneal irritation. Frank peritonitis can ultimately result with perforation. Elevated core temperature is usually not more than 39 °C. The white blood cell (WBC) count is generally between 10,000 and 18,000/mm^3 with a left shift [189]. Higher or lower counts and extreme left shifts are indications of diffuse peritonitis. Acute-phase reactants are being examined in an attempt to increase the accuracy of the preoperative diagnosis. Urinalysis should be done but may be abnormal if the appendix is adjacent to the bladder or ureter.

The presentation and difficulty with diagnosis of acute appendicitis in the elderly deserves special consideration. Most importantly, older patients more frequently delay seeking medical attention for a variety of reasons: difficulty leaving home, fear of hospitalization, decreased ability to appreciate or express symptoms. An elderly patient with a perforated appendicitis who was incorrectly treated for alcohol withdrawal for 5 days prior to being accurately diagnosed has been reported [212]. Burns et al. [213] found that 20% of older patients with acute appendicitis had WBC counts less than 10,000/mm^3 and neutrophil counts less than 75%. Lau et al. [214] found only 43% of old patients with simple appendicitis to have elevated WBC counts. Thorbjarnarson and Loehr [196] recorded an average duration of symptoms prior to admission in patients over age 60 to be 2.5 days. Horattas [215] found that one-third of patients over 60 years of age waited more than 48 h from onset of symptoms before presenting to the hospital. Fewer than two-thirds had “typical” right lower quadrant pain, and one-half had a temperature <37.6 °C. Similarly, Smithy et al. [216] found that only 55% of patients over age 80 had right lower quadrant pain, and 18% did not have abdominal pain. They also noted that only 1 of 13 patients had “typical” periumbilical pain localizing in the right lower quadrant. They hypothesized that because of the smaller lumen diameter of the elderly appendix, which requires less pressure to produce rupture, the old patient does not necessarily experience the prodromal phase of appendicitis with the generalized abdominal pain, anorexia, nausea, and vomiting thought to be caused by visceral distension. Nausea, vomiting, fever, and anorexia were found to be uncommon in old patients by others as well [72, 212]. Burns et al. [213] compared the presentations of young and old patients. They found that twice as many young patients presented “classically,” and old patients were more than two times more likely to delay presentation for more than 72 h after onset of symptoms. Furthermore, in their study old patients were three times as likely to have operation delayed more than 24 h after admission than were the young. Others agree; finding that 13% of patients had their operations delayed more than 48 h after admission [215], further illustrating the difficulty of correctly diagnosing this age group. Sami described a blunted or absent pain response in the elderly [217]. And, perhaps more importantly, some have found that doctors often minimize the importance of the older patient’s pain, attributing it to old age or concomitant diseases [218–220]. Clinicians must be more cognizant of the abdominal complaints in old patients if prompt diagnosis and treatment with resultant decreased morbidity and mortality are to be expected.

The confident diagnosis of acute appendicitis is difficult, and the experienced clinician is wrong 5–25% of the time 201, 221]. Many books and articles have been written describing techniques for diagnosing acute appendicitis [222–224]. The combination of appropriate history, physical examination, and elevated WBC count is thought to be most important for diagnosing appendicitis correctly [225]. Unfortunately, these factors are not often present together [224]. Ultrasonography and focused CT have been used extensively for presurgical evaluation of patients [222, 223, 226]. Despite numerous advances in radiographic techniques, unnecessary explorations occur [223, 227].

C-reactive protein (CRP) has been studied as a tool to aid in the accurate diagnosis of appendicitis [228]. There is a decline in the production of inflammatory mediators and the immune system with aging [208, 229]. CRP is preserved with age. CRP has been found to be consistently elevated only in patients with perforation, perhaps because it first appears in the serum about 8 h after the initial insult and takes 24–48 h to reach peak blood levels [228]. Thus, elevated serum levels are often found only with prolonged symptoms, which correspond to high perforation rates. Obviously, if symptoms progress rapidly, there is no time for serum CRP levels to rise. CRP is not specific for appendicitis: It also increases with any inflammation, surgical trauma, and acute myocardial infarcts [228].

CT scanning has made accurate diagnosis easier. More liberal use of CT scanning can lead to the diagnosis of appendicitis in older patients where this diagnosis was not entertained [230]. Despite this, outcomes including perforation rates and duration of hospitalization may not be affected. Despite advances in preoperative modalities, an accurate diagnosis of acute appendicitis is made in only 30–77% of the elderly on admission and in only 70% preoperatively [212, 216, 221, 231]. Between 14% and 33% of older patients have operations more than 24 h after admission [213–216, 231].

Management

Antibiotics first treatment of acute uncomplicated (nonperforated) appendicitis has been receiving support. Multiple prospective studies and reviews have been published [232–237]. A large retrospective state database study found appendectomy rates of less than 10% over a mean follow-up of over 7 years [238] Others have found somewhat higher rates while still concluding nonoperative management is safe and effective [239]. Six prospective studies evaluated antibiotics first treatment [233–235, 240–242]. Nine percent of patients randomized to antibiotics required surgery during the initial hospitalization, many of whom had misdiagnosed complicated disease at presentation. Another 19% of the remaining patients had recurrence within the first year, for a 29% failure rate at 1 year. These failures did not present with increased risk of complicated appendicitis at surgery. These studies show that antibiotics as a first line of treatment is safe and permits nonoperative intervention in 75% of patients at 1 year. Decreasing initial failure of antibiotics first can be accomplished by more accurately diagnosing complicated appendicitis. Risk of undiagnosed neoplasm has been studied as a reason to avoid antibiotics first treatment in older patients. Wright [243] specifically looked at patients over 40 who were initially treated with appendectomy (suggesting noncomplex disease) and found a neoplasm rate of 0.7%. Of the 62 patients who were treated without initial surgery, presumably due to complicated disease, and then underwent interval appendectomy, 16% had a previously undiagnosed neoplasm. This suggests that uncomplicated appendicitis in adults is probably not associated with increased risk of neoplasm, but complicated appendicitis is. Some authors have suggested antibiotics first treatment of acute uncomplicated appendicitis for high operative risk patients such as those with recent MI, drug eluting stents, etc. Though not specifically studied, perhaps the elderly may fit this suggestion as well. Specific study in the elderly is currently lacking.

Early, aggressive operative treatment, when chosen, is imperative to minimize mortality in the elderly. In fact, Burns [213] suggested that "based on the lack of significant complications in those patients with a false-positive diagnosis and the 65% perforation rate in older patients, we feel an even earlier and more aggressive surgical approach is warranted." Operative treatment for acute appendicitis remains resection of the offending organ. Hydration and correction of electrolyte imbalances prior to urgent operation is prudent. Untoward delay before exploration may allow progression of the disease and ultimately free rupture of the organ with resultant peritonitis. Preoperative broad-spectrum antibiotics are administered intravenously and are continued postoperatively if necrosis or perforation is discovered. All pus should be evacuated, localized abscess cavities irrigated thoroughly, and appropriate closed-suction drains employed if abscess cavities are encountered [213]. The skin should be left open in complicated cases. When a normal appendix is discovered, the abdomen should be systematically examined to search for the origin of the symptoms; resection of the normal appendix is usually appropriate.

Nonoperative management of abdominal abscesses is well known. CT-guided drainage of abscesses allows resolution of the acute septic process followed by elective, internal operative treatment, thereby avoiding emergency surgery with its attendant morbidity [89, 90, 153, 244]. Acute appendicitis with a contained abscess responds well to drainage [219, 245]. Further, nonoperative management of these complex patients results in less complications and re-operations compared with patients who underwent emergent appendectomy [246]. Initial nonoperative treatment is frequently safer than emergent surgery. Many of these patients will recover with their appendixes in place. There is controversy on whether interval appendectomy (AI) should be done on these patients. Factors to consider include cost, chance for recurrent appendicitis, and undiagnosed neoplasm.

Senekjian [247] used mathematical models to determine that interval appendectomy after nonoperative resolution of phlegmonous appendicitis is cost effective until the patient is 33 years old, due to higher recurrence rates with duration of life. Clearly, IA the elderly is probably not cost effective.

Repeat appendicitis has been reported to be as high as 37%. Marin [245] retrospectively looked at a large database and identified 864 out of

32,938 patients who were treated nonoperatively and did not undergo elective IA. Recurrent appendicitis occurred in only 5% of 864 nonoperatively treated cases. The median time to first recurrence was about 1 year. Similarly, concern for repeat appendicitis is not an important indication for IA in the elderly.

Undiagnosed neoplasm after complicated appendicitis treated nonoperatively is a real problem. Multiple studies have examined this problem. Undiagnosed neoplasm occurs much more frequently in complicated appendicitis, when compared with uncomplicated presentation [243, 248, 249]. Age has been shown to be a significant risk factor of neoplasm associated with appendicitis [250, 251]. Carpenter found all patients with noncarcinoid neoplasm presented with complicated appendicitis with perforation or abscess formation [248]. Wright studied over 6,000 consecutive patients [238]. Of the 188 patients who were treated with nonoperative management, 89 subsequently underwent IA. Appendix neoplasm was found in 11 of these, including 6 mucinous neoplasms and one adenocarcinoma. Interestingly, in patients over 40, 16% had some type of neoplasm. Smaller studies have found higher rates [249–251]. Conversely, in these older patients undergoing routine appendectomy, neoplasm was found in only 0.7%. These findings suggest that due to a significant risk of clinically important neoplasm, routine IA should be performed in all elderly patients (with complicated appendicitis) medically stable enough to withstand surgery. Furthermore, elective interval appendectomy lends itself well to the laparoscopic approach, as stressed by Greig and Nixon [252]. Thus, nonoperative first-line treatment of complex appendix disease, with interventional radiologic help allows conversion from acute emergency operation with its attendant increase in complications to elective IA. This path should always be entertained when dealing with complex appendix disease in the elderly.

Ileocecal resection and primary anastomosis are reserved for the markedly inflamed cecum. Rarely, resection cannot be performed safely because of the inflammatory reaction. In these cases, irrigation and drainage are performed, and interval appendectomy is scheduled for 6–12 weeks later. The reader is referred to general surgical textbooks for the detailed operative technique.

Lau et al. [209] found a 38% perforation rate in old patients operated on within 24 h of the onset of symptoms, suggesting aggressive disease. Wolff and Hindman [253] agreed, finding a perforation rate of 41% in old patients with onset of symptoms within 24 h of operation. However, Burns et al. [208] found that one-third of young and old patients operated within 24 h had perforation. Von Tittle [254] also found that roughly one-third of old patients with perforation had symptoms less than 24 h. Older patients present with perforated disease at a much higher rate than the young.

Complicated Appendicitis: Differences Between Young and Old Patients

Luckmann [196] found that only 53% of patients over age 80 in California had their operation on the day of admission, compared to more than 80% of young patients. More impressively, in patients with abscesses, more than 85% of young patients had operations within 1 day of admission, compared to only 57% of those older than 80 years. This further attests to the difficulty accurately diagnosing and treating acute appendicitis in the elderly. One study revealed that 17% of elderly patients were treated without accurate diagnosis prior to being admitted with acute appendicitis [214]. Incorrect diagnosis rates in the elderly are as high as 25% [255].

In-hospital observation has been shown to decrease negative operative rates safely without increasing the perforation rate [255, 256]. This suggests that the out-of-hospital delay is most important for determining the aggressiveness of disease. Lau et al. [209] found a statistically significant increase in perforation rates in elderly patients when surgeons delayed operation for more than 25 h. Klein [216] also found increased perforation and abscess rates in old patients with increasing delays of operation. Because of the difficulty diagnosing old patients, attempting to decrease perforation rates through hospital observation in the elderly is unwise.

Many authors have examined laparoscopic versus open appendectomy [256–261]. One prospective randomized study found that patients used fewer analgesics and returned to full activities sooner compared to those exposed to conventional operative techniques [260]. Some have found fewer wound infections with laparoscopic techniques [262–264]. A large comparative study and a prospective randomized study both found advantages for laparoscopic approach to appendicitis, without increased abdominal abscesses [265, 266]. One obvious advantage of laparoscopic appendectomy is the ability to view the entire abdomen and pelvis in cases where the diagnosis is in question.

Konstantinos [267] examined more than 1,000 consecutive laparoscopic operations for suspected appendicitis. They had a conversion rate of less than 1% and 1.1% wound infection rate with no intra-abdominal abscesses or deaths, despite a 14% ruptured or gangrenous appendix rate and 4% having intra-abdominal abscesses. They also found significantly shorter hospital stays and quicker return of bowel function. Paranjape [268] examined three different time periods and how laparoscopy changed outcomes in the elderly. They found an increased use of CT scanning, fewer patients presenting with classic symptoms, increased correct admission diagnoses, fewer perforations, and fewer complications in the most recently treated group. They also found shorter hospital stays with laparoscopy. Their operative time was similar for both open and laparoscopic approaches.

Laparoscopically treated appendicitis in elderly North Carolina residents has been studied as well [269]. The patients who underwent conventional and laparoscopic operations were comparable with regards to age, gender, and comorbidities. Fifty-five percent presented with perforated appendicitis. There was a steady increase in laparoscopic use over time, rising from 11.9% in 1997 to 26.9% in 2003. Advantages found in the laparoscopic group includes shorter length of stay (4.6 vs. 7.3 days), higher rate of discharge to home (91.4% vs. 78.9%), fewer complications (16.3% vs. 20.8%), and a lower mortality (0.4% vs. 2.1%). As important is overall hospital costs, which shows a trend for lower total costs for the laparoscopic group, $17,031 vs. $19,587.

Conclusion

In conclusion, 10% of all appendicitis occurs in the elderly. Older patients present atypically and often delay seeking medical treatment. Diagnosis is difficult owing to blunted symptoms and response to inflammation. Perforation occurs more frequently and possibly faster than younger patients. High index of suspicion and liberal use of CT scanning can facilitate correct diagnosis. Interval appendectomy should be performed in those treated nonoperatively for perforating disease due to increased risk of neoplasm. Laparoscopic technique decreases complications, shortens hospital stay, increases home discharge, and is not associated with increased hospital costs (Figs. 1, 2, 3, 4, and 5).

Lower Gastrointestinal Bleeding in the Elderly

58

Hadley K. Wesson and Michael E. Zenilman

Contents

Abstract

This chapter will discuss common causes, clinical assessment, and the medical and surgical management of lower gastrointestinal bleeding in the elderly. The chapter will outline how this approach differs from a younger patient population and address the unique needs of the elderly.

Case Presentation: Diverticular Bleeding

A 75-year-old woman presented to the emergency department with bleeding per rectum. She was tachycardic and hypotensive. She had a past medical history diverticulosis, seen on colonoscopy 10 years earlier. Her rectal exam was negative for any palpable masses, but a large amount of dark blood was noted on her gown and on digital rectal exam. Two large bore IVs were started and infused with normal saline boluses. She responded well and her vital signs normalized. Her hemoglobin was noted to be 8.5 g/dl; as such, she did not require a blood transfusion at this time. An upper gastrointestinal bleed was considered as a source, and she underwent gastric lavage in the emergency department via placement of an NGT. This was negative and her vital signs remained stable. The gastroenterology

R. A. Rosenthal et al. (eds.), *Principles and Practice of Geriatric Surgery*,
https://doi.org/10.1007/978-3-319-47771-8_75

service was consulted for a colonoscopy, but they did not think at the time she would tolerate the prep needed to undergo a colonoscopy. As such, she underwent a CT angiography that showed no evidence of an active bleed. Extensive colonic diverticula were noted on CT. She was admitted for observation, and clinically, she had no additional episodes of lower gastrointestinal bleeding. At the time of her discharge, she was instructed to follow up with gastroenterology for an elective colonoscopy which confirmed diverticulosis.

Case Presentation: Colorectal Malignancy
A 70-year-old man presented to his primary care provider with one episode of bleeding per rectum. His history was remarkable for fatigue and a recent 15 pound weight loss. He had never had a colonoscopy. His rectal exam was unremarkable except for a positive fecal occult blood test. He was hemodynamically stable and his hemoglobin was 9.5 g/dl. He was referred to gastroenterology for a colonoscopy that showed a large fungating mass of the right colon. The mass was biopsied and tattooed during the procedure. It was noted that it was not currently bleeding. Biopsies confirmed adenocarcinoma. He was then referred to surgery who proceeded to stage the malignancy. A CT of the abdomen, pelvis, and chest showed no signs of distant metastasis. Laboratory evaluations, including a CBC, chemistry, and CEA level, were remarkable for anemia and an elevated CEA. He underwent an uneventful laparoscopic right hemicolectomy. Following a review of the patient's pathology that showed T3 N1 adenocarcinoma, he referred to medical oncology to discuss chemotherapy options.

Introduction

Gastrointestinal bleeding is one of the most common causes of hospitalization due to gastrointestinal disease in the United States, of which lower gastrointestinal bleeding accounts for 30 to 40% of all gastrointestinal bleeds. The elderly are more likely to have a lower gastrointestinal bleed than younger adults. In fact, a retrospective review found an 80-year-old is 200 times more likely to have a lower gastrointestinal bleed than a 20-year-old [1]. While mortality from a lower gastrointestinal bleed is relatively low, advanced age is one of the strongest predictors of mortality [2, 3]. For these reasons, it is essential that the operating surgeon has a firm grasp of the causes and management of lower gastrointestinal bleeding in the elderly. In this chapter, we will outline common causes of lower gastrointestinal bleeds and an approach to management. We will also pay particular attention to special considerations that need to be made when caring for the elderly during a lower gastrointestinal bleed.

Causes of Lower Gastrointestinal Bleeding in the Elderly

Historically a lower gastrointestinal bleed was defined as any bleed distal to the ligament of Treitz. However, the American College of Gastroenterology's 2016 Guidelines redefined a lower gastrointestinal bleed as any gastrointestinal bleed isolated to the colon or rectum [4]. The guidelines also distinguish between acute and chronic bleeding. An acute lower gastrointestinal bleed commonly presents with melena or hematochezia and can be accompanied with hemodynamic instability. In contrast, a chronic lower gastrointestinal bleed may result in a positive fecal occult blood test and is associated with iron deficiency [5]. Common causes of lower gastrointestinal bleeding in the elderly are diverticulosis, colonic angioectasias, malignancy, colitis, and anorectal disorders such as hemorrhoids (Table 1).

Table 1 Common causes of lower gastrointestinal bleeding in the elderly

Common causes of lower gastrointestinal bleed
Colonic diverticulosis
Colonic angioectasias
Colorectal malignancy
Inflammatory bowel disease
Ischemic colitis
Anorectal disorders

Diverticulosis

Diverticulosis is common in the elderly: in western populations, up to 50% of people greater than 60 years of age have radiographic evidence of diverticulosis [6]. As people age, the colonic wall weakens. This, along with increased intraluminal pressure, can result in diverticula. These protrusions occur where branches of the vasa recta perforate through the circular muscle fibers. Only the mucosa remains to act as a barrier between the vessel and the bowel lumen (Fig. 1). As the perforating vessels are exposed to chronic insult, the vessels can erode into the mucosa, resulting in bleeding. As much as 20% of elderly adults with diverticula will develop bleeding [7]. The vast majority of bleeding often stops spontaneously, but 5% of patients can experience life-threatening bleeding.

Colonic Angioectasias

Angioectasias are dilated tortuous submucosal veins found throughout the gastrointestinal tract, but most commonly in the cecum and ascending colon [8]. While the etiology is not fully understood, it is thought that these angioectasias develop from chronic, low-grade colonic contractions. This causes congestion and obstruction of the submucosal veins. In turn, the capillaries dilate, resulting in small arteriovenous collaterals and ultimately an arteriovenous malformation (Fig. 2) [8]. This malformation abuts the colonic mucosa and can cause bleeding. While colonic angioectasias can occur at any age, it occurs most frequently in the elderly, manifesting as severe hematochezia. Approximately 90% resolve spontaneously, but rebleeding can occur.

Colorectal Malignancy

Colorectal cancers are the third most common cancer in the United States. They cause 10% of hematochezia in the elderly, resulting from erosions of the surface of the tumor. While bleeding is common in colorectal cancer, occurring in up to 50% of patients, it is often low-volume and associated with anemia. Massive hemorrhage is uncommon in colorectal cancer [9].

Colitis

Lower gastrointestinal bleeding from colitis in the elderly occurs most commonly from inflammatory bowel disease or ischemia [6]. Inflammatory colitis is associated with bloody diarrhea due to the presence of friable, edematous mucosa. Among inflammatory bowel diseases, bleeding from ulcerative colitis is much more common

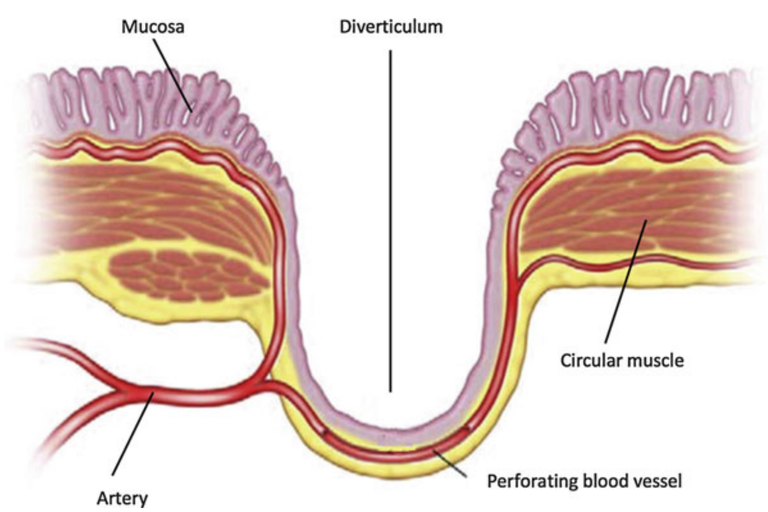

Fig. 1 Exposure of the perforating blood vessel in diverticulosis. (Adapted from [33])

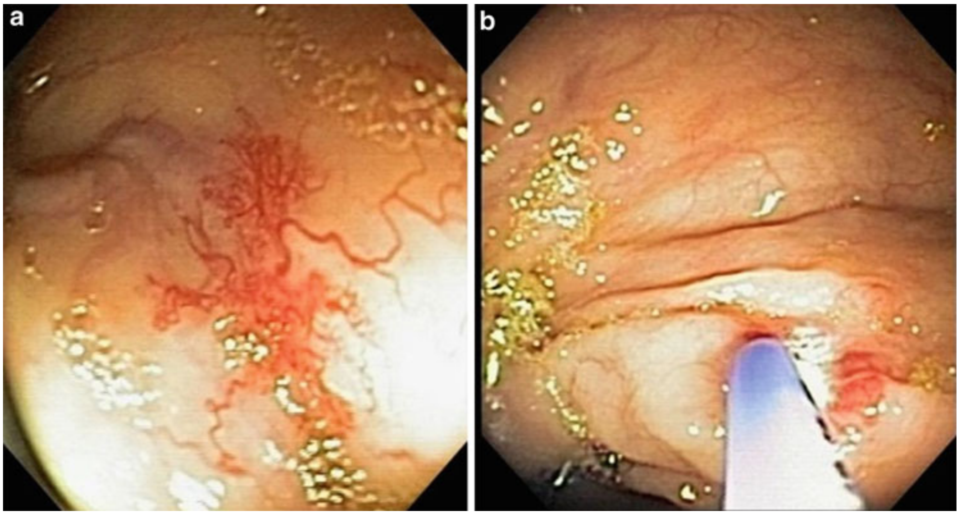

Fig. 2 (**a**) Colonic angioectasias as seen on colonoscopy. (**b**) Colonic angioectasias following argon beam ablation. (Image courtesy of Mahmood Solaiman, MD, Gastro Associates & Central Maryland Endoscopy)

than from Crohn's disease in the elderly. While massive bleeding from inflammatory colitis is thankfully relatively rare, it can result from pancolitis, which may necessitate emergent total abdominal colectomy.

Ischemic colitis can present with acute abdominal pain and bloody diarrhea: ischemia leads to mucosal friability and wall sloughing that can cause blood per rectum. Approximately 90% of colonic ischemia occurs in patients greater than 60 years of age. Comorbidities that increase the risk for either embolic or non-embolic ischemic events, such as arrhythmias or heart failure, also increase the risk of ischemic colitis. The severity of ischemic colitis can vary from mild transient colitis to fulminant gangrenous colitis. Symptoms can vary, but bleeding can occur at any stage of colitis [10].

Anorectal Disease

Benign anorectal disease, such as hemorrhoids and anal fissures, can cause lower gastrointestinal bleeding. The most common reported symptom of internal hemorrhoids is bleeding, typically associated with defecation and almost always painless [11]. Rubber band ligation of internal hemorrhoids can be a simple and effective way to treat hemorrhoidal bleeding. Bleeding from an anal fissure is usually self-limiting and resolves when the fissure can heal through the use of fiber supplementation, increased water intake, and/or topical calcium channel blockers [12]. Significant bleeding from anorectal diseases is rare.

Assessment of Lower Gastrointestinal Bleeding in the Elderly

History, physical examination, and laboratory evaluations are the essential first steps in assessing a patient with a lower gastrointestinal bleed. A history of syncope, signs of tachycardia, hypotension, or orthostatic hypotension are suggestive of a significant blood loss. Any patient, regardless of their age, with hemodynamic instability should be stabilized and resuscitated prior to undergoing any diagnostic testing. Lower gastrointestinal bleeds are usually slower and less severe that upper gastrointestinal bleeds. As such, when treating a patient with shock and blood per rectum, the clinician must consider an upper gastrointestinal bleed as a possible source. In this case, nasogastric lavage and upper endoscopy are useful to identify the cause of the bleed (Fig. 3).

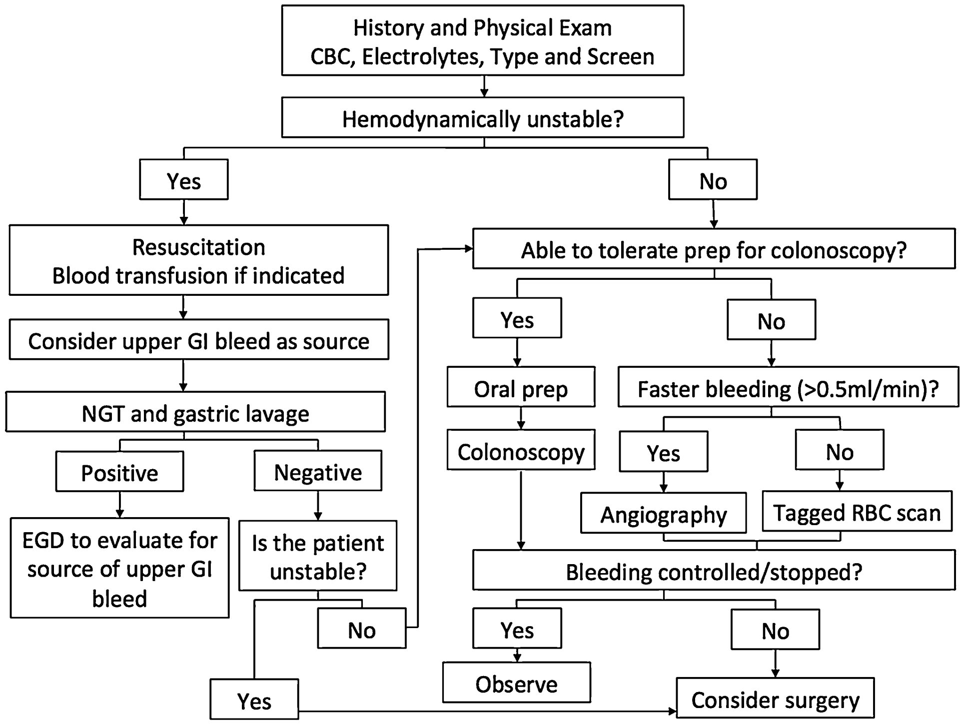

Fig. 3 Approach to a lower gastrointestinal bleed in the elderly

It is important to clarify the nature of the bleeding, such as the color, amount, frequency, and duration to help establish a differential diagnosis [13]. It is equally essential to assess the presence or absence of abdominal pain and have the patient describe the pain. Understandably, this history can be difficult and time-consuming to obtain especially in the elderly but all the more worthwhile if the practitioner can narrow their differential diagnosis to direct management [14]. For example, colorectal malignancy, diverticular bleeding, and angioectasias are typically painless, while abdominal pain with loose bloody stools may be more likely due to colitis.

Obtaining an accurate medical history is never more paramount than in the elderly, as cardiopulmonary, renal, and hepatic dysfunction are associated with an increased risk in mortality and morbidity [15]. Additionally, reviewing and confirming the accuracy of the patient's medications are important steps in the assessment. The practitioner should keep in mind that some medications that are more prevalent in the elderly, such as aspirin, antiplatelet, and anticoagulation agents, can cause or exacerbate a lower gastrointestinal bleed.

An elderly patient may not be able to acutely articulate their history, especially if they are in distress or discomfort. Family members, other advocates, and the patient's primary care provider are essential in contributing to this history. Every effort must be made to contact these individuals to understand not only the context in which the patient has experienced the bleed but also to understand up front the patient's wishes regarding further medical treatment [16].

Once a history has been obtained, a complete physical exam is important, including vital signs. Cardiac and pulmonary exam findings may add to the patient's overall assessment. In the case of the elderly, this may influence their treatment options including their ability to tolerate surgery, should that be deemed necessary. Physical exam findings include an abdominal exam, which may reveal tenderness or distention.

A rectal exam should be performed in all patients presenting with lower gastrointestinal bleed; arguably this part of the exam has been overlooked in recent years with radiographic advancement, leading some to cunningly deem it "a lost art." [17] We argue this part of the exam should not be missed. The rectal exam is an opportunity to assess for hematochezia and anorectal pathology, such as hemorrhoids. Anoscopy may also be of use if the source of the lower gastrointestinal bleed is thought in the lower rectum or anal canal. It is important to note the presence of gross blood, as this is an independent predictor of the severity of the lower gastrointestinal bleed [18]. Given that an elderly patient may have limited mobility, performing a rectal exam may be more difficult and cumbersome for the provider. As such, it is important to ask for assistance from nursing and other healthcare providers to ensure the patient can be safely positioned on their side to allow for an adequate exam.

Laboratory tests should be performed on all patients presenting with lower gastrointestinal bleed and should include a CBC, electrolytes, a clotting profile, and a type and screen. Lactate levels may also be useful in guiding resuscitation for a patient in shock [19].

Management of Lower Gastrointestinal Bleeding in the Elderly

The initial management begins with resuscitation, especially if the patient is hemodynamically unstable. Resuscitation must be implemented with caution in elderly patients who may have cardiac comorbidities and cannot tolerate aggressive intravenous fluid. Blood transfusions are recommended cautiously, keeping in mind current national recommendations regarding when and how to transfuse. One unit of packed red blood cells should be administered when the patient's hemoglobin drops below 7 g/dl. However if significant comorbidities are present, such as cardiovascular disease, current guidelines recommend the threshold to transfuse be increased to 9 g/dl [4].

Once the appropriate resuscitation measures are underway, the next step in management is to determine the source of the bleeding. There are multiple choices in terms of which intervention is most appropriate for the patient, including colonoscopy, computed tomographic angiography, mesenteric angiography, and nuclear scintigraphy. There is a lack of evidence within the literature as to the optimum initial approach to management. As such, most experts agree the physician should be aware of the advantages and disadvantages of each of these choices and make the best decision for the patient based on their presentation at the time of the bleed [20].

Although no one test has emerged as the gold standard in the management of lower gastrointestinal bleed, colonoscopy is often considered the initial procedure of choice [4, 21]. It can be both diagnostic and therapeutic. This should be performed urgently, when the patient is stable and is able to tolerate a bowel prep. Studies show that colonoscopies performed early within the 24 h of admission are associated with higher rates of diagnosis and hemostasis and a decrease in hospital length of stay [20, 22, 23]. Current guidelines recommend a bowel prep consisting of 4–6 L of polyethylene glycol solution over a 4-h period [4].

While colonoscopy is usually well tolerated, elderly patients are at a higher risk for complications than younger adults [12]. Yet despite this, the benefits of a diagnostic and therapeutic colonoscopy appear to outweigh the risks in the setting of a lower gastrointestinal bleed. This is true for even the very elderly patients [24]. Thus it is widely agreed upon that the age of the patient should not prohibit the gastroenterologist from proceeding with the procedure; it should however inform both the gastroenterologist's and the anesthesiologist's approach to the patient [12].

Therapeutically, colonoscopy offers the ability to provide endoscopic hemostasis. These methods include diluted epinephrine injection, thermal coagulation, and mechanical therapy. Thermal coagulation includes bipolar electrocoagulation, heated probe, or argon beam. Mechanical therapies include endoscopic clips or band ligation. Diluted epinephrine injection should be used in combination with thermal or mechanical therapies to minimize the risk of recurrent bleeding [4].

Lower gastrointestinal bleeding caused by diverticulosis and angioectasias is more likely to benefit from endoscopic hemostasis. Mechanical therapy with endoscopic clips is recommended for treatment of diverticular bleeding [25]. Given that the wall of the diverticulum is thin, clips theoretically reduce the risk of bowel perforation compared to thermal coagulation [4]. Argon beam coagulation is the preferred treatment for colonic angioectasias because it is associated with a shorter depth of tissue injury [4]. Approximately 85% of bleeding from colonic angioectasias will resolve with argon beam (Fig. 2) [8]. Coagulation with hot biopsy forceps is currently not recommended for the treatment of colonic angioectasias because it is associated with a high risk of serious complications, including perforation [8]. Patients who experience recurrent bleeding after achieving hemostasis with colonoscopy may be candidates for repeat colonoscopy.

Lower gastrointestinal bleeding from ischemic colitis, ulcerative colitis, and colorectal malignancy are usually not amenable to endoscopic hemostasis, although colonoscopy may help to localize the site of the bleed.

Historically, angiography was reserved for the treatment of upper gastrointestinal bleeding. However, recent advances in the field have enabled transcatheter angiography with super-selective embolization to emerge as the treatment of choice for some cases of lower gastrointestinal bleeds [26]. Angiography is now a preferred modality for patients with brisk bleeding who are not stable enough for colonoscopy or who would not tolerate an adequate bowel prep. Angiography however may be negative and thus of little yield for intermittent or slower bleeds (<0.5 ml/min) [13]. Angiography is also therapeutic: it allows for super-selective embolization of arteries less than 1 mm in diameter with the use of microcoils, absorbable gelatin sponges, cyanoacrylate glue, or ethylene vinyl (Fig. 4) [13].

CT angiography and radionuclide technetium-99 m-labeled red blood cell scintigraphy, also referred to as a tagged red blood cell scan, can be used to diagnose lower gastrointestinal bleeds. While tagged red blood cell scans can detect bleeding rates as low as 0.1 ml per minute, recent studies suggest that CT angiography is also highly sensitive and specific at identifying the site of active bleeding [13, 27, 28]. Although not therapeutic, both studies are important tools to localize the bleed (Fig. 5). If patients fail or cannot tolerate other therapeutic interventions, such as colonoscopy or angiography, and surgery is recommended, it is important that every effort is made preoperatively to localize the bleeding and potentially avoid a subtotal colectomy. In this setting, CT angiography and scintigraphy can be of tremendous benefit.

A surgical consultation is indicated for patients with ongoing lower gastrointestinal bleed who have failed endoscopic or radiographic attempts to stop the bleed. While currently considered a “last resort” option, surgery is required in approximately 10–25% of patients with lower gastrointestinal bleeds [19]. One noted exception is in the case of hemorrhaging colorectal cancer, where surgery may be the most effective and definitive treatment. Other indications for surgery are hemodynamic instability after transfusion of more than six units of blood, slow bleeding requiring more than three units of blood per day, inability to stop bleeding via colonoscopy or endovascular attempts, and recurrent hemorrhagic shock [9].

As previously emphasized, localization of the bleed is essential prior to surgery to prevent a missed lesion or subtotal colectomy. If it is not possible to localize the bleed within the colon or rectum, and an upper gastrointestinal bleed has

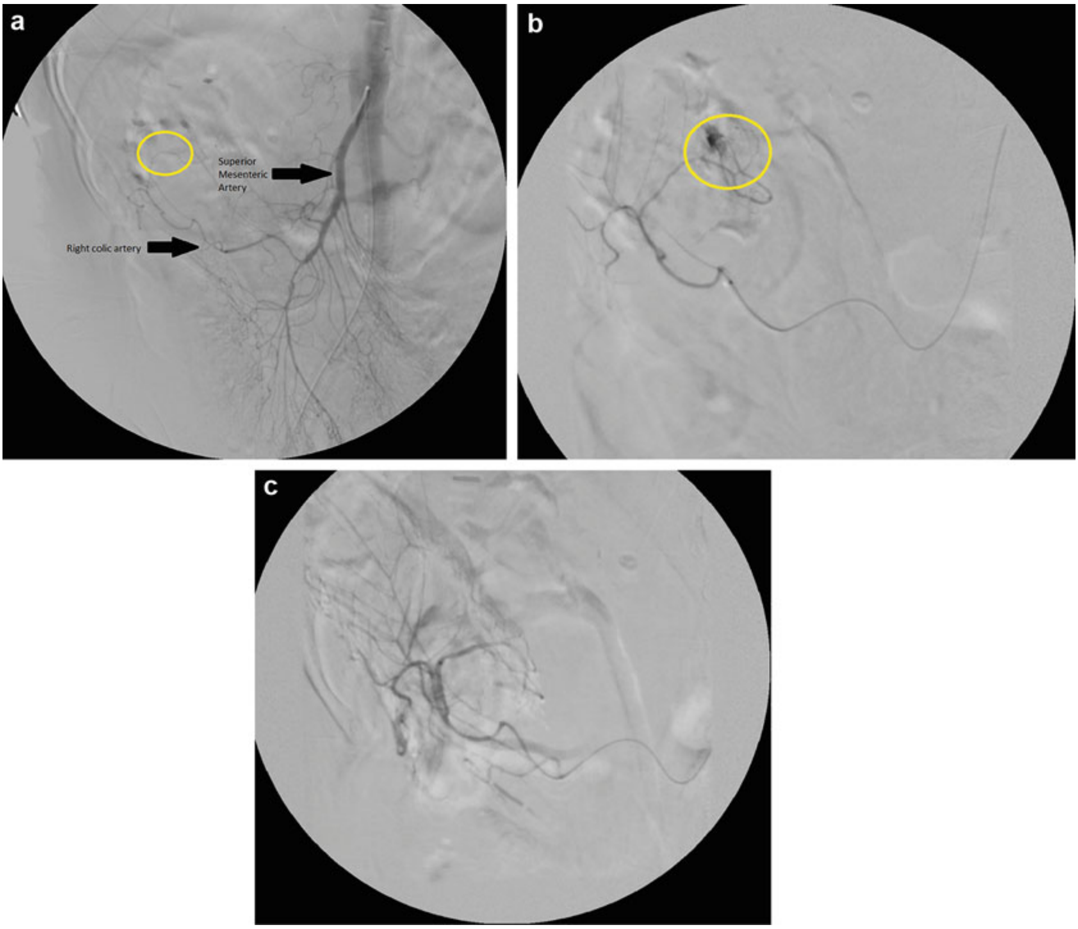

Fig. 4 (**a**) Angiogram in an 83-year-old woman with an acute lower gastrointestinal bleed from right colic artery terminal branches at the hepatic flexure (yellow circle). (**b**) Angiogram in an 83-year-old woman with an acute lower gastrointestinal bleed from right colic artery terminal branches at the hepatic flexure showing blush (yellow circle). been ruled out, a subtotal colectomy may be indicated. While the operative techniques, whether laparoscopic or open, remain the same regardless of age, the surgeon must take into account the elderly patient's comorbidities and frailty before, during, and after the surgery [29].

Many studies confirm that older populations undergoing urgent surgery have a higher risk of postoperative mortality and morbidity [30]. Efforts should be made before surgery to discuss these risks with patients and their families. This can ensure the patient's goals of care are not only recognized by the medical team but are also met throughout the patient's hospitalization [31]. Prior to emergent or urgent surgery in the elderly, screening tools such as the frailty index score or the Vulnerable Elders Survey may be of benefit to the surgeon in predicting postoperative complications and length of stay [30, 32].

Conclusion

The aging population in the United States will continue to grow, and lower gastrointestinal bleeds will continue to be more prevalent in

Fig. 5 Radionuclide technetium-99 m-labeled red blood cell scintigraphy in an 83-year-old woman that localized an acute lower gastrointestinal bleed to the hepatic flexure. (Image courtesy of Andrew Morton, MD of American Radiology)

our hospitals. When assessing and managing a lower gastrointestinal bleed in the elderly, the approach should be multifaceted involving the gastroenterologist, surgeon, radiologist, geriatrician, family members, and the patient themselves. Through a thoughtful and timely approach, we can strive to provide excellent medical care and ensure we are listening to and meeting the needs of our patients.

Hip Fracture

Contents

Abstract

Hip fracture is a common injury in older adults. Hip fractures are fragility fractures and caused by osteoporosis and a propensity for falls. Classification is according to fracture morphology and the type of fracture guides for surgical treatment. Most patients sustain a low-energy fall and cannot walk after breaking their hip. They are admitted through the emergency department to the hospital. Urgent surgical repair gives the best outcomes and should be performed as soon as feasible. Femoral neck fractures are generally treated with arthroplasty, while intertrochanteric and subtrochanteric fractures are treated with internal fixation. Internal fixation is either with a sliding hip screw and side plate or intramedullary hip screw. A coordinated approach using medical co-management allows for early surgery and reduction in postoperative complications. Standardization of orders reduces errors and prevents the use of unnecessary tests and medicines which harm elderly patients. Patients should be allowed to bear weight as tolerated after surgery and mobilized quickly. Treatment of osteoporosis to prevent further factures is important to prevent future fractures. Mortality

Hip fracture · Femoral neck fracture · Intertrochanteric fracture · Delirium · Atypical fracture · Osteoporosis · Fragility fracture

Introduction

Hip fracture is a common injury in elderly patients resulting from a low-energy fall. Hip fractures are treated surgically with either repair or replacement. The surgery should be performed urgently to reduce risk of postoperative complications. A coordinated team approach to management between a medical doctor and orthopedic surgeon gives optimal results as patients usually have multiple medical comorbidities. The use of standardized order sets helps to minimize mistakes and medicines that harm elderly patients and reduce the use of unnecessary tests. In the postoperative period delirium, urinary retention and congestive heart failure are common occurrences and should be prevented. Early mobilization with full weight bearing helps to decrease risks of blood clots and pressure ulcers. A rehabilitation stay is common after hip fracture to strengthen patients to get back home. Overall mortality rates are substantial after hip fracture, and many patients do not return to their previous level of function.

Preoperative Care

Hip fracture is a low-energy injury in patients with weak bones. Patients often are frail and have medical comorbidities that increase their risk of falling. Osteoporosis leads to a high risk of fracture with each fall. Injuries are most commonly a fall from standing height and result in an inability to walk. Patients with a hip fracture may be found down and may have been without care for significant periods of time. Most commonly patients are taken to the emergency room. The leg is often rotated externally and shortened and motion of the limb is very painful. Diagnosis is made with

Fig. 1 A magnetic resonance image with T2 weighting is shown of the hip. A stress fracture is seen in the calcar area of the femoral neck

plan radiographs which reveal the fracture in almost all cases. If a fracture is not seen on x-ray, magnetic resonance imaging (MRI) is the next best test to look for occult fracture (Fig. 1) [1]. Other diagnoses in the differential include pelvic fractures, which are also a common fragility fracture.

In some circumstances, geriatric patients in a high-energy trauma also may sustain a hip fracture. These patients are often multiply injured. In this situation, trauma protocols must be followed. Resuscitation must be performed and life-threatening injuries treated. Elderly patients have less reserve and may be more profoundly affected by multi-system trauma. When the patient is stabilized and resuscitated, the hip fracture should be surgically repaired to allow for mobilization.

Standardized order sets are best practice in the emergency room. Lab should be ordered to assess hemoglobin, electrolytes, and prothrombin time. Electrocardiogram should rule out acute coronary syndrome. A full history and physical exam needs to be performed to look for acute medical conditions. Patients often have dementia and may come from a nursing facility. Obtaining records of the patient's medical conditions should be a top priority. Of importance is an accurate medication list to see if the patient is on a blood thinner medication. Patients with a hip fracture are typically dehydrated due to blood loss from the fracture and from the time spent before being found down. Intravenous fluids should be started with normal saline at 150 ml/h [2].

The goal of the preoperative phase is early surgical repair. Early surgery decreases complications and morbidity. Precisely how early surgery should occur is debated. In the United Kingdom, the hip fracture audit has picked 36 h as the goal to surgery. The goal is that the sun should not set twice on a hip fracture [3]. The American Academy of Orthopaedic Surgery guidelines have suggested surgery within 48 h [4]. Preliminary results have shown that ultra-early surgery, within 6 h, may give even better results [5]. Delay does nothing but increase time in pain, increase time in which complications can occur, and increase length of stay in the hospital as well as cost of care. Specific medical problems should be addressed promptly and surgical repair performed urgently.

Testing should be minimized prior to surgical repair. There is very little role for echocardiograms or stress tests. Echocardiograms should be reserved for only patients with suspicion of severe pulmonary hypertension or aortic stenosis. In these cases, knowledge of heart function will change anesthetic management. Specialist consultation should also be avoided. These tests are unlikely to change management and will cause delay [6].

Pain should be managed and not ignored. Initially low doses of narcotic pain medicine should be given to achieve pain relief [7]. The use of nerve blocks has been shown to be very beneficial for hip fracture patients. This can be done in the emergency room to give pain relief without the side effects of narcotic pain medication. Fascia iliaca nerve block can be performed by trained emergency room doctors or anesthesiologists [8]. Patients should be rapidly admitted to the hospital so that they can be on a hospital bed rather than a stretcher [9]. Traction is not helpful and does not improve pain control [7].

Careful attention should be paid to medication review with geriatric principles in mind. The Beers list was developed by the American Geriatrics Society, and this list shows medication that are harmful to elderly patients [10]. Standardized orders will prevent the use of medications such as meperidine or diphenhydramine which are known to promote delirium. Many patients with hip fracture have pre-existing dementia that may or may not be complicated by delirium [11]. A mental status evaluation is important to recognize cognitive impairment. A mini-cog test should be performed to determine if dementia is present. In the hospital, the CAM score can be used by nursing staff to look for delirium. The small things are important to prevent delirium. Hearing aids and glasses are potentially lost in the transfer to the hospital, and without these, many elderly patients cannot see or hear making delirium very likely. Emergency rooms are also loud busy places, and early floor transfer helps to calm patients.

Getting early involvement from family should be started in the emergency room. Patients may not be able to give informed consent for surgical repair on their own. DNR orders may already exist, and these are very important to institute during hospitalization. Discharge planning should begin at hospital admission as most patients with hip fracture cannot go directly home after surgical repair.

The goal of this first phase of care is early surgery. Acute medical conditions such as dehydration need to be rapidly addressed. A problem in 20–30% of hip fracture patients is the use of blood thinning medicines prior to the fall. The use of aspirin and clopidogrel should not delay surgical repair [11]. Warfarin should be rapidly reversed to lower the INR. The precise INR needed for surgical repair is debated. The use of oral and intravenous vitamin K should be given in the emergency room. The INR can then be rechecked. If still elevated, fresh frozen plasma should be given to reverse the anticoagulation [12]. Direct oral anticoagulants (DOAC) are becoming more popular and pose problems for the surgeon as they are not easily reversible. Little data exists about how much time should elapse prior to surgery when a patient is on a DOAC. Probably, surgery should be delayed based on the hall life of the medication, usually in the range of 48 h [13]. This is one of the few recommended delays prior to surgical repair.

Surgical Treatment

Surgical treatment is based on fracture type [14]. The hip can break in three main areas, the femoral neck, the intertrochanteric region, and the subtrochanteric region (Fig. 2). Femoral neck fractures may be nondisplaced or displaced. Nondisplaced fractures can be treated either with screw fixation or arthroplasty. Internal fixation of displaced fracture has a high failure rate, and randomized studies have shown arthroplasty to be superior [15, 16]. Healing potential is limited in the femoral neck. Displaced fractures are best treated with arthroplasty. This may either be partial or total hip replacement (Fig. 3). The type of arthroplasty utilized is based on the activity level of the patient. Active patients have less pain and superior outcomes with total hip arthroplasty [17]. Less active patients do not benefit from total hip arthroplasty and are best treated with hemiarthroplasty. Total hip arthroplasty has a higher rate of dislocation than hemiarthroplasty [18]. It is recommended that a cemented stem be used for hip fracture patients as there is a lower risk of periprosthetic fracture and loosening than if a uncemented stem is used [15, 19]. This is due to the poor bone quality found in hip fracture patients.

Intertrochanteric fractures occur in the metaphysis of the bone that has far superior healing

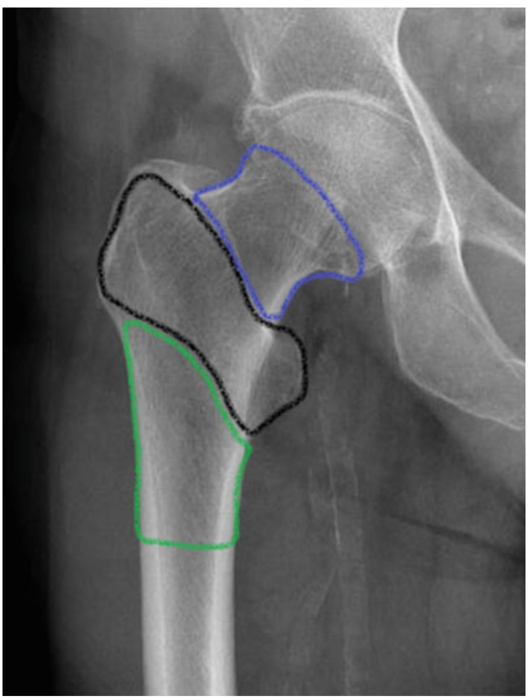

Fig. 2 Typical fracture patterns in the hip: the blue area highlights the femoral neck, the black area is the intertrochanteric and the green area is the subtrochanteric region of the proximal femur

Fig. 3 An AP radiograph of the hip shows a cemented partial hip replacement or hemiarthroplasty. The acetabulum is left unresurfaced, and the metal of the arthroplasty interfaces with articular cartilage

characteristics than the femoral neck. These fractures are treated with internal fixation. This may either be with a sliding hip screw and side plate (Fig. 4) or an intramedullary hip screw (Fig. 5). Depending on the amount of fracture fragments and the direction of the fracture, some intertrochanteric fractures are more innately stable than others. The stable fractures are best treated with the sliding hip screw and side plate. Unstable fractures, especially reverse oblique fractures, are best treated with an intramedullary hip screw [20]. Technique is important when hip screws are used. Fracture reduction should be obtained first prior to screw insertion. The screw should be inserted centrally and deep in the head to prevent screw cutout [21].

Subtrochanteric fractures are below the level of the lesser trochanter and should be treated with intramedullary hip screw. One type of subtrochanteric fracture pattern is the atypical fracture. These fractures develop from long term (>5 years) of bisphosphonate therapy [22]. Bone turnover is turned off, and an area of brittle bone forms usually in the subtrochanteric femur. A stress fracture then develops and the femur breaks. In these cases, intramedullary hip screw is used

Fig. 4 A sliding hip screw with side plate is pictured in an AP image radiograph of the hip. This device is used to treat stable intertrochanteric fractures that have an intact lateral buttress to allow the device to have an end point to sliding. The screw is a separate piece from the side plate. The screw slides within the barrel of the side plate to allow fracture compression with weight bearing

Fig. 5 An AP radiograph of the hip shows an intramedullary hip screw. This device is used for unstable devices. The intramedullary nail acts as the lateral buttress to provide an end point for the sliding hip screw

for treatment. Medical treatment of the frozen bone is critical. Bone turnover markers should be assessed and bisphosphonates stopped. A metabolic bone consultation is needed to follow this long term. These fractures take longer to heal than routine subtrochanteric fractures [23].

The type of anesthesia for hip fracture has been debated. Overall no differences have been seen between spinal and general anesthesia in outcomes or delirium rates [24].

Postoperative Care

Early mobilization is critical after hip fracture repair. All patients should be allowed to weight bear as tolerated [25]. If the surgeon does not feel that the repair is adequate to allow for this, then the wrong surgical technique was chosen. Patients should be mobilized out of bed to chair the day of surgery and should eat all meals in a chair. Physical therapy evaluation is necessary, and a walker should be used for ambulation. Patients may have pre-existing mobility problems prior to the fracture. In some cases, the robust patient with a hip fracture may be able to be discharge directly home from the hospital. In most cases, further post discharge rehabilitation is required. In the United States, this is either an acute rehabilitation center or a subacute nursing facility. These facilities should develop a plan for the patient to continue mobilization and strengthening and hopefully allow for discharge back to the pre-fracture environment. At 1-year follow-up after hip fracture, there is a mortality rate of about 20–30%. About half of patients returned to their pre-existing activity levels, and the other half require more ambulatory aids.

Thromboprophylaxis is important for hip fracture patients. Without treatment, rates of deep vein thrombosis or pulmonary embolism are high. Early surgical repair and mobilization are important factors in prevention. Mechanical compression devices should be started in the emergency department. After repair, some type of thromboprophylaxis should be utilized for a minimum of 3 weeks. Current guidelines recommend warfarin, low molecular weight heparin, or direct thrombin inhibitors [26].

Postsurgical medical care is best with co-management. In this model of care, both a medical physician and a surgeon manage the patient and can write orders. Communication and organization are very important so that each team knows what they are responsible for. Co-management allows for the medical physician to become a true peri-surgical specialist, able to expect routine postoperative problems such as congestive heart failure or urinary tract infection and to prevent and treat these promptly [27].

Fracture prevention is critical and should be started at the time of hip fracture. Hip fracture patients have osteoporosis and are at high risk for future fractures. Osteoporosis workup and treatment should be started at admission. Vitamin D levels should be checked and repletion given. Coordination after discharge for osteoporosis care is difficult, and a system must be organized. The best situation is a fracture liaison service with osteoporosis clinic [28]. In this situation, follow-up with the surgeon and the osteoporosis clinic happens at the same place and visit. The importance of osteoporosis care can be stressed with the patient and family. Bisphosphonates play a large role in initial treatment of osteoporosis [29]. Another aspect to fracture prevention is a fall prevention screening. This is best performed when the patient is to be discharged home and should involve a home visit to remove rugs and prepare the dwelling to minimize the risk of future falls [30].

System Improvements

The use of an organized hip fracture service has led to both improved care and less expensive care [31]. The idea of value is very important. By decreasing costs and improving results, value is created. The use of basic principles of a hip fracture service has been shown to improve value. This includes standardization of order sets, co-management, and early surgery. By standardizing the process, errors can be reduced or eliminated. For the hip fracture patient, this is by elimination of unnecessary tests and consults as well as elimination of medications that can harm the elderly patient. Standardization of osteoporosis care will lead to fracture prevention. Co-management allows for experts to care for these complex patents. Complications can be avoided. Early surgery helps to reduce length of stay and reduce the risk of iatrogenic mistakes. Patients are mobilized faster, take less opioid medications, and are at less risk for delirium and other complications.

Other models for care internationally have also been shown to improve care. The approach in the United Kingdom has been to develop nationally mandated rules for hip fracture care that are checked with live time observation. The National Hip Fracture Audit examines time in the emergency department, time to surgery, and use of geriatric co-management. These are reported and posted on a nationally available website. Hospitals falling below the standards are fined. A hip fracture database accompanies the audit to examine outcomes. This approach has led to a nationwide significant decrease in 1-month hip fracture mortality [32]. This type of reduction has not been seen with any other approaches. Clearly the development of national standards that are guided by payment is effective in improving care.

Scandinavian hospitals have led the world in providing high-quality randomized controlled studies and the use of hip fracture registries to guide our treatment decisions. Studies have shown that arthroplasty is better than internal fixation for displaced fractures and that total hip arthroplasty is better than hemiarthroplasty in active patients [16, 33–35]. The Trondheim hip study has examined the role of geriatric care and found that geriatric management with aggressive rehabilitation gives better results than management by the orthopedic surgeon [36].

In the United States, bundled payments are changing hip fracture care. Currently the mandated CCJR bundle involves all hip fracture patients who are treated with arthroplasty. Payments are the same as those who get elective total hip replacement. Fracture patients are clearly different and cannot be maximized before surgery. They also often need post discharge in patient care. These factures make bundling of hip fracture patients difficult [37]. The bundled movement is increasing with the start of SHFFT which will bundle care for the remaining femur fracture patients and is to start in 2018 [38]. This approach gives hospitals a set amount of money and allows them to spend it on patients as wisely as possible. This approach will strongly support the use of early surgery and co-management to lessen complications. It will really focus on post discharge care to minimize the time in a rehab unit and to maximize the return to home life [39].

Clinical Vignettes

Femoral Neck Fracture

An 88-year-old lady with a history of hypertension, previous breast cancer, and a previous stroke with some left-sided weakness fell onto her left hip. She lives at home with her husband and ambulates within the house with a walker. On exam, her leg is shortened and rotated, and motion

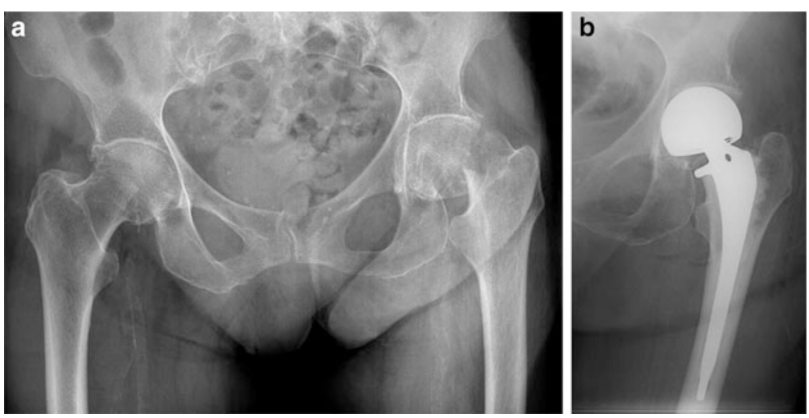

Fig. 6 Vignette 1 – femoral neck fracture. (**a**) AP radiograph at the time of injury of the hip shows a displaced femoral neck fracture. (**b**) AP radiograph of the hip shows a cemented hemiarthroplasty. The ball of the implant seems to be correctly sized, and the stem appears well cemented

of the hip is very painful. The left leg does have weakness as residual from the previous stroke. She does not take any medications for osteoporosis. Plan radiographs reveal a displaced femoral neck fracture (Fig. 6a). Options were discussed. With her poor bone quality, internal fixation is a poor option due to the very high rate of a second surgery. With her relative low function, hemiarthroplasty is a better option than total hip arthroplasty. The benefits of hemiarthroplasty are higher joint stability with lower dislocation risk. The downside is possibly higher rate of subsequent pain in the hip. In low-activity patients, this risk is minimized. She underwent a cemented hemiarthroplasty without complication (Fig. 6b). She left the hospital for a subacute nursing facility and went home 3 weeks later where she continues to use the walker for ambulation. Previous stroke is set up for weaker bone due to disuse osteopenia and higher rates of falls due to muscle weakness and poor balance. The patient was referred for metabolic bone evaluation for vitamin D repletion and bisphosphonate treatment.

Intertrochanteric Fracture

An 88-year-old lady who lives with her son at home fell and had a hip fracture. She had previous coronary bypass surgery in the distant past. She was admitted to the hospital and that evening underwent fracture fixation. She had a stable two-part intertrochanteric fracture (Fig. 7a), and a sliding hip screw with side plate was used for fracture fixation (Fig. 7b). She was started on immediate full weight bearing. Two days after surgery, she was discharged home with her family. She was doing well but developed pneumonia and was rehospitalized. She had a subsequently second rehospitalization for congestive heart failure. At the 6-week point, she was home and doing well with ambulation. She was having no pain in the hip. She was started on vitamin D and calcium. This case illustrates the complex medical condition of elderly patients with hip fracture. Two readmissions occurred after her fracture fixation for medical problems.

Atypical Hip Fracture

A 65-year-old lady was walking and felt her hip snap. She fell and was found to have a hip fracture. She has a history of ibandronate use for 10 years. She has a history of hypertension and rheumatoid arthritis and takes methotrexate and prednisone. She was found to have a displaced subtrochanteric femur fracture

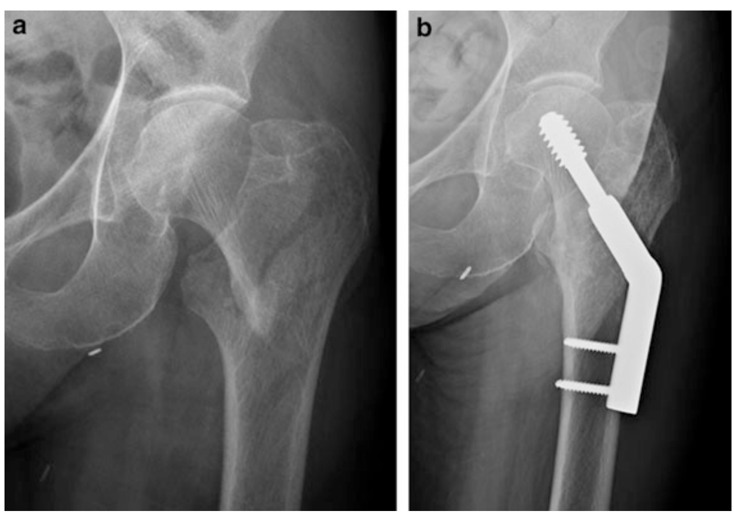

Fig. 7 Vignette 2 – intertrochanteric fracture. (**a**) Shows the injury radiograph with a two-part intertrochanteric hip fracture. (**b**) The radiograph shows the fracture fixation with sliding hip screw and side plate

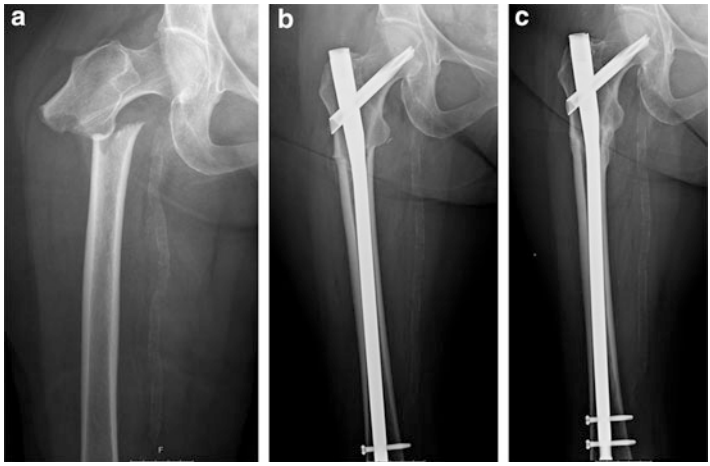

Fig. 8 Vignette 3 – atypical hip fracture. (**a**) Injury radiograph shows a displaced subtrochanteric hip fracture. The fracture line is horizontal in direction. (**b**) AP radiograph shows the intramedullary hip screw used for fracture fixation. The fracture is well aligned. (**c**) One-year postfracture radiographs show healing of the fracture with no change in rod position

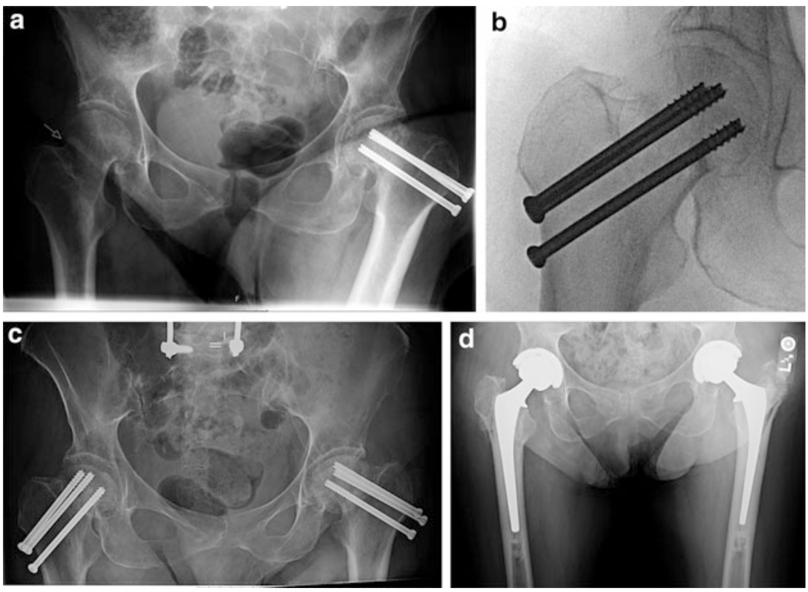

Fig. 9 Vignette 4 – failed screw fixation. (**a**) This AP radiograph shows an acute femoral neck fracture on the right hip. The arrow points to an impacted minimally displaced fracture. The left hip has cannulated screw fixation from previous fracture with a healed shortened fracture. (**b**) Intraoperative fluoroscopy shows the fracture fixation with three cannulated screws in good position. (**c**) Follow-up radiographs show that the right hip has also collapsed and is markedly short with screw back out. (**d**) Both hips were treated with total hip replacement in sequential fashion. This AP radiograph shows the total hip replacements with uncemented acetabular components and cemented femoral components

(Fig. 8a). In hind sight, previous x-ray showed evidence of a thickening of the lateral cortex of the subtrochanteric area with impending fracture (Fig. 8b). The patient had an atypical femur fracture from bisphosphonate use. She was treated with intramedullary nailing and subsequent follow-up with the metabolic bone service (Fig. 8c). Her bone turnover markers were extremely low, and she was taken off of the bisphosphonates. Her fracture years have gone on to complete healing, and she has no pain in the hip (Fig. 8d).

Failed Screw Fixation

A 72-year-old lady with a medical history significant for coronary artery disease and peripheral vascular disease had previous bilateral hip fractures treated with screw fixation about a year ago (Fig. 9a, b). She has had progressive pain of both hips with shortening of the legs since her surgeries. Both hips are quite painful and very stiff, and she is now very limited in her activities of daily living. She is mostly in a wheelchair and can barely walk. She would like to get back to ambulation. She lives with her husband at home. Her x-rays showed evidence of collapse and shortening of both femoral necks with evidence of now posttraumatic osteoarthritis (Fig. 9c). On both sides, the screws have backed out significantly and are prominent. She had a malunion of the fracture on the left and a nonunion on the right. After discussing options, she proceeded with sequential bilateral conversion to total hip replacement. Cemented stems were used due to her poor bone quality and high risk of periprosthetic fracture (Fig. 9d). Subsequently, she has done very well. At latest follow-up she is walking with a cane and is living at home and is pain-free and very pleased with results.

Conclusion

Hip fracture is a common and life-threatening injury in older patient. Fractures occur due to low-energy falls, and patients often have multiple medical comorbidities. Treatment is surgical with fracture repair that depends on the exact fracture type. Femoral neck fractures are treated with arthroplasty, while intertrochanteric fractures are treated with internal fixation. Early surgery and prevention of complications are crucial to success. This is best achieved with standardized order sets, streamlined care, and medical co-management. Despite best efforts, mortality is high and loss of function common.

Abstract

Total joint replacement has developed over the past 50 years into a reliable surgical procedure. Arthritic joints are routinely excised and metal implants placed. Joint replacement is used to treat osteoarthritis, inflammatory arthritis,

R. A. Rosenthal et al. (eds.), *Principles and Practice of Geriatric Surgery*,
https://doi.org/10.1007/978-3-319-47771-8_77

osteonecrosis, and posttraumatic arthritis. Implants are attached with or without bone cement. The articulation, or bearing surface, has improved markedly with time. Early bearing surfaces were softer than current ones and polyethylene wear was very common. Wear particles activated macrophages and a subsequent cascade of events produced osteolysis, bone loss, and implant loosening. The advent of highly crossing polyethylene has led to the expectation of lifelong use in most patients. Modern anesthetic and rehabilitation techniques have allowed for short hospital length of stay or even outpatient joint replacement surgery. Patient-recorded outcomes of joint replacements are excellent after surgery. Healthcare reform has led to the use of bundled payments for joint replacement. In response to bundled payments, new protocols to maximize patient's health prior to surgery have been developed, improving results and outcomes of this already very successful surgery.

Introduction

Replacement of joints with artificial surfaces has become common in the human body. Orthopedic surgeons currently replace joints in the fingers, wrist, elbow, shoulder, spine, hip, knee, ankle, and feet. The most commonly replaced joints are the knee and hip. Starting in the 1960s, hip replacement was markedly improved and is now an extremely reliable procedure. Knee replacement also is markedly improved with very good results. Osteoarthritis, inflammatory arthropathies, osteonecrosis, and posttraumatic arthritis are the most common reasons for joint replacement. Replacements typically use metal parts that are attached to the bone either with or without bone cement. The implants have an articulation which is the moving part within the replacement. With the advent of modern bearing surfaces, wear rates of implants have markedly decreased. The most common complications of joint replacement are infection, loosening, pain, fracture, and dislocation. With the increase in the elderly population, the numbers of joint replacements are increasing. Improvements in anesthetic and rehabilitation techniques have led to the introduction of outpatient joint replacement. In the United States, healthcare reform has led to a payment mechanism for doctors and hospitals termed bundled payments. Bundled payments are radically changing joint replacement surgery. Within this system, all fees of all providers and all hospitals and care within 90 days of surgery are paid for with one lump sum. This fee includes costs of any complications or readmissions. Bundled payments have led surgeons to maximize patient's health before surgery to try as best as possible to assure a quick and smooth recovery.

Total Hip Replacement

History

While types of hip replacements existed in the early twentieth century, the field was really started with vigor by John Charnley, an English surgeon. He developed a regimented approach to total hip replacement based around strict surgical protocol and infection prophylaxis. His initial surgeries utilized an acrylic bearing surface and all failed. Despite this dramatic failure, Charnley continued his efforts at hip replacement and began to use polyethylene as the bearing surface. He approached the hip by removing the greater trochanter. The osteotomy was repaired at the end of the case with wires. He used cemented implants and a 22 mm head size to minimize the wear of the plastic acetabular component. His method became very successful, and his teachings were spread to the United States and throughout the world [1].

In the 1970s, the use of uncemented implants was developed by several surgeons. To install these implants, reamers are used on the acetabular side and the metal component is impacted and attached with screws. The reamer used is 1–3 mm smaller in diameter than the cup allowing for a press fit. A polyethylene liner is then inserted inside the metal cup. On the femoral side, broaches and reamers are used to mill the inside of the femur. The implants have a rough coating and are wedged into the bone. Modular implants were developed to allow better restoration of length, offset, and stability of the hip. The femoral stem has a trunnion with a Morse taper, and the head ball is impacted onto the trunnion. Modularity allows for different lengths and diameters of head size to let surgeons obtain correct leg length and adequate soft tissue tension. The surgical technique has been further refined and is now performed routinely throughout the world [2]. In the United States alone, over 300,000 hip replacements are performed each year.

Indications

Hip replacement is performed for a variety of indications. Osteoarthritis of the hip is the most common. Other indications are inflammatory arthropathies such as rheumatoid arthritis, osteonecrosis, hip dysplasia, hip impingement, or arthritis from trauma or infection. Plain radiographs are the first modality used to diagnose arthritis of the hip. Patients with arthritis present with pain that is typically in the groin or buttock. Pain is often worse with activity and is better with rest. Patients may notice that the hip is getting stiffer and that they have trouble reaching down to put on socks or tie their shoes. They may have trouble cutting their toenails. The patient may notice that the leg is shorter than the other side from the wear of the hip.

On physical examination, hip motion will be limited when compared to the other side. In particular, flexion and internal rotation will reproduce the symptoms, and the patient will hurt in the groin region. On physical exam it is important to rule out other causes of pain around the hip, such as pain from the lumbar spine with radiculopathy down the leg. Pain can also be in the soft tissues around the lateral aspect of the hip. Pain around the iliotibial band and greater trochanter is called trochanteric bursitis. The patient may have more than one of these problems around the hip region.

Fig. 1 AP radiograph of the hip shows osteoarthritis of the hip. There is joint space narrowing and osteophytes on the edge of the acetabulum and the femoral head

If physical exam points toward the hip as the source of pain, plain radiographs should be taken. The radiographs should be examined for signs of joint space narrowing (Fig. 1). Other signs of osteoarthritis include osteophytosis, joint line sclerosis, and periacetabular cyst formation. Patients with osteonecrosis may have a normal hip x-ray. If the x-ray is normal and it seems that the patient has hip pain on exam, the next study should be an MRI scan. This will show evidence of other pathology in the hip such as a labral tear or femoral acetabular impingement. MRI is also an excellent test to look for osteonecrosis of the femoral head (Fig. 2).

Patients diagnosed with osteoarthritis of the hip are first treated nonoperatively [3]. Activity modification should reduce high-impact activities, and the patient may require the use of a cane or walker. Anti-inflammatory medication should be prescribed if there are no contraindications. Acetaminophen is also helpful for pain. Glucosamine chondroitin has not been found to be helpful for osteoarthritis. Opioid medication should be avoided if possible. Another option for

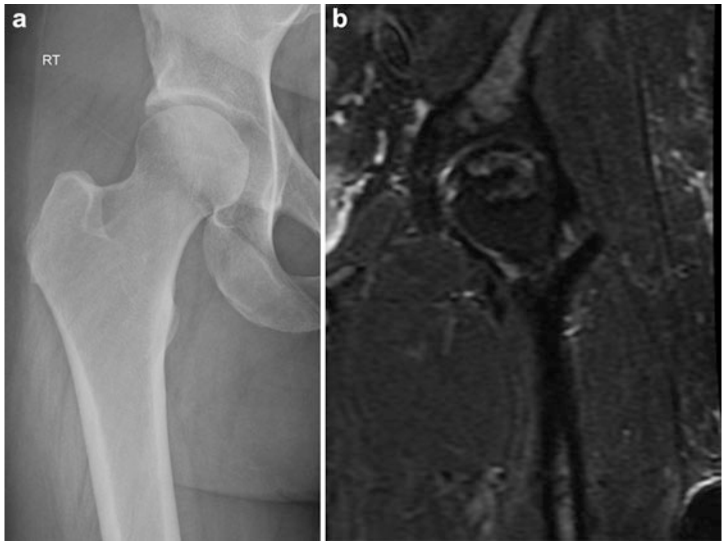

Fig. 2 Imaging osteonecrosis of the femoral head. (**a**) AP radiograph of a patient with osteonecrosis and hip pain. The radiographs do not show the lesion. (**b**) T2-weighted MRI scan shows the lesion within the weight-bearing region of the femoral head

treatment of pain is an intra-articular cortisone injection. For the hip, this requires either fluoroscopic or ultrasonic guidance. Injection is a temporary treatment option. Weight loss and physical therapy may also help hip pain from arthritis.

The decision for surgery should be based around the failure of these treatment options and continued worsening pain. The patient should have severe enough pain that it is affecting his or her activities of daily living. The patient should reveal that they cannot do things that they would like to do in life. If this is true and the radiograph reveals osteoarthritis, total hip replacement is an excellent option. In the past, other procedures such as partial or hemiarthroplasty and resurfacing arthroplasty have been performed with poor results, and these procedures should be avoided [4].

Surgical Technique

There are three main surgical approaches to hip replacement. These include the anterolateral, anterior, and posterior approaches to the hip (Table 1). Each of these approaches uses a different muscular interval to access the hip joint. The optimal approach has been debated for 40 years, and each of the approaches has pluses and minuses [5]. The anterolateral approach comes from the side of the hip and involves taking off a portion of the gluteus medius and minimus tendons. This gives excellent access and exposure to the hip joint. Hip replacements are very stable after an anterolateral approach and have low rates of dislocation. However, by approaching through the gluteus medius, there is a low rate of problems with the tendon after surgery. If this fails to heal, the patient may develop a symptomatic limp called a Trendelenburg gait [6].

The anterior approach comes through the front of the hip in the interval between the tensor fascia lata and sartorius muscles. The hip is very stable to posterior dislocation as the posterior structures are not damaged. Patients may feel more weak in the front of the hip. The anterior approach has been made popular recently with the intraoperative use of fluoroscopy and special surgical table [7]. However, the approach itself is not new and has been used for over 40 years with excellent results. The anterior approach has a higher rate of femoral fracture and loosening [8]. Fixation of femoral fractures is also more difficult with this approach and may require another incision.

The third main approach to the hip is the most commonly used in the United States and is the posterior approach. With this approach, the external rotators are taken off, and the hip is dislocated posteriorly. This is an excellent approach affording wide exposure. The posterior approach is perhaps the easiest approach to extend if any

Table 1 Approaches to hip arthroplasty

Approach	Interval	Pros	Cons
Anterior	Between tensor fascia lata and sartorius	Theoretically muscle sparing	Higher rate of femoral fracture and loosening Difficult to extend
Anterolateral	Through the gluteus media	Lowest dislocation rate	Abductor damage with Trendelenburg gait
Posterolateral	Through external rotators	Most easily extensile	Higher dislocation rate

intraoperative problems happen or if revision arthroplasty is needed. The negative with this approach is that there is a slightly higher risk of posterior dislocation. This is improved with careful soft tissue closure of the capsule at the end of the case. While these approaches have been debated for years, there is no clear winner, and the experience of the surgeon performing the surgery is the most important aspect of picking which approach should be used [9].

With all approaches, after the hip is exposed, the femoral head is cut and removed (Fig. 3). The acetabulum is then exposed and the soft tissues including the labrum and the tissues in the fovea are removed to give good visualization. Hemispherical reamers are then used to shape the acetabulum so that the acetabular component can be impacted (Fig. 4). Most typically, uncemented acetabular components are used, although cemented components also have good results, particularly in elderly patients. If using an uncemented acetabular component, supplemental screws may be utilized. At this point in the procedure, a trial liner is placed into the shell (Fig. 5).

The surgeon then exposes and prepares the femur. The canal is opened, and depending on the system to be used, sequential reamers and broaches are used (Fig. 6). The femoral component may be inserted with or without bone cement. If an uncemented component is used, this must have an excellent press fit and be wedged into the femur. Several designs of uncemented femoral implants exist. These are shaped differently and have coating either on the top portion of the implant or extending all the way to the end of the prosthesis. Many designs exist that have shown excellent clinical results [10]. It is critical that the coating allows ingrowth to extend circumferentially around the implant. After placing the femoral component, a trial head ball is placed. An intraoperative x-ray is taken to assess size, positioning, and leg length. The hip is tested though range of motion to make sure that it is stable. The real liner and head ball are placed, and the incisions are closed.

Implant Design

Design of hip replacement implants have changed over the years [11]. The acetabular component may be cemented or uncemented. Uncemented components have a rough coating to allow for bony ingrowth. The size of the finish or coating has been found to be important. Bone ingrowth is best with a pore size of 100–150 microns [12]. Initial fixation must be stable with micromotion of less than 150 microns to allow for bone ingrowth [13]. The bone must subsequently grow into the

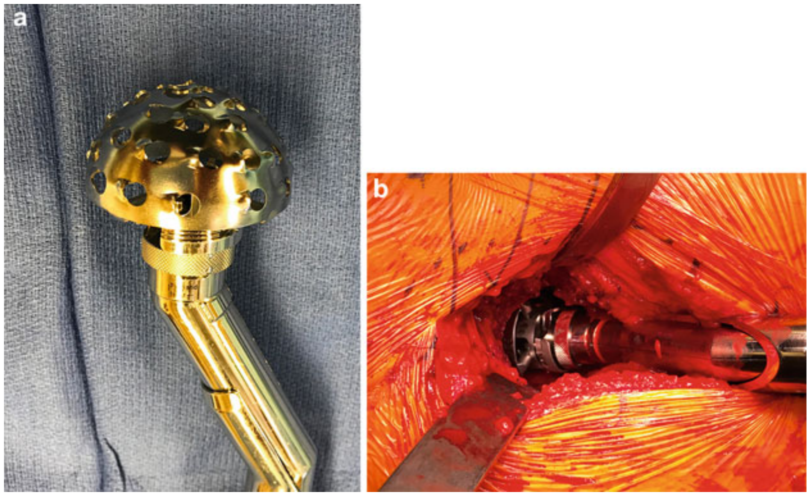

Fig. 4 Acetabular reamers are used to shape the acetabular bone for implant insertion. (**a**) The reamer is hemispherical in shape with a cheese grater-like surface. (**b**) The reamers are used in increasing sizes until a diameter 1–3 mm smaller than the implant to allow for a press fit

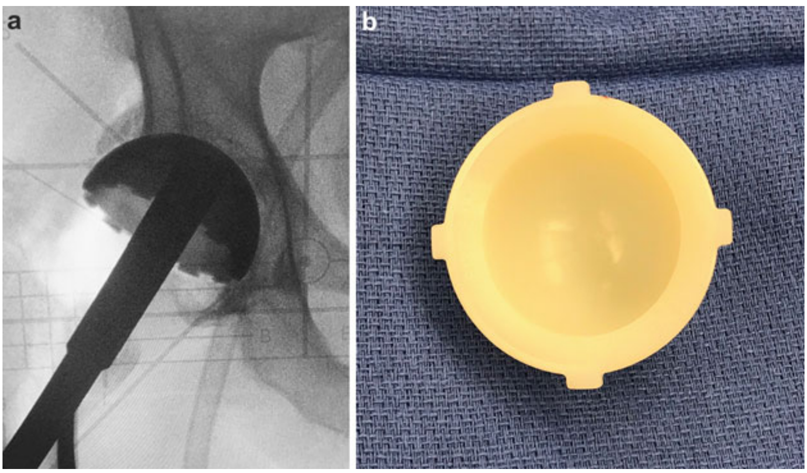

Fig. 5 The acetabular component has a rough surface for bone ingrowth. A locking mechanism inside the cup allows for insertion of a modular polyethylene liner that serves as the bearing surface for the hip. (**a**) This intraoperative fluoroscopy picture shows the acetabular component being driven into the acetabulum. (**b**) The liner is pictured which is made of highly cross-linked polyethylene. It has a locking mechanism to fit into the cup and a smooth inner surface

implant so that the implant becomes osteointegrated. Many finishes exist that are successful, some with hydroxy-apatite coatings.

There are different bearing surfaces, or liner and head ball combinations, that are used for hip arthroplasty. In the past, a polyethylene liner was most typical. About 15 years ago, methods were found to make the plastic harder with a process called highly cross-linking. Changes in how liners are packaged have also led to a decrease in free radicals and subsequent liner oxidation and degradation [14]. Initial polyethylene liners would wear, and if the wear was over 0.1 mm per year, the patient typically became symptomatic. The polyethylene wear would cause small polyethylene microscopic particles to develop in the hip. The particles stimulate macrophages and activate the receptor activator of nuclear factor kappa-B ligand pathway to stimulate osteoclast to resorb bone around the implant [15]. Over time this could become catastrophic. The newer highly cross-linked polyethylene liners have been

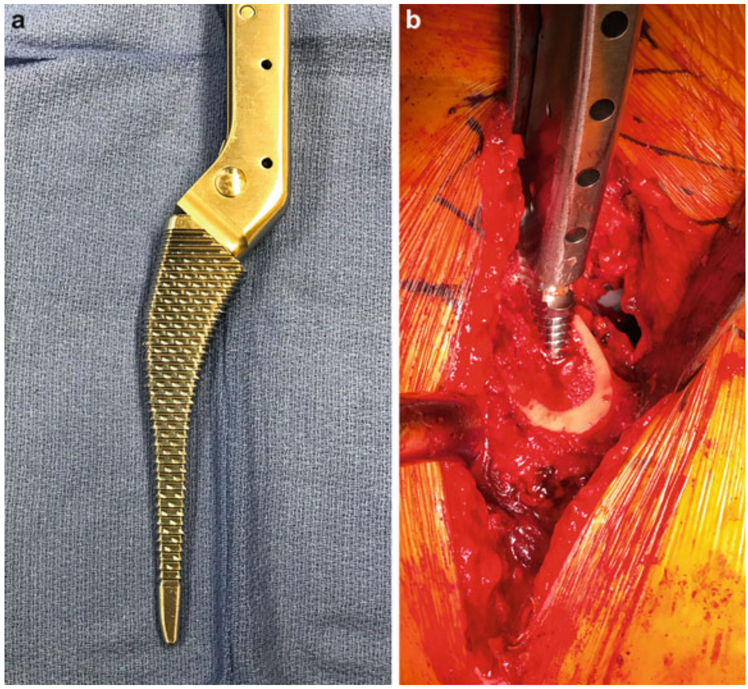

Fig. 6 Broach used to shape the femoral canal has cutting surfaces. (**a**) A broach is pictured. The broach mirrors the shape of the implant. (**b**) An intraoperative photograph showing a broach within the femoral canal. Increasingly larger sizes of broach are impacted until a stable fit is obtained

very successful. Wear rates at 13 years out from implantation are less than 0.01 mm per year [16, 17]. The most common head ball material used is highly polished cobalt-chrome steel.

Other bearing surfaces have been developed including metal-on-metal, ceramic-on-plastic, or ceramic-on-ceramic articulations. Metal-on-metal articulations have led to complications. These were initially made popular with the hope that a very large head ball size could be used. A large femoral head would lessen dislocation rates. At the same time, it was felt that wear of this surface would be better than with a polyethylene liner. However, this has not been the case. In many cases catastrophic metallosis has developed with allergic reactions and a macrophage-induced process with soft tissue and bone destruction. Failure of metal-on-metal implant led to the recall of the Depuy ASR metal-on-metal articulation and many revision surgeries. These can be catastrophic as the metal debris can work into the musculature and the bone around the hip [18].

Ceramic bearings have been used with success. Ceramic head balls are now commonly used with highly cross-linked polyethylene liners. Ceramic-on-ceramic has been a successful articulation but is harder to install than a polyethylene liner. The ceramic liner must be precisely placed into the cup, and if it is off just slightly, problems can occur. There is a low but real rate of squeaking that can be audible with ceramic-on-ceramic articulations [19]. With the medium-term success of highly cross-linked polyethylene liners, surgeons are hopeful that this will be the uniform articulation of choice in the future.

There are many designs of femoral implants. Cemented designs such as the original Charnley design have been incredibly effective, and subsequent cemented implants using a dual taper geometry have also met with excellent success. Uncemented implants of many designs are also successful. These include designs to wedge the implant into the top part of the metaphysis of the femur in different ways. Uncemented designs also may use the diaphysis of the femur for fixation. Uncemented designs do have higher rates of periprosthetic fracture than cemented designs, particularly in osteoporotic bones. These fractures may occur during surgery or years later from a fall. Uncemented designs also have a low rate of pain due to mismatch of the modulus of elasticity of the implant to bone. This is more common with diaphyseal fixation than with metaphyseal fixation [20].

Outcomes

The use of patient-reported outcomes (PROs) is becoming more important to accurately assess the outcome of total hip replacement [21]. Several scores now exist that can be quick and easy to use. The most common of these are the Hip dysfunction and Osteoarthritis Outcome Score (HOOS) or the Patient-Reported Outcomes Measurement Information System (PROMIS) developed by the National Institute for Health. These scores supplant previously used scores, such as the Harris Hip Score, that were collected by observers (typically the surgeon). Currently there is a push to move to collection of routine outcomes using PROs. Current medical record systems are poor, and often surgeons must buy separate software systems for collection of data. Hopefully the future will allow routine collection of data as mandated by healthcare reform laws. The use of registries has improved care worldwide and allowed surgeons to quickly find implant designs that are less successful and remove these from the market [22]. Excellent registries exist in Australia and Scandinavia. The American Joint Replacement Registry is relatively new and behind that of other countries. This registry is growing and hopefully will allow for prompt recognition of inferior implants in the future.

Complications

Complications after hip replacement may be major or minor. Major complications include mortality, thromboembolic events, loosening, dislocation, fracture, infection, and damage to nerves, blood vessels, and tendons. Mortality rates after total joint surgery are low and are less than 0.1% 30 days out of surgery [23].

Thromboembolic events include deep vein thrombosis and pulmonary emboli. Prophylaxis used by surgeons includes medication and mechanical means. Early mobilization is now commonly employed. In the past, patients would not move and would be at bed rest after surgery. Now, patients mobilize the same day of surgery and often go home the next day. Compression devices are utilized to decrease rates of deep vein thrombosis and are either foot pumps or sequential compressive devices. Thromboprophylaxis includes aspirin, low-molecular weight heparins, warfarin, or direct thrombin inhibitors. It is debated what the best option is, and this is currently unknown. Recommendations for joint replacement have been standardized between the American Association for Hip and Knee Surgeons and the American College of Chest Physicians [24].

Wear of the polyethylene liner is another complication of hip replacement. This may lead to osteolysis and loosening of the implant. It is possible for the head ball to wear through the liner and through the metal cup, creating vast amounts of metal debris and damage to the bone and musculature (Fig. 7). Wear rates have decreased with modern highly cross-linked liner.

Aseptic loosening may happen after hip replacement on either the femoral or acetabular

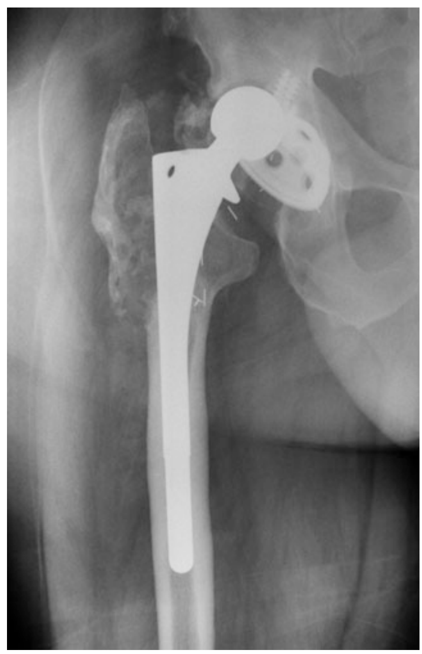

Fig. 7 An AP radiograph of a hip replacement where the head has worn through the metal socket of the acetabular implant. This was more common with older polyethylene liners with poor wear characteristic. This leads to metallosis, an extensive infiltration of pericapsular tissues with black metal debris

side. The etiology of this is an unstable implant at the time of implantation. Aseptic loosening is typically diagnosed with pain with weight-bearing and with radiographs which reveal lucencies around the implants. Loosening of cemented implants may also occur and typically develop over time. Aseptic loosening, if symptomatic, can really only be treated by revision surgery to put a stable implant in place. Revision implants are typically longer and engage more bone on the femoral side. On the acetabular side, these may require augments and multiple screws to get solid fixation.

Dislocation is an unfortunate complication of hip replacement. This may occur in the immediate postoperative period or many years after surgery. Late dislocations typically occur because of wear of the plastic liner and require revision surgery. First-time dislocations are generally treated with closed reduction under anesthesia. After reduction of the hip, a brace may be placed to try and prevent the hip from dislocating. If dislocation occurs several times, revision surgery is required to fix the problem. This may involve changing the position of the implants, the use of a larger head ball, or the use of a constrained liner.

Periprosthetic fracture is an increasing complication of hip replacements, especially as patient's age and become more osteoporotic. This is most common around the femoral implant due to a fall. Periprosthetic fractures generally require surgery. This may either be with plate fixation if the implant is stable or with revision surgery if the implant is loose.

Infection of implants occurs in about 1–2% of patients. About half of infections occur immediately after surgery and the other half may occur years later. Acute infections usually are due to intraoperative contamination. Later infections may be from hematogenous spread of other infections in the body such as sepsis, urinary tract infections, or dental infections. The most common organism to infect a joint replacement is staphylococcus. Bacteria form a layer, called a biofilm, on the metal implants. This allows the bacteria to become very difficult to eradicate with retention of implants. Approaches to prosthetic joint infection with antibiotics alone do not succeed. Antibiotic suppression may be used in ill patients who would not tolerate surgery. Washout of the joint with retention of implants and subsequent antibiotics may be successful in acute infections that are diagnosed within 3 weeks of the infecting event. More commonly, infections are chronic and implants must be totally removed and the bone surgically debrided to eradicate infection. The implants may be replaced immediately using a one- or two-stage approach. In a one-stage approach, implants are removed and permanent revision implants placed during one surgery. In a two-stage approach, after removal of implants, a spacer is placed to allow local drug delivery, and the infection is treated with 6 weeks intravenous antibiotics. Subsequently, the spacer may be removed and revision implants placed. Overall, about 80–90% of infections are thought to be cured with this approach. Success depends on the health of the host, on their ability to fight infection, and on the precise type of bacterial infection. Hip infections are serious events with high rates of morbidity and mortality [25].

Leg length differences are a common problem after hip replacement surgery. Most typically the arthritic hip is shorter than the nonarthritic hip due to wear of the cartilage and bone. With surgery, the hip is lengthened to equal leg lengths. It is possible for the leg to be overlengthened during surgery. This may be done by the surgeon in an attempt to make the hip as stable as possible to reduce the possibility of dislocation. Sometimes the leg length difference may be due to weakness of the hip muscles, producing a pelvic tilt. In this case the actual leg length is equal, but the patient perceives the leg to be longer. Usually this improves with strengthening. True leg length differences are treated with a lift in the contralateral shoe.

Damage to the sciatic or femoral nerves may occur after hip replacement. Usually these result from stretching of the nerves due to retractor placement. Sciatic nerve palsy may also occur from overlengthening of the leg. Nerve palsies are more common in patients with dysplasia. About 50% of cases have return of function.

Total Knee Replacement

History

Initial knee replacements utilized hinged devices and were developed in the 1960s. These devices did not perform well. In the early 1970s, Dr. John Insall pioneered the cemented condylar knee replacement. In this design, the femur and tibia are resurfaced, and a plastic liner is placed that locks into the tibial component. The collateral knee ligaments give stability to the device. This was a much-improved design from the initial hinged knee and led to wide acceptance of knee replacement. Subsequently the condylar knee has been modified and improved into the current modern designs of implants. One of the main improvements have been better tools to reproducibly install the device in the correct alignment.

Fig. 8 An AP radiograph of the knee showing osteonecrosis of the medial femoral condyle due to protease inhibitor therapy. The large lesion within the bone causes pain and may collapse leading to articular damage and wear. Complete fragmentation and collapse is seen in this image

Indications

The primary indication for total knee replacement is osteoarthritis of the knee. Other indications are inflammatory arthritis and posttraumatic arthritis. Osteonecrosis is less common in the knee than in the hip (Fig. 8). Osteoarthritis is a common condition leading to wear of the articular cartilage and tears of the primary shock absorbers in the knee, the menisci. There are three main compartments, or anatomic areas, within the knee. These include the medial, lateral, and patellofemoral compartments. Arthritis may affect one or multiple compartments of the knee (Fig. 9). In the United States, osteoarthritis of the knee is about twice as common as in the hip. Obesity is directly related to rates of knee arthritis.

Treatment of osteoarthritis of the knee includes the use of nonsteroidal anti-inflammatory medications, acetaminophen, braces, ice, heat, gels and creams, physical therapy, and activity modification. More severe pain can be treated with injection therapy. Cortisone injections help for a limited period of time. Evidence is uncertain whether hyaluronic acid injections help symptoms. AAOS Guidelines do not recommend the use of hyaluronic acid injections [26]. These injections do not build up cartilage in the knee and are more expensive than cortisone therapy. If these treatments fail to give pain relief and if the patient has disability from the knee and loss of function, then knee replacement may be a good option.

Patients with knee arthritis typically develop stiffness of the knee and may develop deformity from wear of the cartilage and bones. Deformity may be in a valgus, or knock-kneed, alignment when the wear is in the lateral compartment or varus, or bow-legged, deformity when the wear is more in the medial compartment. If only one compartment is affected, a partial knee replacement may be considered [27]. Most often, more than one compartment is involved, and a total knee is performed.

Diagnosis of knee arthritis is done with history, physical exam, and plain radiographs. Radiographs will show joint space narrowing, joint line sclerosis, and osteophytosis. In the case of normal x-rays, MRI may be considered to

(**b**) The lateral compartment is worn creating a knock-kneed or valgus deformity of the leg. (**c**) A lateral radiograph shows wear in the patellofemoral compartment of the knee

examine the menisci, ligaments, and cartilage in the knee.

Surgical Technique

Total knee replacement is performed through an arthrotomy on the medial side of the knee. The knee is exposed and osteophytes removed. Cutting blocks are then used to make the cuts to align the prosthesis. Most commonly the tibial cut is made at 90° to the shaft of the tibia. The femoral component is aligned at between 5 and 7° of varus. This allows for restoration of correct alignment of the limb. This method of cuts is termed classical alignment. Another type of alignment is called anatomic [28]. In this alignment, the tibia is placed in 3° of varus and the femoral component at about 9° of varus. Both of these give the same overall alignment of the limb (Fig. 10). Little difference has been found between these methods as long as overall alignment is achieved [29]. Precise cutting jigs are used to allow for sizing of the components and correct alignment (Fig. 11). Alignment must be checked in three planes: the coronal plane, the sagittal plane, and the rotation of the implants. Rotation is very important to allow for proper patellar tracking (Fig. 12). In general, the femoral and tibial components must be placed in slight external rotation. Internal rotation will cause patellar maltracking.

The position and rotation of the femoral component can be performed through two general methods. One is called gap balancing, and the other is called measured resection. Basically these methods depend on whether the bony cuts are made first and ligament balancing is performed second or whether ligament balancing is performed first and then the cuts are made. Results of these two methods of placing the implants are comparable [30]. After the cuts are made, the ends of the bones are prepared. Most total knee replacements are implanted using cemented technique (Fig. 13), although some uncemented designs have been successful. Overall cemented designs have better results than uncemented designs [31].

Fig. 10 A long-standing x-ray shows coronal alignment of the knee. When aligned correctly the line drawn from the center of the femoral head to the center of the ankle should pass through the center of the knee. On the right side, the leg has a varus deformity from deformity of the femur. The line from the center of the femoral head to the ankle is medial to the center of the knee

A polyethylene liner attaches to the tibial component and articulates with the femoral component. A variety of different styles of liner exist. The patella may be left unresurfaced or be resurfaced. Results do not greatly differ, and this is an area of controversy [32]. After the implants are placed, the arthrotomy and skin are closed.

Implant Design

The most common type of bearing surface for a knee arthroplasty is a cobalt-chrome femur on a polyethylene liner. The polyethylene may be highly cross-linked to potentially obtain better wear. The wear process is different mechanically in the knee when compared to the hip. In the knee, there are also rolling, sliding, and rotation motions at the joint surface, which can lead to delamination, pitting, and fatigue failure of the polyethylene [33]. While highly cross-linked polyethylene is thought to be an improvement in the knee, the improvement is more modest than in the hip due to these other biomechanical forces on the plastic. Ceramics and coated metals such as zirconium exist on the femoral side although ceramics may be more prone to implant fracture.

There are different designs of knee replacements that reflect different levels of constraint of the implants. The least-constrained design is

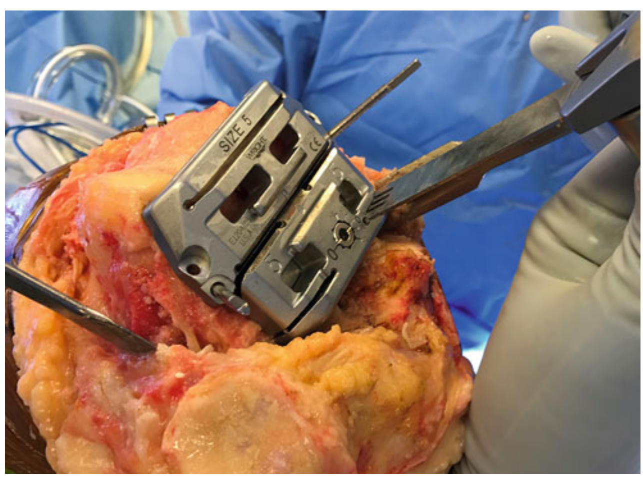

Fig. 11 Intraoperative photograph showing a cutting block placed on the distal femur. Slots in the blot allow for the saw to make precise cuts

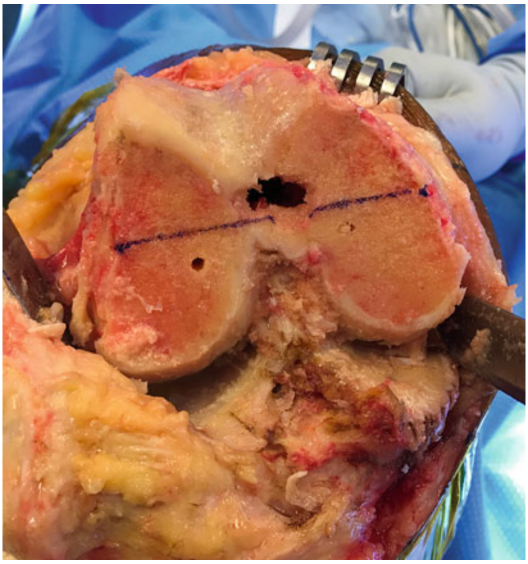

Fig. 12 An intraoperative photograph showing correct rotation of the femoral implant. The implant should not be internally rotated and should be aligned with the epicondyle axis of the femur, which is marked

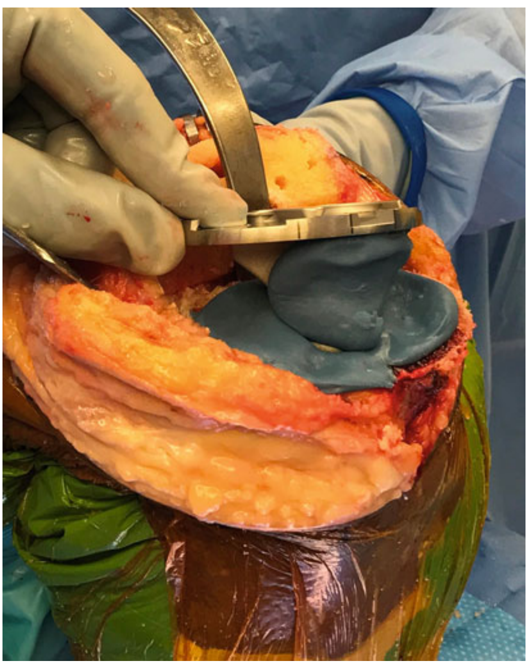

Fig. 13 Intraoperative photograph showing bone cement placed on the tibia. The implant is then impacted, and the bone cement interdigitates into the cancellous bone. This particular type of cement has a blue dye so that it can be identified later for removal

called a cruciate-retaining total knee replacement. In this design the anterior cruciate ligament (ACL) is resected, and the posterior cruciate ligament (PCL) is left intact. The bearing surface has a flat design that is unconstrained (Fig. 14). There are modifications of this with more lipped liners that may provide more constraint. Another commonly used design is termed the posterior cruciate-sacrificing knee. In a traditional PCL-sacrificing design, the femoral implant has a box, and the tibial liner has a peg, which limits posterior translation of the implant like the PCL. In revision designs more constraint is necessary, and the peg may be much larger, or a rotating hinge may exist. Despite the many designs of primary knees, there have been no outcome differences seen between PCL retaining or sacrificing designs [34].

Outcomes

Results of knee replacements are not as good as total hip replacements. More patients with a total hip feel they have a natural feeling hip in place. Patients with a knee replacement often have some type of click or pop to the knee. Overall, about 81% of patients are satisfied with total knee replacement [35]. About 10 or 15% have pain that is difficult to understand. It's hard to know whether these patients had less severe arthritis to start or whether there is some complex biomechanical factor that is not adequately replaced by the replacement. This is a subject of great interest and research.

Much recent focus is in on the use of better outcomes scoring systems after knee replacement. As in the hip, initial outcome scores were doctor-collected. Now, patient-recorded outcome scores, performance-based measures, and registries are being used [36].

Complications

Complications of total knee replacement include stiffness; pain; fracture; infection; damage to nerves, blood vessels, or tendons; thromboembolic events; and mortality. Stiffness is very

Fig. 14 A cruciate-retaining liner is shown. The liner does not have a central peg

common in knee replacements [37]. In general, the more motion a patient has before surgery, the more they will have after surgery. It is difficult to regain more motion in a patient with a stiff knee. Physical therapy is thought to be beneficial after total knee replacement in order to get the knee moving. It hurts the patient to move the knee, and thus they will want to get stiff if left to their own efforts. If adequate knee motion is not restored, the knee may be manipulated under anesthesia to try and get more motion. This should be done within 3 months of surgery [38]. To walk upstairs reciprocally, a patient needs 90° of motion of the knee. 110 degrees is needed to achieve most activities of daily living. Full extension is necessary to walk with an even gait. Significant flexion contracture is quite debilitating. Patients with hip and spine disease are particularly prone to flexion contracture. Marked stiffness can be treated with revision surgery. In most cases a full revision is needed to try to improve motion.

Pain that is difficult to understand occurs after knee replacement. A thorough workup should be taken to look for malposition of implants, stiffness, infection, or aseptic loosening [39]. Aseptic loosening is more common in patients who are obese or very large. These patients are susceptible to tibial subsidence, and a tibial component with an additional stem should be considered in these patients. Loosening is diagnosed with x-ray and is treated with revision surgery.

Periprosthetic fracture is a complication on the rise after knee replacement. This may occur right after surgery or later in time. This is more common in patients with osteoporosis. Fixation of periprosthetic fractures depends on fixation of the total replacement. If the implant is well fixed to the bone and sufficient bone remains, then plate fixation works well. If the replacement is loose or not attached to the bone, this must be revised and the bone fixed [40].

Infection is rapidly becoming the most serious complication after knee replacement. Treatment is similar to prosthetic joint replacements in the hip. Chronic infection should be treated with implant removal and either one- or two-stage revision and antibiotics. Recurrent infections are treated with knee fusion or above knee amputation.

Flexion instability may occur if an implant is not balanced correctly [41]. In this situation the knee is looser in flexion than in extension. This may lead to pain, chronic effusions, or instability. This is treated first with bracing and quadriceps strengthening. If this fails, revision surgery may be necessary.

Damage to nerves and blood vessels is rare but can be catastrophic. Stretch of the peroneal nerve is more common in patients with severe valgus deformity, where the nerve is stretched with realignment of the knee. Vascular injury occurs in about one in 10,000 cases. It is difficult to diagnose and if not picked up very quickly will often lead to amputation. If found rapidly a vascular surgeon can bypass the knee. Diagnosis of vascular injury is often delayed by subsequent development of compartment syndrome.

Minimally Invasive Surgery, Bundled Payments, and Changes in Joint Replacement

Over the past 20 years, many improvements in total hip and knee replacement have occurred. These include improvements in implant fixation, materials, and bearing surfaces. The surgical procedure has been streamlined, and recovery time has been shortened. Faster recovery has long been a goal of surgeons. Initially in the early years of joint replacement, patients were in the hospital for a long period of time and weight-bearing restrictions were used. Over the past 20 years, smaller incisions, termed minimally invasive surgery, have been popularized. Initial waves of enthusiasm met this practice and direct-to-patient marketing made minimally invasive techniques very popular. Subsequent research has shown that it is not the length of the incision but more the techniques used for pain control, anesthesia, and rehabilitation that have made the difference in patient recovery.

Pain control with the use of periarticular injections and regional techniques has led to decreased use of narcotics after surgery. This has decreased the side effects of narcotics including nausea and confusion. Immediate weight-bearing is now routinely employed after replacement surgery. This allows patients to mobilize the day of surgery. Another huge advance in joint replacement has been in blood conservation policies. The use of tranexamic acid to limit bleeding during surgery combined with the elimination of allogenic blood transfusion and lower transfusion thresholds has dramatically reduced blood transfusions after surgery. Ten years ago the rate of blood transfusion after a joint replacement was approximately 40% nationally. With the use of modern blood conservation policies, this rate has been reduced to approximately 1–2% [42]. As the use of blood transfusion is thought to be related to prosthetic joint infection, this will hopefully improve infection rates.

While these changes have gradually occurred, over the past 5 years, bundled payments have been adopted by payers, including Medicare, to try to reduce the amount of healthcare expenditure on joint replacement surgery. Bundled payments were first introduced as a voluntary program of Medicare called the Bundled Payments for Care Improvement Initiative (BPCI). Hospitals or physicians could voluntarily apply to participate. In a bundled payment, one payment is given for all care given within 90 days of surgery. This includes the surgery, the hospital stay, all doctor's fees, and all rehabilitation and post-discharge care. The payment also includes any readmissions or other care that occurs in the 90-day period. Bundled payments put the provider or hospital financially at risk for poor outcomes or expensive care. BPCI was felt to be successful and to improve care while decreasing costs [43]. The Comprehensive Care for Joint Replacement Model (CCJR) is now mandatory in 65 geographic regions in the United States [44].

The use of bundled payments has changed surgeons' thoughts about joint replacement. The hospital or doctor group is now at risk for the outcomes of the patient. If any complications occur, these are taken out of the overall payment to the group or hospital. This system puts a lot of emphasis on proper screening of patients and proper maximization of patients prior to surgery. The term that has been used is modifiable risk factors [45]. These risk factors include obesity, cigarette smoking, dental condition, opioid use, uncontrolled diabetes, and other uncontrolled medical problems. All of these conditions can be improved upon prior to surgery and have been shown to lead to more complications after surgery. Obesity, for instance, is a major factor in predicting infection after joint replacement. Patients with a body mass index over 40 have significantly higher risk of infection and other complications. This is true with poor dental condition, cigarette smoking, and uncontrolled diabetes. This has led surgeons to develop programs to maximize patients. Surgeons now require patients to go to smoking cessation classes or weight reduction programs prior to surgery. The use of chronic opioid medications before surgery has also been shown to lead to poor results after joint replacement [46]. In one study, it was shown that reducing the amount of preoperative opioids in half improves results after surgery [47]. To achieve success in a bundled payment model, it is necessary to improve modifiable risk factors so that patients can do better after surgery. One infection can financially cause great harm if the patient is readmitted in a bundled payment system. In a fee-for-service model, this is not true.

Preoperative education is also important to properly educate patients prior to surgery. Education helps in allowing for early discharge and in reducing readmissions after surgery. The preoperative joint class is best shown to improve results when required by patients and their families. This should be a formal program that involves therapists and discharge planners.

The postsurgical protocol of surgeons has also changed with the introduction of bundled payments. Most patients now spend one night in the hospital after routine hip or knee replacement. In some cases the surgery is performed as an outpatient procedure. Patients are now routinely mobilized the day of surgery.

In a bundled payment system, the biggest influence on overall cost of care is the rate of complications after surgery, readmissions of the patient, and the use of post-admission services. These include home care, home health, home physical therapy, outpatient therapy, or admission to a nursing home or rehabilitation center. In the past, a 2- to 3-week stay in a rehabilitation center or nursing home was almost routine after joint replacement. However, patients that are discharged to home instead of a nursing home and use no home health services have lower readmission rates. Patients who are stratified for medical comorbidities have a higher rate of readmission if admitted to a nursing home rather than going home [48].

It has recently been shown that physical therapy may not give any advantage after total hip replacements [49]. A self-guided exercise plan seems to give the same results. This is probably not as true after knee replacement where stiffness is such a great problem. In this case patients can now be immediately referred to outpatient physical therapy after surgery. This approach has several advantages. Mobilization is a good thing for patients. Outpatient physical therapy requires them to leave the house and walk just to get to the therapy site. It also means they need to have thought about who is going to take them to therapy after surgery. This level of organization and support really helps after a joint replacement. Education prior to surgery is important. Most centers have education classes with required attendance prior to surgery. By requiring this ahead of time, many problems can be avoided. There are still some patients where a nursing home stay cannot be avoided. These would include those with several arthritic joints or those with absolutely no social help. An example may be an elderly patient who has no family and is also caring for their spouse.

In bundled payment models, it is very important that excellent follow-up be achieved. Follow-up phone calls are a necessity. Access of the physician day or night by the patient is very important so that patients can be directed to follow up in clinic rather than in the emergency room where they are likely to be readmitted [50]. Follow-up at 2 weeks in the office helps to avoid problems and assure the patient is on the right track. In terms of recovery, most patients are doing well 4–6 weeks after surgery. They continue to improve in mobility and strength all the way up to a year.

Clinical Vignettes

Vignette 1: Routine Total Hip Replacement

A healthy 53-year-old man presents with progressive right hip pain especially in the groin area. His leg feels shorter than the other side. He is having trouble timing issues and walking distances. The pain is a little better with anti-inflammatory medication. On physical exam, his hip is stiff with range of motion, and extremes reproduce his symptoms. Plain x-rays show advanced osteoarthritis with joint space narrowing and osteophytes (Fig. 15a). Options were discussed, and he was felt to have maximized nonoperative treatment. He elected to undergo total hip replacement. This was performed

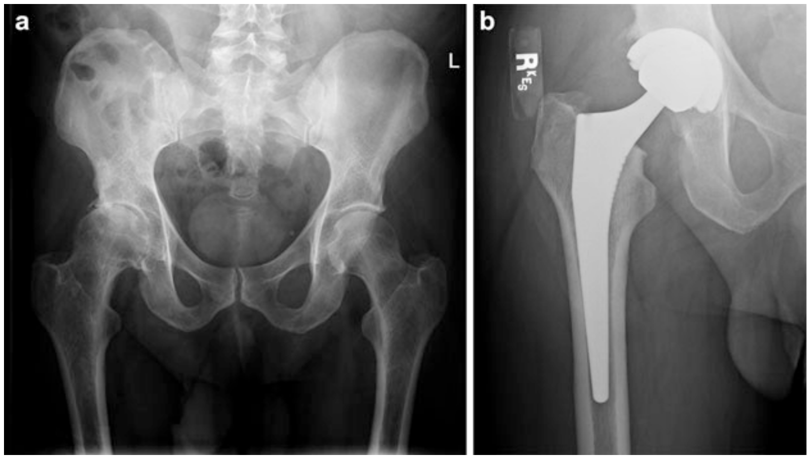

Fig. 15 Vignette 1: Routine total hip replacement. (**a**) AP pelvis radiograph showing a severely arthritis right hip. There is marked joint space narrowing with complete loss of articular cartilage. (**b**) AP hip radiograph showing the uncemented total hip replacement with good position of implants

with an uncemented device, and he was discharged home the next day. He performed a self-directed therapy program and did not require blood transfusion. He has done very well after surgery and at 6 weeks was pain-free and back to his normal activities of daily living. His implants appear to be stable on radiographs (Fig. 15b).

Vignette 2: Complex Total Hip Replacement

A 43-year-old woman was in a motor vehicle accident and sustained a right acetabular fracture and dislocation of the hip (Fig. 16a). Medically she has a kidney transplant that has performed well for 20 years. She was treated with closed reduction and subsequent internal fixation with partial hip resurfacing (Fig. 16b). She was morbidly obese at the time. Over the past 2 years, she has developed worsening hip pain in the groin with any activity. Physical exam show a stiff painful hip. Radiographs show broken hardware and marked joint space narrowing with post-traumatic arthritis of the hip (Fig. 16c). She presented with a BMI of 48, and weight loss was counseled to improve on this modifiable risk factor. She has been successful at losing weight, and her BMI is now 39. She would like to undergo conversion to total hip replacement. The screws and hardware were removed, and hip replacement was performed with uncemented components (Fig. 16d). She has done very well since surgery and is pain-free and mobilized. Often total hip replacements are more complicated than a standard procedure. Hardware may have to be removed and bone defects reconstructed.

Vignette 3: Loose Total Hip Replacement

A 49-year-old man underwent total hip arthroplasty 9 months previously. He had had progressive pain in his hip. This has not gotten better and is worse with walking and weight-bearing. It is sharp and in the proximal femur region. His x-ray shows evidence that his uncemented hip stem has not ingrown. There is lucency around the femoral implant on the x-ray (Fig. 17a). He had a negative workup for infection and was treated with revision surgery with a long uncemented stem that gets fixation in the bone of the femur diaphysis. He did very well with this and is pain-free at 1 year (Fig. 17b).

Vignette 4: Primary Total Knee Replacement

An 87-year-old man is referred to orthopedic clinic with left knee pain. He states that it has

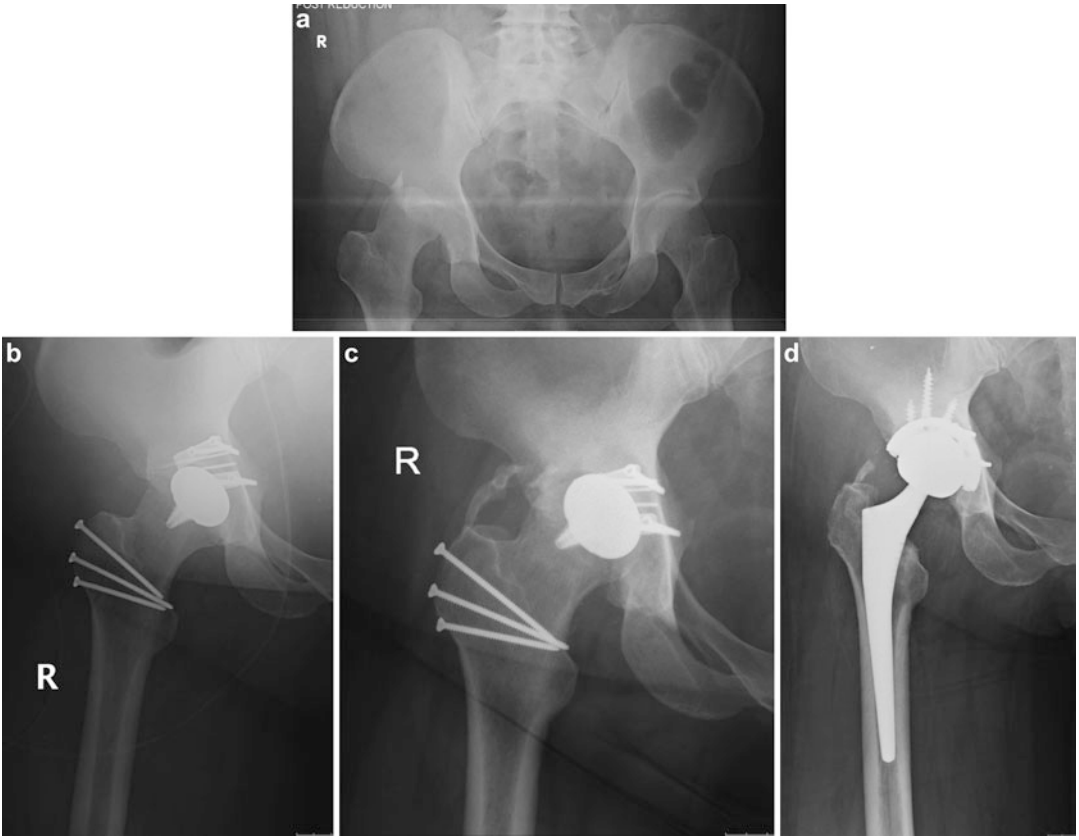

Fig. 16 Vignette 2: Complex total hip replacement. (**a**) Injury AP radiograph showing a dislocated right hip with acetabular fracture (**b**) Postoperative AP radiograph showing acetabular fixation and partial hip resurfacing (**c**) AP hip radiograph showing decreased joint space and post-traumatic arthritis (**d**) Postoperative radiograph showing an uncemented hip replacement. The screws were left in the acetabular region to avoid damage to the sciatic nerve

been present for many years but has started to bother him more over the past several months. His primary care doctor injected his knee about 1 year ago, but he did not get any relief from this. He is starting to have trouble walking long distances and walking downstairs and hills. He has to walk downstairs backward. He has been using a cane for the last 2 weeks after he sustained a fall and hyperflexed his knee. The patient is very healthy for his age but underwent bypass surgery many years ago and is still followed by cardiology. On exam, his knee range of motion has crepitus but is quite good from 3 to 100°. He has a slight varus deformity that is worse with standing. X-rays show severe osteoarthritis of the knee, primarily in the medial and compartment (Fig. 18a). He feels like he has maximized non-operative treatment and NSAIDS and acetaminophen are not helpful. He would like to plan for knee replacement.

He underwent a cemented total knee replacement with patella resurfacing. He was discharged the following day and completed 4 weeks of outpatient physical therapy. At 3 months, he feels the knee pain is gone. His knee range of motion is 0–100°. He is walking well without ambulatory aid. His x-rays show his implants to be in good position (Fig. 18b, c).

Vignette 5: Infected Total Knee Replacement

A 79-year-old man had a total knee replacement 10 years ago, and this has been well functioning (Fig. 19a). His medical history includes atrial

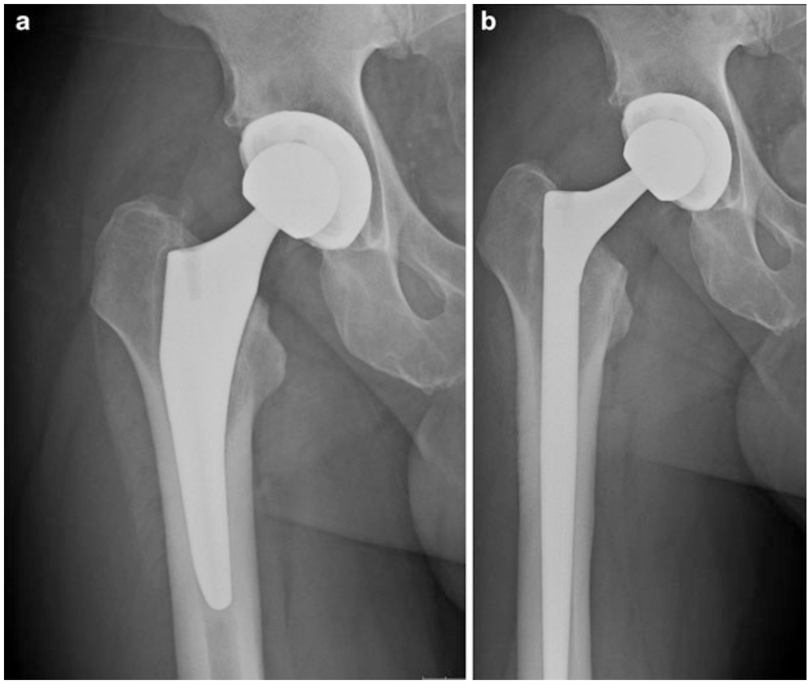

Fig. 17 Vignette 3: Loose total hip replacement. (**a**) AP radiograph of a painful hip replacement. The femoral component has a lucency around the implant in the proximal ingrowth area of the prosthesis. The implant is not ingrown and is loose. (**b**) AP radiograph of a revision total hip with a long fluted conical stem. The stem is wedged into the femoral shaft to give fixation and appears stable and ingrown

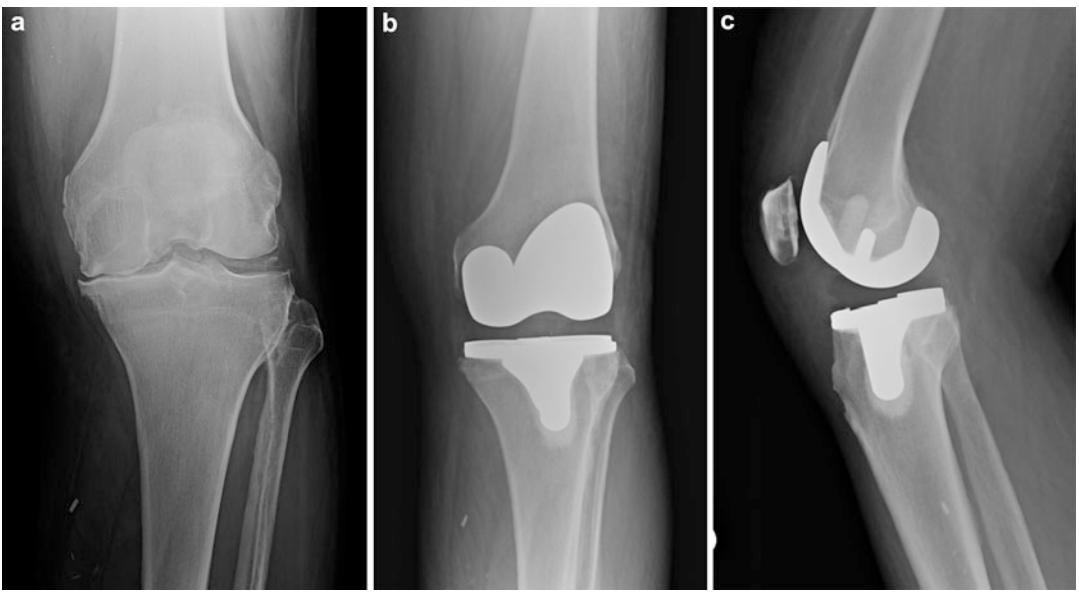

Fig. 18 Vignette 4: Primary total knee replacement. (**a**) AP radiograph of the knee showing joint space narrowing and irregularity in the medial compartment. Calcification of the lateral meniscus is visualized. (**b**) AP radiograph showing a cemented total knee replacement. (**c**) Lateral radiograph of the total knee replacement

fibrillation and a pacemaker with chronic warfarin therapy. He developed 5 days of acute pain in the knee. The knee was markedly swollen with painful and limited range of motion. Aspiration of the knee was positive for infection. Because of the acute onset of symptoms, he was treated with a washout and liner exchange with intravenous antibiotics. After treatment and the end of antibiotics,

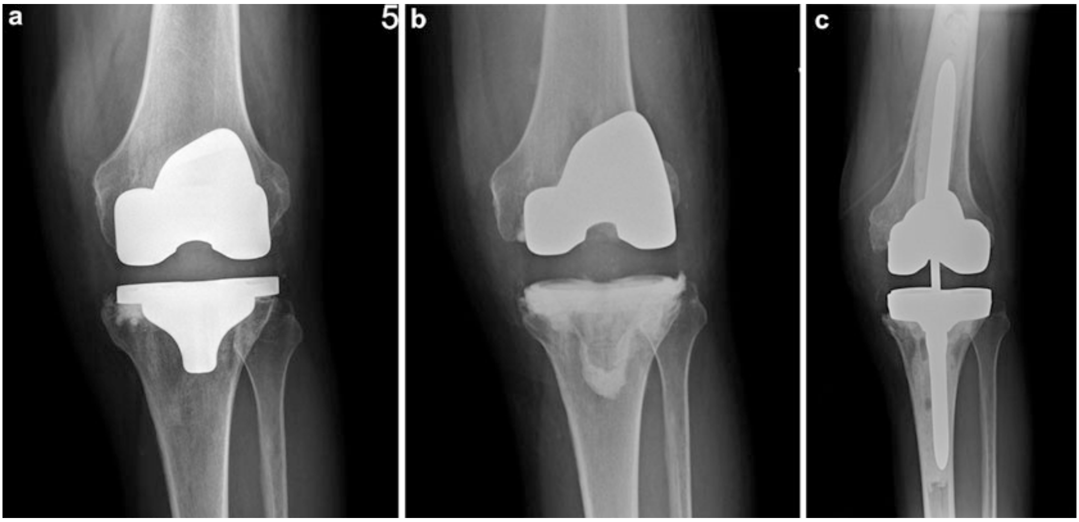

Fig. 19 Vignette 5: Infected total knee replacement. (**a**) AP radiograph showing a cemented total knee replacement that is infected. A lucency is seen under the cement on the lateral side of the tibial tray. (**b**) AP radiograph showing an articulating spacer with antibiotic laden cement. (**c**) AP radiograph showing the final revision total knee replacement with cemented stemmed implants

he developed worsening pain and swelling and was again found to have a positive aspiration. He was subsequently treated with removal of the knee replacement. Bone stock was sufficient for an articulating spacer (Fig. 19b). His cultures grew *Staphylococcus caprae,* and he was treated with ceftriaxone and vancomycin for 6 weeks per infectious disease consultation. He subsequently had reimplantation surgery with cemented stemmed revision implants (Fig. 19c). He has done well and at 6 months, has had no recurrence of infection, and has gotten back to playing golf. Infected joint replacement is a severe problem and often results in multiple surgeries. The patients are often unwell with complex medical issues. In this case, an articulating spacer was able to be used so that the patient could weight bear and be mobilized. In many cases, bone loss or soft tissue coverage is too severe, and a static spacer is used, so the patient cannot weight bear.

Conclusion

Total joint replacement is an extremely valuable procedure. Both total hip and knee replacement have been shown to give excellent long-term results with the reduction in pain and improved function. Joint replacements are primarily used for osteoarthritis of the joints, but other conditions such as inflammatory arthritis, posttraumatic arthritis, and osteonecrosis also respond well to total joint replacement. Improvements in anesthetic and recovery protocols have led to outpatient joint replacement. Modern bearing surfaces using highly cross-linked polyethylene have markedly reduced wear rates. Most patients undergoing primary total joint replacement should not require any further surgical intervention. Recent developments in bundled payment models have led to emphasis on prevention of complications and rapid recovery after surgery.

Burns in the Older Adult

61

Mile Stanojcic and Marc G. Jeschke

Contents

Abstract

Today, there are approximately 40 million people in the United States over the age of 65. As the population ages, this figure is projected to drastically increase to nearly 90 million by the year 2050. With this in mind, as the elderly population increases, it is expected that the incidence of elderly burn victims will as well. This chapter provides insight into the epidemiology, prognosis, and physical considerations in the management and treatment of elderly burn patients. Furthermore, it will explore the acute phase response after burn injury, infections and sepsis, and long-term outcomes. Thermal injuries have a unique manifestation relative to other forms of trauma, and the following sections will demonstrate that this creates further difficulties in older adults. The

Elderly · Burns · Mortality · Outcomes · Sepsis

Introduction

Burns are a major global health burden with a greater incidence in developing countries than developed. Unlike other forms of trauma, burn injuries affect nearly every major organ system. Acutely, the nature of a burn injury results in patients being vulnerable to open wounds, infections, complications, and death. Upon discharge, they further endure economical, psychological, and emotional difficulties with extensive rehabilitation and reconstruction. The complex nature of a burn injury requires medical expertise from a variety of backgrounds, and since the introduction of specialized burn centers, this has significantly improved the care provided to these patients. Despite being extremely effective, it also results in significant costs and financial burden on healthcare. A comprehensive review of 156 studies found that the average cost per burn patient in high-income countries was $88,218 [1]. A single-center retrospective study in Australia found similar results with their average costs totaling AU$71,056 (US$73,532) per patient [2]. The most significant components of cost are hospital length of stay, staffing, operating costs, and dressings, all of which increases with increasing % TBSA (total body surface area) burned.

Today, there are approximately 40 million people in the United States over the age of 65. As the population ages, this figure is projected to drastically increase to nearly 90 million people by the year 2050 [3]. With this in mind, as the elderly population increases, it is expected that the incidence of elderly burn victims will as well. This chapter provides insight into the epidemiology, prognosis, and physical considerations in the management and treatment of elderly burn patients. Furthermore, it will explore the acute phase response after burn injury, infections and sepsis, and long-term outcomes. Thermal injuries have a unique manifestation relative to other forms of trauma, and the following sections will demonstrate that this creates further difficulties in older adults. The growing body of literature in elderly burn patients in the last decade reflects the inherent challenges when treating and also sheds light on the demand for improved therapeutic regimes for this growing population.

Epidemiology

Burn injury is a devastating form of trauma and occurs when cells of the skin or other tissues are destroyed by flames, hot liquids (scald burn), or hot solids (contact burn) [4]. It is estimated globally that 11 million cases of burns require medical attention and account for approximately 300,000 deaths [4]. In the United States, nonfatal burn injuries requiring medical attention are attributed to nearly 500,000 cases annually [5]. Although the treatment of severely burned patients has been continuously improving, death from such injuries is still a primary concern and accounts for more than 4,500 per one million annually in the United States [6]. Primary factors known to determine mortality in burn patients include age, burn size, inhalation injury, and sepsis [6]. Despite 90% of burns being preventable, burns are a neglected form of trauma that has tremendous financial impact on healthcare.

Elderly burn patients represent 13–20% of burn center admission, yet they comprise the highest death rate among the overall burn population [7]. Older adults are more vulnerable to burn injuries due to declining physical, motor, sensory, and cognitive performance [8]. As a result, elderly have burns that are greater in severity, deeper, and increased likelihood of inhalation injury [9]. The majority of thermal injuries in elderly occur within the kitchen and bathroom [10]. A review of 23,180 patients from the American Burn Association National Burn Repository revealed that the injury characteristics in elderly include flame

(41%), scald (24%), contact (5%), chemical (1%), and electrical (1%) [11]. The majority of these injuries occurred at home (56%), and inhalation injuries were present in 10–13% of cases. Despite adult burn victims reflecting a predominantly male population, however in elderly, there is a progressive increase in female victims with increasing age.

It was previously reported that burns in elderly were the fourth leading cause of death, and they are the second population at greatest risk for death due to residential fires [12, 13]. In addition, older adults do not tolerate burns as well as children and adults. Alden and colleagues previously reported that even small scald burns (7% total body surface area) resulted in 22% mortality [14]. In fact, the LA_{50} (percentage of total body surface area that is required to be burned for 50% mortality) in children is above 90%, whereas in patients >70 years old, it is less than 40%, and in patients over 80, it is under 20% [4]. Despite a declining prevalence of burn injuries globally and key advances in therapeutic strategies to improve patient outcome, they still cause significant morbidity and mortality in patients [4].

Prognosis

Determining outcomes and predicting survival is a vital part of guiding the course of burn care [15]. One of these predictors that are most commonly used is the Baux score. The Baux score was originally described as a method to predict mortality in burn patients by simply adding the age and % TBSA, with scores >75 resulting in poor outcomes [16]. Since its introduction in the early to late 1970s, numerous models have been extensively studied and validated to guide burn care providers when determining treatments [17, 18]. Specifically in elderly, Wibbenmeyer and colleagues showed that the Baux score was successfully able to predict mortality in 87% of patients [19]. Another approach that was pioneered at the Birmingham Burn Centre is probit analysis. Using age and severity of injury as standardizing factors, the probit technique determines the percentage of mortality that is inclusive of the entire dataset (both survivors and non-survivors) [20]. The most widely used extension of this work that is used today would be the LA_{50}. The LA_{50} (lethal area 50%) represents the severity of burn injury of a given population that results in 50% mortality. This was later extended by Zawacki et al. to include the influence of inhalation injury to predict mortality [21]. Prediction of elderly mortality is not an easy task which is due to the biological differences of elderly. Mobility, socioeconomic activity, and medical history can vary greatly and affect outcomes of burn elderly.

Despite significant improvements in outcomes of burn patients in part due to improved critical care bundles and protocolized burn care, the best outcomes possible can still be found in children followed by adults than elderly [22]. When comparing elderly burn patients to children and adults, older adults have unfortunately not benefitted from the same advances in mortality improvements [6]. In fact, elderly burn patients have an LA_{50} that has remained unchanged for decades and further indicates this neglected cohort [23, 24]. In 1949, Bull and Squire showed that the LA_{50} was approximately 40% for a 40-year-old and nearly 10% in a 70-year-old [20]. With the modernization of burn care and technological advances, recent reports have consistently shown that adults LA_{50} is between 70% and 80%. Unfortunately, these advances in burn care have not been as effective in elderly who have an LA_{50} of 30–35%. When exclusively considering adults over the age of 70, this proportion decreases to 28% [24, 25].

Along with the increased incidence of mortality, elderly burn patients are at greater risk for complications during acute hospitalization. These complications include pulmonary edema, pneumonia, and congestive heart failure [24]. During hospitalization, it has been shown that elderly burn patients have slower recoveries and longer lengths of admission [26]. Alterations in the dermal layers with age result in deeper injury wounds and delayed/prolonged wound healing [10]. As a widely accepted hallmark of post-burn manifestation, elderly patients have a dampened immune and metabolic responsiveness that drive these aforementioned negative consequences, which will be discussed in later sections.

Taken together, little improvements have occurred in the past decades to increase the survival of elderly burn patients. They continue to face an uphill battle to survive both the burn injury itself and complications while hospitalized. As one recent report suggested, perhaps outstanding questions need to be addressed in order to achieve these outcomes. These include the following: should early excision or elapsed surgeries take place to improve wound healing, what criteria should be used to monitor fluid resuscitation, and, lastly, will early mobilization improve rehabilitation [27]?

Table 1 Clinical frailty scale

Score	Classification	Description
1	Very fit	Robust, active, energetic, and motivated
2	Well	No active disease symptoms, often exercise/occasionally fit
3	Managing well	Well controlled medical problems, not regularly active
4	Vulnerable	Not dependent on others, symptoms limit activity
5	Mildly frail	More evident slowing, limited dependence on others
6	Moderately frail	Help needed with all outside activities and daily living
7	Severely frail	Completely dependent on personal care

Adapted from Ref. [30]

Frailty

As adults age, there is a progressive reduction in protective mechanisms such as thinning of the skin (vascularity and cellularity) and overall sensitivity, which contribute to the higher risk of burn injuries. Along the same lines, elderly also have impaired vision, decreased coordination, poor mobility, and reduced reaction time to get out of harm's way. This is likely responsible for the higher prevalence of inhalation injuries [28]. Another term associated with old age that is used to describe vulnerability to abnormal homeostasis and stress response is frailty [29].

Put simply, frailty is assessed by taking into consideration an individuals' physical activity and nutritional status [29]. As introduced in the previous section, regardless of the approach used, outcome prediction relies extensively on the age of the patient. However, chronological age does not always reflect the physiological or metabolic characteristics. With this in mind, the frailty score was recently shown to be a valid and improved predictor of outcomes in elderly burn patients [30, 31]. As shown in Table 1, the Canadian Study of Health and Aging created a frailty scoring based on clinical judgment. Upon assessment of physical activity level and ability to perform daily living tasks, it consists of 7-point scale from fit and independent to completely dependent on personal care.

In 2013, a study conducted by Masud et al. assessed 42 burn patients frailty scores based on the initial assessment from admission records [30]. They found that patients with better frailty scores or pre-morbid capacity were more likely to survive the burn insult and treatment. They also had significantly more individuals who underwent and survived surgical debridement. Another noteworthy study conducted by Romanowski et al. investigated the relationship between frailty score and clinical outcomes. They found that a higher admission frailty score was associated with non-survivorship and increased likelihood of being discharged to a nursing facility versus home [31]. Thus, frailty scoring has consistently shown to be associated with predicting outcomes in elderly burn patients, and subsequent studies are warranted to determine whether it may also extend to complications or benefit of surgery.

Acute Phase Response

Arguably, the profound hyperinflammatory and hypermetabolic response that occurs after burn injury are the main characteristics that distinguish itself from other forms of trauma. In fact, greater burn injury severity has been shown to result in an increased pro-inflammatory response that contributes to muscle catabolism [32]. Thus, in order to understand the complexity of the post-burn

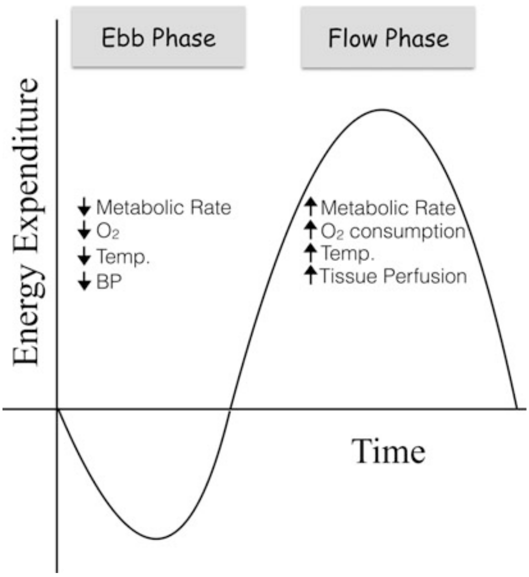

Fig. 1 Posttraumatic metabolic alterations – ebb and flow phases. (Adapted from Ref. [33])

response, both immune and metabolic alterations need to be considered. In the early 1940s, nutritional scientist Cuthbertson introduced the "ebb" and "flow" phases after injury to describe metabolic changes occurring after major trauma (Fig. 1) [33]. First, the "ebb" or shock phase is characterized by reduced total metabolism and diminished peripheral blood volume in circulation. The "flow" or traumatic inflammation phase begins 3–5 days after injury with increases in metabolic activity and various aspects of circulation (hyperemia, exudation, leucocytic migration, etc.) to collectively stimulate a repair process. Although numerous studies have demonstrated the immune and metabolic alterations after injury, elderly burn patients have proven to follow a different course.

Various cytokines, such as IL-1, IL-6, and TNF, have been utilized as markers related to the severity of burn injury. Some of the early markers associated with the initial inflammatory (acute phase) response include IL-6, IL-8, IL-10, TNF-α, and IL-1β [34]. There are varying levels of these cytokines in patients that can be used to distinguish survivors and non-survivors. Specific markers of non-survivors include the elevated expression of IL-6 and IL-8, as well as granulocyte-colony stimulating factor (G-CSF) and monocyte chemotactic protein 1 (MCP-1) [34]. Previous work on a large prospective study of 242 burn patients showed that the entire inflammatory response was profoundly altered up to 2–3 years post-burn [35]. Pro-inflammatory cytokine synthesis or "cytokine storm" is a systemic response to manage deleterious effects of thermal injury in an attempt to restore homeostasis. However, when this response is prolonged post-trauma, it can result in stress-induced hyperglycemia, insulin resistance, hypermetabolism, and catabolism, which are precursors to organ dysfunction and lead to increased risks of infection, sepsis, and death [34]. The prevention of excessive inflammation is a key component of post-burn treatment because of its dynamic relationship with the hypermetabolism and impaired glucose metabolism that are also occurring.

A recent study conducted by Jeschke et al. elucidated the pathophysiological response in elderly burn patients. They demonstrated that even 4 weeks after injury, elderly burn patients are still hypermetabolic with a resting energy expenditure as high as 150% of normal. This aberrant metabolic response was further supported by decreased expression of metabolic markers C-peptide, glucagon-like peptide-1, pancreatic polypeptide, and peptide YY. Consistent with the notion of non-responsiveness, elderly burn patients also had reduced ER stress in adipose tissue. Immunologically, older adults had reduced neutrophil infiltration and macrophage proportion in adipose tissue from the site of injury. Lastly, they showed that systemic inflammation had an acute hypo-inflammatory response preceded by a late surge in inflammation, which will be discussed further below [36].

Inflamm-Aging/Immunosenescence

Inflamm-aging has been increasingly used to describe elderly patients and suggests that there is a global reduction in the ability to cope with stressors with an overall progressive increase in the pro-inflammatory state. Cytokines such as IL-6, IL-1β, and TNF-α are deregulated, and the presence of a chronic inflammatory state impairs the ability to fight off future complications, all of which have shown to be increased in elderly burn patients [37, 38]. Another principle used to describe the elderly immune response is immunosenescence. Immunosenescence is described as the progressive deterioration of the immune system brought on by aging and hinders the host response to pathogens and insult. In healthy elderly, this includes macrophage alterations and reduced antigen-presenting capacity and impairments in natural killer cell, neutrophil, and T-cell activity [39, 40].

A recent study demonstrated the immunosenescence in elderly burn patients by comparing the temporal changes in immune trajectories [41]. The authors observed that during the acute phase (<7 days post-burn), there was a dampened or hypo-responsiveness of pro-inflammatory, chemokine, and immune mediator cytokines in elderly patients. Interestingly, after 14-day post injury, there was a late surge and elevated expression. Beyond 30 days after burn, a dramatic decline occurred which the authors propose is consistent with immune exhaustion. These findings were consistent when comparing non-sepsis and sepsis elderly patients where there was a lack of acute surge in inflammation, which was evident in adults. When elderly patients were stratified based on survivorship, it was observed that there were no differences between the groups and further supports the difficulty in identifying susceptibility to negative outcomes. Thus, elderly burn patients support a "failure to launch" immune characteristic. Collectively, these recent studies demonstrate the aberrant metabolic and immune responses that occur in elderly burn patients. Furthermore, they introduce this systemic hypo-responsiveness to insult that is believed to be the underlying factor for their greater susceptibility to infections and sepsis.

Infection and Sepsis

In the past, patients were most likely to succumb to their injuries due to uncontrollable factors such as age, severity of burn, and inhalation injury. Presently the paradigm has shifted as resuscitation improved, and now sepsis is the leading causes of death in severely burned patients. This in part is attributed to the loss of the skin barrier after injury that results in a heightened risk of wound infections. Sepsis continues to challenge burn-trauma patients in part due to difficulty detecting, defining, and treating.

Infections

It is estimated that between 50% and 75% of burn-related deaths are a direct result of infections and related complications [42]. With the excision of the skin's natural protective barrier, burn wounds are vulnerable portals of microbe infiltration. Unfortunately, any form of infiltration can lead to serious infection due to the ability of a burn injury to suppress the immune system. These infections can leak into the bloodstream and spread throughout the circulatory system, causing bacteremia as well as septic shock. Burn wound infections are a primary concern during the course of treatment due to their potential to create serious complications that will increase the risk of mortality [42]. Bacteria like *Pseudomonas aeruginosa*, which may come from endogenous flora or the environment, are capable of forming biofilms at the wound site that enable the formation of persister-type cells [43]. *Staphylococcus aureus* is another common opportunistic bacteria of concern in post-burn patients due to its ability to generate many virulence factors that allow it to thrive [44]. Bacteria can invade the tissue and make it more difficult to heal or treat the actual burn. Furthermore, the burn wound may become infected after surgery if a donor graft or the excised host tissue is not epithelized properly. New treatment methods allow earlier detection of possible infections, which means they can be addressed before serious complications ensue.

Infections in elderly burn patients are a major concern and frequent occurrence relative to their adult counterparts. It is estimated that 30% of elderly burn patients have burn wound infections and remain an ongoing challenge for burn care providers [36]. This in part is a result of the inflamm-aging and immunosenescence discussed in the previous section. Heightened cytokine production and low-grade inflammation result in an increased severity and prevalence of infection [38]. Elderly burn patients are more susceptible to wound infections (i.e., bacterial) due to the large surface area creating optimal conditions for colonization [45]. Despite origins in the burn wound, these infections can quickly cause bacterial pneumonia, systemic infections, and sepsis [45]. Numerous preventative measures have been reported to avert infection in elderly burn patients including aggressive and early excision of deep burn wounds, early skin grafting, and presence of malnutrition [9]. Collectively, this increased incidence of infections serves as the precursors for subsequent complications and sepsis.

Sepsis

The greatest threat with burn injuries is septic shock or organ dysfunction, which is the leading cause of death [42]. Burn sepsis is usually caused by invasion of the wound site that may result in infection, which spreads systemically to other areas of the body. Sepsis is accompanied by a multitude of symptoms including hyperglycemia, hypotension, and either hypothermia or hyperthermia [42]. Opportunistic pathogens thrive in an immunosuppressed host (i.e., elderly burn patients) and are frequently the source of sepsis.

Elderly burn patients are at greater risk for developing infections and sepsis due to the dysregulated immune response. If untreated, these complications can quickly persist and develop into multiple organ failure and death [10]. A recent study investigating the immune trajectory of adult and elderly patients after burn injury revealed that unlike adults, older adults have a dampened or non-responsive immune response after insult [41]. Stanojcic et al. found that elderly burn patients lacked an acute surge of immune-responsiveness to insult relative to adult counterparts. Interestingly, when elderly patients were stratified based on occurrence of septicemia, it was shown that the majority of inflammatory cytokines and chemokines were unable to distinguish the non-sepsis and sepsis groups. The majority of surge in inflammation in septic elderly occurred late (>30 days post injury). When extending this analysis to the onset of sepsis, elderly burn patients with late onset had significantly reduced proportion of cytokines relative to both adults and elderly with early-onset sepsis. The most striking finding was unlike early-onset septic patients that had a survival of 80%, late-onset sepsis in elderly resulted in 30% survival. Collectively, this study demonstrated the inherent difficulty in distinguishing the susceptibility to sepsis in elderly burn patients and further supports the difficulty in treating these patients with inept immune function. Extending this notion of a “late fight” phenotype in septic elderly, a recent study also demonstrated surges in CD14+/HLA-DR+ monocytes (hallmark of immunosuppression in burn injury) occurring beyond 30-day post-burn [36].

A visual representation of the immune response in adult and elderly patients during sepsis can be found in Fig. 2. As shown in Panel A (adult sepsis), when presented with pathogen or bacterial challenge, this will result in an acute immune response that includes the recruitment of various cell types including monocytes, macrophages, neutrophils, and extensive cytokine secretion. Comparing this to the response in septic elderly (Panel B), the same challenge is met with a dampened immune response with less immune cells recruited and decreased activity. Overtime, adult septic patients will clear the threatening pathogens (in most cases) and will conclude the immune response where innate immune cells undergo cell death (Panel C). Unlike adults, elderly septic patients’ insufficient response will result in not all pathogens and bacteria being cleared, the immune cells will exhaust, and the refractory period or recovery will ensue (Panel D). Upon doing so, this places the elderly at the greatest risk for unresolved infection to spread and induce multiple organ failure and death (Panel D).

Treatment options for trauma patients with burn-induced injuries are regularly improved as research reveals new methods of diagnosing and preventing infection or sepsis. Despite providing

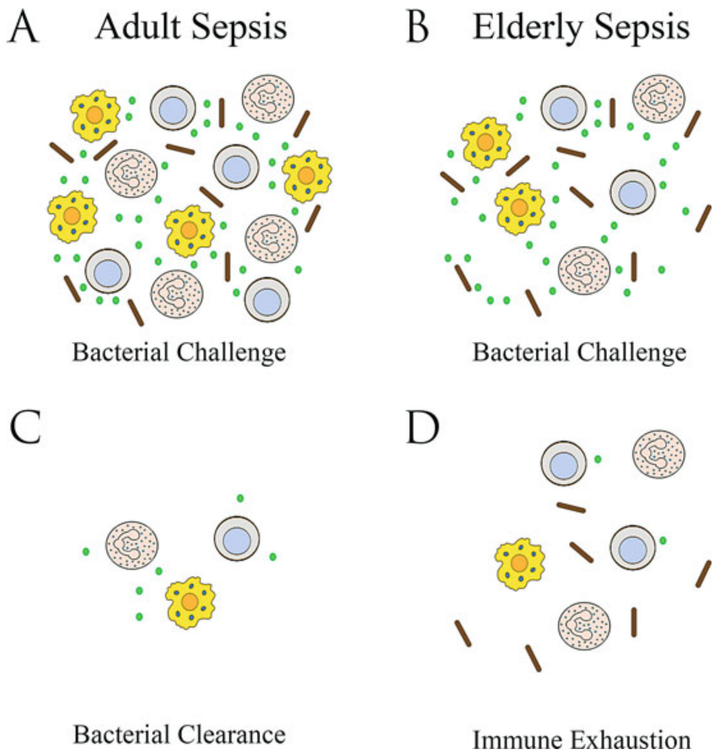

Fig. 2 Comparing the immune response to pathogenic challenge in adult and elderly septic patients

the best critical care possible to patients, a gray zone still exists of what additionally can be done to avoid sepsis. Unlike sepsis, currently there are various approaches to alleviate the hypermetabolic response and support immune function, the most well-established being beta-blocker treatment using propranolol, [46]. Outside of burn trauma, sepsis therapy in critically ill patients focuses on supporting organ function and perfusion. However, there is no globally accepted therapeutic intervention to prevent or predict sepsis, thus making it very challenging to present therapeutic ideas and vision to treat something that will inevitably occur. The ability to prevent sepsis would be a monumental medical advancement for burn patients as the majority of the post-burn complications are sepsis-related.

Long-Term Outcomes

Elderly burn patients have significantly worse outcomes than adult and children counterparts. As demonstrated by minimal increase in the LA_{50}, little progress has been made toward improvements. Numerous factors have been proposed that contribute to this increase in poor outcomes including previous medical conditions, thinning of the skin, increasing susceptibility to complications, inflamm-aging, and immunosenescence that inhibit the ability to mount an adequate immune response, infections and sepsis, frailty score, and nutrition [30, 31, 37, 38, 41]. When comparing genders, it has been suggested that the premenopausal hormone effects (greater hormonal secretion and reduced inflammation) result in poor outcomes in adult females. However, in elderly females there is no apparent increase in mortality due to gender [47]. When comparing hospital admissions, elderly burn patients remain in hospital for longer than adults with similar injuries [48]. Upon discharge, elderly burn patients continue to have both functional outcome and psychosocial impairments for up to 1-year post injury [49]. Extending the notion of long-term impairments, elderly burn patients discharged to skilled nursing facilities die more often than those who went home [50]. In fact, elderly burn patients discharged home were 5.9 times more likely to survive. Elderly burn patients face a high probability and multitude of negative outcomes post-burn, and the subsequent section will introduce a newer approach to delineate geriatric patients at risk for mortality.

Recently, a series of studies proposed and validated the Geriatric Trauma Outcome Score (GTOS) used to determine the probability of mortality in severely injured geriatric patients [51]. Using logistical regression modeling in 3,841 geriatric patients, it was shown that age, injury severity score, and performance of a blood transfusion had a high discriminate ability to predict inpatient mortality. The trauma scores range from 50 to 300 and reflect the increased probability of mortality (1–99%). By incorporating variables in the model that are known at the time of admission, the strength in the GTOS comes from being able to have a quick method of determining negative outcomes, a priori. A subsequent multicenter external validation study was conducted using the GTOS [age + (ISS x 2.5) + 22 (if given PRBC by 24 h)]. Using data provided within 24 h after injury, the authors confirmed that the GTOS accurately predicts in-hospital mortality for injured elderly [52]. Future studies are still required in exclusively elderly burn patients in order to determine its efficacy in this population and determine if the same validity in predicting outcomes is upheld.

Conclusion

Elderly burn patients have poor outcomes, and unfortunately despite advances in burn care, this is not reflected in burned elderly. Elderly have a significantly greater mortality after burn when compared to adults with like-size burns. Newer studies recently identified several pathophysiologic responses that are associated with the detrimental outcomes. It appears that elderly are at higher risk to develop multi-organ failure, are unable to decrease their metabolic needs over time, express profound alterations in glucose and fat metabolism, have an impaired and reversed immune-response with the inability to adequately respond to stress, and, lastly, have a significantly impaired capacity for dermal and epidermal regeneration due to a decreased stem cell pool and dysfunctional stem cells. All of these contributors are pieces of a complex clinical picture, and the next steps are now to further extract these pathophysiological pathways to elucidate more cellular responses and mechanisms in order to develop novel interventions improving the outcomes of severely burned elderly. Another key element that has yet to be addressed is the question about long-term outcomes. Currently, it is unknown what the quality of life and long-term survival of elderly is after burn, and others and we feel that this is an important aspect that requires further investigation.
