Foreword

The management of new information is a major challenge for the modern practitioner of oncology. The reports in authoritative medical journals are weeks or months old and may sound obsolete to the readers. Big pharma learned how to bypass the news embargoes of scientific organizations and floods the internet with preliminary information concerning their products.

National guidelines organizations, such as the National Cancer Center Network (NCCN) practice guidelines, so far have provided a realistic approach to the sorting of incoming data. Thanks to panels of national experts, these organizations are able to incorporate new information in their guidelines very timely. In such informational landscape, it is legitimate to ask whether there is still room for medical textbooks that may require years to complete.

The new textbook of *Geriatric Oncology* by Martine Extermann, M.D., Ph. D., and colleagues provides several affirmative answers to this question.

The easiest answer is that the book lends itself to rapid updates thanks to a digitalized format. Most medical textbooks nowadays offer a digitalized edition, so this approach is definitely important but certainly not new or novel.

A number of more substantial answers may be found in the content of the book. More than a new discipline or a new specialty, more than a task force aimed to collect data on the management of older patients with cancer, *Geriatric Oncology* is a new frame of mind. As such it needs to be properly articulated in the chapters of a book and cannot be collapsed in tweets or headlines. For the formation of practitioners of oncology and of geriatrics, a textbook of geriatric oncology may have the same weight as a textbook of human anatomy or human physiology for a first-year medical student.

The study of geriatric oncology includes the definition of age from a clinical and a biological standpoint, the interactions of age with cancer development, cancer growth and cancer treatment, the inclusion of social issues in medical decisions, and a decisional frame of reference aimed to provide personalized care based on individual life expectancy, tolerance of stress, and treatment goals. To further complicate the issue, aging itself is evolving. In his novel *La fin de la nuit* published in the early mid-1930s, François Mauriac describes the main character as “an older woman” at age 45! Today it is not unusual for a woman to carry on a pregnancy even at a later age. It is common to hear that

today's seventies are yesterday's fifties in terms of function and health. Parallel to the evolution of age are the advances in cancer understanding and treatment. We do need a construct of aging capable to accommodate these advances.

These different aspects of aging and cancer intersect each other as the threads of a carpet and generate what we call a complex situation. Complex from the Latin cum *plexere* means to "weave together." In a sentence, we could say that geriatric oncology involves the management of complexity.

Management of complexity is definitely a new direction in medicine. Evidence-based medicine has been fed by the results of clinical trials that by definition excluded complex patients. The design of traditional trials was focused on the disease and for these reasons the selection criteria included excellent performance status, absence of multimorbidity, and social independence. Though most trials have removed an upper age limit from the inclusion criteria, nonetheless the majority of older people have been "de facto" excluded. While the older population has increased dramatically during the last decades and individuals over 65 represent now more than 50% of cancer patients in the Western world, the participation of older individuals to clinical trials of cancer treatment has not augmented, until clinical trials have been designed specifically for older individuals. Despite their role in advancing the treatment of cancer, clinical trials may not prove the best instruments to study complexity.

Based on decades-long experience in treating and studying of older patients, Dr. Extermann and her associate editors, all from the most prestigious institutions in the USA and abroad, have provided in this book a most valuable blueprint to the management of complexity. For the practitioners of oncology (physicians, advance practice professionals, nurses, pharmacist, dietitians), this book illustrates the assessment of functional age along with the unexpected interactions of aging and cancer treatment and alerts the readers about some unexpected findings, such as the higher risk of cancer-related mortality with advancing age. On this core message the practitioner may add new information as they emerge.

For the practitioners of geriatrics, *Geriatric Oncology* provides important information about new forms of cancer treatment that can be adapted to individual situations. Such information is essential to advise the patient and to establish a meaningful cooperation with their oncological counterpart. Until very recently, the only treatment available for metastatic non-small cell lung cancer was cytotoxic chemotherapy, which was unsuitable for frail patients. Today targeted treatment as well as immune checkpoint inhibitors may prolong the life and the quality of life even of these patients. Likewise, the management of oligometastatic disease with loco-regional treatment may relieve the symptom and prolong the survival of patients affected by different forms of cancer without the toxicity of systemic treatment.

For clinical scientists this book is an invaluable resource. In addition to summarizing state-of-the-art research, it illustrates alternative approaches to the study of older cancer patients. These involve clinical trials for patients with

functional deficit and comorbidity, including previous malignancies, the exploration of biological markers of aging in cancer patients, and the institution of rapid access databases.

Finally, perhaps the most important message of the book is that a team approach is essential to unravel complexity. Only a team involving practitioners of both specialties may lead to the most effective medical decisions and the most promising study protocols.

Dr. Lodovico Balducci

Preface

As the world population is aging, other diseases are increasingly replaced by cancer as a cause of morbidity and death. Half of all cancers occur beyond the age of 70 in developed countries, and that proportion is steadily increasing. Developing countries are beginning to be confronted with the problem as well. In older patients the challenge of treating cancer is compounded by other factors such as comorbidities, high variability in interindividual functional status, social support, polymedication, and other geriatric issues. As the field has grown and knowledge of the interaction of aging and cancer has expanded, we felt the need of creating a common resource where a large amount of information could be found and tailored to a reader's individual needs. A decade or two ago, this would have meant a straightforward printed comprehensive textbook, such as the one published by Lodovico Balducci et al. (2004). In this digital age, we took the opportunity to use a combined format: an online format in the Springer reference collection which allows chapters to be published individually as soon as they are written or updated and a printed textbook for the reader who wants the convenience of browsing through the pages to get an overview of a topic or wants to cross-reference back and forth several chapters. The online chapters can also be downloaded individually by readers with a focused interest without needing to buy the whole book.

In building this reference book, we wanted it to be useful to the multidisciplinary community involved in geriatric oncology: both geriatric and oncology specialists, clinicians, and researchers. We therefore divided the book into eight parts. The first part, on epidemiology and public health, addresses the worldwide scope of the epidemics and how to address it. The second part, on the biology of cancer and aging, explores several aspects in which the biology of aging either favors or protects against cancer and how it impacts cancer biology and behavior. Researchers and translational clinicians interested in understanding the underpinnings of aging and cancer will find there a trove of information. The third part, on the pathophysiology of aging and cancer, gets closer to the clinic, as it explores several aspects of physiologic aging and disease that will interact with cancer development, outcomes, and treatment. Knowledge of these issues will be very helpful for the clinicians treating these patients. The fourth part addresses how geriatric assessment and management can help guide and improve the treatment of these patients. This is a field in rapid evolution as several randomized trials are in progress and one that will be well worth looking at periodically in the online chapter updates.

The fifth and the sixth parts, on hematologic malignancies and solid tumors, respectively, delve into individual cancers and will appeal to the oncology specialists treating these specific tumors with data specific to older patients as well as to clinicians seeking practical solutions. The seventh part is centered on patient care issues. Geriatric oncology is the ultimate personalized care, as personalization is not only to the cancer but also to the highly diverse patients that we become with aging. From symptom control to spiritual issues, this part explores many aspects that matter highly to our patients. The final part is aimed specifically at researchers in geriatric oncology. Our authors share their hard earned experience in research methods to advance the evidence on which we base the treatment of these patients. It is a well-known fact that older patients are underrepresented in cancer research. By sharing methodological insights, we hope to inspire researchers young and old to address the gap in knowledge for the good of older cancer patients worldwide.

We wish you an enjoyable and instructive reading and will welcome your feedback.

January 2020

Acknowledgments

A reference publication such as this one is a large-scale endeavor that is not undertaken alone. We want to thank the more than a hundred authors who have contributed their chapters. This is really an example of how the wonderful oncogeriatric family can come together for a common publication. We also want to thank the extraordinary supportive and patient editorial team at Springer, notably Barbara Wolf and Alexandra Bakowski, who tirelessly encouraged busy authors and editors in making progress in this work. Without them, this book would not have seen the light of day.

Volume 2

About the Editor

Dr. Martine Extermann is Professor of Oncology and Medicine at the University of South Florida. She is the Program Leader of the Senior Adult Oncology Program at the Moffitt Cancer Center. She earned her medical diploma and her medical Ph.D. at the University of Geneva, Switzerland. She has a Swiss Board Certification in Internal Medicine, specialty Oncology-Hematology. She also holds ABIM certifications in Internal Medicine and Medical Oncology. She has worked at Moffitt since 1994 and has been a Faculty Member since 1997. Her research focuses on cancer in the elderly. Her main areas of investigation are comorbidity, comprehensive assessment, and prediction/prevention of treatment toxicity in older cancer patients.

She is Past President of the International Society of Geriatric Oncology (SIOG), of which she is also a founding board member. She served or is serving on several ASCO committees and on the Editorial Board of the *Journal of Clinical Oncology*. Dr. Extermann was presented at ASCO 2009 with the B.J. Kennedy Award for Scientific Excellence in Geriatric Oncology. In October 2014, the International Society of Geriatric Oncology (SIOG) presented Dr. Extermann with the Paul Calabresi Award. On October 10, 2015, Dr. Extermann was presented with a Lifetime Achievement Award in Geriatric Oncology by the German Society of Geriatrics and German Society of Hematology/Oncology in Basel, Switzerland.

About the Section Editors

Etienne Brain
Institut Curie/Hôpital René Huguenin
Saint-Cloud, France

Etienne Brain has been working since 1998 as a medical oncologist at Institut Curie (Paris and Saint-Cloud). He obtained his M.D. in Medical Oncology from Paris-Descartes University in 1995, as well as a Ph.D. in Pharmacology (2005) after initiating (pre)clinical works on alkylation in the USA (Dana-Farber Cancer Institute and Boston University 1995–1996). He got a diploma to supervise research (Versailles/Saint-Quentin University 2010) and in Management and Health Economics (Bocconi University, Milan, 2014–2015).

Dr. Brain is Chair of the EORTC Breast Cancer Group. He also chairs the French DIALOG Intergroup (GERICO/UCOG), dedicated to clinical trials in older cancer patients (geriatric oncology). He is Past President of the International Society of Geriatric Oncology (SIOG) and the co-organizer of the SIOG International Course in Geriatric Oncology (Treviso, Italy) with the Università Cattolica del Sacro Cuoro.

His work comprises clinical practice and research in oncology, mostly for breast tumors and sarcomas, striving constantly for the older populations.

William Dale
City of Hope Duarte – Comprehensive Cancer Center
Duarte, USA

William Dale, M.D., Ph.D., is the Arthur M. Coppola Family Chair in Supportive Care Medicine.

Dr. Dale completed his medical and graduate school training at the University of Chicago and did his residency in Internal Medicine and fellowship training in Geriatrics at the University of Pittsburgh. He is a board-certified geriatrician and palliative medicine physician with a doctorate in Health Policy.

Dr. Dale has devoted his career to the care of older adults with cancer. In 2006, he established the Specialized Oncology Care and Research in the Elderly (SOCARE) Clinic at the University of Chicago, which offers interdisciplinary, individualized, and integrated treatment to optimize quality of life for older cancer patients.

He has over 100 publications on medical decision making, behavioral economics, quality of life, and frailty evaluation in older adults, primarily those with cancer. He has been funded by the National Institute on Aging (NIA), National Cancer Institute (NCI), American Cancer Society, the John A. Hartford Foundation, and the Foundation of Informed Medical Decision Making, among others. He is a co-investigator for the National Social Life, Health, and Aging Project (NSHAP), a national survey and biomeasure collection on the health, well-being, and social life of over 3,000 older adults.

Tamas Fulop
University of Sherbrooke
Sherbrooke, Canada

Tamas Fulop, M.D., Ph.D., is Professor of Medicine and Geriatrics and Senior Researcher at the Research Center on Aging, University of Sherbrooke, Québec, Canada. He is in charge of the geriatric oncology clinic. He was the Deputy Director and has directed the Biology Research Program of the Research Center on Aging for more than 10 years. He obtained his M.D. at Geneva University. He received his Ph.D. in Biochemistry and Immunology from the Hungarian Academy of Sciences and was a Postdoctoral Fellow at the University Paris XII in Biochemistry. Dr. Fulop's CIHR funded research is focused on immune response changes in T cells and neutrophils and the mechanism of inflammation with aging and age-related diseases in humans. His current interest is in the pathogenesis of Alzheimer disease, as well as of cancers in old individuals. He is also interested in the immune-inflammatory changes occurring in frailty. Dr. Fulop has authored more than 300 publications.

He is Recipient of the Presidential Award of the International Association of Gerontology and Geriatrics (IAGG) and Fellow of the Gerontological Society of America since 2001 and member of the Canadian Academy of Health Sciences. He served on the executive committee of IAGG. He serves on the GSA Publications Committee and BS Leadership Committee. He is on the Editorial Boards of *Experimental Gerontology*, *Biogerontology*, *Gerontology*, *Immunology and Aging*, and *European Geriatric Medicine* and is Section Editor of the *BMC Geriatrics*. He is the Editor in Chief of the *Interdisciplinary Topics in Gerontology and Geriatrics* and *Advances in Geriatric Medicine and Research*.

Heidi D. Klepin
Comprehensive Cancer Center of Wake Forest University
Winston-Salem, NC, USA

Heidi D. Klepin, M.D., M.S., is Professor in the Department of Internal Medicine, Section on Hematology and Oncology, at the Wake Forest School of Medicine. She is a dually trained geriatrician and oncologist with a clinical and research focus on geriatric oncology. She also earned a master's degree in Health Sciences Research from Wake Forest University. Her clinical work focuses on a Geriatric Oncology Clinic, providing cancer care to adults 75 years of age or older. Her scholarly work is dedicated to improving the lives of older adults with cancer. Her research investigates the following themes among older adults with cancer: (1) patient-level characteristics as predictors of treatment outcomes; (2) the impact of chemotherapy on physical, cognitive, and emotional health; and (3) interventions such as exercise to minimize treatment-associated disability and improve quality of life.

Population Trends in Aging and Cancer

1

Lars Lund

Contents

Abstract

Several recent studies from Denmark have shown that age is the strongest risk factor for developing cancer. These reports gave an overview of the trends in cancer incidence, mortality, prevalence, and relative survival in Denmark from 1980 to 2012 focusing on age, comparing persons aged 70 years or more with those aged less than 70 years. Data was collected from the NORDCAN database with comparable data on cancer incidence, mortality, prevalence, and relative survival in the Nordic countries. The Danish data originate from the Danish Cancer Registry and the Danish Cause of Death Registry with follow-up for death or emigration until the end of 2013. The studies found a higher incidence and mortality rates of all sites, but in nonmelanoma skin cancer, the relative survival was lower among persons aged 70 years or more than those aged less than 70 years. The age distribution remained constant over time while the percentage of persons dying from cancer decreased with time up to the age of 79 years but increased for those aged 80 years or more, in whom about a third of all cancer deaths occurred in 2012. There was an increase in the number of prevalent cancer cases aged

70 years or older. Politicians and healthcare providers have to make a strategy for treatment of elderly cancer patients due to expected increase in the elderly population.

Keywords
Aging · Cancer · Elderly · Survival · Mortality

Introduction

For the last decades, cancer has been recognized as the leading cause of death in the western world. This, combined with large birth cohorts after World War II, has led to a high proportion of elderly where age is the strongest risk factor for developing cancer (Ewertz et al. 2016). The number of incident cancers is expected to increase up to 30% in Denmark and 45% in the States especially among persons aged more than 65 years (Ewertz et al. 2016; Engholm et al. 2014; Smith et al. 2009).

It is important to prevent cancer by different efforts, e.g., stop smoking, which is the main cause of cancer-related deaths in Europe and the States with a quarter and one-third of all deaths. It is also possible to prevent or diminish cancer-related deaths. There are many other preventable risk factors such as overweight, lack of physical activity, unhealthy diet with high content of fat or sugar, excessive red meat, foods high in salt, lack of whole grain, excessive alcohol intake, and too much exposure to UV radiation (Independent UK Panel on Breast Cancer Screening 2012). Screening is another tool for preventing cancer or early detection, and thereby leads to higher chance of curative treatment, e.g., breast-, bowel-, and prostate cancers.

Recent research also provide insight in different tissue types which gives rise to human cancers millions of times more often than other tissue types (Tomasetti and Vogelstein 2015). The authors from Johns Hopkins University, USA, reported in *Science* that the lifetime risk of cancers of many different types is strongly correlated (0.81) with the total number of divisions of the normal self-renewing cells maintaining that tissue's homeostasis. They concluded that the majority is due to "bad luck," i.e., random mutations arising during DNA replication in normal, noncancerous stem cells. This is important not only for understanding the disease but also for designing strategies to limit the mortality it causes. Others claim that it is a too pessimistic view, and one of the recent studies concluded that stem cell divisions per se do not cause cancer (Rozhok et al. 2015). The correlation between stem cell divisions and cancer risk is a product of age(ing), and the lifetime number of stem cell divisions is an inappropriate product of division rate and standing number of stem cells to predict risk. The mutation rate per stem cell division could be higher in some tissues and at older ages, or immune surveillance might change in different tissues and compromised at older ages. Aging and cancer could have shared mechanisms. The authors concluded that in future etiologic studies, it is crucial to involve the age at which cancer occurs. Studies of changes that happen over age, such as reduced immune surveillance and stem cell aging, could yield interventions that help prevent cancer.

Bladder Cancer

Bladder cancer (BC) is a disease of the elderly that occurs most commonly beyond the age of 70 years and is the sixth most common cancer in the US (Jemal et al. 2010). BC is a highly deadly disease if untreated having a five-year mortality approaching 90% after diagnosis and an overall five-year survival around 50% (Clark 1978; Ferlay et al. 2007). In the coming years, the incidence of BC in the elderly will rise, and therefore, it will become increasingly important to understand whether the elderly with BC are either "fit or frail" with respect to undergoing radical cystectomy or bladder preservation therapy with chemoradiation. The recent study found an increase in average annual number of bladder cancers from 1478 to 1810 (22%) during 1980 to 2012, with close to 60% occurring in the elderly population (Jensen et al. 2016). The incidence rates were 7–10 times higher in persons aged 70 years or more compared with younger persons.

Mortality rates were decreasing with time in all age groups but 90+ year old men. The one- and five-year relative survival improved significantly with time for all age groups both in men and women. The prevalence increased two times among men and women. Incidence rates of cancer of the urinary bladder and urinary tract increased up to around 2005 and then decreased while mortality rates decreased slightly over the period resulting in an increasing survival and prevalence. Incidence and mortality rates were much higher and survival rate was lower in persons aged 70 years or more than in younger persons. The incidence of BC has increased over time across most age groups in Denmark. It is important to perform randomized clinical trials for determining the influence of age on the decisions of the surgical approach as well as chemo/radiotherapy for the elderly patients with urothelial cancer compared to younger patients.

Kidney Cancer

The incidence of kidney cancer increased dramatically during the past two decades in the western world (Engholm et al. 2010; Chow et al. 1999). This increase reflects mainly smaller tumors due to increased use of abdominal imaging, such as computed tomography (CT) and ultrasound (Janzen et al. 2003; Jemal et al. 2008). A number of risk factors have been identified for developing kidney cancer, such as cigarette smoking, obesity, hypertension, and antihypertensive medication, but the etiology remains unknown (Lipworth et al. 2009). Data from NORDCAN showed that the proportion of patients diagnosed with kidney cancer over the age of 70 years has decreased from 43% in 1980 to 32% in 2012 in men and remained almost constant in women, around 50%. Incidence rates were at least five times higher in men aged 70 years or more but there was no particular trend with time (Azawi et al. 2016). In men aged less than 70 years, the incidence rates started increasing around 2000. The incidence rates were lower in women but with a similar pattern as in men. Mortality rates remained stable over time in persons aged 70 years or more while they decreased with time in younger women. Both the one- and the five-year relative survival increased steadily over time for all age groups but the survival was lower for patients aged 70 years or more than for younger patients. The prevalence increased three times from 1559 patients being alive after kidney cancer in 1980 to 4713 in 2012. In the present study, the elderly over 70 years represented more than one-third of all kidney cancer patients. The surgeon facing the elderly patient has to get validated methods to assess the patient's functional and cognitive level, their nutritional status, comorbidities, and the impact of polypharmacy, all of which are common in the elderly. Patients with metastatic disease can now be treated with systemic medication such as targeted therapy with thyrosine kinase inhibitors (TKIs) and inhibitors of the mammalian target of rapamycin (mTORinhibitors). More patients with metastatic kidney cancer are now being offered systemic treatments with metastatic disease. A recommendation of dose modification for elderly patients with metastatic kidney cancer is needed (Azawi et al. 2016) and TKI or mTOR treatments should be offered to elderly patients on the same terms as younger patients. The study concludes that when managing kidney cancer in the elderly it is essential to establish interdisciplinary collaborations between different specialties, such as surgeons, clinical oncologists, and geriatricians, to be able to deliver the best possible care in the future.

Prostate Cancer

Prostate cancer has become the most common nonskin cancer diagnosed in the developed countries and the third leading cause of death among men (Jemal et al. 2011). In Europe, about 190,000 men are diagnosed annually with prostate cancer and around 80,000 men die annually of prostate cancer (Damber and Aus 2008) Prostate cancer is generally a disease of the elderly ($\geq$70 years) and few men are diagnosed before the age of 50 years (Heidenreich et al. 2014). A Danish epidemiological study examined the incidence, prevalence, and survival

rates of prostate cancer for men in Denmark during a 32-year period (Poulsen et al. 2016). The series demonstrated that the overall incidence and prevalence of prostate cancer have been increasing steadily. The average annual number of newly diagnosed prostate cancers rose from 1297 patients in 1980 to 4315 patients in 2012. The prevalence increased consistently in all age groups more than seven-fold in the period, from 3987 patients in 1980 to 28,951 patients in 2012. The cancer-specific mortality in Denmark has slightly increased over the observed period, in coherence with the growth of the population, resulting in unchanged mortality rates, with the exception of the patients above 80 years, where the mortality rates are increased. This observed difference may be due to a number of factors including diagnostic and treatment approaches in more frail or terminally ill men. The one- and five-year relative survival for prostate cancer improved significantly for all age groups over the time period from 1980 to 2012. However, as the authors note, the major difference in findings compared to other countries including those in the Nordic region is the relatively late introduction of treatment with curative intent in the Danish medical system.

Gynecologic Cancer

Gynecologic cancers comprise cancers of the cervix uteri, corpus uteri, ovaries, fallopian tubes, vulva, and vagina. They accounted for 19% of the 5.1 million estimated new cancer cases, 2.9 million cancer deaths, and 13 million five-year prevalent cancer cases among women in 2002 (Sankaranarayanan and Ferlay 2006). Cervical cancer accounted for 493,000 new cases and 273,000 deaths; uterine body cancer for 199,000 new cases and 50,000 deaths; ovarian cancer for 204,000 new cases and 125,000 deaths; cancers of the vagina, vulva, and choriocarcinoma together constituted 45,900 cases. More than 80% of the cervical cancer cases occurred in developing countries and two-thirds of corpus uteri cases occurred in the developed world.

Cervical cancer is a sexually transmitted disease caused by human papilloma virus (HPV) in almost all cases. The disease is more prevalent in lower socioeconomic groups and in women with multiple sexual partners. Smoking is an independent risk factor for squamous cell cervix uteri cancer (Idehen et al. 2017). Cervical cancer is the fourth most common cancer in women worldwide with an estimated 528,000 new cases in 2012 with approximately 85% occurring in low-resource countries. In 2012, there was an estimated 266,000 deaths due to cervical cancer with 87% occurring in low-resource countries. A recent study want to explore factors associated with immigrants' lower participation rates in cervical screening participation among women of Russian, Somali, and Kurdish origin in Finland (Alam et al. 2008). They found that women who refrain from using reproductive health services where those who are unemployed and less educated, as well as those with poor language proficiency, and they might need more information on the importance of screening participation.

In Denmark and other high-resource countries, cervical cancer is primarily diagnosed in women aged 25–70 years with a peak in the incidence at 30–40 years and a smaller peak at 75–80 years. The cause of cancers of the ovaries and fallopian tube cancer is multifactorial and until recently basically unknown. Use of hormonal contraceptives for at least 5 years, multiple deliveries, and, to a lesser extent, breast feeding decreases the risk, whereas the number of years with ovulation is positively associated with an increased risk. A recent, large meta-analysis (Collaborative Group on Epidemiological Studies on Ovarian Cancer 2015) ovarian and fallopian tube cancer is most common in high-resource countries and is worldwide the sixth most common cancer in women with approximately 238,000 new cases and approximately 152,000 deaths in 2012. Danish women have the second highest incidence of ovarian and fallopian tube cancer worldwide (Ewertz and Kjaer 1988). Worldwide, the incidence of corpus uteri cancer (endometrial cancer) almost displays the same geographical distribution as ovarian cancer and is most commonly diagnosed between the age of 40 and 75 years with a peak

incidence around 70 years in Denmark. A study from Denmark described the trends in incidence, mortality, prevalence, and survival in Danish women with gynecologic cancer from 1980 to 2012 comparing women aged 70 years or more with younger women (Ør Knudsen et al. 2016). The incidence for cervical cancer decreased among women aged less than 70 years and remained stable among the elderly. The mortality rate was 2–3 folds higher among 70+-year-olds than younger women. The mortality rates, however, decreased in all age groups from 1980 to 2012. For ovarian and fallopian tube cancers, the incidence was almost constant, whereas the average annual number of deaths decreased over time from 466 in 1980 to 396 in 2012. The mortality rate was 3–4 times higher among the elderly. The mortality rate decreased among women less than 70 years during the entire period. The average annual number of newly diagnosed corpus uteri cancer increased from 631 in 1980 to 773 in 2012. The mortality rate was higher among the 70+-year-olds as compared with younger women. Overall, the mortality rates decreased during 1980 to 2012. They concluded that mortality rates and survival are age-dependent with a significantly shorter survival in the group of elderly.

Breast Cancer

Breast cancer is the frequent cancer among women and the incidence has been increasing steadily in Denmark since the 1960s and the mortality has declined resulting in an improvement in survival. The improved prognosis is assumed to be the result of earlier diagnosis and better treatment. Gender is the strongest risk factor for developing breast cancer with a male:female ratio of approximately 1:100 (Mouridsen et al. 2008). Age has a risk of developing breast cancer both in men and in women with increasing incidence rates with increasing age. The menopause has a protective effect in women in contrast to men with an age-specific incidence curve as a straight line of a constant increase with age (Clemmesen 1948).

The BRCA1 and BRCA2 genes increase the risk for developing breast cancer (Brinton et al. 2014). A recent study found that the proportion of patients diagnosed with breast cancer over the age of 70 years increased with time to 29% of women and 44% of men in 2012 (Jensen et al. 2016). Incidence rates increased with time and peaked around 2010 in all age groups except for those aged 90 years or more. Mortality rates were clearly separated by age with increasing mortality rates by increasing age group for both women and men. Patients aged more than 70 years had a poorer relative survival than those aged less than 70 years. There is a substantial variation in breast cancer treatment by age, probably because of the lack of knowledge about treatment effects in the elderly. Data collected from elderly women not treated in clinical trials show that clinician preferences influence the choice of adjuvant chemotherapy for elder patients. They concluded that poorer survival of Danish breast cancer patients over the age of 70 years is likely to be due to inferior treatment and nonadherence to treatment guidelines. There is a need for clinical trials focusing on patients over the age of 70 years.

Hematological Cancer

The etiology of hematological malignancies remains largely unknown but radiation and previous chemotherapy predispose individuals to acute myeloid leukemia (AML) while immunosuppression has been linked to the development of lymphoma. The incidence of the majority of hematological malignancies increases with age, the only exceptions being acute lymphoblastic leukemia and Hodgkin's lymphoma (Smith et al. 2011). Half of the patients with hematological cancer are older than 70 years at diagnosis (Smith et al. 2011) with comorbidity as well as a higher risk of toxicity and mortality from treatment complications (Norgaard et al. 2006). Westin found a lower improvement in patients over the age of 55 compared with the younger population (Westin 2004). A recent study of 180,000 European patients with hematological lymphoid neoplasms demonstrated that the oldest age groups receive a suboptimal diagnostic workup and therefore treatment (Marcos-Gragera

et al. 2011). A nationwide Danish study investigated the incidences and mortality rates among patients with AML, multiple myeloma (MM), non-Hodgkin lymphomas (NHL), and chronic lymphocytic leukemia (CLL) focusing on the elderly and oldest-old population (Ocias et al. 2016). They found that the incidence rates of AML, MM, NHL, and AML were 10–50 times higher among the population aged 70 years or more than among the younger population. An increasing incidence with stable or decreased mortality rates was seen mainly among elderly patients with NHL during the last few decades, leading to increased survival and a greater prevalence of patients with NHL. There was an increased relative survival and prevalence in the elderly patients with MM and CLL, while the trends of the incidence rates were inconclusive for these diseases. Survival among patients with AML improved most notably in those aged below 70 years leading to an increased prevalence of AML patients predominantly in this age group. They concluded that the improvements in diagnostics and treatment had led to an increased survival and therefore prevalence of elderly patients with AML, MM, NHL, and AML during the last 30 years.

Upper Gastrointestinal Cancer

Malignancies in the upper G-I tract includes esophagus, stomach, and small intestine with a very poor prognosis. Gastroesophageal cancer is the second most frequent malignancy worldwide and the second most common cause of cancer-related death. Together, they account for nearly 1.4 million new cases and 1.1 million deaths every year (Jemal et al. 2011; Parkin et al. 2005). Knowledge about efficacy and toxicity to chemotherapy, radiation, and targeted therapy is primarily derived from clinical trials including highly preselected and fit patients. However, in several trials of patients with cancer, e.g., stomach cancer, older patients were often excluded leading to a median age of 60 years for patients included in clinical trials (Shitara et al. 2012). A recent study described incidence, mortality, and survival in patients diagnosed with esophageal, stomach, and small intestine cancer according to differences in age and time periods (Schønnemann et al. 2016). They found that the proportion of male patients over the age of 70 years diagnosed with esophageal cancer was constant over time but increased in females in 2012. Incidence rates increased with time and continued to rise in all ages. Mortality rates were clearly separated by age groups with increasing mortality rates by increasing age group for both sexes. Relative survival increased slowly over time in all age groups. The proportion of older male and female patients with stomach cancer increased to 50% and 54%. Mortality rates decreased and have been constant during the last decade for both women and men. Relative survival increased modest over time in both genders and all age groups. They conclude the need for clinical trials focusing on patients over the age of 70 years with coexisting comorbidity.

Colorectal Cancer

Colorectal cancer (CRC) constitutes nearly 13% of all malignancies in both males and females and with 447,000 new cases in Europe; CRC is the second most frequent (Ferlay et al. 2013) and is a disease of the old age. The development is multifactorial with genetic susceptibility, environmental, and dietary factors. Increased BMI, red meat intake, cigarette smoking, low physical activity, low vegetable consumption, and low fruit consumption are all associated with increased risk of CRC (Johnson et al. 2013). Over the past two decades, the survival of patients with CRC has increased constantly. The median overall survival for fit patients with metastatic CRC included in clinical trials has increased from 6 months to more than 24 months (Kopetz et al. 2009). An epidemiological study evaluates CRC in Denmark up to 2012 focusing on trends in incidence, mortality, and prevalence among older patients (Brændegaard Winther et al. 2016). They found that the incidence of CRC has increased over the past three decades. Incidence rate has increased in patients with colon cancer, but showed a

decreasing trend in the oldest patients with rectal and anal cancers. Mortality has diminished in younger patients with colon cancer, but increased with increasing age. In rectal and anal cancers, mortality has decreased, except in the elderly. This correlates to a decreasing incidence rate. Prevalence is widely increasing mainly because of increased incidence and longer survival, which is reflected in the increasing one- and five-year age-specific relative survival after a diagnosis of colon, rectal, and anal cancers. They concluded that there is limited knowledge on how to optimize treatment in older CRC patients and future focus must be on how to select and plan the treatment for especially elderly CRC patients.

Integrating Geriatric Oncology in Public Health Planning

2

Contents

Abstract

If more than 30% of cancers occur at present in France among elderly people, it is estimated that this proportion will reach 50–60% within the next two or three decades. To deal with and anticipate this challenge, successive national Cancer Control Plans have included specific actions on the organization of the treatment of elderly cancer patients. The organizational framework is based on an oncologist-geriatrician partnership at the head of oncogeriatrics coordination units. After a pilot phase conducted in 15 health-care institutions, it has been deployed in 22 regions of mainland France and in one overseas territory. These units are mainly intended to ensure that patients receive cancer treatment suitable for their overall health and age. This organization evolves with both the

evolution of the health landscape (in accordance with the modernization law of the health system of 26 January 2016) and the territorial reform that identifies 13 regions in mainland France and five regions in overseas. It also has to take into account not only the therapeutic initial decision but also the patients pathway and their quality of life during and after the cancer treatment. The ability to adapt is essential to fully optimize the treatment of these elderly people suffering from cancer who will shortly represent the vast majority of people with cancer.

Keywords
Geriatric oncology · Elderly · Cancer · Models of care

Introduction

Cancer is a common disease for elderly (≥ 75 years old) people. Various models of care are evaluated around the world to improve their care and are constantly evolving. In France, the successive Cancer Control Plans helped to structure the geriatric oncology into an organization which, though very hospital-centered during its pilot phase, expanded into regional frameworks to ensure fairness of treatment with a patient-centered system. The following chapter describes the work achieved during the first two Cancer Control Plans and, by analyzing the strengths and weaknesses of this organization, presents the development prospects of the treatment of elderly person suffering with cancer.

Epidemiology in France

Advanced age is the most important risk factor for cancer. The median age at cancer diagnosis is 68 years in men and 67 years in women in France.

Cancers occurring at a median age > 70 years are three among males: colorectal cancer (71 years), gastric cancer (72 years), and bladder cancer (74 years); and seven among females: kidney cancer (70 years), esophageal cancer (73 years), liver cancer (74 years), colorectal cancer (75 years), gastric cancer (77 years), and bladder cancer (79 years) (Les Cancers en France 2015).

The latest 2015 data estimated 63,551 (30.1%) new cancer cases among men and 58,385 (33.6%) among women aged 75 and over (Leone et al. 2015). After the age of 85, respectively 18,177 and 23,770 cancers were diagnosed. Three cancers represent half of the cancer in elderlies. In men, prostate, lung and colorectal cancers remain the most common cancer. In women, breast, colorectal, and lung cancer are the most common.

Around half of the deaths caused by cancer occur within the elderly, with 39,600 deaths out of 84,000 in men (i.e., 47.1%) and 36,840 out of 65,400 in women (i.e., 56.3%). For both sex, three cancers represent nearly half of the cancer death. However, in men, lung cancer is the first cause of death by cancer, followed by prostate cancer and colorectal cancer. In women, breast cancer remains the first cause of death by cancer, followed by colorectal cancer.

Prevalence of people with a cancer in France in 2008 is estimated at around 3 million people (Colonna et al. 2014). In elderlies, there are respectively 682,699 (43.5%) men and 466,769 (33.1%) women with a history of cancer during their life. Prostate cancer and breast cancer are the most common cancers.

These few data underline the imperative to cope with cancer in elderly patients, which will represent the vast majority of cancer patients within one or two decades.

Public Health Planning and Health-Care Policy in Geriatric Oncology in France

The French National Cancer Institute (INCa)

It was created by a public health law on 9 August 2004. It is a government health and science agency in oncology, whose mandate is to integrate cancer control and research in France and to implement the cancer control plan 2014–2019.

2003–2007 Cancer Control Plan

This first plan aimed at coordinating public health providers involved in cancer in the areas of

prevention, screening, health care, research, patient, and close relatives support.

One task of this plan was dedicated to oncogeriatrics, for the promotion and coordination in epidemiology, prevention, treatment strategies, and clinical trials for elderly persons with cancer (Measure 38). Major advances in healthcare organization for cancer patients occurred during this plan, as the mandatory multidisciplinary tumor board, the implementation of quality measures (announcement procedure, the delivery of a personal care plan, the access to supportive care, the fixation of activity threshold for authorizations to treat cancer patients, and the participation of the general practitioner (GP) in cancer care networks. These actions contributed to enhance cancer care, including for the elderly.

2009–2013 Cancer Control Plan

This second plan was built around three cross-cutting themes: to take more effectively into account health inequalities, individual and environmental factors, and to strengthen the role of the referring practitioner (GP).

This plan focused on the care management for elderly cancer patients. Setting up nationwide oncogeriatrics coordination units (UCOGs), expanding the use of a geriatric assessment tool, and developing recommendations for treatment strategies tailored to the elderly for cancers with the highest incidence were scheduled (Action 23.4). The target of 5% of elderly (> 75 years old) patients in clinical cancer trials was suggested (Action 4.2).

2014–2019 Cancer Control Plan

The management of this plan is provided by a committee co-chaired by the Ministers for Health and for Research. The French National Cancer Institute coordinates the monitoring of this plan.

One of the key objectives is "To cure and prevent cancers: giving every person everywhere in France equal opportunities." Objective 2 of this ongoing plan is to ensure quality and security of cancer care. Two actions are dedicated to elderly people, in order to address their specific needs: Action 2.16 evaluates and adapts the specific organization for elderly people with cancer, in order to improve clinical practices, and structures clinical research, as an integral part of this specific organization, while Action 2.17 targets mandatory university education in geriatrics for all oncologists and cancer specialists.

Current Assessment

Health-Care Modalities

INCa analyses and publishes every year data collected in the national hospital discharge data base in order to describe the hospitalizations related to cancer care.

A total of 6.64 million hospitalizations related to cancer care were identified in 2014, among them 1.6 (≈24%) concerning the elderly (≥ 75 years old) cancer patients (Cancers in France 2014). More than 370,000 patients were concerned, among them one third of them being ≥85 year old.

These hospitalizations were linked to chemotherapy (33%), radiotherapy (23%), surgery (10%), palliative care (4%), and to other care (30%) including transfusions, endoscopic examinations, and hemodialysis for cancer patients.

Hospital activity was mostly distributed in local hospitals (36%), clinics (23%), academic hospitals (21%), and cancer centers (12%). This distribution underlines the importance of a geriatric oncology organization at a local level.

Oncogeriatrics Coordination Units (UCOGs)

A call for projects was launched by INCA and the Ministry of Health at the beginning of 2011, with the aim of creating one UCOG in each of the 22 regions and the five overseas departments (Fig. 1 – Map of UCOGs in France).

These UCOGs do not represent a new additional structure. They are based on a formalized collaboration between an oncologist and a geriatrician. Most of these partners are MD-PhD in university hospitals authorized to treat patients with cancer and have received five missions:

- To adjust cancer treatments for the elderly

  There are two major and opposite challenges to face for elderly patients: firstly to prevent undertreatment only based on age, and, in the other side, to avoid an overtreatment

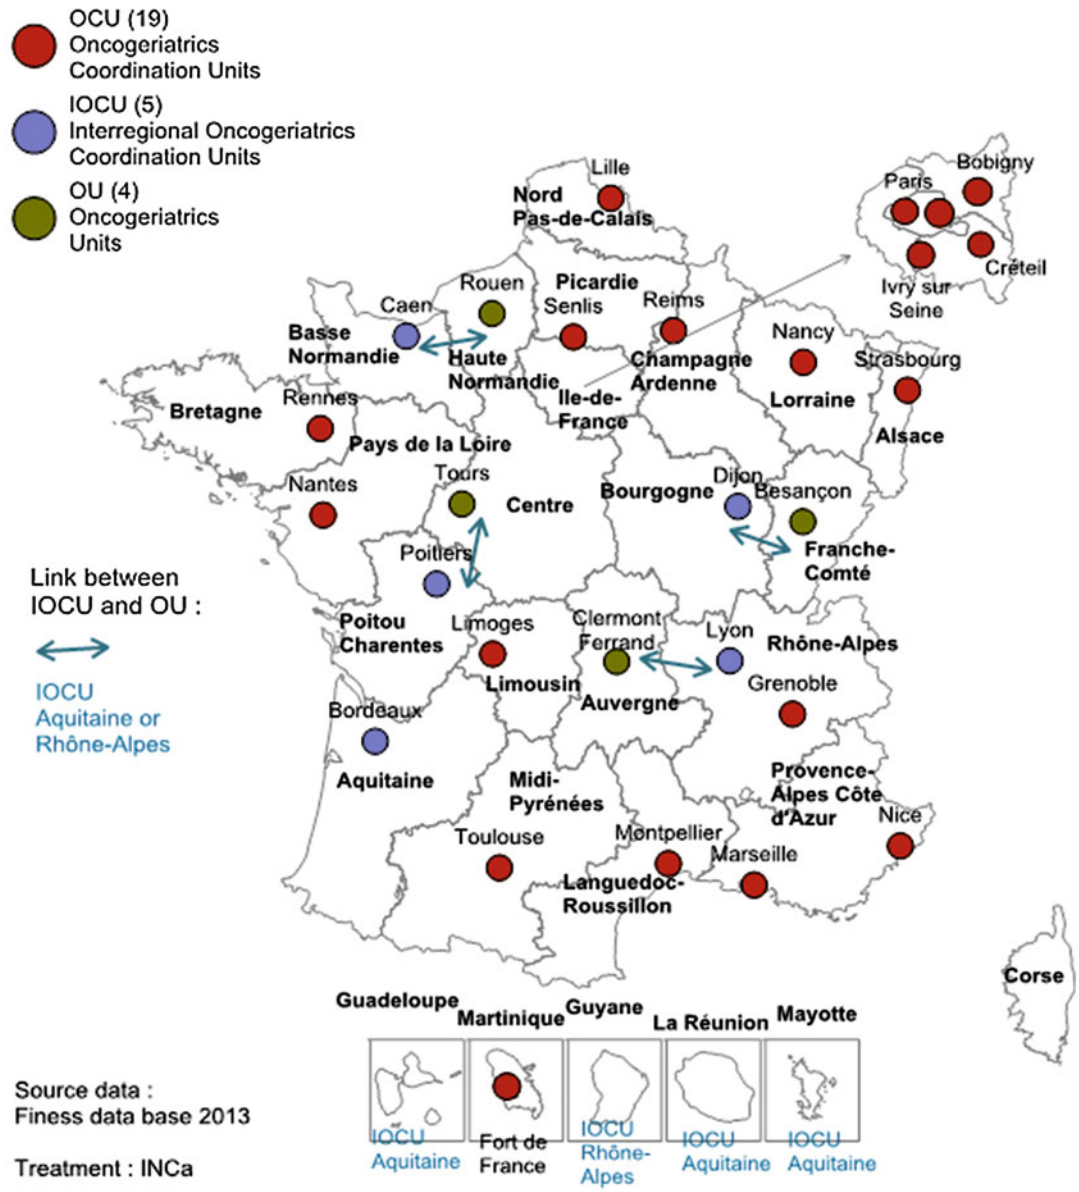

Fig. 1 Oncogeriatrics coordination units (Source: Monitoring of the scheme for care and clinical research in oncogeriatrics - January 2015, Support for the decision; INCA, March 2015; Date de publication: octobre 2015; ISBN: 978-2-37219-140-1; ISBN net: 978-2-37219-141-8; http://www.e-cancer.fr/Expertises-et-publications/Catalogue-des-publications/Monitoring-of-the-scheme-for-care-and-clinical-research-in-oncogeriatrics-January-2015. Last access date: 25 Nov 2016)

that had not considered or weighted the frailty or vulnerability, comorbidities, and polymedication of the patient. The Comprehensive Geriatric Assessment (CGA), acknowledged as the gold standard, is time-consuming (Extermann and Hurria 2007). Therefore, the first identified step to an oncogeriatric approach is to obtain that cancer patients $\geq$75 years old have systematically a geriatric prescreening test, in order to detect those

patients who should benefit from specific supportive care or CGA assessment before the treatment decision (Soubeyran et al. 2014). The next step is to have the result of this prescreening test on time for the patient's file multidisciplinary team discussion (MTD) in order to define the most appropriate cancer treatment and the optimal appropriate geriatric support; a geriatrician should integrate the multidisciplinary team if necessary. In a survey conducted in five EU countries, multidisciplinary discussions about treatment patterns for elderly cancer patients were not part of standard procedure anywhere (Anhoury et al. 2009).

- To allow that each elderly cancer patient benefits from this oncogeriatric approach

  Organizing an oncogeriatric approach for all elderly cancer patients induces the involvement of two additional partners at a regional level: the Regional Health Authority and the cancer coordination network.

  Indeed, the French health-care system governance includes 17 Regional Health Authorities (covering mainland France and overseas departments) in charge of coordinating regional health projects at the interface with healthcare practitioners and users. Inclusion of geriatric oncology development in regional projects is major to promote close collaboration between the various stakeholders involved.

  Cancer coordination networks were set up during the first Cancer Control Plan as coordination structures at a regional level between health facilities and healthcare practitioners. In order to favor active collaboration between oncologists and geriatricians, a vast majority of these networks have already established a webpage dedicated to geriatric oncology, including the list of regional healthcare institutions authorized to treat cancer patients, the full range of geriatric health-care services as well as the list of healthcare providers in the domain of geriatric oncology. Regional cancer coordination networks also participate to diffuse the information about (i) cancer treatment and the modalities of a prescreening geriatric test, (ii) the access to a comprehensive geriatric assessment (CGA) and/or a geriatrician consultation, and (iii) national guidelines dedicated to elderly patients with cancer when available.
- To stimulate specific research projects in oncogeriatrics

  The development of new treatment strategies, the risks and benefits ratio of using new drugs, but also pharmacokinetic and pharmacodynamics data of common drugs, post-marketing studies, and interventional trials are urgently needed in this population of patients.

  Nevertheless, enrollment of patients above 75 years old in cancer clinical trials remains low (Sher and Hurria 2012). In France, 4858 patients above 75 years old were included in a clinical trial in 2015 (Fig. 2 – Chart showing the trend in the number of patients aged $\geq$75 years enrolled in a clinical trial from 2007 to 2015, either academic or pharmaceutic trials); the vast majority of these trials were academic. So, only around 6.3% of elderly people with cancer benefit in 2015 from a clinical trial, offering them accessibility to an innovative medication or an innovative strategy.

  In order to boost clinical research in geriatric oncology in France, INCa supported a cooperative research group "DIALOG" in 2014, pooling UCOGs teams and "GERICO" research teams (launched in 2002 by the French National Federation of Cancer Centers).

  Since 2007, all clinical trials conducted in France in the domain of cancer are registered on the website of INCa: http://www.e-cancer.fr/Professionnels-de-la-recherche/Recherche-clinique/Le-registre-des-essais-cliniques (last access date: 11/25/16). Analysis of this data basis shows 1947 trials open for elderly (>65 years old) cancer patients in August 2016. A more precise analysis shows that 209 of these trials are phase II or phase III randomized open trials, concerning 42 (20%) hematologic malignancies, of which 15 lymphoma, 28 (13%) breast cancers, 18 colorectal (8.6%) cancers, 17 non–small cell lung cancers (8,1%), and 12 (5,7%) prostate cancer. Clearly, the distribution of cancers in clinical

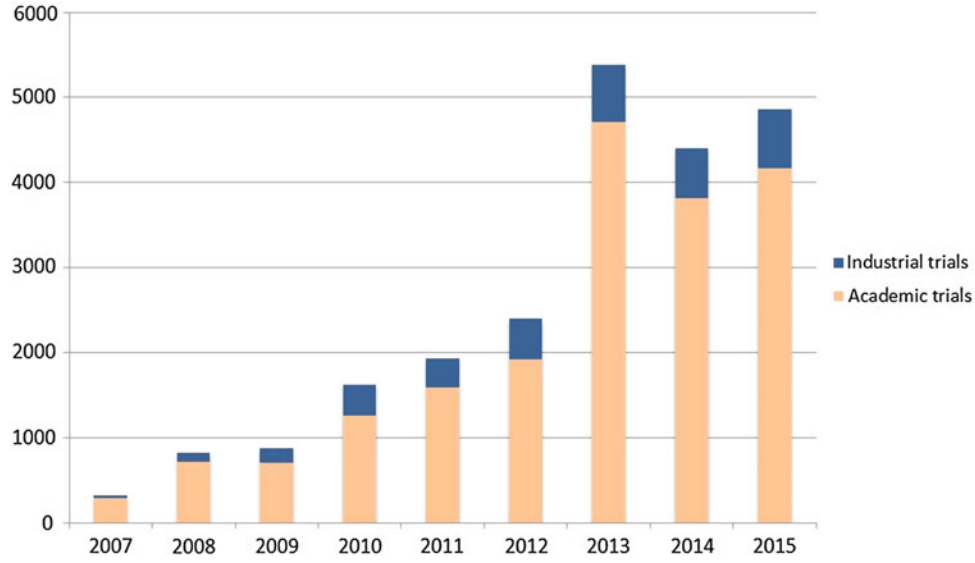

Fig. 2 Stimulate specific research projects in geriatric oncology (Source: ONCOG_EC | Traitement: INCa - lesdonnees.e-cancer.fr - 2016 (http://lesdonnees.e-cancer.fr/Themes/prise-en-charge/La-prise-en-charge-des-populations-specifiques/Oncogeriatrie#ind5807) (last access date 25 Nov 2016) and Monitoring of the scheme for care and clinical research in oncogeriatrics - January 2015, Support for the decision; INCA, March 2015; Date de publication: octobre 2015; ISBN: 978-2-37219-140-1; ISBN net: 978-2-37219-141-8)

research does not reflect the epidemiological data in the elderly. Among these trials, 41 are more specifically dedicated to senior cancer patients. However, there is a wide discrepancy in the design of these trials despite clear recommendation (Wildiers et al. 2013):

- 27 trials concern patients age range 18 to 70, 75, 80, or 85 years
- 1 trial concerns patients ≥50, 1 ≥ 60, ≥ 65, 4 ≥ 70 and 1 ≥ 80 years old
- 1 trial includes patients 60 to 75, two 65 to 85, and one 70 to 89 years old

A minimum geriatric data set is highly recommended in order to allow comparison of results in clinical trials and their adoption in general population (CGA remaining the gold standard). The classical exclusion criteria such as systemic hypertension or diabetes mellitus need to be revised, as well as biological parameters such as elevated serum creatinine or abnormal blood count. Wide inclusion criteria followed by subgroups analysis according to comorbidities should avoid selection bias in clinical trials in this specific population. Another possibility is to conduct a clinical trial for all adult people and analyze separately the elderly cohort (Huria et al. 2014).

Selection of endpoints in geriatric oncology research is being extensively discussed. Quantity of life gain (such as overall survival and/or progression-free survival) has to be balanced against "clinical benefit" and quality of life (such as preservation of functional capacity, ability to carry out daily tasks, and no rehospitalization).

Targeted therapy in older patients with solid tumors remains a largely unknown domain (Kelly et al. 2014). Under-representation of elderly patients in registration trials does not permit to predict potential adverse effects in these patients.

- To promote medical and paramedical training

  Academic medical training in oncogeriatry has been set up for more than 10 years, mostly organized by academic geriatricians. Around 800 health-care providers, half of them

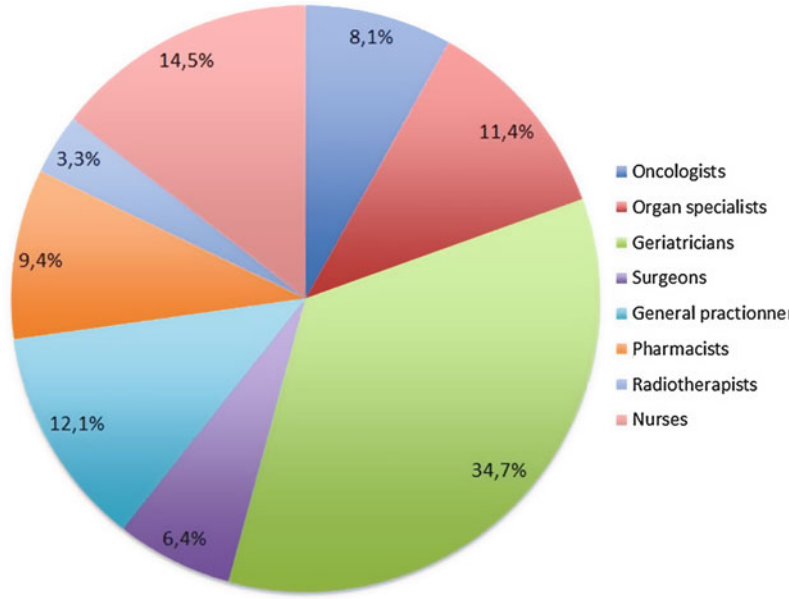

Fig. 3 Promote medical and paramedical training in geriatric oncology (Source: ONCOG_PRO_NAT | Traitement: INCa - lesdonnees.e-cancer.fr – 2016 (http://lesdonnees.e-cancer.fr/Themes/prise-en-charge/La-prise-en-charge-des-populations-specifiques/Oncogeriatrie#ind5805). Last access date: 25 Nov 2016)

geriatricians, follow this professional training each year (Fig. 3– Distribution of 841 health professionals with a university training in 2014, according to their category and specialty). Continuous training has also been organized for oncologists, geriatricians, as well as general practitioners (GPs), pharmacists, nurses, and mobile geriatric unit professionals.

However, in view of demographic trends, geriatric oncology should become a daily practice. In this context, it seems urgent to include theoretical and practical geriatrics training in the French university courses for oncologists, hematologists, but also surgeons, and other specialists. This action will be finalized in 2017.

– To promote information dedicated to patients, caregivers, and public

Communication should point out to the benefit of a personalized treatment adjusted to cancer (type, stage, etc.) and patient characteristics. The effectiveness of some of the innovative treatments such as targeted therapies should be described. The importance of participating in clinical trials should be explained to patients and their families. Communication should also target caregivers, particularly GP. There is an urgent need to improve the referral of elderly cancer patients by GP to cancer specialists, as well as to better integrate GP in the care pathway of this specific patient population (Kurtz et al. 2010; Chicoulaa et al. 2016).

– To implement databases enabling the prospective collection of data

Currently, there is no national data base allowing to improve the knowledge of this specific population and its medical care.

There are limited data. Thus, the French Society of Thoracic and Cardiovascular Surgery created in 2003 a national online database, Epithor®, inviting all the thoracic surgeons to register data concerning the types of thoracic surgical procedures, but also data concerning age, comorbidities, complications, and follow-up. More than 155,000 procedures from 102 institutions have been registered. Comparison of data on the surgical treatment of lung cancer between octogenarians and younger patients points out that surgical treatment should not be denied on the age criteria alone (Rivera et al. 2011).

At the present time, there are no available data concerning elderly patients with cancer treated at a community level and these data are urgently needed to optimize equity of care.

Funding

UCOGs benefit from a public annual funding of 5.2 M€. Most of this funding permits to recruit and pay health-care providers (geriatricians, oncologists, nurses, medical secretaries, and coordination actors).

UCOGs have to account for their activity in the form of online annual reports and a synthesis of their activities is published on the INCa website: http://lesdonnees.e-cancer.fr/Themes/prise-en-charge/La-prise-en-charge-des-populations-specifiques/Oncogeriatrie (last access date: 11/25/16).

Key Achievements and Strengths

Collaboration Between Oncologists and Geriatricians

The specific UCOGs organization aims to lead to a real bridge between these two specialties. Through the successive cancer control plans, this organization has been evolving from a pilot structure to a patient-centered organization, whatever the health-care setting.

Awareness of Clinical Research Importance in Geriatric Oncology

Eleven out of the 29 (38%) oncologists coordinating an UCOG published as first author or coauthor at least one article referenced in PubMed dedicated to geriatric oncology in 2015 or early in 2016 (Chicoulaa et al. 2016; Canouï-Poitrine et al. 2016; Corre et al. 2016; Farcet et al. 2016; Ferrat et al. 2015, 2016; Landre et al. 2015; Lange et al. 2016; Laurent et al. 2015; Oziel-Taieb et al. 2016; Pamoukdjian et al. 2015; Petit-Monéger et al. 2016; Rivoirard et al. 2016; Sabatier et al. 2015). These articles concern a wide variety of cancers: colorectal, breast, ovary, lung, pancreas, but also broader issues as geriatric assessment and chemotherapy toxicity. They include either prospective or retrospective cohort studies, randomized or not randomized clinical trials, systematic review with or without meta-analysis.

Weak Points

A Large Discrepancy of the Oncogeriatric Approach Between the Regions

Some of the UCOGs have been developing a close collaboration between oncologists and geriatricians at local level, with an effective coordination of the different health care practitioners through cancer regional network. Others have been favoring a more innovative model, developing virtual MTD meetings dedicated to elderly patients with cancer, or establishing an oncology unit dedicated to elderly patients care, or even a geriatric unit dedicated to cancer patients acute care. These models cannot be rolled out. The same applies to the organization of a systematic CGA assessment for each elderly cancer patient in a few UCOGs.

An Oncogeriatric Approach Limited to the Initiation of Cancer Treatment

The successive French Cancer Control Plans focused on a close collaboration between oncologists and geriatricians at the time of cancer diagnosis and of the first-line therapeutic proposals. However, elderly patients with cancer require a rigorous coordination of the health care practitioners during the whole care pathway. Indeed, cancer treatments may induce fast functional declines and/or severe adverse effects (Hoppe et al. 2013); cognitive impairment during or after chemotherapy may have a major impact in this vulnerable population (Mandelblatt et al. 2014). Improvement of survival even in this population entails optimizing life path by geriatric and oncologic interventions during the long-term survival (Mohile et al. 2016).

Performance Indicators Remain Hard to Determine

The evaluation of this model of care for elderly cancer patients is difficult (Magnuson et al. 2014). Indicators such as overall survival or disease-free survival are not available; so, improvement of outcome for patients who benefit from the

oncogeriatric approach cannot be demonstrated, compared to patients who did not. Improvement of cancer treatment decision-making was shown in limited groups of patients (Caillet et al. 2011; Chaïbi et al. 2011).

Future Prospects

From Oncogeriatrics to Geriatric Oncology

Oncogeriatrics is in our mind not a new medical specialty.

It is of extreme importance that all physicians involved in cancer treatment (oncologists, hematologists, radiation therapists, surgeons, etc.) grip with the geriatric oncology approach, and acquire a better knowledge of benefits and risks of the different cancer treatments in this specific population. The geriatric interventions proposed such as nutrition rehabilitation, social support, and management of cognitive problems have to be part of the supportive care and implemented right from the start of the treatment.

Strengthened Coordination Between the Different Health-Care Professionals

As previously underlined, a close cooperation between oncologists and geriatricians at a hospital level is the keystone to promote medical and paramedical training in geriatric oncology. But other health professionals play a key role during the care pathway of elderly cancer patients: general practitioners (GP), home nurses, and pharmacists. Assessment of daily medication leads to deprescribing, avoiding potentially inappropriate medication and/or polypharmacy, and lowering the risks of severe side effects (Nightingale et al. 2015; Scott et al. 2015). Deprescribing should be included in medical training in geriatric oncology.

Geriatric Oncology Across the Care Pathway

Cancer plans focused on the rolling-out of a screening tool and MDT discussion with geriatricians when needed at the first cancer treatment proposal. Good clinical practice recommendations have to be developed for frequent cancers in this population. A large availability of software tools such as the electronic medical records, cancer communication files, individualized care plans (PPS), and postcancer individualized care plan (PPAC) could facilitate information sharing and improve the coordination around the patient. Geriatric interventions have to be part of these healthcare plans, as well as supportive care interventions. Evaluation of the use of these tools in the elderly is easy and could be a good indicator of quality of care.

Better Access to Innovative Treatments

During the past decade, numerous recommendations and guidelines to develop clinical research and facilitate the access to innovative cancer treatments to elderly persons were published (Hurria et al. 2014; Wildiers et al. 2013). Trials to evaluate dosing scheme in accordance to frailty, to better predict toxicity/tolerability of chemotherapy, efficacy, and tolerance of targeted therapies, to better assess the impact of geriatric interventions are urgently needed. Since 2010, sixteen integrated centers specialized in early-phase clinical trials in cancer were granted designation by the INCa. The review of the first 3 years of designation shows that 27% of trials initiated in these centers are phase I trials. Availability of innovative treatments and development of phase I trials for elderly people with cancer have to be encouraged in these structures.

Evaluation of the Geriatric Oncology Approach

A few relevant indicators have to be defined in order to evaluate the benefit of such an approach during the care pathway, among them outcome and/or quality of life indicators.

Integrating e-Health Technology

The feasibility of computer-based self-administered cancer-specific geriatric assessment (CSGA) in older cancer patients has been demonstrated:

consent, touchscreen computer use, completion in a short time (20 min) with or without assistance (mostly due to lack of computer familiarity) (McCleary et al. 2013).

Mobile technology could be introduced in clinical practice, providing insights about patient experience and facilitate the detection and warning of potential adverse effects.

A web-based platform of symptom self-reporting could improve communication between elderly isolated patients and health-care providers.

New Forms of Financing

Discussion about a new allocation of funding is ongoing. Several factors need to be taken into account:

- The care of the elderly population in local health-care institutions authorized to treat cancer patients.

  The importance of an effective coordination, mainly provided by the cancer regional networks.
- Involvement of numerous health-care professionals during the whole care pathway.

Conclusion

The integration of the organization of geriatric oncology in French Cancer Control Plans allowed better adapting the therapeutic strategy for each patient and encouraging the implementation of clinical trials. The model based on the identification in each region of an oncologist–geriatrician partnership in charge of the coordination of the treatment is expected to evolve as the modernization act of the health system will impact the overall organizational framework in oncology. Several challenges have to be faced such as the implementation of a compulsory training program in geriatrics in the university oncology curriculum, or the coordination of health-care professionals all along the health-care pathway. The sharing of information through an oncology electronic medical record is critical.

Abstract

The population of older cancer patients continues to rise, and there is an increasing need for the continuing development of healthcare informatics and health technology. Rising healthcare costs among an aging population has shifted priorities toward cost-effective and value-based care. Inevitably, population health and predictive modeling becomes a greater focus in an attempt to better risk-stratify a physiologically and functionally diverse group of patients. Translational bioinformatics and precision medicine challenge the understanding of an individual environment and endeavors to enhance standard models of health and behavior on a more personalized level. Wearable sensors with an array of capabilities may represent an emerging tool for managing the older cancer patient. Though the use of modern technology has increased in older individuals over time, a broad implementation of health technology will require more senior adults to accept innovative approaches to healthcare. To bridge this digital divide, improvements must be made in terms of usability, data collection, privacy, speed, volume, and cost. With the aid of developing technologies, patient-reported outcomes may also become more easily collected and utilized in real-time patient care. The potential to utilize a smart and connected home that interfaces with patients and reports to providers is on the horizon.

Keywords

Healthcare informatics · Wearable technology · Sensors · Mobile health · Patient-reported outcomes

Introduction

The number of adults with cancer continues to increase and the general population has concurrently become older. Navigating a health system effectively for a growing group of older individuals requires both patients and providers to optimize the use of time- and cost-saving advances such as healthcare informatics and health technology. This chapter will explore the rising costs of healthcare and the need to prioritize value-based care, potentially with the use of population health management and predictive modeling. Novel health technologies are discussed in the context of their ongoing applications for the older cancer patient.

Rising Costs of Healthcare Among an Aging Population

Healthcare spending in the United States has grown markedly since the enactment of Medicare and Medicaid in the 1960s. Between 1970 and 1993, the increase in real national health expenditure (NHE) exceeded the growth of the gross domestic product (GDP) by 2.7% per capita annually (Blumenthal et al. 2013). The increase in healthcare spending has prompted multiple government efforts to implement change and to modify health policy and structure. In 2015, US healthcare spending reached nearly $10,000 per person and accounted for over 17% of the economy (National Health Expenditures 2015 Highlights n.d.). The largest components of this spending were inpatient hospital care, outpatient physician and clinical services, and prescription drugs. The United States consistently ranks highest in the world for healthcare spending by GDP (World Development Indicators).

As the population continues age, it is estimated that by the year 2030, over 20% of the US population will be over the age of 65 (Ortman et al. 2014). Older adults account for a greater percentage of healthcare spending due to having more comorbid medical conditions and requiring more acute and subacute care later in life. From the late

1980s to early 2000s, Medicare spending reflected a significant increase in chronic disease and outpatient management (Thorpe et al. 2010; Thorpe et al. 2004). Interestingly, raising the cost-sharing for ambulatory care among older adults was suggested to increase overall healthcare spending due to eventually relying more on inpatient services (Trivedi et al. 2010). As outpatient visits decreased, hospitalizations and days of inpatient care increased. Advances in medical innovation also account for a large portion of the increased healthcare costs (Blumenthal et al. 2013). These innovations consist of novel therapies including medications as well as medical devices that have been implemented for a spectrum of chronic diseases such as cancer and heart disease. Improvements in diagnosis have also been made with the increased use of advanced imaging modalities such as magnetic resonance imaging (MRI) and positron emission tomography (PET).

Value-Based Healthcare

In an effort to make healthcare advances sustainable, it is imperative to factor in value to medical decisions. Inherent to this medical decision making (MDM) is the concept of physician stewardship (Reuben and Cassel 2011). Fundamentally, every clinical decision is a value judgment and risk-benefit analyses by the provider. These decisions may be influenced by public policy and payer regulations, but nonetheless, the actions taken remain in the hands of the immediate provider.

As an example, a frail 92-year-old patient with end-stage heart failure and oxygen-dependent emphysema, who is admitted after sustaining a hip fracture from a mechanical fall and is incidentally found on imaging to have a new lung mass, has many important decisions to be made. Discussions regarding the possibility of surgery for hip repair, consideration of a diagnostic work-up for the lung mass, and conversations surrounding the overall trajectory and goals of care are likely topics. Healthcare decisions involving value, especially among older adults with competing comorbidities and tenuous life expectancies, are understandably challenging.

Medical value can be defined as health outcome achieved per dollar spent (Porter 2010). However, outcome may have different meanings depending on perspective. Economic analyses of medical spending in the latter portion of the twentieth century revealed increasing cost per year of life gained as each decade passed (Cutler et al. 2006). Adults over the age of 65 had the largest cumulative change from 1960 to 2000 by average per capita spending. In order to be sustainable, healthcare spending must have limits. Increased cost affects both public and private payers. A common strategy in managing healthcare cost is to reduce payment, benefits, or eligibility. An alternative plan would be aimed at minimizing waste or low-value care (Berwick and Hackbarth 2012). Indeed, there have been increased efforts toward informed discussions and decisions about commonly used tests, treatments, or services. The Choosing Wisely campaign was a collaboration among several medical societies in an effort to reduce waste in the healthcare system (Cassel and Guest 2012; Morden et al. 2014).

One possibility for abstracting more healthcare value from the existing models of care is to better identify and understand each population of patients and then target interventions toward the specific individuals most likely to receive benefit. Such an approach may have the potential to lead to change in reimbursement and eventually policy reform.

Population Health

As the population of older individuals continues to rise, the prevalence of chronic medical conditions and functional impairments will also increase. Given the rise in the cost of healthcare, innovative approaches to combine technology with increased care coordination are going to be essential to improve outcomes and reduce cost. Population health management (PHM) represents the aggregation of patient data across multiple health information technology resources (e.g., primary care providers, other health professionals, caregivers, family members, home health, and patients) (Philips). This data can be analyzed and constructed into actionable patient records, which

healthcare providers can utilize to implement actions with the goal of improving health outcomes while decreasing cost. PHM is an important model in healthcare reform because it entails evaluating patients, determining and assigning risk, and applying interventions to manage individuals at highest risk.

Predictive Modeling

Predictive analytics uses data and statistical tools to forecast which patients are most likely to be at increased risk for health problems and cost more healthcare dollars (Berardo). Health care organizations are beginning to apply predictive analytics to large clinical data sets in an effort to identify higher-risk patient populations and intervene prior to serious illness. Translating predictive analytics into changes in patient care represents a significant culture change. It requires the collection of real-time, or near real-time, data and the timely processing of this information into reports that are easy to interpret and act upon. Inevitably, automated tools will need to be developed in order to apply these analytic and management strategies across populations of patients (Berardo 2017). This model also requires that novel health technologies enable users and providers to confidentially access and assess health risk data. When individual risk is identified and requires attention, personalized guidance can be provided to patient, caregiver, or provider (Berardo 2017). This model for population health management is invariably linked to precision medicine and thus a personalized approach to healthcare.

Precision Medicine

The core of precision medicine couples established clinical and pathologic indices with state-of-the-art patient profiling to create diagnostic, prognostic, and therapeutic strategies precisely tailored to each individual patient (Mirnezami et al. 2012). Implementing precision medicine requires integration of clinical data with genomics or other physiologic profiling to characterize an individual patient's disease process. For example, recent studies have examined the potential usefulness of precision medicine through pharmacogenomic testing to optimize drug regimens and manage polypharmacy in older adults (Finkelstein et al. 2016a, b). There are now also many examples of such targeted interventions in tumor molecular profiling and cancer genomics. Identifying gene mutations and molecular abnormalities is becoming a fundamental component of the diagnostic work-up of a malignancy. In fact, over the coming years, cancer treatment may shift away from traditional determination by cell type or tissue of origin to instead targeting identified molecular changes within the tumor itself (NCI). It is not surprising that oncology research receives a substantial portion of the NIH funding to advance precision medicine (NCI). Efforts to characterize individual physiology and health states will continue to emerge and become integrated into medical research (Li-Pook-Than and Snyder 2013). This integrated personal profiling is a key component to assessing individual risk and planning targeted interventions, the backbones for precision healthcare.

Translational Bioinformatics

Translational bioinformatics is the development of storage, analytic, and interpretive methods to optimize the transformation of increasingly voluminous biomedical and genomic data into proactive, predictive, preventive, and participatory health (AMIA). Progress has been made toward utilizing genomic medicine at the point of care and seamlessly integrating into the electronic medical record (EMR) (Baselga 2013). However, the diversity of data has now extended beyond just genomics. An *individualome* is a data model that encapsulates elements of environmental, social, behavioral, biomedical, and clinical factors of an individual patient (Shameer et al. 2017). This data can be generated by wearable devices (e.g., distance or steps walked) or biosensors (e.g., continuous heart rate or blood glucose monitoring). Further investigation of this data

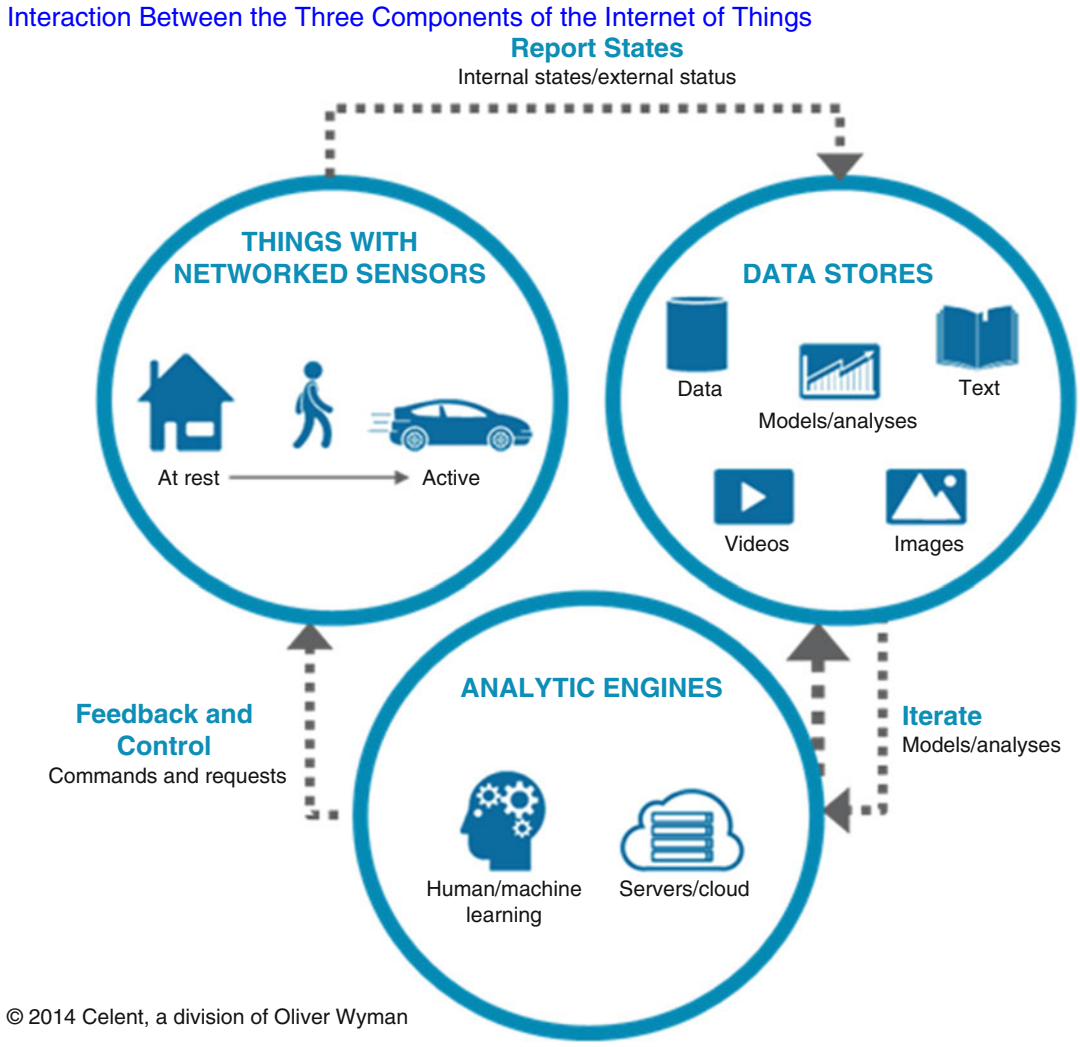

Fig. 1 Interaction between the three components of the internet of things (reprinted with permission from Celent)

incorporating individual socioeconomic information as well as local variations in environment may provide additional precision in developing predictive models capable of identifying and estimating causal or reactive roles that contribute to illness or wellness (Shameer et al. 2017).

Internet of Things

The Internet of Things (IoT) is the network of physical objects or "things" embedded within electronics, software, sensors, and network connectivity, which enables these objects to collect and exchange data (Fig. 1) (Mann 2015). The essence of IoT in healthcare resides in the source of the data, which are the sensors. Smart devices now have the capability to generate constant data on activities, events, and influencing factors that provide visibility into health and support the decision-making processes in medicine. There are also, however, several inherent challenges in leveraging data from IoT including volume, speed, computing ability, analytics, and security (Mann 2015). Remote data is collected in high volume and with rapid speed. With multiple data

streams generating information simultaneously, integrating all of it becomes even more data intensive. The computing ability of each individual device is likely insufficient to analyze all of the data, thus it must be transmitted to a central unit capable of both big data storage and high-performance analytics. Any large-scale data transmission inevitably extends the computing environment and the associated security risk.

The Smart Home

A smart home is one that includes internet connection with one or more devices that can be controlled through applications on a smart phone, smart watch, tablet, or smart television (Baik 2016). Connected homes are important as the vast majority of baby boomers desire to age within their own homes or communities (AARP 2014). Technology within smart and connected homes usually plays a role in home functionality, health monitoring, or lifestyle enhancement. The potential benefits for aging adults are overwhelming – light and temperature control, sensors that detect movement and environmental conditions, automated medication dispensers, and personal health monitors for blood pressure, heart rhythm, blood glucose, weight, physical activity, or falls (Baik 2016).

There are several inherent challenges to consider including signal clarity, bleed through, and user support (Better Connecting Seniors At Home 2016). Ensuring signal clarify is crucial as home environments can be expected to have multiple technologies that can increase the risk of interference or cross signals. Common household items such as microwaves are known to emit output that could be potentially disruptive (Better Connecting Seniors At Home 2016). Further, if an older individual were living in a dense community, technologies from neighboring environments may bleed over. It is also unrealistic to expect constant in-home user support to resolve technical issues, thus a remote support system must be developed and implemented to reach a wide population (Better Connecting Seniors At Home 2016).

The smart home represents a way for older adults to become more connected. Individuals in less populated areas can have access to a larger network of providers through the use of technology. This can also be helpful for seniors with disability or those who simply have transportation difficulties. Access to timely care is becoming an important metric for healthcare systems (Better Connecting Seniors At Home 2016). When applied across a population, the remote monitoring via a smart home system can help to risk-stratify patients and identify at-risk patients who require prompt medical attention. When used on an individual level, the system also has the potential to detect abrupt changes or deviations from one's norm to send immediate alerts or communication. In this manner, these smart systems extend an older individual's safety and social support (Better Connecting Seniors At Home 2016).

Evolving Technology and the Use of Health Technology

Over the course of the twentieth century, an abundance of new technologies and communication methods has evolved. Large, wired home telephone lines have steadily been replaced by smaller, wireless cellular phones. The emergences of lightweight, high-speed laptops and tablets have similarly substituted for the use of bulky desktop computers. Arguably, the transmission of data and sharing of information has undergone the most change. With an ever-increasing virtual and connected space, the sharing of files no longer requires a physical vehicle such as a floppy disk, compact disc (CD), or universal serial bus (USB) flash drive. Storage capacity and processing speed have also increased markedly.

With this growth in technology, comes the opportunity to utilize these tools to improve healthcare systems. Implementation may consist of patient reminders, education, counseling, screening, or intervention (Balas et al. 1997). Indeed, the primary goals of incorporating technology into healthcare are to improve communication and access to health resources while simultaneously managing cost (Dorsey and

Topol 2016). The true value of health technology stems from the dual ability to remotely monitor and remotely intervene. This has been increasingly studied in the fields of cardiology (Chaudhry et al. 2010; Inglis et al. 2015; Ong et al. 2016) and endocrinology (Lanzola et al. 2016), where remote monitoring has been used to collect diagnostic data, which can accelerate timely intervention. A critical limitation to these types of studies centers around compliance with health technology use. In fact, this is a component that large studies have been inconsistent about standardizing or ensuring.

Technology and Health Technology Use Among Older Adults

The use of technology by older adults has increased in the new millennium. In the year 2000, less than 10% of individuals over the age of 75 had internet access or went online. Recent studies have reported that 50% of individuals over the age of 75 have internet access and 60% of individuals over the age of 65 go online (Perrin and Duggan 2015). Challenges to internet access and use include the cost of an internet service plan, lack of training and support, physical disability or impairment, privacy concerns, and general skepticism. Among older adults with an annual household income of greater than $75,000, 90% go online (Older Adults and Technology Use 2014). For older adults who are connected to the internet, over 70% report being online daily and over 80% are online multiple times a week. Nearly half of online seniors are using social media and networking websites (Older Adults and Technology Use 2014). A 2016 survey of adults over the age of 60 demonstrated that over 65% had cellular phones and over 90% has cable or satellite television. This survey also showed that only 40% had a smart phone and only 25% had a fitness tracker (2016 Technology Survey Older Adults, Age 59–85+ 2016).

As older adults increase their use of general technology, the growing application of health technology becomes a logical integration of this behavior. A systematic review specifically on sensor monitoring to measure and support daily functioning in older people showed a scarcity of studies (Pol et al. 2013). Another systematic review explored the priorities for technology acceptance among elders and identified cost, privacy, safety, and utility as key components (Peek et al. 2014). Health information technology was suggested to be more accepted by community-dwelling elders if it contributed to aging in place (Fischer et al. 2014). A survey of over 200 adults over the age of 60 found that in-home monitoring of activities by ambient sensors was valued for the purposes of living at home longer, more safely, and independently and for timely detection of emergencies as well as gradual health problems (Claes et al. 2015). Visualizing activity data was also of importance. Interviews with a group of older adults showed sensor monitoring was valued as a strategy for independent living and encouraged the participants to remain more active (Pol et al. 2016). Additional features that improved older adults' perceptions of health technology was whether they were simple, reliable, effective, and tailored to individual need (Hawley-Hague et al. 2014).

Patient-Reported Outcomes and Technology

Health outcomes can be reported by various domains: provider account (e.g., global impression, physical exam findings), physiologic results (e.g., vital signs, lab or imaging tests), or patient-reported (e.g., symptom control, function, overall quality of life). Physiologic results tend to be the most objective measure of outcomes; however, patient-reported outcomes (PROs) for older adults may be more insightful of the patient perspective (Testa and Simonson 1996; Schwartz and Sprangers 2002). A patient-reported outcome is the measurement of any aspect of a patient's health status that comes directly from the individual, without modification or interpretation by another observer. PROs can be collected in many formats including paper forms, online surveys, or in-person response. Questionnaires may be generic instruments to evaluate broad symptoms

and quality of life metrics or they could be targeted instruments examining specific symptoms of interest. PROs can be used to evaluate symptoms, adherence, health status, or care satisfaction. PROs are also being explored as a quality measure in cancer care (Stover and Basch 2016). When used longitudinally, PROs offer insight into variation in symptoms or function. PROs may also allow the opportunity to monitor for disease progression. Integrating PROs into treatment assessments has been increasingly common and continues to expand rapidly (Testa and Simonson 1996; Basch et al. 2016a).

However, it is well known that PROs are inadequately reported in clinical trials, which limits the value of partial assessments (Calvert et al. 2013). Efforts to improve upon PRO measurements in terms of reliability, validity, sensitivity, and specificity will be important in ongoing research as technology becomes adapted into healthcare. With advances in technology, survey methods have improved and the ability to collect PROs via the internet or on a smart device now exist (Basch 2017). In fact, the speed of technology now offers the ability for providers to receive timely alerts or notifications when worrisome symptoms or a decline in function is noted (Basch 2017).

Patient-reported outcomes for cancer symptoms, treatment-related symptoms, and quality of life can significantly influence physician decision-making and cancer care (Lipscomb et al. 2007; Clauser et al. 2007). Commonly followed symptoms in cancer patients include pain, nausea, and fatigue (Di Maio et al. 2016). The National Cancer Institute has developed a patient-reported outcome version of the common terminology criteria for adverse events (PRO-CTCAE) to improve the extent to which these measures can be captured in cancer clinical research (Basch et al. 2014). The PRO-CTCAE was subsequently validated in a large outpatient study of nearly 1000 adults undergoing cancer treatment (Dueck et al. 2015). More recently, a randomized controlled trial of over 700 cancer patients showed that symptom monitoring with patient-reported outcomes accompanied by appropriate interventions had the potential to decrease emergency room visits and improve survival (Basch et al. 2016b).

Assessing Cancer and Aging

Cancer incidence increases with age and the number of older individuals with cancer will increase dramatically over the coming decades. It is estimated that by 2030, 70% of cancer diagnoses will be made in persons age 65 or older (Smith et al. 2009). There is tremendous heterogeneity within the geriatric population, encompassing a wide range of performance status and functional capability. Given this variability, older cancer patients are at increased risk of both undertreatment and overtreatment, which can affect toxicity and survival (Wildiers et al. 2014). Several treatment guidelines have recommended utilizing geriatric assessment for older cancer patients; however, this is no consensus on the best instrument to use (Extermann et al. 2005; Decoster et al. 2015; NCCN 2016). Completing a comprehensive geriatric assessment (CGA) can be time-intensive in a busy oncology practice and abbreviated screening tools remain poorly sensitive (Hamaker et al. 2012; Augschoell et al. 2014). Prior studies have shown that collecting simple measures of functional status activities of daily living (ADLs) and instrumental activities of daily living (IADLs) have prognostic value in elderly cancer patients (Maione et al. 2005). Gait speed and Timed Up and Go (TUG) have also been shown to be strong predictors of mortality, functional decline, and complications (Soubeyran et al. 2012; Hoppe et al. 2013; Ferrat et al. 2015; Pamoukdjian et al. 2015). Multiple tools and scales have been developed and validated for predicting cancer treatment-related toxicity (Hurria et al. 2011; Extermann et al. 2012; Hurria et al. 2016). For example, Hurria et al. combined objective parameters of baseline diagnostic data, such as hemoglobin and creatinine clearance, with baseline functional assessments, such as hearing, gait, and falls to generate a risk score that prognosticates one's chances of experiencing chemotherapy toxicity. These assessment tools may in certain cases be superior at risk stratifying older cancer patients compared to more subjective physician assessments such as the Karnofsky Performance Status (KPS). As health technology expands in use, it is anticipated that functional

assessments can be done more consistently and objectively. Prospective, randomized studies are currently underway to further explore the use of health technologies in older adults with cancer (Meguerditchian et al. 2016; Paul et al. 2016).

Wearable Sensors and Geriatric Assessment

The use of sensors in healthcare has been increasing over the past several decades. Inertial sensors have been used to record mobility assessments such as the Timed Up and Go (TUG) and to stratify older patients by sensor-identified frailty (Greene et al. 2014; Toosizadeh et al. 2015). Wearable sensors have also allowed for the objective and discriminative assessment of older adults' physical function during activities such as gait and position change (Grimm and Bolink 2016). Sensor-based assessments of sit-to-stand performance have been shown to reflect objective and self-reported aspects of functional status in the elderly (Regterschot et al. 2015). Data from wearable sensors can be incorporated into machine learning models to distinguish extremity use from ambient movement, which provides a critical level of distinction (McLeod et al. 2016).

The prominence of falls in the geriatric population makes this an important parameter to monitor for and potentially predict. There have been numerous studies utilizing wearable sensors to quantify limb movement and gait and to compare these metrics with fall outcomes (Marschollek et al. 2011). A few studies have suggested the superiority of sensor-based classification compared to other standard measures such as the TUG test or the Berg balance score (Greene et al. 2012). In a population of dementia patients, sensor-derived physical activity data was found to be independently predictive of fall risk and may have had higher diagnostic accuracy compared to conventional fall risk measures (Schwenk et al. 2014). The next important step will be to utilize sensor-based data to formulate protocols for intervention in high-risk patient populations (Danielsen et al. 2016).

Wearable sensors have developed the ability to capture subtle physiologic changes in posture, movement, localization, vital signs, and sleep patterns. Having an extensive volume of information for an individual allows for unique baselines to be established. Sensors can then detect personal differences in physiologic parameters that may be suggestive of early disease (Li et al. 2017). Smartwatches have also incorporated sensing technology into their applications and studies to validate these interfaces have been performed with prospective comparisons ongoing (Mortazavi et al. 2015). A feasibility study of a small sample of older adults was followed longitudinally using sensor technology applications to monitor mobility and daily activities (Chung et al. 2016). Wirelessly collected sensor data can be used to generate objective ADL assessments (Zhang et al. 2014).

New technologies are potentially advantageous over traditional geriatric oncology assessments due to increased objectivity when compared to performance scales such as Karnofsky (KPS) or Eastern Cooperative Oncology Group (ECOG), which may be subject to provider bias and variability (Kelly and Shahrokni 2016a). This is a topic of growing research interest as commercially available wearable devices have become readily available and accessible to patients and providers (Kelly and Shahrokni 2016b). Simple pedometry and PROs were assessed on a hematopoietic stem cell transplant unit and regression models showed correlation of activity data to patient-reported symptoms such as pain, fatigue, nausea, and shortness of breath (Bennett et al. 2016). The symptom severity and decline in physical health were reflected by decrements in the objectively captured performance of daily activities. A recent systematic review exploring the relationship of functional performance status with PROs showed that these domains captured some consistency in the patient experience but also varied and provided unique information (Atkinson et al. 2015). A system that can dually capture both functional assessment and patient-reported outcomes would be a tremendous tool for geriatric oncologists.

As wearable sensors continue to improve in sensitivity and capability, the opportunity to utilize these electronic devices for assessing older adults with cancer becomes a promising prospect. In the future, as more predictive metrics become developed through the use of modern technology such as wearable sensors within a smart and connected home, it will be important to compare this information to traditional assessments. In order to successfully integrate growing, innovative technologies into the healthcare system, their value must be proven on both a cost and utility level. With the growing population of older adults with cancer, this would be a prime population to further clinical trials that examine the potential for population health management through risk stratification and targeted intervention, to improve care and quality on both an individual and population level.

Role of Cell Cycle Control, Checkpoints, and DNA Repair Mechanisms in Stem Cells and Changes with Aging and Cancerogenesis

4

Andreas Brown and Hartmut Geiger

Contents

Abstract

The regulation of cell cycle progression, checkpoint activation, and DNA repair in stem cells is distinct from the regulation in progenitors and differentiated cells. For a broad range of types of stem cells, such as embryonic, muscle, and hematopoietic stem cells, these mechanisms have already been described. Either a complete absence or corrupted activity of checkpoints such as the G1/S damage response and the decatenation checkpoint was found or strong alterations in DNA repair mechanisms could be identified. Moreover, stem cells also activate their own distinct checkpoints, such as the novel differentiation checkpoint. It is currently not completely understood why stem cells maintain these distinct regulatory checkpoints and how they contribute to tissue homeostasis, stem cell function, and genome integrity. Furthermore, it is unclear how these mechanisms change upon aging and whether alterations in them significantly contribute to the

transformation process and the development of diseases, such as MDS and leukemia. The following chapter will provide a general overview of cell cycle control, checkpoint activity, and DNA repair mechanisms in hematopoietic and other adult stem cells as well as progenitor cells and their relevance for genome integrity, homeostasis, aging, and disease. We will further highlight checkpoint proteins as potential pharmaceutical targets to treat age-related diseases.

Keywords
Cell cycle · Hematopoietic stem cell · Checkpoints · Leukemia

Introduction

Proper cell cycle progression and the associated control mechanisms ensure high fidelity of cell division, maintenance of genome integrity, and tissue homeostasis. Every round of cell division though might result in threats to the cell and the genome, such as stalled replication forks, entangled chromosomes, improper mitotic spindle formation or the generation of reactive oxygen species (ROS), and DNA intercalators (Lopes et al. 2001). For instance, more than 100,000 DNA lesions are generated each day in every cell (Jackson and Bartek 2009). Many of these incidents have the potential to induce DNA or chromosomal damages which, if unrepaired, will eventually result in mutations or aneuploidies (Pellman 2007). To ensure proper repair of DNA damage and resolution of chromosomal abnormalities, the cell possesses a comprehensive portfolio of cell cycle–checkpoint mechanisms. These signaling cascades play a role primarily during cycle transitions, such as the G1/S, the G2/M, or the mitotic (M) checkpoints, but are also active during the progression through replication, such as the intra-S-phase checkpoint. A growing body of evidence suggests that these checkpoints are essential for ensuring the low rates of mutations and high functionality even after several rounds of cell duplication. Especially long-lived adult stem cells depend on the reliable function of these mechanisms as they need to self-renew and thus generate perfect copies of themselves to ensure the lifelong availability of a functional stem cell pool. In addition, they do also need to give rise to differentiated cells and generate tissue, and therefore, for example, DNA mutations will eventually affect all offspring and thus a large number of cells in a tissue. It is speculated that upon aging and cancerogenesis checkpoint and DNA repair mechanisms become compromised leading to the inability to correctly arrest at cell cycle boundaries to properly repair DNA damages, or, if required, to induce senescence and apoptosis (Sperka et al. 2012). Abrogation of checkpoint control might also contribute to both the deregulation of the self-renewal ability and loss of differentiation. Indeed, an increasing amount of evidence suggests that many of these mechanisms are deregulated in hematopoietic stem and progenitor cells (HSPC)–derived malignancies, such as myelodysplastic syndrome (MDS) and acute myeloid leukemia (AML).

This chapter focuses on the current knowledge of cell cycle regulation, checkpoints, mechanisms of genome maintenance, and DNA repair in HSPCs as well as in other adult stem cells and how these mechanisms can change and become disrupted upon aging and contribute to malignant transformation. We will also discuss current efforts using inhibitors targeted against important regulators of these checkpoints to treat diseases like leukemia.

Regulation of the Cell Division Cycle, Genome Maintenance, and Checkpoint Activity in Stem and Progenitor Cells

General Overview

Hematopoietic as well as other stem cells mostly reside in a quiescent state in which most cellular activities including metabolism are held to a minimum level (Cheung and Rando 2013). So, why is cell cycle control so important to them? The majority of blood cells is short-lived and needs to be replaced on a daily basis. These mature cells

ultimately originate from stem cells. So while they cycle infrequently, stem cells need to undergo cell division cycles, in which they need to balance self-renewal and differentiation, while maintaining DNA and structural integrity.

A eukaryotic cell cycle is divided into several phases: G1, S, G2, and M phase. The entry and progression through these phases are essentially controlled by cyclin-dependent kinases (CDKs) together with their binding partners and regulators termed cyclins (Sánchez and Dynlacht 2005). The transitions between cell cycle phases are tightly controlled, and upon these transitions, the activation of the corresponding checkpoints prevents the entry into the consecutive phases. Before the cell enters S phase, potential existing DNA damage, such as pyrimidine dimers and single and DNA double-strand breaks (DSBs), needs to be efficiently recognized and eliminated by repair systems to ensure proper DNA replication. To do this, cells might not enter S phase but stay arrested at the G1 boundary. This is especially important as DNA damage that occurred during G1 phase, if neglected, would most likely result in mutations and be distributed to sister chromatids during S phase. Similarly, unrepaired DNA damage which occurred during the G2 phase of the cell division cycle would be even more severe given that the resulting mutations would be delivered to daughter cells, as mitotic cells do not really initiate DNA repair processes due to impeded accessibility of DNA upon condensation (Orthwein et al. 2014). DNA damage pathways are active also during S phase: Here, the cell can initiate mechanisms that will result in a temporal halt of replication.

A special cell cycle phase is G0 phase, as it does not occur in highly proliferative cells (like in cell culture). Especially HSCs and many types of progenitor cells (MPPs) primarily reside in this phase which, in contrast to senescence, is not a permanent cell cycle arrest. Up to 90% of adult HSCs reside in this G0 phase during which transcription, translation, and metabolism are held at a minimum level. Some HSCs thus only divide a few times during the lifetime of the organism. In contrast, during early fetal development, most HSCs are actively cycling with a doubling rate of roughly 14 h with no or few cells resting in G0 (Catlin et al. 2011). The percentage of quiescent HSCs increases further with aging and ultimately reaches levels above 95% in HSCs (Bowie et al. 2006; Ema and Nakauchi 2000). It is speculated that this maintenance of quiescence protects HSCs from the accumulation of mutations (Weiss and Ito 2015), as proliferation goes along with cellular stress, such as the generation of ROS and other DNA-intercalating agents, although this dogma has been recently critically discussed (Beerman et al. 2014; Mohrin et al. 2010). An overview of checkpoint control mechanisms in HSCs is shown in Fig. 1.

Role of CDKs, Cyclins, and CKIs in HSPCs

CDKs (cyclin-dependent kinases) are enzymes that drive progression depending on the current position within the cell division cycle. Together with cell-cycle specific expression of their activators (cyclins), they are the key regulators of the cell cycle. Most of the cell cycle defects found in tumors, such as unregulated proliferation, chromosomal, and genomic instability, are directly or indirectly mediated by the deregulation of CDKs (Malumbres and Barbacid 2005). What is the function of the various CDKs? Whereas CDK2 is required to drive G1/S transition and S phase progression together with Cyclin A or E, respectively, CDK1 is essential for transition through G2 and M. Besides these kinases, also CDK4 and CDK6 play important roles in cell cycle progression: CDK4 operates during the G1-S transition phase where it is mostly bound to cyclin E and regulates the activity of retinoblastoma (pRb), an important player of the DNA damage response (DDR). A similar role is performed by CDK6. Recently, interesting findings have been published illustrating the role of CDK4 and CDK6 in adult stem and progenitor cells: Whereas CDK4 seems to have a role in ensuring proper G1-S transition in neuronal stem cells and prevents their premature differentiation (Lange et al. 2009; Lim and Kaldis 2012), CDK6 has been claimed to be a novel negative regulator of HSC maintenance and quiescence: It was shown that expression and activity of this kinase is essential

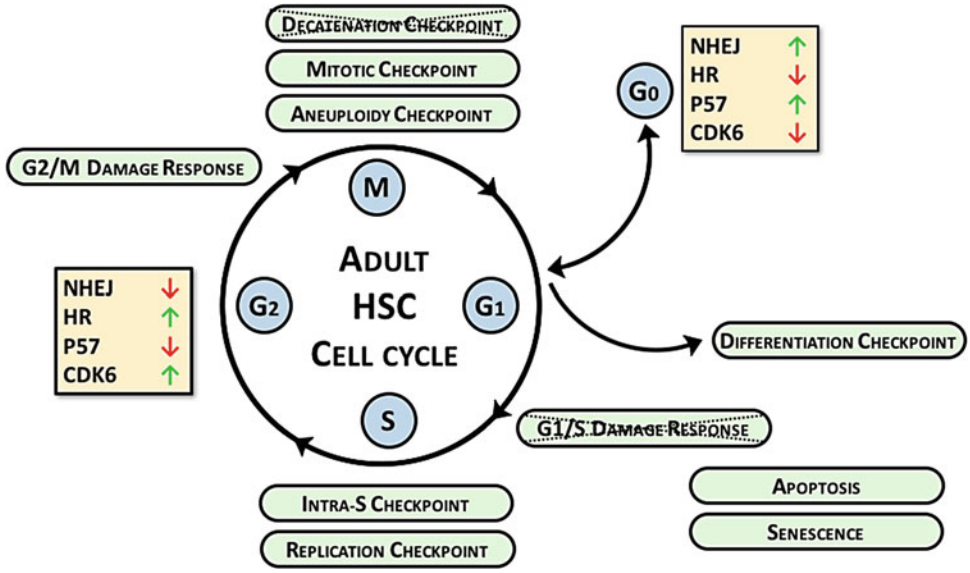

Fig. 1 Mechanisms of genome integrity in adult HSCs. A broad range of evidence suggests that cell cycle control, checkpoints, DNA repair pathways, and other mechanisms to ensure genome and functional integrity greatly differ compared to the corresponding mechanisms in mature tissue. Whereas HSCs lack proper G1/S and decatenation checkpoints, they activate the so-called differentiation checkpoint upon DNA which is not present in somatic cells. Depending on the cell cycle phase, HSCs activate different mechanisms to repair DSBs and different cell cycle regulators

for enabling the entry of HSCs into the active cell cycle. Consistent with this, ST-HSCs already show high expression of CDK6 (Laurenti et al. 2015; Scheicher et al. 2015). Interestingly, more and more data point into the direction that CDK2, CDK4, and CDK6 seem to be rather dispensable for somatic tissue and only crucial for HSPCs and other highly specialized (stem) cell types. For instance, CDK2 has been reported to be dispensable for normal somatic tissue development but pivotal in certain types of cancer stem cells (Berthet et al. 2003; Ortega et al. 2003).

For most of the known cyclins important roles in HSPC regulation have been demonstrated: Whereas cyclin A has been shown to be required for proliferation of HSCs and ES cells, it seems to be dispensable in differentiated tissue, such as fibroblasts (Kalaszczynska et al. 2009). Cyclin C has been suggested to be involved in the transition from quiescence to active proliferation, as deletion of the gene results in an increase of the quiescent HSC fraction and engraftment benefits upon transplantation (Miyata et al. 2010). Also critical for proper stem cell function is cyclin D: Loss of cyclin D (gene deletion) reduces the duration of the HSC cell cycle leading to functional defects (Choi et al. 2014). Finally, especially under stress conditions, such as 5-FU treatment, cyclin E is required for proper cell cycle entry and colony forming ability of HSPCs (Campaner et al. 2013).

Over the last decade, a growing body of evidence revealed that CDK inhibitors (CKIs) are also important mediators of stem cell function. CKIs form two families, the INK4 family and the Cip/Kip family with their major members p21(Clip1), p27(Kip1), and p57(Kip2). P57 plays a crucial role in maintaining HSC and neuronal stem cell quiescence, and it is rapidly downregulated upon differentiation into less primitive progenitors (Furutachi et al. 2013; Matsumoto et al. 2011). In a similar fashion, p27 together with p57 regulates the size of the HSC pool (Zou et al. 2011). As defects within the HSC pool and hematopoiesis mainly occur in p57 knockout mice and not in p27 or p21 knockout strains, it is tempting to speculate that it is the most critical CKI of the Cip/Kip family for HSC maintenance

and functionality (Matsumoto et al. 2011). P21 is one of the most important targets of p53 within the G1/S damage response pathway. Whereas some researchers claim an important role of p21, especially in the DDR of HSCs (Insinga et al. 2013), other publications support a minor role of the protein in ES cells as well as HSCs (van Os et al. 2007; Zhang et al. 2013). Expression of the INK4 family member p16 has been shown to be high in human HSCs while its expression decreases upon differentiation into progenitors, indicating that p16 might play a role in maintaining HSC dormancy (Furukawa et al. 2000). However, the deletion of p16 in mice does not affect hematopoiesis indicating that p16 might act in HSCs species specific (Serrano et al. 1996). P15 is not expressed in murine HSCs and similar to p16, upon genetic deletion the hematopoietic compartment is not altered. P18, on the other hand, shows high expression in quiescent HSCs and HSCs devoid of p18 harbor severely compromised cell cycle progression and overall engraftment (Yu et al. 2006). P21 and p27 are also involved in the regulation of self-renewal of other types of adult stem cells, like neural and intestinal stem cells (Fasano et al. 2007; Kippin et al. 2005), while the members of the INK4 family, p15, p16, and p18 contribute to the regulation of the self-renewal of brain, lung, and pancreatic stem cells (Janzen et al. 2006; Pei et al. 2007).

Together, these findings demonstrate that a large number of CKIs have a pivotal role in regulating self-renewal and cell cycle progression in HSCs and other types of stem cells, whereas some CKIs, however, seem to be dispensable.

DNA Repair and Cell Cycle Arrest Pathways in HSPCs

Cells encounter up to 10 DSBs per day. Although the number is likely to be lower in quiescent HSCs due to their hypoxic nature and low metabolic activity, it is clear that HSCs need an efficient strategy to repair DSBs and other types of DNA damage. ES cells and adult stem cells are very unique in terms of cell cycle regulation, DNA repair, and checkpoint activity. The resilience of HSCs toward DNA damage though remains controversially discussed. While the laboratory of Emmanuelle Passagué and others claim that HSCs are more resistant toward DNA damage than progenitors (Insinga et al. 2013; Mohrin et al. 2010; Pietras et al. 2014), other data support that HSCs do not accumulate a lot of DNA mutations and rather induce apoptosis or senescence upon DNA damage (Milyavsky et al. 2010; Moehrle et al. 2015; Shao et al. 2014). In general though, the common denominator seems to be that HSCs do not easily accumulate DNA mutations.

In order to ensure this genomic integrity, cells harbor distinct sets of pathways which are activated upon various types of DNA damage. The most important of this pathway is the DNA damage response (DDR) pathway, which is usually activated by DSBs. The key sensor of damage in this pathway is the MRN complex which consists of the three proteins Mre11, Rad50, and Nbs1. Upon a DSB event, this complex is rapidly assembled at the site of damage, ensuring the spatial proximity of matching DSBs and the activation of mediators, such as ATM. The presence in for example embryonic and adult stem cells of this basic but very critical DNA damage response pathway has been confirmed by multiple groups. However, although the activation of this pathway in HSPCs does not differ from the one found in fibroblasts, the effectors are distinct and the outcome depends also on the kind of stem cell. For example, it has been suggested that in HSCs, when situated in G0/G1 phase of the cell cycle, the predominant pathway in repairing DSBs is most likely the error-prone nonhomologs end-joining pathway (NHEJ) (Mohrin et al. 2010; Shao et al. 2012). Upon activation or differentiation of HSCs, however, the cell switches to the homologs repair (HR) pathway which has got a higher fidelity rate as it can rely on sister chromatids as source templates for DNA repair. Interestingly, different types of adult stem cells use mechanisms to repair DSBs distinctly: LGR5+ intestinal stem cells, for instance, mostly use the HR pathway in contrast to HSCs (Hua et al. 2012), whereas hair follicle bulge stem cells also preferentially use the NHEJ pathway (Sotiropoulou et al. 2010). Other DNA repair mechanisms, such as nucleotide excision

Table 1 Role of checkpoints, cell cycle regulators, and DSB repair pathways in HSCs and upon leukemogenesis in AML

Checkpoint/DNA repair pathway/ Cell cycle regulator	Situation in (quiescent) HSCs	Situation in AML
DNA damage response (DDR)	Active (Milyavsky et al. 2010)	Upregulated (Malumbres and Barbacid 2009)
G1/S damage checkpoint	Downregulated/absent (Moehrle et al. 2015)	Active/inactive (Malumbres and Barbacid 2009)
G2/M damage checkpoint	Unknown, probably active (Brooks et al. 2014; Moehrle et al. 2015)	Active (Didier et al. 2008)
S-phase checkpoint	Unknown	Inactive (Seedhouse et al. 2009)
Mitotic checkpoint	Unknown, probably active (Rohrabaugh et al. 2008)	Inactive (Boyapati et al. 2007; Schnerch et al. 2013)
Decatenation checkpoint	Inactive (Damelin et al. 2005)	Active/inactive (Brooks et al. 2014; Wray et al. 2009)
CDK6	Not expressed (Laurenti et al. 2015; Scheicher et al. 2015)	Overexpressed (Placke et al. 2014)
P57	Upregulated (Matsumoto et al. 2011)	Downregulated (Chim et al. 2005)
Nonhomologues end-joining pathway (NHEJ)	Upregulated (Mohrin et al. 2010)	Upregulated (Brady et al. 2003)
Homologues recombination repair pathway (HR)	Downregualted (Mohrin et al. 2010)	Abrogated/downregulated (Jacoby et al. 2014)

repair (NER), base excision repair (BER), and mismatch repair (MMR), have also been shown to be active and pivotal in HSCs (Beerman et al. 2014; Desai and Gerson 2014; Li et al. 2012). Thus, various DNA repair pathways in HSCs are necessary to maintain cell function (Table 1).

The G1/S and G2/M damage checkpoints initiated by the DDR pathway are important mechanisms that arrest cells at the corresponding transitions to enable DNA repair, differentiation, apoptosis, or senescence. Whereas the G1/S checkpoint plays an important role in differentiated cells, its role in stem cells remains still unclear as we and others demonstrated that this checkpoint might be impaired in stem cells: Embryonic stem (ES) cells, HSCs and less primitive progenitor cells do not arrest at the G1/S boundary in response to DNA damage induced by gamma irradiation, but enter the active cell cycle via S phase following the induction of massive amounts of apoptosis (Aladjem et al. 1998; Malashicheva et al. 2000; Moehrle et al. 2015). We also demonstrated by in vivo analyses that the lack of the retinoblastoma protein in HSPCs, usually critical for activation of the G1/S checkpoint (Weinberg 1995), did not alter the G1/S checkpoint response, further supporting that the G1/S response is impaired in HSCs (Moehrle et al. 2015). Similarly, other groups reported that DNA damage in conjunction with p21 activity induces HSC activation, cell cycle entry, and several rounds of cell duplication and thus not a G1/S arrest (Insinga et al. 2013). Considering an impaired G1/S checkpoint of HSPCs in vivo, it is tempting to speculate that HSCs are not really resilient toward DNA damage but employ a different strategy to resolve the issues: It could be more beneficial to remove damaged cells from the stem cell pool instead of trying to repair damage, even if this damage is less severe. Considering that HSCs have to preserve lifelong genome stability, this strategy could be advantageous. The absence of a strong G1/S activation in HSPCs is though still controversially discussed. The Passegué group presented data on purified HSPCs which were treated with cytokines to allow proliferation before irradiating them. These HSPCs stop proliferating upon DNA damage. The HSPCs then also, under these conditions, try to repair DNA damage instead, displaying a general low level of apoptosis after irradiation. In this experimental set-up, HSCs devoid of P53 continue to proliferate and do not induce an arrest upon irradiation. While most laboratories rely on

AnnexinV as a marker for early and global apoptosis, the Passegué group assessed the cleavage of Caspase 3 as an apoptosis marker. However, as HSCs are very different in terms of cell cycle control and checkpoint activation, it cannot be ruled out that HSCs might also activate distinct, p53 and Caspase 3 independent apoptotic pathways. Surprisingly, in contrast to murine ES cells, it has been reported that human ES cells indeed activate a G1/S response, suggesting that the activation of cell cycle checkpoints might be species-dependent (Bárta et al. 2010).

In contrast to the G1/S checkpoint, the Geiger group hypothesizes that HSCs arrest at the G2/M boundary upon DNA damage, although this mechanism has not really been studied yet in HSPCs. Maybe a proper G2/M damage response, which is induced upon DNA damage in HSCs, in combination with the ability to induce apoptosis would actually be beneficial for HSCs, as it were fatal to let DNA-damaged cells entering M phase, during which DNA repair processes are downregulated.

Besides boundaries at the end of the G1 and G2 phases of the cell division cycle, cells also apply checkpoints to limit the likelihood of mutations during DNA replication. Not only DNA damage but also basic mechanical and supply problems, such as stalled replication forks, nucleotide deficits in addition to DNA lesions can lead to a halt of the replication process. Whereas the replication checkpoint is only activated as a response to the aforementioned replication problems, the intra-S-checkpoint is activated by DSBs. Similar to the activation of the G1/S damage checkpoint also sensor/transducer proteins like ATM/ATR, Chk1/2, and p53 are required for this process. However, there are also other sensors involved, such as Rad3 and Mec1 (Labib and De Piccoli 2011). In general, it is believed that these S-phase checkpoints play a minor role in (embryonic) stem cells and are not fully developed (Hyka-Nouspikel et al. 2012), but up to now there are no clear data about the existence of these checkpoints in stem cells. ES cells, when treated with replication inhibitors, rather initiate S phase than activating replication specific checkpoints (Desmarais et al. 2012; Desmarais et al. 2016). Novel data from our laboratory also suggest the absence of this checkpoint in HSCs, at least in response to irradiation: HSCs display relatively high S and G2/M phase contents 16 h after irradiation in conjunction with high levels of apoptosis and no block in S-phase, further indicating that S phase-specific checkpoints might be absent in HSCs (Moehrle et al. 2015).

Mitotic, Decatenation, Differentiation, and Other Checkpoints

The mitotic or spindle assembly checkpoint (SAC) is an essential safety mechanism that generates a "wait anaphase" signal during mitosis. This signal remains active until the spindle apparatus is established at all chromosomes. Subsequently, the cohesion rings which entangle the sister chromatids will be dismantled, initiating anaphase. Strikingly, one single unattached kinetochore is sufficient to rapidly activate the checkpoint and to halt sister-chromatid segregation. This essential checkpoint has been extensively studied in eukaryotic cell lines. Key players of the checkpoint are the Aurora kinases which phosphorylate components of the kinetochore. These are the phosphorylation sites to which Mad2, Bub1, and Bub3 will bind leading to the stable formation of the mitotic checkpoint complex (MCC), followed by binding of Cdc20. In this situation, Cdc20 is unable to operate as the main coactivator of the anaphase-promoting complex (APC/C), the most important upstream trigger of sister chromatid segregation. Consequently, mitosis is temporarily halted (Musacchio and Salmon 2007).

Surprisingly, this checkpoint has so far not been studied in detail in embryonic or adult stem cells. One recent publication, however, demonstrates its requirement for muscle stem cell differentiation (Kollu et al. 2015). Furthermore, a study made in *Drosophila* embryos strongly suggests a role of this checkpoint in neuronal stem cells: Loss of the SAC leads to brain damage, reduction of the progenitor cell pool, and increased apoptosis (Poulton et al. 2017). Rohrabaugh and colleagues suggested already in 2008 that

undifferentiated hematopoietic cells arrest in mitosis as a response to spindle drug treatment and interpreted this arrest due to mitotic checkpoint activity. They further found out that prolonged treatment of these cells with spindle drugs induces apoptosis (Rohrabaugh et al. 2008). Furthermore, the laboratory of Sean Morrison provided evidence that an intact spindle apparatus in HSCs is crucial for preventing aneuploidy, making a proper mitotic checkpoint in HSCs likely (Gan et al. 2010). In accordance, aneuploidy also leads to microcephaly in neuronal stem cells (Marthiens et al. 2013). Using trisomic HSCs in a competitive transplantation experiment, decreased engraftment was observed, suggesting that a compromised mitotic checkpoint (an underlying problem in trisomies) indeed impairs HSPC function (Pfau et al. 2016). Furthermore, when the authors used bone marrow cells isolated from mice hypomorphic for the essential checkpoint component BubR1, engraftment defects were observed in a serial transplantation approach starting from the 2nd transplantation round. In the 3rd round, these deficient HSPCs did not engraft at all. In total, the authors speculate that HSPCs harbor a special mechanism that selects against aneuploidy. However, it cannot be ruled out that this mechanism may represent a unique pathway, which acts independently from the SAC. In summary, although there is only limited knowledge on the mechanisms of the SAC in adult stem cells, its deregulation, and likely subsequent events like aneuploidy seem to critically impair stem cell function.

Another important instrument ensuring genome integrity and preventing aneuploidy in somatic tissue is the so-called decatenation checkpoint. This mechanism involves the activity of topoisomerase II and is triggered during mitosis as a response to chromosome entanglement (Luo et al. 2009). This checkpoint has been demonstrated to be active primarily in cancer cells (Wray et al. 2009). The activity of the checkpoint can be tested by applying the topoisomerase inhibitor ICRF-193 (Downes et al. 1994). Using this approach, it could be shown that the decatenation checkpoint is impaired or absent in mouse ES and human HSPCs (Damelin et al. 2005). Interestingly, when ES cells are undergoing differentiation in response to all-trans-retinoic acid, a reduction of aberrant chromosome segregation can be observed indicating that upon differentiation the checkpoint regains activity (Damelin et al. 2005). Whether this checkpoint is also inactive in murine HSPCs and other adult stem cells has not been determined yet.

A stem cell-specific mechanism to DNA damage is the differentiation checkpoint. One of the key characteristics of HSCs aging is the preference toward myeloid differentiation (Rossi et al. 2005). The team of Lenhard Rudolph illustrated that HSCs activate a specific checkpoint upon severe DNA damage, namely the differentiation checkpoint. This checkpoint which is initiated very early after irradiation enables lymphoid differentiation of HSCs and thus their removal from the stem cell pool (J. Wang et al. 2012). Consistently, this checkpoint was also observed in melanocyte stem cells (Inomata et al. 2009). As it is also induced by G-CSF treatment, the checkpoint might also play a role in rapidly regenerating lymphoid cells after injury.

Besides the aforementioned checkpoints, HSCs also activate other distinct mechanisms to prevent DNA damage to occur. First of all, HSCs are mostly quiescent, have very low metabolic levels, and reside in a hypoxic niche. All these factors contribute to low levels of ROS, one of the main causes of DNA damage in HSCs. They also have to ability get rid of intracellular ROS via high expression of connexion-43 gap junctions (Taniguchi Ishikawa et al. 2012). Yamazaki et al. suggested in 2007 that quiescent HSCs also lack lipid raft clustering by simultaneously high P57 (Kip2) expression enabling low mutation rates (Yamazaki et al. 2006). In addition, for the efflux of other various potential DNA-damaging agents, HCSs express high levels of certain ABC transporters (Zhou et al. 2001). Strikingly, the maintenance of HSC quiescence remains the most important mechanism of HSCs to ensure life-long functionality and low rates of mutations. Consequently, serial rounds of transplantation lead to complete HSC exhaustion (Yahata et al. 2011).

Apoptosis and Senescence

Apoptosis and senescence are central for ensuring the functional and genomic integrity of somatic and stem cells. As mentioned before, HSCs induce massive apoptosis in response to DNA damage (Moehrle et al. 2015). Similarly, HSCs can also undergo senescence upon irradiation (Shao et al. 2014). Both of these pathways are highly active also due to the high abundance of the p53 protein in HSCs, and its activity is crucial for inducing cell death in these cells. Together with its regulators PUMA and ASPP1, p53 induces apoptosis in these cells (Shao et al. 2010; Yamashita et al. 2015). Although some data argue that HSCs are rather resistant to irradiation and DNA damage unlike progenitors or differentiated cells (Mohrin et al. 2010), others clearly see a dramatic increase in apoptosis as judged by AnnexinV staining and loss of HSCs in bone marrow after irradiation (Moehrle et al. 2015). The differences described in the literature might be explained by the use of distinct markers for apoptosis assessed in such experiments. Similarly, high levels of apoptosis were observed in human HSCs isolated from cord blood indicating that murine and human activate similar mechanisms upon irradiation (Milyavsky et al. 2010). It is not clear yet which apoptotic pathways are the dominant ones in HSCs. It is possible that HSCs activate both p53-dependent and independent pathways.

Alterations upon Aging and Malignant Transformation

In human and mice, the bone marrow of aged individuals consists of up to 10 times more HSCs compared to young entities (Morrison et al. 1996). Most of these aged HSCs are myeloid biased and may be derived from only a few clones, a process known as clonal expansion, which is a major hallmark of stem cell aging (McKerrell and Vassiliou 2015). It is currently unclear how the mechanisms discussed in this chapter change during aging and whether these changes are engaged in the decline of functionality of HSCs and the increase in the incidence of leukemia and other diseases. Interesting findings indicate that the number of mutations found in AML patients only increases moderately with age whereas the number of leukemia cases is known to increase exponentially (Rozhok et al. 2014). This finding contradicts a dogma in which malignant transformation is mainly driven by the accumulation of DNA mutations.

Changes of Cell Cycle and Checkpoint Control upon Aging

Most researchers agree that one aspect of HSC aging is clonal expansion that goes along with an overall decline in reconstitution ability and a bias toward myeloid differentiation. It has been shown that aged HSCs are more quiescent than young HSCs and, as a response to genotoxic stress, they initiate less cell cycle entry and proliferation (Moehrle et al. 2015; Pietras et al. 2011). Studies from our laboratory indicate that HSCs from irradiated old mice are still not able to activate a functional G1/S arrest. Similarly, a relative increase in the G2/M population in these cells can be observed indicating that also aged HSCs activate a G2/M damage response. However, the same study points in the direction that the relative number of old G0/G1 HSCs is not reduced as dramatically upon DNA damage compared to young HSCs, suggesting that more old than young HSCs remain transiently in a G0/G1 status and do not enter the active cell cycle (Moehrle et al. 2015). One possible explanation for this observation may be increased senescence in these cells. Regarding functional aspects of DDR mechanisms, changes upon aging have been described as well: The deficiency of the DDR components ATM and ATR leads to exhaustion and induces a premature aging phenotype (Maryanovich et al. 2012; Ruzankina et al. 2007). Furthermore, aged HSCs which were irradiated with low doses show reduced self-renewal capacity. Other checkpoints also seem to be altered in aged stem cells: BubR1 has been identified as one candidate gene which influences the aging process. BubR1 heterozygous or

hypomorphic mice display many aging aspects also in the stem cell department indicating that reduced mitotic checkpoint activity may be involved the aging process (Baker et al. 2004). As mentioned before, the myeloid-biased shift in HSCs is very likely linked to their clonal expansion. However, it is not clear why there is a preference for myeloid biased and not lymphoid biased HSCs upon aging. One possible explanation might be proliferation advantages of these HSCs or due to alterations in cell cycle control mechanisms (Cho et al. 2008; Dykstra et al. 2011). Not only HSCs are affected by clonal drifts: This phenomenon also occurs in other stem cells, such as muscle and neuronal stem cells (Collins et al. 2007). Interestingly, in other stem cell departments, such as intestinal stem cells the clonal drift seems to be neutral and nonbiased (Lopez-Garcia et al. 2010; Snippert et al. 2010). Another aspect of stem cell aging is the apolar nature and a preference for symmetric cell division indicating that aged HSCs activate altered cell cycle control mechanisms (Florian et al. 2012). Strikingly, in the past several years, successful efforts have been presented in terms of stem cell rejuvenation (Florian et al. 2012; Loffredo et al. 2013). It still has to be assessed, however, whether also youthful checkpoint activities and cell cycle regulation are restored upon rejuvenation.

Role of Checkpoint and DDR Deregulation in Leukemogenesis

Many types of leukemia are thought to be driven by cancer stem cells. A broad range of evidence suggests that AML, CML, and other types of leukemia, as well as hematopoietic malignancies such as MDS, are derived from HSPCs in a process called leukemogenesis (Eriksson et al. 2015).

A massive amount of evidence suggests the deregulation of important key players of cell cycle and checkpoint control mechanisms in leukemia. Although there are no clear data yet about the activity of the SAC checkpoint in HSPCs, there have been several publications suggesting the deregulation of the SAC in leukemia, especially in AML: The important regulator of the SAC, BubR1, is very often deregulated in AML and other types of leukemia. Appropriate activity of BubR1 has been demonstrated to be crucial for proper function of megakaryocytes, a cell type which essentially relies on sustained checkpoint activity due to its polyploid nature (Wang et al. 2004). Schnerch and colleagues reported that in most AML patients a downregulation of the corresponding protein is common. This goes along with high activity of the APC/C and premature degradation of the anaphase inhibitors cyclin B1 and securin. Importantly, by stabilizing cyclin B1 or by overexpressing BubR1 in AML cell lines, the sensitivity of these cells to spindle drug treatment and appropriate mitotic checkpoint activity can be regained (Schnerch et al. 2013).

Furthermore, other reports indicate that patients with t(8;21) AML also harbor an abrogated SAC. This form of leukemia is characterized by the appearance of the fusion protein AML-ETO (Yuan et al. 2001). Researchers have shown that securin and cyclin B1 are downregulated in the presence of AML-ETO (Boyapati et al. 2007). Upon overexpressing of a truncated variant, AML1-ETO exon 9a, which is present in patients as well, cell lines fail to appropriately arrest upon spindle drug treatment and show several indications of failed mitotic checkpoint activity, such as premature degradation of securin, chromosome bridges, micronuclei, and aneuploidy. This aspect can be explained by downregulation of BubR1 upon overexpression of the fusion protein (Boyapati et al. 2007). Similarly, the expression of other components of the mitotic checkpoint, such as Mad2 and Bub1, also have been shown to be deregulated upon leukemogenesis (Ru et al. 2002). In some leukemia, a deregulation of the SAC has been found that involves Blinkin, a mitotic regulator, which is frequently found as an MLL-fusion partner in AML. As Blinkin is required for the recruitment of MCC components, its MLL-fusion form it can no longer regulate the SAC, leading to genetic instability (Kiyomitsu et al. 2007). Moreover, Mad2, another MCC component, is downregulated in ALL

(Krapf et al. 2010). In addition, also Aurora kinases are frequently mutated or overexpressed in AML. Consequently, they have been suggested to be promising targets for pharmaceutical treatments (Ye et al. 2009). Specifically, Aurora B is very often overexpressed in AML. Using an inhibitor against Aurora B together with other anticancer drugs, cell cycle arrest and apoptosis could be induced (Oke et al. 2009). Furthermore, a growing body of evidence suggests the essential contribution of the abrogated functionality of cohesins in leukemogenesis. These genes are important regulators of genome stability and their presence prevents premature sister chromatid segregation during mitosis. Consequently, cohesin genes, such as *STAG2*, are very frequently found to be mutated in AML and MDS (Wong et al. 2015).

Whereas CDK6 is not expressed in quiescent HSCs but required for ST-HSCs, it is overexpressed in leukemia (Laurenti et al. 2015; Placke et al. 2014; Scheicher et al. 2015). Another component of the DDR, pRb often presents with downregulated expression in leukemia (Paggi et al. 1995). Furthermore, the expression of BRCA1 and BRCA2, two DDR genes, are also often downregulated in AML, leading to decreased cell cycle arrest ability and low DNA repair fidelity (Yoshida and Miki 2004). Importantly, mutations in these genes are very frequently found in therapy-induced AML (t-AML) patients (Cole and Strair 2010). This can mostly be explained by hypermethylation of the corresponding promoter regions caused by loss of proper DMT3A function, one of the most frequently mutated genes in AML (Cole and Strair 2010). Interestingly, it has been shown that many mutations associated with leukemia, such as concerning p53 among others, already exist/are found before the pathogenic rise of leukemia (Wong et al. 2015).

There is a broad range of evidence for impaired DDR and DNA damage repair mechanisms in leukemia-derived cells. It is suggested that leukemic cells harbor intact DNA damage repair mechanisms but these are uncoupled from DDR pathways and other checkpoints (Boehrer et al. 2009). Cancer stem cells like glioma stem cells present with an enhanced cell cycle checkpoint response as well as DNA repair activity (Bao et al. 2006). In lung cancer stem cells, an enhanced repair of DSBs and a lack of S-phase checkpoint activity were found (Desai et al. 2014). It may not be surprising that many cancers including leukemia often show the (re)activation of DDR mechanisms indicated by high ATM, Chk1, and Chk2 expression. As the G1/S checkpoint is downregulated in ES and some adult stem cells including HSPCs, it is tempting to speculate that one consequence of leukemogenesis might be the reactivation of the G1/S damage response, at least in some types of leukemia. Consequently, proteins involved in DDR are promising targets for anticancer therapy. Very important contributors of leukemogenesis are also histone and epigenetic modulators. Five of the ten most mutated genes in AML and MDS encode for histone-modifying enzymes and DNA methyltransferases. This often directly affects the gene expression of cell cycle regulators. Very well documented, for instance, is the downregulation of CKIs in leukemia, such as p14, p15, and p16, due to aberrant promoter methylation (Melki et al. 1999). In conclusion, the deregulation of checkpoints and the DDR is frequently observed in leukemia. This indicates that changes in these mechanisms might critically contribute to leukemogenesis.

Treatment of Malignancies by Intervention of Checkpoint/Cell Cycle Control

As discussed in this chapter, deregulation of checkpoint and cell cycle control may play an important role in aging and aging-associated diseases such as leukemia. Consequently, checkpoint components could be novel promising targets for pharmacological treatment. As p53 is very frequently mutated in AML and MDS (Christiansen et al. 2001; Ok et al. 2015), DNA damage checkpoint responses cannot act appropriately and very often apoptosis cannot be initiated as a response to severe DNA damage (Li et al. 2016). The

overwhelming evidence of deregulated p53 activity in cancer makes it a promising target for anticancer therapy. Indeed, there are several studies suggesting the reactivation of a mutated and dysfunctional P53 protein by small chemical compounds, for instance by Apr-246. This molecule aims to help mutated and truncated P53 to its native folding thus restoring its function as a transcriptional activator (Bykov et al. 2002; Saha et al. 2013). Other strategies involve affecting downstream- or upstream targets of p53 or direct binding partners to restore the ability of cells to induce apoptosis (Andreeff et al. 2016; Stivala et al. 2012). A supporting approach during leukemia treatment could involve maintaining quiescence in HSCs: By inhibiting CDK4/CDK6 in these cells upon simultaneous chemotherapy, cell cycle entry and HSC exhaustion can be prevented (He et al. 2017).

Especially components of the DDR, such as ATM, ATR, and Chk2, are commonly mutated and deregulated in leukemia cells (Guarini et al. 2012; Morgado-Palacin et al. 2016; Takai et al. 2002). Often unfavorable mutations in these genes lead to the inability to appropriately react to DSBs mostly due to upregulation or gain of function. Consequently, some of the corresponding proteins have also been suggested to be suitable targets for inhibitors. Indeed, inhibitors against ATM (KU-59403) (Batey et al. 2013), ATR (AZD6738) (Kwok et al. 2016), Chk1/Chk2 (UCN-01) (Gojo et al. 2013) are currently under development or in various clinical phases. All these inhibitors are suggested to treat leukemia, in part by inducting checkpoint override or restoring apoptotic pathways. In addition, it has been shown that in AML cells by stabilizing p53 and p21 to induce a G1 arrest, apoptosis can be reinitiated (Kojima et al. 2008). Moreover, the inhibition of Chk1 in conjunction with genotoxic therapeutics to induce DNA damage also seems to be a promising approach (Didier et al. 2008). Finally, targeting Plk1 has been suggested for the treatment of hematopoietic malignancies as well, as it is often overexpressed in these cells: Indeed, inhibition of Plk1 by small chemical molecules leads to cell cycle arrest and apoptosis (Brandwein 2015).

Conclusions/Directions

Adult stem cells are of pivotal importance for the whole organism: They are responsible for the renewal of most somatic tissue at every step of life and therefore fundamental for tissue homeostasis. One hallmark of aging is the functional decline of stem cells leading to increased exhaustion, clonality, biased differentiation, and higher susceptibility for malignant transformation. However, it is yet unclear how stem cells age and which mechanisms support this process. In this chapter, we discussed how primarily HSCs regulate cell cycle progression and DNA repair and how changes in these processes contribute to the functional decline of stem cells. The probability of developing leukemia is dramatically increased upon aging, and this phenomenon cannot exclusively be explained as a consequence of the accumulation of DNA mutations. HSPCs seem to rather "deregulate" mechanisms upon aging like checkpoints that are critical for preventing leukemic transformation. However, more research will be necessary to better understand these mechanisms in stem cells and how they contribute to aging and disease.

Abstract

Cellular senescence is a state of irreversible growth arrest activated by a complex response to stress signals that lead to DNA or mitochondrial damages. Thus, cellular senescence derives from stress-activated programs, as opposed to other cellular states of irreversible growth arrest, such as post-mitosis and terminal differentiation, which are a consequence of developmental-activated programs. Senescent cells are characterized by the expression of different nonexclusive markers with various functions, and most senescent cells secrete a suite of cytokines, growth factors, and proteases, known as the senescence-associated secretory phenotype (SASP). The senescence growth arrest represents a potent barrier to prevent the propagation of damaged cells and to maintain tissue homeostasis. Moreover, the senescence program is a well-established

tumor suppressive mechanism, and different anticancer therapeutic strategies are aimed to induce cancer cells to senesce. However, an excessive accumulation of senescent cells and their secretory phenotype can drive different pathologies associated with age, including cancer. Thus, cellular senescence can begin as a potent tumor suppressive mechanism and end with a tumor-promoting passing through positive modulation of tissue repair. For this reason, interventions aimed at interfering with the deleterious functions of senescent cells are under development.

Introduction

Cancer is the second most common cause of mortality worldwide. Nonetheless, cancer death rates have declined by more than 1% per year in men and women over the past 10 years, most likely due to advances in biomedical research; still, 15 million new cancer cases and more than 8 million deaths from cancer occurred worldwide in 2013 only. It is notable that the yearly decline in the cancer death rate is most prominent in younger, compared to older (>45 years of age), individuals. Age is the single most significant risk factor for developing cancer, and the vast majority of malignant tumors that are treated in clinics today occur in older patients (Extermann 2010).

In general terms, aging represents the slow and progressive deterioration of key biological functions, resulting in the accumulation of multiple pathologies and ultimately leading to organismal death (Kirkwood 2005). Aging is a well conserved phenomenon, and similar age-associated marks can be observed in a variety of different species going from yeasts to humans. However, the aging process is highly variable and intrinsically complex, due to its establishment and development from intricate interactions between genetic, environmental, and stochastic factors (Montesanto et al. 2012). Several fundamental mechanisms that drive the age-related deterioration of cellular and organismal functions have been described, but a uniform theory on how these processes arise, interact, and exert their roles is lacking.

A key discovery for the understanding of the aging process emerged more than 50 years ago when Hayflick and Moorhead found that human diploid cell strains undergo irreversible growth arrest after extensive serial passages in culture, a phenomenon described as "cellular senescence" (Hayflick and Moorhead 1961). This intrinsic clock that limits the life-span of human cells might potentially explain the restricted capacity of the human body to regenerate tissues in the long-term. Thus, aging could be explained by the "wear and tear" theory, first introduced by Dr August Weismann in 1882: body parts eventually wear out due to accumulation of senescent cells that are not able to proliferate and regenerate damaged tissues. Moreover, additional paracrine functions of senescent cells, such as the senescence-associated secretory phenotype (SASP) – a complex secretory program which includes several proinflammatory and pro-growth factors – can contribute to degenerate tissues (Loaiza and Demaria 2016).

However, the deleterious role of age-associated senescent cells for tissue homeostasis is contrasted by beneficial functions during development and in young age. The senescence growth arrest serves as an alternative to apoptosis during embryogenesis, where senescent cells appear to play an essential role in optimizing the development of certain embryonic structures (Munoz-Espin et al. 2013; Storer et al. 2013). Likewise, the non-cell-autonomous SASP can be beneficial by promoting wound healing and regeneneration and by limiting excessive fibrosis (Demaria et al. 2014; Jun and Lau 2010). Thus, based on experimental evidences, the senescence program can be seen as an example of "antagonistic pleiotropy," a theory introduced by Dr George Williams in 1952: An evolutionary selected mechanism which has beneficial effects during youth but has deleterious side effects at older ages.

The antagonistic pleiotropy of senescent cells can also be seen in the context of tumorigenesis. The activation of the senescence program restrains the onset and accumulation of damaged, and potentially oncogenic, cells early in life (Campisi 2001). Moreover, the SASP reinforces the tumor immunosurveillance, further limiting the spread of cancer cells throughout local and distal tissues. Tumors are often characterized by loss-of-function mutations of essential senescence players, such as p53 or p16, and mice that can bypass senescence develop tumors early in life (Campisi 2001). Many standard anticancer therapies, such as radiation or chemotherapy, induce senescence and exploit its tumor suppressive functions. However, cells harboring mutations in key genes for the induction and establishment of the senescence program are often able to develop resistance to such therapies. Moreover, these treatments hit noncancer cells and induce senescence in normal cells, with accumulation of nonproliferating cells in tissues and development of low levels of chronic inflammation, a situation that resembles an aged environment. These therapy-induced senescent cells might be responsible for a number of adverse reactions to cancer interventions (Demaria et al. 2017). To overcome the late deleterious effects of cellular senescence, an increasing interest is raising towards interfering with harmful aspects of the senescence program (Soto-Gamez and Demaria 2017). This approach is being developed around two different strategies: (1) elimination of senescent cells to reduce the SASP and to create space for the spread of healthy and undamaged cells; (2) inhibition of specific SASP factors to reduce chronic levels of harmful inflammatory and growth factors. However, these strategies come with new costs for the homeostasis of the organism.

This chapter offers a summary of the complexity of senescence phenotype, and an overview of the steps that lead a potent tumor suppressive mechanism to become pro-tumorigenic. Moreover, it discusses how senescent cells can be pharmacologically targeted in view of new anticancer therapeutic strategies.

Cellular Senescence

Induction of Cellular Senescence

The first example of cellular senescence was shown by the limited replicative potential of human cells, initially described by Hayflick and colleagues (Hayflick and Moorhead 1961). This so-called replicative senescence (RS) derives from a DNA damage response (DDR) signaling which is activated as a consequence of critically short telomeres. Telomeres shorten during each mitotic cell division and quickly become critically short and dysfunctional (Shay and Wright 2005). However, telomere length does not reflect organismal life-span, as mice carry telomeres 5–10-times longer than in humans but have a life-span 30-times shorter.

Telomere attrition activates a DNA damage response without effective repair, leading to activation of p53 (Herbig et al. 2004). p21 and p16 are the two main tumor suppressor pathways responsible for the replicative arrest of senescent cells. p21 binds and inhibits CDK1, CDK2, and CDK4/6 complexes and is tightly controlled by the activity of p53 in response to DNA damage (He et al. 2005). p16 is a CDK4/6 complexes inhibitor, and its expression is controlled by either epigenetic and transcriptional changes (Rayess et al. 2012). During replicative senescence, P53-mediated p21 accumulation acts as an early event in inhibiting cellular proliferation, while p16 levels reach maximum level at a later stage and are possibly independent from telomere shortening (Stein et al. 1999).

Conditions of persistent activation of the DDR without repair are caused by strong genotoxic stress such as ionizing radiation and chemical agents. These stresses can cause DNA double-strand breaks (DSB) across the genome and consequent induction of DDR signaling and p53 activation. After X-rays, a large fraction of exogenously induced persistent DDR markers is associated with telomeric DNA in a telomere length-independent fashion (Fumagalli et al. 2012). The accumulation of persistent damage at telomeres might be due to the irreparability of telomeric tracts, which is a consequence of their functions

in preventing chromosomal fusions. In contrast, heavy ions promotes a different type of DNA damage – two or more individual lesions within one or two helical turns of the DNA molecule – which is in some instances irreparable (Zhang et al. 2016).

Different types of chemicals used in cancer therapy are based on inducing mutations in target cells. Topoisomerase poisons, such as etoposide and doxorubicin, interfere with the activity of the topoisomerase enzymes, mostly leading to single- and double-strand breaks. Alkylating agents and platinum compounds cause generation of monofunctional DNA adducts and arrest of replication, leading to the formation of random-strand breaks. The senescence program that is activated upon genotoxic stress is commonly defined as "therapy-induced senescence" (TIS).

Consistent with its role as a tumor suppressor mechanism, senescence is also induced upon strong mitogenic signals. Expression of oncogenic *Ras* in primary human and rodent cells results in a permanent G1 arrest, mediated by p53 and p16, and in the induction of a phenotype indistinguishable from replicative senescence (Serrano et al. 1997). The cell-cycle arrest through DDR signaling is triggered by the production of reactive oxygen species (ROS) and aberrant DNA replication, which lead to persistent DSB (Lagouge et al. 2006). The aberrant expression of oncogenes is not the only mitogenic signal that can induce senescence. Indeed, prolonged exposure to interferon-β triggers a senescence program that involves p53 activation and DNA damage signaling, which is activated by the accumulation of ROS (Moiseeva et al. 2006).

Primary ROS, such as hydrogen peroxide and superoxide anion radical, are released from the reduction of oxygen during ATP synthesis from the mitochondria and can further react with metal ions or other reactive oxygen species and form secondary ROS, such as hydroxyl radical. These secondary ROS are highly unstable and can react with all kinds of macromolecules causing cellular damage (Correia-Melo and Passos 2015). Indeed, oxidative stress can induce telomere damage and activate DDR, which leads to senescence. Furthermore, it has been shown that telomeric DNA is more sensitive to oxidative stress, since guanine rich regions are more susceptible to oxidative modifications. The role of ROS in telomere damage and senescence has been confirmed by the increased life-span in cell cultures when ROS have been decreased by the addition of antioxidants, reactive oxygen scavengers, and low ambient oxygen concentration (Correia-Melo and Passos 2015).

ROS levels increase in senescent cells as a result of signaling through p21-MAPK14 and TGFβ pathway, which causes further DNA damage induction and DDR, creating a persistent feedback loop (Passos et al. 2010). High oxygen concentrations promote accumulation of p21 but not of p16, possibly in a Reactive Oxygen Species (ROS)-dependent manner (Passos et al. 2010). In contrast, conditions of hypoxia seem to favor the induction of p16 (Zygmunt et al. 2002). Additionally, recent reports indicate that mitochondrial perturbations can induce senescence beyond production of free radicals. For example, inhibition of the ETC complexes I, II, or III by rotenone, 2-thenoyltrifluoroacetone, or antimycin A, respectively, activates senescence (Wiley et al. 2016).

A less-explored inducer of cellular senescence is represented by epigenetics perturbations. Indeed, changes in chromatin organization can trigger the senescence response, although the mechanisms are not well understood. A potential explanation relies on a p16-dependent and p53- and telomere-independent activation of a senescent state in response to disruption of heterochromatin by chromatin relaxation mechanisms, partly mediated by histone deacetylase agents (Munro et al. 2004). An alternative explanation relies on the indirect activation of DDR signaling: Deacetylase inhibitors, which induce senescence, can activate ATM and promote DDR signaling in the absence of actual DNA damage (Pazolli et al. 2012).

Phenotype of Senescent Cells

In addition to growth arrest, senescent cells exhibit a number of additional features. However,

none of these features is unique for the senescent phenotype, making the identification of senescent cells a challenging task, particularly in vivo (Hernandez-Segura et al. 2017). Senescent cells are metabolically active and characterized by accumulation of stress granules response, including lysosomes. Increased lysosomal content is associated to the activation of acidic β-galactosidase, a common marker to detect senescent cells in culture and in tissues which is not necessary to induce senescence (Dimri et al. 1995).

Senescent cells exhibit enlarged cellular size, flattening, larger nuclei, irregular nuclear envelope, and changes in the composition of the nuclear lamina and in chromosome condensation. At dysfunctional telomeres and at nontelomeric sites, senescent cells present DNA damage foci, such as γH2AX or 53BP1, which activate the (ATM)–p53–p21 signaling required for growth arrest (Nakamura et al. 2008). However, these foci do not constitute a specific marker because most cells can repair the DNA damage without undergoing senescence, and because the DDR signaling can be activated without actual DNA damage, as it occurs upon treatment with histone deacetylase inhibitors. Chromatin domains stained densely by DAPI and rich in H3K9me3 and HP1, possibly at silenced pro-proliferative genes, are also visible in senescent cells (Narita et al. 2003). However, SAHF are detected only in human cell culture and they have not been observed in tissues positive for p16 expression and possessing other features of cellular senescence (Kosar et al. 2011). The loss of lamin B1 is also observed in senescent cells, which has been found to be a key factor in chromatin reorganization during senescence, including dramatic changes in the distribution of trimethylation on histone H3 (Shah et al. 2013).

Gene expression profile during senescence is profoundly affected (Hernandez-Segura et al. 2017). For example, increased expression of p16 is a common marker to identify senescent cells in vivo and in vitro. This protein is generally absent in healthy young cells, but it becomes progressively upregulated with aging (Baker et al. 2016). Other important changes in gene expression, already mentioned before, correspond to the loss of lamin B1 and the activation of the p53 pathway (Serrano et al. 1997). Most senescent cells upregulate the transcription of a number of genes encoding for secreted proteins, known as senescence-associated secretory phenotype or SASP (Coppe et al. 2008). This secretory phenotype is transcriptionally activated by the DDR (Rodier et al. 2009), and cells that undergo senescence due to ectopic overexpression of p21 or p16, but without activation of DDR, do not develop a SASP (Coppe et al. 2011). The SASP is positively regulated by several proteins acting upstream in the DDR cascade such as ATM, NBS1, and CHK2 (Rodier et al. 2009). However, a main regulator of DDR, p53, has an inhibitory effect, and its inactivation in senescent cells causes hyperexpression of SASP (Coppe et al. 2008). The SASP is also regulated by NF-kB and C/EBP-β, which are transcription factors that modulate immune and inflammatory responses (Loaiza and Demaria 2016). Another transcription factor, GATA4, is stabilized to activate the transcription factor NF-κB, which initiates the SASP and facilitates progression to senescence (Kang et al. 2015). The SASP is composed of pro-inflammatory cytokines (e.g., IL-1α, IL-1β, IL-6, and IL-8), growth factors (e.g., HGF, TGFβ, and GM-CSF), chemokines (e.g., CXCL-1, -3, and -10), and matrix remodeling enzymes (e.g., MMPs). The diverse biochemical activities induced by the components of the SASP suggest that it constitutes a mechanism to communicate with other cells and to modulate the local microenvironment.

From Tumor Suppression to Tumor Promotion

Tumor Suppression

Cellular senescence is caused by several pro-tumorigenic stimuli, including proto-oncogenes, growth factors, and metabolic stress. A common feature of senescent cells induced by different stimuli is the activation of pathways which inhibit the cell cycle. Thus, cellular senescence acts as a potent tumor suppressive

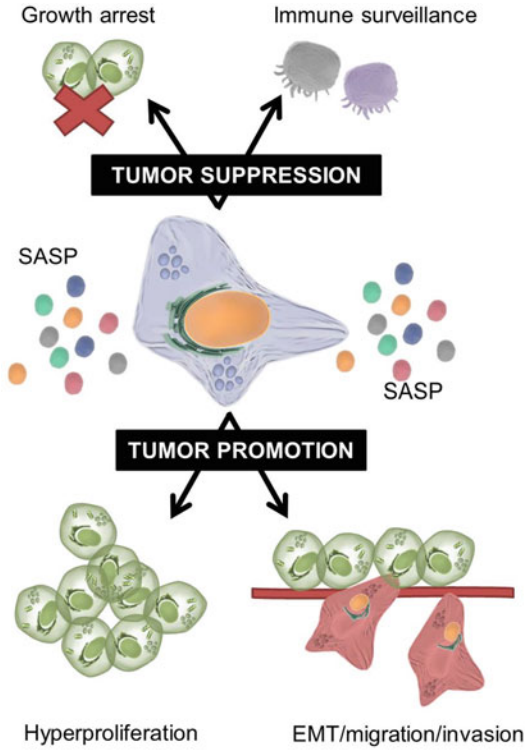

Fig. 1 Senescent cells (middle panel) can exert opposite functions during tumorigenesis. As tumor suppressors, they can inhibit growth and promote immune surveillance (top panel); as tumor promoters, they can enhance proliferation of surrounding cells and activate epithelial-to-mesenchymal transitions (EMT), favoring migration and invasion of cancer cells (bottom panel)

mechanism to prevent excessive and uncontrolled proliferation (Fig. 1). As described above, this oncosuppressive role is mainly dependent on two pathways: the p53 and the pRB/p16 pathways (Loaiza and Demaria 2016).

p53 activation is essential for the establishment of senescence. p53 is mainly induced in response to DNA damage by the kinases ATM and ATR, which are able to suppress the levels of the p53 inhibitors MDM2 and MDM4 (Stommel and Wahl 2004). Several genes are transcriptionally regulated by p53 and have been linked to the induction of senescence (Yasaei et al. 2013). However, one of the most established p53-target genes is p21, an inhibitor of the activity of cyclin-CDK2, CDK1, and CDK4/6 complexes.

p16 covers important roles for both initiation and maintenance of senescence. p16 binds to CDK4/6 and prevents its interaction with cyclin D (Serrano et al. 1993). This binding inhibits the phosphorylation of pRB and the nuclear localization of E2F (Stevaux and Dyson 2002), thus arresting the cell at the G1/S checkpoint of the cell cycle. p16 expression is repressed by the PRC complex and by specific epigenetic marks (Witcher and Emerson 2009), and induced by transcription factors, including PPAR-γ and ETS1 and ETS2 (Gan et al. 2008; Ohtani et al. 2001).

In support of the potent oncosuppressive role of cellular senescence, defects in either the p53 or p16 pathway greatly increase organismal susceptibility to cancer. Indeed, the majority of the human cancers harbor mutations of p53 and/or p16, while KO mice for either of the proteins develop cancer at a very early stage (Donehower et al. 1992; Sharpless et al. 2001).

In both human and mice, cells that express senescence markers are abundant in premalignant lesions but scarce in the cancers that eventually developed, including SA-βgal and DDR signaling (Collado et al. 2005).

Thus, cellular senescence restrains cancer by imposing a cell-autonomous block to the proliferation of oncogenically damaged/stressed cells (Loaiza and Demaria 2016).

In some tissues, reactivation of p53 induces senescence and tumor regression (Ventura et al. 2007; Xue et al. 2007), and a large number of small molecules to reestablish normal p53 functions has been developed for cancer treatment (Khoo et al. 2014).

The tumor regression observed after the reactivation of p53 is partially due to the inflammatory response induced by the secretory phenotype of senescent cells. SASP components elicit the recruitment and activation of immune cells, particularly NK and T cells, which can remove senescent, damaged, and/or potentially tumorigenic cells (Soto-Gamez and Demaria 2017). The SASP-mediated activation of the immune system might be an important player in premalignant lesions. Indeed, the secretion of chemokines and cytokines by senescent hepatocytes control

the premalignant niche through a $CD4^+$ T cell-mediated adaptive immune response that is defined as "senescence surveillance" (Kang et al. 2011).

Some of the SASP factors are also essential to maintain the senescence state and to propagate the senescence state to the surrounding cells.

During oncogene-induced senescence, the inflammatory signaling initiated by the cytokines IL-6 and IL-8 cover an essential role to maintain the growth arrest and the secretory phenotype (Kuilman et al. 2008). In addition to the autocrine mechanism, the SASP can transmit senescence to healthy cells. The insulin-like growth factor binding protein-7 (IGFBP-7) promotes both apoptosis and senescence in cells expressing the BRAF oncogene (BRAFV600E), via either autocrine or paracrine mechanisms (Wajapeyee et al. 2008). Moreover, the propagation of senescence can also be modulated by TGF-B family ligands and IL-1 signaling. Interestingly, this "secondary" senescence cannot further induce senescence via paracrine action, arguing in favor of a self-limiting process of senescent cells and the SASP (Acosta et al. 2013).

From Wound Healing to Tumor Promotion

Hyperproliferation is a well-defined feature of cancer cells, but it also covers an essential role for generating new tissue after damage. A well-defined tissue repair mechanism has been demonstrated in the skin. Skin wound healing is divided in four different phases: (1) hemostasis, responsible for blood clotting; (2) inflammation, which is responsible to clear out the tissue from damaged cells and pathogens, (3) proliferation, whose role is to synthesize new tissue, and (4) remodeling, when the tissue acquire its original functionality and composition. The proliferative phase begins with the formation of granulation tissue and new blood vessels, followed by re-epithelialization and wound contraction. It is not surprising that cellular senescence intervenes to limit the proliferation of the healing tissue in order to maintain homeostasis and prevent aberrant growth. Cellular senescence is activated during tissue repair by the induction of p16 and p53, similarly to the mechanisms that define tumor suppression (Demaria et al. 2014; Jun and Lau 2010; Krizhanovsky et al. 2008). Still little is known about how these pathways are engaged, but it has been suggested that the matricellular protein CCN1, which is rich in the damaged tissue environment, might promote senescence in a ROS-dependent fashion (Jun and Lau 2010). Tissue repair-induced senescent (TRIS) cells develop a secretory phenotype which is in part overlapping with the SASP associated with irradiated or oncogene-induced senescent (OIS) cells (Coppe et al. 2008; Demaria et al. 2014; Jun and Lau 2010; Krizhanovsky et al. 2008; Kuilman et al. 2008).

It is interesting to observe that these TRIS-associated factors can potentially promote cancer progression through non-cell autonomous mechanisms. PDGF-AA is a potent mitogenic factor for both normal and cancer cells and promotes angiogenesis stimulation of non-small cell lung carcinomas (Shikada et al. 2005), while different MMPs associated with TRIS cells can promote the progression of cancers of different origins (Egeblad and Werb 2002).

The apparent opposite role of the SASP in promoting both tissue repair and cancer progression is in accordance with observations that cellular behavior, signaling molecules, and gene expression are similarly regulated during wound healing and carcinogenesis. These similarities led Harold Dvorak in 1986 to define cancers as "wounds that do not heal." Since then, different studies addressed this definition, showing how qualitative differences in gene expression and divergence in the quantitative and temporal induction of secreted factors play a major role in defining repair and cancer.

One fascinating hypothesis is that the time of persistence of senescent cells in organs can partly contribute to tissue homeostasis through regulation of secreted factors. Indeed, TRIS cells appear to have a very fast kinetic of induction and clearance, at least in the skin (Demaria et al. 2014; Jun and Lau 2010), while senescent cells associated with aging and age-related pathologies have been

considered as chronically present (Loaiza and Demaria 2016).

Lack of in-depth information on the stresses and mechanisms driving senescence of both normal and cancerous cells at the organismal level constitutes a formidable barrier to advancing our insights into the relationship between cellular senescence and cancer through modeling in the mouse. Nevertheless, early animal studies have documented proof-of-principle for the idea that senescent cells have pro-tumorigenic properties (Fig. 1) (Krtolica et al. 2011). In these studies, co-transplantation of human epithelial cancer cell lines with senescent human fibroblasts was shown to accelerate tumor development in immune-compromised mice. Senescent cells demonstrated this tumor-promoting effect irrespective of whether the senescence-inducing DNA damage response originated from shortened telomeres, oxidative damage, or oncogenic Ras. It should be noted, however, that in these experiments, senescent cells and cancer cells were co-transplanted in a ratio of one to one, a ratio that is unlikely obtained in tumor microenvironments under physiological conditions. Thus, it will be interesting to explore the tumor-promoting properties of senescent cells at lower densities. Lui and Hornsby conducted similar co-transplantation experiments and found that the presence of a small molecule MMP inhibitor partially neutralizes the tumor-promoting effects of senescent cells (Liu and Hornsby 2007). The most straightforward interpretation is that MMPs secreted by senescent cells constitute a prominent tumor-promoting component of the SASP. This view is further supported by the identification of several additional pro-tumorigenic factors in the SASP, including VEGF, GRO-1, and factors that promote epithelial-to-mesenchymal transition such as IL-6 and IL-8 (Loaiza and Demaria 2016). The senescent secretome has been shown to play an important role in promoting liver and colorectal cancers (Pribluda et al. 2013; Yoshimoto et al. 2013).

The accumulation of senescent cells with age could potentially serve as a significant source of sustaining growth factors for tumor cells. Hence, the increased risk of incurring cancer with age could in part be a consequence of the increased number of SASP-expressing senescent cells during aging. However, despite increasing circumstantial and supporting evidence, the impact of senescent cells that accumulate naturally during aging has not yet been rigorously shown to promote late-life cancer progression in vivo.

Accumulation of Senescent Cells

Aging

As discussed in the previous section, the senescence program can contribute to either tumor suppression or tumor promotion. Since the most important single risk for tumorigenesis is age, a possible explanation is that the phenotype of senescent cells is determined by organismal aging. On one side, gene expression and epigenetic alterations that accompany aging can alter the normal senescence response, thus interfering with its anti-tumorigenic activity and increasing the risk of cancer. Thus, age-related deterioration of biological functions might lead to cellular and organismal changes that shift the senescence response from a tumor-suppressive to a tumor-promoting mechanism. For example, mutant H-Ras activation in mouse epidermis induced a differential outcome determined by age (Golomb et al. 2015): while the young skin responded with hyperplasia, the old skin developed dysplasia and gradual progression towards carcinoma. Importantly, old mice were characterized by exacerbated inflammation and excessive cellular senescence. The inflammatory response showed age-dependent increase of proinflammatory cytokines, but also activation of a strong anti-inflammatory Th2 response. Moreover, the expression of Pdl1, a ligand that promotes cancer immune evasion, was upregulated in the aged mice.

On the other side, senescent cells accumulate and persist in older organisms, and they seem to be detrimental for mammals, since they mediate aging features (Baker et al. 2011, 2016). The cause of their accumulation is not completely understood but might be due to the deterioration

of the immune system and/or to impaired DNA repair activity.

Tumor suppression by the senescent response involves cooperative interactions with the immune system, which is often responsible for the effective clearance of senescent cells. The importance of the cooperation between senescent cells and the immune system has also been shown in a liver fibrosis murine model, where natural killer cells preferentially kill senescent stellate cells in vitro and in vivo, thereby facilitating the resolution of fibrosis after acute tissue damage (Krizhanovsky et al. 2008). The progressive decline in tissue regenerative capacities during aging has been attributed mainly to degenerative changes in tissue-specific stem cells as well as in their niches and the systemic signals that regulate stem cell activity (Jones et al. 2014). However, ineffective immune clearance of senescent cells can partly explain the compromised capacity for tissue repair observed during aging. Another important observation for the role of the immune system for senescent cells clearance is evident in humans: immunocompromised patients, under immunosuppressive therapy or with an HIV infection, presented accumulation of senescent cells in the liver (Kang et al. 2011). A major problem with the generalization of the importance of immune-mediated clearance of senescent cells is that most studies focus specifically on the liver. Indeed, melanocytic nevi, clonal, and benign tumors of cutaneous melanocytes exhibit accumulation of senescent cells without immune response (Hoenicke and Zender 2012), suggesting that immune clearance of senescent cells is regulated in complex ways and might be more efficient in certain tissues than others, possibly due to differential expression of SASP components in specific cells. However, nevi typically remain in a growth-arrested state for decades and only rarely progress into malignancy, indicating that the immune system might not always be necessary to prevent cancer.

Age-related decline in cellular capacity to repair the DNA has been extensively studied in vivo and in vitro. Old cells express lower levels of DNA repair proteins and show lower efficiency and higher rate of errors (Gorbunova et al. 2007). Homologous recombination (HR), a highly accurate mechanism for DSB repair dependent on cell cycle, declines sharply with increasing replicative age in normal human fibroblast, showing up to 38-fold decrease in HR efficiency when comparing pre-senescent and young cells (Mao et al. 2012). HR is a repair mechanism dependent on cell cycle; therefore, senescent cells have an intrinsic limited DNA repair capacity as their cell-cycle arrest prevents DSB repair through HR, allowing repair only through nonhomologous end joining (NHEJ) pathway, which is a DSB repair mechanism more prone to error than HR, but independent of cell cycle. Remarkably, NHEJ pathway seems to be also altered during senescence. A study in senescent normal human fibroblasts showed a 4.5-fold decrease in NHEJ efficiency in pre-senescent and senescent cells compared with young cells, and the frequency of precise ligation was higher in young cells, whereas in old cells extended deletions were more frequently observed (Seluanov et al. 2004).

Upregulation of SIRT6 can contribute to improve the age-related decline in DNA repair mechanisms. SIRT6 has been found to be able to rescue the age-related decline in base excision repair. Specifically, SIRT6 reverted the decline of homologous recombination repair during replicative senescence (Mao et al. 2012). Therefore, pharmacological targeting of SIRT6 and other proteins may be an interesting approach to prevent the decline in genome maintenance and, consequently, reducing the amount of DNA damage and senescence that accumulate with age.

Cancer Treatments

Therapies for patients with advanced cancer generally include surgical tumor resection, intensive multimodal chemotherapy, radiation therapy, or a combination of these regimens. Because the tumor suppressive senescence growth arrest is so potent and essentially irreversible, regimens that induce tumor cells to senesce have been proposed as potential anticancer therapies (Nardella et al. 2011). This pro-senescence therapy approach has been developed and refined over the past few

years, and currently a number of compounds with senescence-inducing activities are in clinical trials. However, the induction of cellular senescence as an anticancer therapy strategy is complicated by the potential pro-tumorigenic properties of senescent cells and the SASP. Thus, the ability to harness the antitumor activity of the senescence growth arrest must be balanced against the tumor-promoting potential of the SASP.

Genotoxic and cytotoxic drugs act by non-specifically targeting proliferative cells through different mechanisms. The nonspecificity of these chemotherapies often leads to acute toxicities, which include immunosuppression, pain, fatigue, anemia, nausea, gastrointestinal distress, and hair loss. Moreover, clinical studies of cancer survivors treated during childhood suggest that chemotherapy causes a broad range of long-term side effects, similar to diseases associated with aging, including organ dysfunction, cognitive impairment, and secondary neoplasms (Hudson et al. 2013).

Many chemotherapeutic drugs induce diverse cellular states, including senescence, in the tumor microenvironment. Therapy-induced senescence (TIS) can stimulate immunosurveillance to eliminate tumor cells but can also be a source of chronic inflammation and drug resistance (Ewald et al. 2010). Indeed, a recent study showed that anthracycline treatment of breast cancer patients induces cellular senescence and a SASP in a p16-dependent and telomere-independent fashion (Sanoff et al. 2014). The SASP can potentially explain a number of adverse reactions to chemotherapy (Demaria et al. 2017).

PTEN, a key mediator of the AKT/PKB pathway, is one of the most commonly lost tumor suppressor genes in human tumors, particularly in prostate cancer. Loss of one copy of the PTEN gene strongly predisposes to cancer development (Di Cristofano et al. 1998), while complete PTEN loss can lead to a p53-dependent cellular senescence response (Chen et al. 2005). Therapeutic interventions that severely compromise PTEN activity or the AKT/PKB pathway can be an effective strategy to induce senescence in vivo. Importantly, PTEN-induced cellular senescence does not trigger a DNA damage response or hyperproliferative stage (Alimonti et al. 2010), which is typically induced by the activation of many oncogenes, and thus avoids induction of the SASP that can favor cancer progression.

Preclinical trials of pharmacological agents that activate the senescence-inducing p53/p21 pathway in cancer cells have been initiated. LY83583 (6-anilino-5,8-quinolinequinone), a pharmacological inducer of p21, can promote cellular senescence and inhibit tumor cell proliferation in cultured colorectal cancer cells (Lodygin et al. 2002). Small molecules, such as PRIMA-1 and MIRA-1, which can restore the function of mutated p53, can also promote tumor regression (Wiman 2010). Enhancing stability and/or activity of wildtype p53 by disrupting p53/Mdm2 (Hdm2) interaction has also been developed as a promising anticancer therapy (Nardella et al. 2011).

Tumor cells are thought to be dependent on one or more specific oncogene in order to maintain their malignant phenotypes. The inactivation of a single oncoprotein (e.g., Myc) in experimental mouse tumors can induce tumor-cell senescence and eventual regression of the tumors (Wu et al. 2007). Small molecules that downregulate Myc expression or target interactions between Myc and its obligatory partners (e.g., Max) are being developed as anticancer therapies.

Interfering with Senescent Cells

Senescent cells accumulate late in life, at sites of age-related pathologies or upon excessive genotoxic stress, and genetic interventions enabling the effective clearance of senescent cells in genetically engineered animal models is sufficient to delay a number of age-related phenotypes (Childs et al. 2017). Interfering with senescent cells may be beneficial for the overall health of the animal, and the development of specific interventions that target senescent cells may serve as a therapy to delay age-related tumorigenesis. This strategy can be achieved using three different approaches, but it is important to note that current drugs would not allow for long-term treatments due to intrinsic toxicities.

Selective Induction of Cell Death

"Senolytics" interventions (i.e., drugs that eliminate senescent cells) not only demonstrated the feasibility of extending healthspan, but also evidenced the alleviation of a wide range of preexistent age-related symptoms, including: improved cardiovascular function, reduced osteoporosis and frailty, enhanced adipogenesis, reduced lipotoxicity, increased insulin sensitivity, improved established vascular phenotypes associated with aging, and chronic hypercholesterolemia as well as radioprotection and rejuvenation of aged-tissue stem cells (Childs et al. 2017; Soto-Gamez and Demaria 2017).

Currently, a limited number of senolytic agents have been identified. 2-DG, a false substrate for the glycolytic metabolism, or bafilomycin A1, a specific inhibitor of the lysosomal V-ATPases, were sufficient to reduce the survival of chemotherapy-induced senescent cells and to improve survival of chemotherapy-treated mice bearing lymphomas (Dorr et al. 2013). However, this strategy has not been replicated in other systems or conditions.

Combination of dasatinib and quercetin-reduced senescent cells in fat and liver tissues of old mice, as well as in muscle and fat tissues of irradiated mice. Moreover, this combined treatment alleviated several age-related pathologies, such as impaired cardiovascular function and extended healthspan of the *Ercc1*$^{-/\Delta}$ progeroid mouse model, supporting the therapeutic potential of eliminating senescent cells at old age (Zhu et al. 2015). However, these findings have not been replicated by other laboratories.

The most promising senolytic agent is possibly ABT263, which targets both the antiapoptotic proteins BCL-xL and BCL-2, which has been shown to specifically induce senescent cells to apoptosis (Chang et al. 2016). The anti-senescence properties of ABT263 have been replicated in different other systems and by different laboratories. However, severe side effects associated to long-term treatments with ABT263 make the use of this compound into humans a challenge.

More recently, a peptide interfering with the interaction between p53 and Foxo4 has been shown able to kill senescent cells and improve a number of age-related diseases (Baar et al. 2017). Potential limitations for long-term treatments reside in the poor biodistribution of the peptides and the high risk of immune reactions.

Improvement of the Immune System

Another possible way of eliminating senescent cells is to increase the number and/or activity of immune cells that can selectively recognize and remove senescent cells. Indeed, natural killer (NK) cells and T cells trigger cytolytic responses on senescent cells (Krizhanovsky et al. 2008). Moreover, $CD4^+$ T cell-mediated adaptive immune response initiates an immune-dependent clearance of senescent cells termed senescence surveillance (Kang et al. 2011). The decline in immune function with age is consistent with the high number of senescent cells at old age (Loaiza and Demaria 2016), further supporting the idea that the immune system may limit the number of senescent cells through clearance of these cells. Hence, it may be worth developing a strategy that boosts the immune cells capable of specifically eliminating senescent cells.

Inhibition of the SASP

Decreasing the effect of the SASP may potentially be an alternative strategy to dampen the negative effects of long-lived senescent cells, particularly the pro-tumorigenic functions. NF-κB re-enforces the SASP response (Acosta et al. 2008), and interfering with NF-κB activity and/or targets can be an effective strategy to lower the SASP. An important activator of NF-κB and the SASP is interleukin 1 alpha (IL1A or IL-1α). Increased expression of plasma membrane-bound IL1A in senescent cells activates the plasma membrane bound IL-1 receptor in juxtacrine cells, resulting in upregulation of several transcripts associated with inflammation (Orjalo et al. 2009). IL1A blocking antibody or knockdown of IL1A by RNA interference diminished SASP expression in senescent cells (Orjalo et al. 2009). Compounds

that disrupt IL1A receptor signaling may serve as a strategy to dampen the SASP. Indeed, the glucocorticoids cortisol and corticosterone suppress IL1A signaling in senescent cells and decrease expression of the SASP components, but co-treatment with recombinant IL1A reestablishes the SASP (Laberge et al. 2012). Overexpressing the microRNA miR-146a/b, which knocks down the levels of the IL1A downstream target IRAK1 (also an upstream regulator of NFκB), resulted in decreased SASP expression (Bhaumik et al. 2009). Treatment with the mTOR inhibitor rapamycin also caused downregulation of IL6 and other SASP factors, partly due to suppressing translation of the membrane-bound IL1A (Laberge et al. 2015). Chronic resveratrol treatment also dampens the SASP (Pitozzi et al. 2013), likely through its ability to decrease IκB kinase activity, which leads to decreased IκBα phosphorylation and subsequent NF-κB activation. Other natural compounds, such as apigenin, wogonin, and kaempferol inhibit the SASP by blocking IκBζ expression and reducing NF-κB activity (Lim et al. 2015). Moreover, an increase in NF-κB transcriptional activity is sufficient to activate p38MAPK (Freund et al. 2011), and treatment with p38MAPK inhibitors dampens the SASP (Alimbetov et al. 2015). Other regulators of the SASP include p53, C/EBPβ, Sirt1, and NAD+/NADH redox balance. Functional loss of p53 protein exacerbates the SASP (Coppe et al. 2008). C/EBPβ is implicated in upregulating the SASP and may cooperate with IL-6 to amplify the SASP (Acosta et al. 2008; Kuilman et al. 2008). Sirt1 suppresses SASP expression through histone deacetylation at the promoter regions of SASP factors (Hayakawa et al. 2015), and resveratrol, a compound that activate Sirt1 (Howitz et al. 2003), is capable of dampening the SASP (Pitozzi et al. 2013).

Conclusion

Cellular senescence covers a fundamental tumor suppressive role and prevents the onset of cancer at earlier ages. Moreover, senescent cells are important for proper wound healing and promote tissue regeneration upon injury. However, age-related accumulation of senescent cells with the concomitant development of aberrant secretory phenotypes might promote tumorigenesis at different levels (Fig. 1). Thus, removal of senescent cells and reducing the SASP are being considered potential therapeutic strategies to delay the onset or reduce aggressiveness of tumors. Several drugs have already been identified that selectively target senescent cells but an important aspect remains to fully evaluate the potential toxic effects of such interventions. Proper testing of dosage and timing must be investigated to determine if these drugs would be an intriguing improvement of standard anticancer treatments.

Abstract

Age is the single most important risk factor for cancer development. Of the many age-associated changes paralleling increased cancer incidence, those of the immune system may play a major role in waning defense against tumorigenesis. Thus, immunosenescence may contribute to the higher rate of occurrence of tumors in the elderly. However, exactly how these age-related changes in immunity translate to cancer development is not well defined and understood. With the dramatic recent successes of immunotherapy in some patients for some tumors, there is an increasing concern that immunosenescence may temper responses in older patients. Nonetheless, existing anecdotal data suggest that success rates and side effects of first-generation checkpoint blockade immunotherapy in elderly patients are similar to those in younger subjects. However, success rates are still low, with only a fraction of patients obtaining clinical benefit in most trials, and it cannot yet be excluded that age may play a role in the failure of some therapies in some patients. Thus, although there are no reasons to refuse the elderly these treatments, appropriate clinical trials and not just anecdotal evidence are required to explore this issue further.

Introduction

The immune system evolved to resist many challenges to organismal integrity over the life-span. Eradicating pathogens without doing harm to the host is the most desirable outcome for the organism, but collateral damage and immune pathology may be severe not only in acute infections but also in persistent infections or other sources of chronic antigenic stimulation. Although controversial for many years, it is now incontrovertible that cancers fall into the latter category (Duan and Thomas 2016; Pawelec 2017). Cancer cells probably arise quite commonly over the entire lifetime (Anisimov 2009; Zhang et al. 2017), and the organism must therefore defend itself against these internal challenges. The most efficient protective mechanism is the apoptotic process following a program initiated by DNA damage and mutation responsible for carcinogenesis (Fumagalli et al. 2012). Failing this, cancer cells may be recognized by immune cells which target

them by cytolytic mechanisms such as perforin and granzyme B (Kim and Cantor 2014; Martínez-Lostao et al. 2015). However, there is currently a consensus that, as in defense against microorganisms, the immune system can have opposing roles in cancer and that immunopathology in this instance may manifest as tumor-promoting effects as well as antitumor responses. This depends partly on when the cancer arises and which dynamic relations exist between the immune response and the cancer. For example, as with chemotherapy, immune selection can result in the emergence of non-susceptible variants ("immunoediting") and may explain some of the balance between the cancer and the immune system (Dunn et al. 2004; Vesely et al. 2011; Jacqueline et al. 2016). This concept proposes that initially there is a successful immune-mediated elimination of cancer cells. If some cancer cells would be able to escape from this immune surveillance, there would arise an equilibrium between the cancer and the immune system, which will ultimately favor the selection of cancer cells which will be able to escape elimination. This step may last for decades. Finally, the tumor will physically escape the immune surveillance and manifest itself clinically with even a perversion of the immune system helping tumor growth (Vesely et al. 2011).

This scheme implies that at least initially, the cancer has a certain immunogenicity which permits the immune system to exert its full activity (Imai et al. 2000; Pardoll 2003). This suggests that immune cells, mainly T cells, may sense the new antigens, even if they are weak, released from the tumor cells after the death of some of them due to chaotic growth and vascularization, or innate immune cell-mediated lysis, and presented by dendritic cells (DCs) (Chen and Mellman 2013). The tumor cells are fundamentally self-cells of the organism transformed as a result of genetic mutations. However, most mutations fail to give rise to peptides recognized by the immune system, and those that can be recognized may be tolerogenic depending on the circumstances of their presentation. These antigens thus behave as very weak stimuli, and the organism is not always able to eradicate the cancer cells carrying them, or the immune system is not able to detect them or react to them (Pardoll 2003; Pawelec 2017).

Nonetheless, it is likely that the major antitumor protective mechanisms that the immune system uses to eradicate cancerous cells are the T lymphocytes (Vesely et al. 2011; Martínez-Lostao et al. 2015). These cells are specialized to be able to respond to many specific antigens potentially including those presented by cancer cells. T cells are subdivided into two basic subsets expressing $CD4^+$ or $CD8^+$ coreceptors. The $CD4^+$ T cells are predominantly known as "helper T cells" interacting with other immune cells including B cells, macrophages, and $CD8^+$ T cells to facilitate their differentiation into antibody-producing cells or cytotoxic cells (Chaplin 2010). $CD4^+$ T cells recognize antigens presented by antigen-presenting cells such as DCs in the context of self-MHC II class molecules to initiate $CD4^+$ T-cell activation (Petrova et al. 2012). They are also further specialized into functional subtypes such Th1 (which primarily secrete pro-inflammatory cytokines), Th2 (for anti-inflammatory cytokine production and promotion of antibody production by B cells), and Th17 (pro-inflammatory and autoimmunity supporting) as well as several others (Chaplin 2010; Zhu et al. 2010). Th1 cells, characterized by their expression of the transcription factor Tbet, exert anticancer effects by inhibiting angiogenesis and recruiting actively cytotoxic $CD8^+$ T cells and natural killer (NK) cells (Haabeth et al. 2011; Kouidhi et al. 2017). The Th2 cells are thought to contribute much less to anticancer immunity. Th17 on the other hand may also actively contribute to tumor immunity by the secretion of cytokines Th17 and IL-21 as well as by activating effector $CD8^+$ T cells (Shapiro et al. 2016). The transcription factor RORγt has been identified as the master regulator of polarization of helper T cells toward the Th17 pathway (Ivanov et al. 2006; Guéry and Hugues 2015). Tregs are immune regulatory $CD4^+$T cells which suppress specific immune reactions, such as autoimmune processes, and thus favor cancer escape (Adeegbe and Nishikawa 2013). $CD8^+$ T cells are effector cytotoxic T cells able to kill cancer cells; they are commonly found infiltrating tumors

(tumor-infiltrating T cells or TILs) (Frey 2017; Barnes and Amir 2017). Natural killer cells are also able to destroy cancer cells mainly if they have escaped $CD8^+$ T-cell recognition by down-regulating HLA class I at their surface (Vacca et al. 2016). There are also some occasions when the production of antibodies is required for anticancer immunity involving B cells.

Therefore, the organism needs a functional immune system to resist and control cancer. Boosting immunity therapeutically by immune modulatory treatments (a form of immunotherapy) has recently resulted in a groundbreaking change in the way oncologists approach cancer therapy. Enormous strides in the development of immunotherapy over the last 10 years have not only revolutionized cancer treatment but also led to a better understanding of cancer/immune response interactions (Moynihan and Irvine 2017; Lowry and Zehring 2017; Galati and Zanotta 2017; Melssen and Slingluff Jr. 2017).

However, although clinical trials of immunotherapies may include patients of advanced age, the specific question of whether elderly people behave in the same manner as younger patients has not been put to the test in purposeful clinical trials (Johnson et al. 2017; Elias et al. 2017; Daste et al. 2017). Immunotherapy is of particular interest for the elderly because most clinically meaningful solid cancers arise in older people (Yang et al. 2012; Forman et al. 2013). It is commonly assumed that immune changes with age favor the development of cancers, but data supporting this contention are sparse (Fulop et al. 2013a; Turner and Brum 2017). Indeed, whether immunosenescence may play a role in the emergence of cancer with age is now a crucial question in the light of the marked success of immunomodulatory therapies mostly recorded in younger patients.

Cancer and Aging

Age is considered the single most significant risk factor for many chronic conditions including the majority of common malignancies (Anisimov 2009). Cancer incidence and prevalence increase with advancing age (Saavedra et al. 2017), and around 50% of all cancers are diagnosed in patients over 65 years old (Zhang et al. 2017). Several factors influence this increase, related both to the entire organism and the particular cancer. During aging, there is an increase in oxidative stress, implying that free radical production is increasing and antioxidative defenses are decreasing (Vina et al. 2013; Bauer and de La Fuente 2016). Among other changes, this is a consequence of mitochondrial dysfunctionality (Ristow and Schmeisser 2014; Gonzalez-Freire et al. 2015). With aging, there is a decrease in mitophagy, resulting in failure to eliminate defective mitochondria and more uncontrolled free radical production, leading to mutations and genomic instability (Park and Larsson 2011). This directly favors the emergence of a neoplastic cell.

It has been proposed that a mechanism for avoiding the emergence of malignancy is the phenomenon of replicative cell senescence, as first described by Hayflick (Hayflick and Moorhead 1961). However, senescent cells are metabolically active, presenting a different pattern of cytokine and chemokine secretion known as the "senescence-associated secretory phenotype" (SASP) (Coppé et al. 2008; Rao and Jackson 2016). They produce many pro-inflammatory factors which can favor the occurrence of chronic inflammation preparing a favorable soil for tumorigenesis (Coppé et al. 2008; Childs et al. 2015). Thus, like immunity, cell senescence as a defense mechanism against cancer is a two-edged sword; both mechanisms converge on the question of inflammation (Capece et al. 2017).

Older people tend to manifest a slightly higher basal level of pro-inflammatory serum factors, such as IL 6, thought to contribute to tissue damage and possibly to promote cancer (Minciullo et al. 2016; Setrerrahmane and Xu 2017). There are several pathways contributing to this low-grade inflammation in an aging organism, which can also contribute via several pathways to cancer development. This low-grade inflammation is maintained at least partially by an imbalance between the innate and the adaptive immune system, with the innate arm being overactive (Franceschi et al. 2000, 2007). Chronic antigenic stress from persistent infections, but also from cancer itself, also contributes to this state

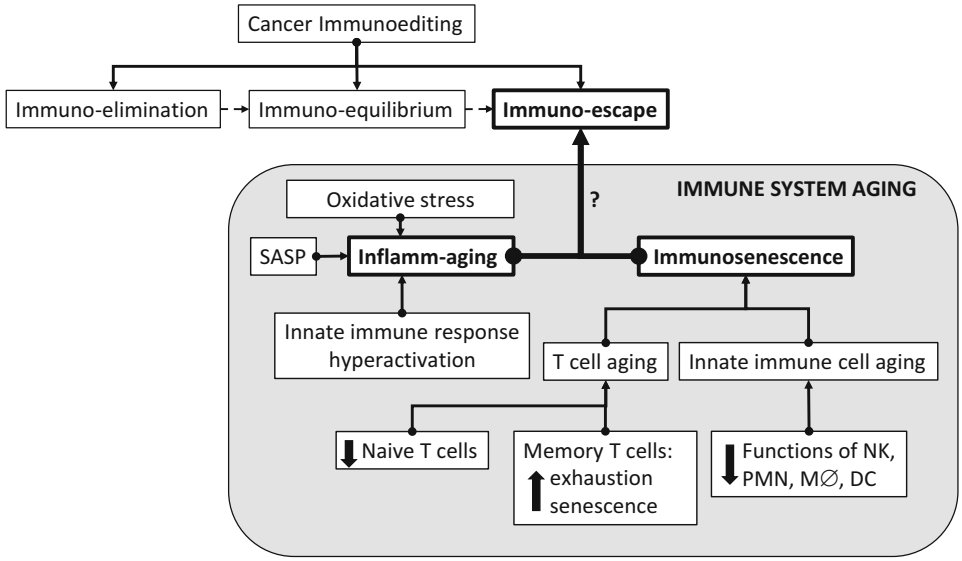

Fig. 1 Concept of the cancer immunosurveillance concept and the putative role of immunosenescence in the increase of tumorigenesis with aging. Initially, the immune system controls tumorigenesis. Cancer-immune system interactions may maintain an equilibrium over decades. Finally, the tumor may become clinically manifest because of immune escape. Immunosenescence and inflamm-aging may contribute to immune escape. *SASP* senescence-associated secretory phenotype

dubbed "inflamm-aging" (Chidrawar et al. 2009; Pawelec 2012; Fougère et al. 2017). It is not known with certitude what is the exact contribution of low-grade inflammation to cancer development with age, but certainly it may contribute by the SASP, the free radical productions, and the shift in immunometabolism (Turner and Brum 2017) (Fig. 1).

It may be the case that chronic infections, particularly by viruses, also contribute to the occurrence of certain cancers, indirectly via the SASP or more directly. Thus, with aging the occurrence of chronic persistent viral infections is increasing and probably either by the induction of chronic inflammation such as in the case of cytomegalovirus (CMV) or by themselves may contribute through oncogenic transformation such as in glioblastoma (Ferguson et al. 2016). Lifelong environmental challenges, such as UV exposure, air pollution, etc., may also be contributing factors. Although it is well established that the incidence of cancer increases with age, coinciding with a decline in immune competence, many other factors, including physical activity level, body composition, and diet, which also change with aging, likely interact (Anisimov 2009).

Finally, one can assume that as mentioned earlier, if the immune response plays a role in cancer immune surveillance, any immune changes occurring with aging (immunosenescence) may to some extent contribute to the increased cancer emergence with aging (Fig. 1). But is there really any evidence for this hypothesis, often assumed to be true in the literature but commonly unsupported by any data?

Immunosenescence and Aging: Does Immunosenescence Matter for Tumorigenesis?

As outlined above, immunity most likely plays a major role in controlling cancer. We also note that many processes contribute to the development of cancer over the life-span. So, what could be the contribution of immunosenescence if any to cancer development?

With aging, many changes have been reported, especially in the adaptive immune system (although these are mostly differences between younger and older individuals, because cross-sectional studies cannot reveal actual changes).

In particular, and reproducibly found in essentially every published study, there is a decrease in the number of naïve $CD8^+$ T cells ($CD45RA^+$, $CD27^+$, $CD28^+$, $CCR7^+$) in the peripheral blood because they have responded to cognate antigen at some point in the individual's life and have differentiated to memory cells (Fulop et al. 2013b; Goronzy et al. 2015; Yanes et al. 2017; Pawelec 2012). Moreover, because of thymic involution at puberty and acute and chronic antigenic stress over the lifetime, as well as age-associated hematopoietic stem cell insufficiency (Denkinger et al. 2015), recent thymic emigrants of new naïve cells are vanishingly rare in the elderly. Hematopoietic stem cells produce less lymphocytes because of the alterations induced by free radicals in their DNA and the decreased production of IL-7 (Hirokawa and Utsuyama 1989; Gruver et al. 2007) shifting the balance toward myelopoiesis. However, there is still a debate on whether the remaining naïve T cells arising either from the thymus or by homeostatic proliferation possess enough TCR repertoire diversity to be able to confront new and emerging antigens, such as new pathogens but also neoantigens from cancers (Appay and Sauce 2014; Goronzy et al. 2015; Pawelec 2017). Recent data suggest a shrunken but not absent TCR repertoire, so it may not be stochastic as to whether a patient can by chance respond to their tumor neoantigens and be protected (Nguyen et al. 2018). Furthermore, it is worth noting that the general decrease of thymic output may be a normal part of the immune adaptation/remodeling during aging, reducing the energy needed to maintain such a system and reducing the errors that might contribute to autoimmune diseases which also increase in the elderly.

Commonly, but not always, parallel to the decreased number of naïve CD8+ T cells, the number of late- and terminally differentiated memory T cells in the effector memory (EM) and TEMRA compartments increases with age (Larbi and Fulop 2014). This is mostly the consequence of chronic immune stimulation either through intrinsic or extrinsic antigens. The most important of these is the cytomegalovirus (Pawelec 2014). These late-stage memory cells are still functional, and some at least may share properties reminiscent of replicatively senescent cells (Effros 2003; Xu and Larbi 2017). These cells should be distinguished from the exhausted T cells arising also from continuous stimulation but not being terminally differentiated and bearing different surface markers (Wherry and Ahmed 2004; Wherry and Kurachi 2015). There is still debate in the aging field as whether all cells in memory compartments are fixed as "senescent" or "exhausted" or whether there is some plasticity in the system (Akbar and Henson 2011; Henson et al. 2015). Whatever the case, the proportions of these cells are increasing significantly with aging (Fulop et al. 2013b).

T-cell exhaustion defines a state of T-cell dysfunction emerging during many chronic infections and cancer (Wherry and Kurachi 2015). It is indicated by poor effector function, sustained expression of inhibitory receptors, and a transcriptional state different from that of functional effector or memory T cells. Chronic exposure to cognate antigen can upregulate PD-1 expression, and PD-1 can, by interacting with its ligand PD-L1, lead to the development of an exhausted T-cell phenotype, characterized by a hierarchical loss of proliferation and cytolytic activity, followed by defects in cytokine production, and eventually deletion (Zarour 2016; Catakovic et al. 2017). As noted above, the boundary between advanced differentiation states and senescence is unclear and its importance therefore hard to determine. CD8+ T cells that may most resemble replicative senescence are characterized by the phenotype $CD28^-$, $CD57^+$, Kand $LRG\text{-}1^+$, have shortened telomeres and increased p38 expression, may be nondividing or require certain special conditions for triggering cell division, and are able to secrete pro-inflammatory cytokines; many also retain significant cytotoxicity toward, e.g., CMV (Larbi and Fulop 2014; Henson et al. 2015; Xu and Larbi 2017). These are late-stage differentiated memory CD8+ T cells; some of which may indeed be senescent, but many of which are possibly retained in a non-proliferative state to preserve their effector function, which is necessary to protect the organism. A minority of these may be actively pathological in that they contain granzymes but not perforin and may

cause granzymopathy and inflammation when the release of the enzyme is triggered (McElhaney et al. 2012).

The other main T-cell subset, the $CD4^+$ T cells, is also essential for optimal antitumor immunity, as mentioned above. With aging the main change is the higher expression of the negative costimulatory receptor CTLA-4 and the concomitant decrease of CD28 expression. Together these changes lead to the decrease of their clonal expansion and function via changes in immunometabolism and signaling pathways. CD40 expression is also decreased. All these changes ultimately lead to their decreased ability to further the activation of $CD8^+$ T cells, instrumental for anticancer immunity.

In this context, it is of note that cancer cells may present two types of antigens to T cells. One type that has attracted a great deal of attention recently is a new antigen arising from mutations, at least some of which may be drivers of oncogenesis and necessary for continued carcinogenesis (Chen and Mellman 2013). These are individual tumor- and patient-specific. Additionally, cancer cells progressively accumulate multiple genetic and epigenetic alterations leading to the expression of numerous such neoantigens (Arlen 2017). The other main category of tumor antigens is shared between cancers of the same type as a result of tissue dedifferentiation or is lineage-specific (Pawelec 2017). This latter may already be present before the clinical manifestation of the cancer and has consequently elicited immune reactions and immune memory. Such memory responses may be better preserved with aging than responses to neoantigens which require the presence of naïve CD8+ T cells. These differences may be successfully exploited during the future design of age-specific immunotherapies (Hurez et al. 2017).

Following antigen recognition, even by memory cells, proliferation leading to clonal expansion is required in order to generate and maintain ongoing responses. However, proliferative capacity is in general decreased with aging (Douziech et al. 2002). This is mainly due to the decreased signaling pathways occurring through the entire signaling machinery starting from the early signaling, such as tyrosine phosphorylation of Lck, eventually leading to the translocation of transcription factors such as NFAT (Larbi et al. 2006). There are not only changes in the feed forward signaling but also in feedback signaling (Le Page et al. 2014). At some steps of the signaling pathway, the inhibitory signals will have proven more powerful than the activation signals, and the cascade will be blocked (Li et al. 2012). There are also changes in the lipid rafts, presently referred to as nanoclusters, in terms of lipid composition and function (Fulop et al. 2014; Schamel et al. 2017). There are increases in the cholesterol content of the membrane rendering it more rigid and the coalescence of the nanoclusters more difficult. This renders immune synapse formation more difficult, leading to the signal transduction changes discussed above (Larbi et al. 2006).

The characteristics of immunometabolism are a very important aspect of T-cell function which change with age and influence T-cell differentiation which is also changing with aging (Weyand and Goronzy 2016). For T-cell clonal expansion, vigorous proliferation requires nutrients such as glucose, lipids, and proteins. T lymphocytes must sense these nutrients and adapt their metabolism to their availability. In the quiescent state, the T cells use oxidative phosphorylation (OxPhos) to produce energy in the most efficient way (Michalek and Rathmell 2010)). However, when T cells are activated, they switch to aerobic glycolysis (Warburg effects) resulting in anabolism leading to biomass production for rapid proliferation (MacIver et al. 2013; Liu et al. 2014; Peng et al. 2016; Kouidhi et al. 2017). The master regulators of these metabolic changes are PI3K, Akt, and mTOR complex signaling pathways (Hahn-Windgassen et al. 2005). There are several intermediates which are specific for the various nutrients such as AMPK, SREBP, or the p70S6 kinase. Together these changes converge on the promotion of greater nutrient utilization (glycolysis and amino acids: glutaminolysis) to facilitate T-cell activation and proliferation (Bettonville et al. 2016). These metabolic changes are needed for an effective Th1 response and antitumor immunity (Jiang and Yan 2016). It is of note that T cells and cancer cells both use aerobic glycolysis for ATP production. Thus, immunometabolism

is different in naïve and effector cells as a result of their adaptation to their functional requirements.

Compared to naïve and effector T cells, memory T cells have increased mitochondrial mass and mitochondrial respiratory capacity to spare (van der Windt et al. 2012), leading to their possession of the maximal respiratory capacity available for a living cell. These cells can very rapidly generate the necessary ATP by relying on lipid catabolism, using so-called β-oxidation (FAO), needed for their long-term survival (Pearce et al. 2009). The fatty acids originate from intracellular lipolysis either by autophagy or by metabolizing lipids such as LDL or VLDL. The master receptor in the transformation of effector cells to memory cells is TRAF6 and AMPK for their maintenance through lipolysis (Rolf et al. 2013).

Important means of tumor escape from immunosurveillance increasing with age may be represented by the "exhaustion" of chronically antigen-stimulated T cells as mentioned above (Wherry and Kurachi 2015). Exhausted $CD8^+$ T cells exhibit more marked upregulation of several inhibitory receptors at the cell surface relative to functional memory or senescent $CD8^+$ T cells. These markers include PD-1, CTLA-4, LAG-3, and TIM-3, which suppress the activation of T cells (Hoffmann et al. 2016). It should be stressed that these cells are neither terminally differentiated nor senescent, and by modulating these receptors, anticancer activities may be restored (Topalian 2017). They use the same metabolic pathways as memory cells, depending on PD-1-mediated lipolysis and FAO (Kouidhi et al. 2017). It is of note that CTLA-4 does not modify cell metabolism but rather influences the genes involved in cell cycle control and signal transduction such as the NFAT and JAK-STAT pathways (Jiang and Yan 2016; Ok and Young 2017). The frequency of these cells is generally found to be increased with age (Pera et al. 2015). There are differences in their metabolic pathways, emphasizing the possibility that this may further impair efficient proliferation (Bettonville et al. 2016). Moreover, these metabolic pathways also govern T-cell differentiation, possibly contributing to the perceived shift away from Th1 responses toward Th2 cells and Tregs with increasing age. The latter are mostly $CD4^+CD25^+$ T cells expressing the transcription factor Foxp3, which confers immunosuppressive function (Nishikawa and Sakaguchi 2010). The higher expression of CTLA-4 on stimulated $CD4^+$ T cells also shifts T cells toward Tregs with a different immunometabolism (Bryl et al. 2001; Kouidhi et al. 2017). Although somewhat controversial, as mentioned above, the numbers and functions of Tregs do seem to increase with age (van der Geest et al. 2014; Raynor et al. 2012; Gregg et al. 2005). It is likely that Tregs are pro-tumorigenic by suppressing the cognate immune response (Nishikawa and Sakaguchi 2010). Hence, age-related differences in Tregs may favor cancer development.

Immune changes with aging also affect the innate immune system (Solana et al. 2012). There is a potentially interesting paradox that a certain type of immune paralysis for most of the innate immune cell functions proceeds together with a concomitant hyperactivation (Fulop et al. 2016). The former manifests by decreased chemotactic, phagocytic, and free radical-producing activity (Fulop et al. 2004), while the latter signifies the overproduction of pro-inflammatory cytokines. These changes mainly affect neutrophils and monocyte/macrophages (Molony et al. 2017; Albright et al. 2016). Moreover, increased CD14+/CD16+ pro-inflammatory nonclassical monocyte populations, and macrophage phenotypes, are shifted toward inflammatory phenotypes (Metcalf et al. 2015; Hazeldine and Lord 2015). Molecules originating from the tumor are sensed as danger-associated molecular patterns (DAMPs) via the pattern recognition receptors expressed by several innate immune cells. These activate macrophages and DCs through TLRs and inflammasome signaling (Agrawal et al. 2017). With age, commonly global impairments are seen in pattern recognition receptor signaling through a reduction in toll-like receptor (TLR) expression and in TLR-induced pro-inflammatory cytokine production (Nyugen et al. 2010; Bandaranayake and Shaw 2016). This could lead to lower activation of adaptive immune responses (e.g., through lower secretion of inflammatory cytokines) and hence anticancer responses.

NK cells also manifest lower cytotoxic activity on per-cell basis than their younger counterparts. The expression of NK-activating and inhibitory receptors is also changed with age (Tarazona et al. 2015), mainly the former, such as NKp30 and NKp46, which are decreased (Manser and Uhrberg 2016). Antigen presentation is also decreased mainly due to altered immune proteasome activity, part of the general intracellular proteodynamic changes with aging (Johnston-Carey et al. 2015). At the same time, pro-inflammatory cytokines produced by DCs are increased (Agrawal et al. 2017). These changes are part of the general inflamm-aging process occurring with aging (Franceschi et al. 2000, 2017). This can play a very important role in maintaining immune alertness but also to decrease its efficiency against the invaders.

So, do these changes with aging indeed contribute to the emergence of cancers over the lifetime? Certainly, they may (Fulop et al. 2011). On the one hand, there is the potential problem that there may not be enough naïve cells to recognize all the newly emerging cancer neoantigens or that even if they can recognize them, they cannot proliferate and generate sufficient functional T cells to be able to eradicate them. Additionally, there could also be competition between the tumor and the activated T cells for nutrients which would further reduce T-cell proliferative capacity and differentiation into effector T cells. Different metabolites such as indoleamine 2,3-dioxygenase (IDO) or arginase-1 produced by cancer cells may also further impair the ability of T cells to combat cancer in the elderly (Chang et al. 2001; Eleftheriadis et al. 2014). Furthermore, the inflammatory environment also favors the development of cancers; it facilitates carcinogenesis by triggering initial genetic mutations or via epigenetic mechanisms. It also promotes cancer progression and metastasis, also by impairing T-cell activation as well as increasing the development of myeloid-derived suppressor cells (MDSC) which are increased with age (Verschoor et al. 2013). Finally, the cytotoxic activities of phagocytic cells are also compromised, which may further contribute to the emergence of cancer cells.

Nonetheless, the debate is not yet completely over as to whether these differences are really contributing to negative outcomes or whether they are just "innocent bystanders." The naïve repertoire may still be sufficiently diverse in some patients, such that the low numbers of naïve cells would not necessarily contribute extensively to tumorigenesis. For example, the fact that there is a plateau in the cancer development after the age of 90 appears to militate also against the common belief that immunosenescence contributes substantially to tumorigenesis. However, this may simply be the result of selection against the great majority of people who do not attain such an advanced age. Conceptually, there remains the basic question of whether immunosenescence precedes, is concomitant with, or is the consequence of the nascent cancer.

Some of these issues may be resolved by longitudinal follow-up of immunosenescence biomarkers to explore association with the development of cancer. However, only a few studies have sought such associations and have failed to find anything significant (Turner and Brum 2017) except for some anecdotal data such as IgA in saliva (Phillips et al. 2015). Other circumstantial evidence may come from cross-sectional studies of the associations of potential immunosenescence markers with clinical outcome. Most studies in this context showed that certain cellular marker constellations, such as $CD4^{+}CD28^{-}CD57^{+}$ or $CD8^{+}CD28^{-}CD57^{+}$, were associated with poorer prognosis in some cancers such as lung cancer (Fornara et al. 2015). Other markers indicated certain differences depending on the timing of blood sampling and the stage of disease, which then become extremely important for interpreting these data. It is also known that cancer treatment may induce potentially senescent T cells expressing, for example, $p16^{INK4a}$ (Demaria et al. 2017). However, besides these markers recent research has indicated that the capacity of peripheral blood T cells to recognize and respond to tumor-associated antigens is a better predictor of survival in several malignancies, including breast cancer, colon cancer, and melanoma. This suggests that the dynamic measurement of T-cell functions is a better biomarker for assessing anticancer

immunity and its outcome even in elderly subjects (Bailur et al. 2015).

So, considering the above issues, it can be postulated that elderly patients may also benefit from immunotherapy, which can be conceptualized as an intervention at any level of the immune response that reinforces the body's immune capacity to combat cancer.

What Are the Currently Used Immunotherapies, and How Might Immunosenescence Impact on Their Success?

Immunotherapies are very diversified and when possible can also often be used in combination and/or together with traditional chemo- and radiotherapy (Hurez et al. 2017). They can be specific to one cell type or may target surface molecules or intracellular molecular mechanisms. Some of them are already in clinical use; the others are experimental. In any case our immunotherapeutic arsenal is constantly increasing as we learn more about how interactions between the cancer and the immune system progress.

Regulatory T Cells (Treg)

Tregs play a major role in the induction of anticancer T-cell dysfunction. Thus, targeting either their functions or their number may be an efficient way to reinvigorate helper and cytotoxic T cells to combat cancer. As mentioned above, age-associated changes to Treg function or number is not clearly defined, although most data support their increase with aging (van der Geest et al. 2014; Raynor et al. 2012; Gregg et al. 2005). However, concomitantly, it was also shown that IL-10 production by Tregs from the elderly is decreased. This was shown in mice using an anti-CD25 antibody, but no data support the use of anti-Treg treatment for cancer in elderly (Hurez et al. 2017). The Foxp3 protein is stabilized by acetylation by HDAC9, promoting Treg development and preventing transcription of IL-2, a cytokine produced by $CD8^+$ T effector cells (Beier et al. 2012). Thus, the use of HDAC inhibitors may have beneficial effects on Treg decrease and could enhance anticancer therapies.

Innate Immunity

The targeting of innate immunity either by decreasing immune paralysis or by mitigating pro-inflammatory activity would be a very meaningful immunotherapeutic intervention, especially when combined with other interventions.

Antigen presentation by DC could be increased either in vivo or in vitro. If we would be able to efficiently present major as well as minor tumor antigens to T cells to boost their cytotoxic activity, this would be of major impact. CD40L or agonist anti-CD40 antibodies may boost DC activation (Khong et al. 2012). In the elderly, a vaccine using CD40L linked to specific antigens would have great clinical potential (Tang et al. 2009). In aging, most of the monocytes and macrophages exhibit pro-inflammatory phenotypes (M1) (Metcalf et al. 2015; Hazeldine and Lord 2015). However, there is a great plasticity between the pro-inflammatory and anti-inflammatory (M2) macrophage phenotypes (Mills et al. 2015). In the tumor environment, it seems that most of the tumor-associated macrophages (TAMs) are of M2 phenotype, favoring tumorigenesis. A paradox seems to exist between the circulating macrophages (M1) being able to combat cancer cells and those TAMs (M2) which seem to favor cancer survival. The most important factors secreted by TAMs are TGFβ and IL-10, which have immune suppressor activities, as well as growth factor activities, and as such favor tumorigenesis (Mantovani et al. 2008). Thus, targeting either transformation in the tumor environment of M2 macrophages to M1 which combat tumors, or the factors produced by them such as TGFβ, may become very interesting immunotherapies in the elderly (Geeraerts et al. 2017). Some tentative approaches using IL-12 or poly-(cysteine 5° to guanine: CpG) with anti-IL-10 receptor antibody with the aim of converting M2 to M1 macrophages have been be envisaged (Watkins et al. 2007). Recently, an antagonist of M-CSFR has been designed to block the transformation in the tumor

microenvironment of macrophages to M2 type (Pyonteck et al. 2013; Bonelli et al. 2018).

Like macrophages, neutrophils in the tumor environment may acquire an N2 phenotype, also favoring tumorigenesis (Hurt et al. 2017). N1 neutrophils are efficient at combating cancer, but with aging, there is not only a decrease in the tumor antagonist effector functions of neutrophils, but they become pro-inflammatory. So, the same intervention strategies would apply to neutrophils as for macrophages – but there are no such strategies as these cells are so short-lived that most investigators have not considered them likely to be a valuable target.

Finally, the innate system myeloid-derived suppressor cells have received a great deal of attention recently. These cells are essentially immature myeloid cells of neutrophilic or monocytic origin having immunosuppressive properties (Gabrilovich 2017; Sica and Strauss 2017). There are few data on their status in aging, but one report indicates that they are increased in the elderly (Verschoor et al. 2013). Certainly, they are increased in inflammatory diseases and in many cancers where they suppress antitumor immunity and represent a strong prognostic factor for survival (Sun et al. 2012; Azzaoui et al. 2016). MDSCs secrete factors such as IL-10 and arginases which suppress T-cell antitumor immunity (Marvel and Gabrilovich 2015). They promote the appearance and function of Tregs and also favor the maintenance of the M2 macrophage phenotype (Zhao et al. 2015; Gabrilovich 2017). MDSCs are very likely to make a major contribution to decreasing immune responses in aging and to inhibit antitumor immunity in the aging host (Flores et al. 2017). Thus, targeting these cells would be of the outmost importance (Shipp et al. 2016).

Adoptive Cell Transfers

There is again a great deal of interest in expanding tumor-specific T cells in vitro (e.g., TILs or chimeric antigen receptor (CAR)-bearing T cells) and then adoptively transferring them into patients. In the elderly, there is no report concerning specific CAR-T treatment, but if necessary functionally impaired geriatric CAR-T cells could be rescued supporting the possibility for a successful treatment in elderly in the future (Guha et al. 2017). The findings with active DC-based vaccines were seldom directly correlated to age, so it is difficult to draw direct conclusions on the efficacy of such an adoptive DC-based vaccine transfer. Studies in the future are needed to fill this therapeutic knowledge gap.

Recently, NK cells have also been reconsidered for adoptive immunotherapy, given the realization that cancer cells may escape CTL killing by downregulating HLA molecules, which should render them susceptible to natural killing (Tarazona et al. 2017). NK inhibitory receptors mainly recognize HLA class I molecules and prevent target cell killing. This is already exploited in the control of hematological malignancies after allogeneic stem cell transplantation when inhibitory receptors on NK cells are mismatched with recipient HLA molecules (Ruggeri et al. 2008). The NK cells are also used for adoptive immunotherapy. They are expanded outside of the organism and consequently transfused. This has many potential problems which are difficult to overcome such as the maintenance of the cytotoxic capacity in vivo.

A novel clinical approach is to exploit chimeric antigen receptor-transduced cell transfer. This involves engineering a modified T-cell receptor with (an MHC-unrestricted) antigen recognition portion from an antibody into T cells from the patient, expanding them in vitro and then transfusing them back into the patient (June et al. 2014; Glienke et al. 2015). Preliminary data are showing that the efficiency of CAR T cells from the peripheral T cells of elderly patients is decreased both in terms of decreased efficacy of their generation as well as in their effectiveness against cancer cells. A recent report described a manipulation which could restore effective functioning of CAR T cells in vitro from old T cells (Guha et al. 2017). This technique may hold promise in elderly patients mainly with the acute lymphoblastic leukemia (Huguet and Tavitian 2017). This technique has recently also been used to target NK cells against CD19 and CD20 in B-cell malignancies (Tarazona et al. 2017).

mTOR Inhibitors

Inhibition of mTOR has been shown to increase longevity in mice. Thus, the idea emerged that rapamycin can be used as an antiaging drug (Roth and Ingram 2016). mTOR is also a very important pathway for T-cell immunometabolism as well as for differentiation, and mTOR suppression favors the development of Tregs. Nonetheless, in the clinical setting, the use of a very low-dose mTOR inhibitor rapamycin can boost antitumor immunity (Pedicord et al. 2015). It seems that rapamycin can reduce PD-1 expression on T cells through the modulation of FOXO1 and as such increase T-cell functions. Thus, mTOR inhibitors may increase antitumor T-cell immunity. However due to their numerous side effects, it is unlikely that they will become major adjuncts to immunotherapy in elderly people.

TLR Agonists

TLRs are important pathogen-associated molecular pattern (PAMP) recognition receptors (Satoh and Akira 2016). These receptors, via their signaling pathways, by their by-products may influence the adaptive immune system (Mikulandra et al. 2017). An early effective immunotherapy approach exploited TLR ligation in bladder cancer by bacille Calmette-Guérin (BCG), an attenuated *Mycobacterium bovis* preparation. This treatment clearly increases survival but mainly in people less than 75 years of age (Margel et al. 2011). The exact mechanism of action of this treatment is not known, but increased innate immune responses are likely to be responsible. So, this is an FDA-approved immunotherapy treatment for bladder cancer in elderly individuals.

Immune Checkpoint Inhibitors (ICI)

Following activation, PD-1, a member of the Ig superfamily, transmits inhibitory signals that abrogate T-cell receptor (TCR)-mediated activating signals and downregulate T-cell activation. Ligands of PD-1 include PD-L2, which is primarily expressed on APCs, and PD-L1, expressed on many types of cells including tumor cells, immune cells, epithelial cells, and endothelial cells (Hato et al. 2016; Zou et al. 2016).

A recent breakthrough in immunotherapy is the recognition that exhausted T cells expressing either programmed cell death 1 (PD1, CD279), programmed cell death ligand 1 (PD-L1), or cytotoxic T-lymphocyte antigen 4 CTLA-4 (CD152) or both can be functionally reactivated. These inhibitory coreceptors can be blocked by antibodies designated "checkpoint inhibitors" (Pardoll 2012; Sharma and Allison 2015). These antibodies block the negative signals initiated by these receptors resulting in decreased T-cell killing functions to eliminate cancer cells. The number of these inhibitory receptors on T cells has been shown to increase with age contributing also to their decreased proliferation (Channappanavar et al. 2009). This might explain why data from pivotal studies is discordant, with less efficacy in older versus younger patients for some cancers (head and neck, non-small cell lung cancer (NSCLC), and renal cancer (RCC) and similar for others (melanoma and bladder cancer). This lack of efficacy could also probably be correlated to the small number of elderly patients included in clinical trials (Elias et al. 2017; Daste et al. 2017; Hurez et al. 2017). The high expression of PD-L1 is probably a predictive factor for some tumors; this seems to be independent of age. There are now other immune checkpoint molecules which further identify exhausted T cells such as lymphocyte activation gene 3 (Lag-3) and T-cell immunoglobulin, T-cell immunoreceptor with Ig and ITM domains (TIGIT), and mucin-domain containing 3 (Tim-3). These receptors are also increased with aging and are future targets for ICI therapy (Baitsch et al. 2012; Nguyen and Ohashi 2015; Hurez et al. 2017).

There are presently two clinically exploited immune checkpoint inhibitors. Monoclonal anti-PD-1 antibodies are most successfully used in different cancers such as melanoma, (NSCLC), lymphoma, and head and neck cancer (Wang et al. 2018; Sharma and Allison 2015). PD-1 is expressed preferentially on the surface of effector

memory (exhausted) T cells. Clinically, the impact of age on the immunotherapy response has not been systematically described. However, several meta-analyses confirmed the remarkable efficiency of ICI in elderly subjects too (Elias et al. 2017; Daste et al. 2017). This treatment most likely also affects other cells expressing the PD-1 such as NK cells, B cells, myeloid cells, and DCs (Fanoni et al. 2011). Thus, this treatment not only restores T-cell functions but also influences antibody production, NK cell cytotoxicity, and the suppressive activity of MDSCs (Velu et al. 2009)). Not only PD-1 but also PDL-1 may be expressed by myeloid cells in the tumor microenvironment, and their modulation may also increase antitumor immunity mediated by T cells (Herbst et al. 2014). Recent trials of the anti-PD-1 monoclonal antibody nivolumab demonstrated efficacy for NSCLC (Reck et al. 2016). In that trial, there was a lower efficacy of immunotherapy with nivolumab for patients older than 75 years (Sgambato et al. 2017). However, these results need to be interpreted cautiously due to the small sample size of these subgroups.

CTLA-4 antibodies are also very efficient immune checkpoint modulators most often used for metastatic melanoma. CTLA-4 binds CD80 or CD86 on antigen-presenting cells and abrogates the capacity of T cells to further respond to their specific antigens. When the CTLA-4 receptor is blocked, inhibition is relieved, and the capacity of the T cell to respond is regenerated. In early trials, 10–20% of metastatic melanoma patients showed clinical responses and went on to experience a substantial survival advantage, never achieved before with any other treatment (Hodi et al. 2010). This was a major advance in cancer and especially in melanoma therapy. As a result, the antibody ipilimumab was the first to be licensed by the FDA, in 2011.

Taken together, it appears that neither anti-PD-1 (e.g., pembrolizumab) nor anti-CTLA-4 (e.g., ipilimumab) treatment shows clear patient age-dependent decreases in efficacy and safety (Elias et al. 2017; Daste et al. 2017; Johnson et al. 2017; Pawelec 2017). This further questions how immunosenescence interferes with the application of immunotherapy.

Even more recently, this technique of using immunomodulatory checkpoint antibodies to enhance antitumor immunity has been extended to include NK cell checkpoints. Thus, the inhibitory receptors on NK cells responding to HLA class I molecule such as KIR and NKG2A have been also targeted by specific antibodies, so far only in preclinical trials (Tarazona et al. 2017). However, there are no data from the elderly on the efficacy and toxicity of these treatments. It should be noted that although these treatments are not free of toxicity, it does not seem worse in elderly patients (Daste et al. 2017). Pruritus, rash, diarrhea, nausea, and liver toxicity were the most specific AEs in the older population. Frequencies of these toxicities were similar in younger and older patients, with a slight increase in rash in the latter (10% vs. 7%). Hence, some patients are not responding which can be explained by the decreased immune response with aging, more specifically the decrease in T cells bearing these receptors and the overwhelming presence of senescent cells in a pro-inflammatory milieu.

Thus it can be clearly stated that older age is not a contraindication to immune checkpoint inhibition, and instead functional status may be a more relevant consideration. However, the overall toxicity profile, efficacy, and relative risks and benefits in comparison with other therapies have not been studied comprehensively for tumor types other than melanoma, and they will need further study.

Elderly Participation in Clinical Trials

There are usually very few patients over 70 years of age in the majority of antitumor clinical trials. The FDA has been recommending the inclusion of elderly people in clinical trials for many years. This paucity of trials in the elderly is rendering it difficult to assess the impact of immune changes occurring with aging on anticancer immunotherapy. It is not only age that matters but also comorbidities commonly seen in the elderly, such as renal or hepatic dysfunction (Johnson et al. 2017). Moreover, some of these elderly

subjects are frail or have Eastern Cooperative Oncology Group (ECOG) status >2. The inclusion of these patients is of high importance to assess the effects of immunotherapy in older patients, especially for checkpoint blockade. Thus, it is the outmost importance in general to include elderly in these trials. Of course, this also raises ethical questions regarding survival, cost, and social acceptability, mainly in the context of palliative treatment.

Conclusions and Future Perspectives

Aging is accompanied by many changes in immunity. Neither the extent nor the physiological significance of all of the many differences seen in people of different ages is completely clear thus far or even which of these differences are actually age-associated changes. Most of the data seem to suggest a decrease of immune function with advancing age, but others indicate increases or no change. Most importantly, the significance of these changes for the development of age-associated disease including cancer is not known with any certitude (Fig. 1). The recent success of finally being able to exploit immune surveillance of tumors to cure some patients makes it imperative to determine whether immunosenescence decreases antitumor immunity. It is clear that many additional factors are likely to play a role in the increasing cancer incidence with age, at least up to extreme old age. In the current era of immunomodulatory antibody immunotherapy shown to be dramatically effective in a fraction of mostly younger patients, there is a justified concern that these treatments may be less effective in the elderly because of the aforementioned immune changes with aging. This is presently difficult to establish as most of the elderly cancer patients are not participating in clinical trials. However, when they are included, results so far are similar to those in younger subjects, also with a similar toxicity profile. These mostly anecdotal data suggest that the elderly will be able to benefit from immunotherapy. However, specific trials are needed to confirm and extend these positive results, particularly in the context of directed targeting of neoantigens. It is clear that multimodal and multi-target treatments may become the standard of care for a personalized application mainly in elderly people with their immune history and potential longstanding coexistence with the nascent cancer. New strategies will also emerge with the better understanding of natural anticancer immunology and age-related changes (Table 1).

Table 1 Immunotherapies: present and future for the elderly

Adaptive immunity	
Adoptive transfer	CAR T cells
	DC-based vaccine
	NK cell expansion
Immune checkpoint inhibitors	PD-1/PD-L1
	CTLA-4
	LAG-3
	Tim-3
Tregs	Future
Innate immunity	
Neutrophils	Future
Macrophages	MCSF-R
MDSCs	Future
TLR agonists	Future
NK cells	Checkpoint blockade
Inflammation	Future
Immunometabolism (mTOR pathway)	
Nutrition	Rapamycin
Life style	Exercise
SASP	Senolytics

Vladimir N. Anisimov

Contents

Abstract

The incidence of cancer increases with age in humans and in laboratory animals alike. There are different patterns of age-related distribution of tumors in different organs and tissues. Aging may increase or decrease the susceptibility of various tissues to initiation of carcinogenesis and usually facilitates promotion and progression of carcinogenesis. Aging may predispose to cancer at least by two mechanisms: tissue accumulation of cells in late stages of carcinogenesis and alterations in internal homeostasis, in particular, disturbances in immune and endocrine system. Increased

susceptibility to the effects of tumor promoters is found both in aged animals and aged humans, as predicted by the multistage model of carcinogenesis. Aging is associated with number of events at the molecular, cellular/tissue, and systemic/organismal levels that influence carcinogenesis and subsequent cancer growth. The available data on the effects of environmental carcinogens on life span and the aging at different levels of integration are critically analyzed. The exposure to various mutagenic agents, i.e., 5-bromodeoxyuridine, alkylating substances, carcinogenic polycyclic aromatic hydrocarbons, nitroso compounds, and ionizing radiation, decreases the life span of treated animals in direct proportion to dose and was considered as an acceleration of aging. There are significant similarities between normal aging features and effects of environmental carcinogens on DNA, neuroendocrine and immune system, and carbohydrate and lipid metabolism, whereas main difference was observed at cellular level.

Carcinogenesis • Aging • Multistage model • Cancer microenvironment • Geroprotectors

Introduction: Aging and Cancer – Two Related Phenomena?

Cancer is a common cause of disability and death in the elderly: Over 50% of malignant neoplasms occur in persons aged 70 and above (Yang et al. 2012; Forman et al. 2013). The relationship between aging and cancer is not clear: Considerable controversy surrounds the mechanisms that lead to increased incidence of cancer in the aged. Two major hypotheses have been proposed to explain the association between cancer and age. The first hypothesis holds this association a consequence of carcinogenesis duration. That is, the sequential carcinogenic steps that are required for the neoplastic transformation of normal tissues develop over several years, and cancer is more likely to become manifest in older individuals by a process of natural selection. Peto et al. (1985) suggested that the high prevalence of cancer in older individuals simply reflects a more prolonged exposure to carcinogens. The incidence of cancer is a power function of the duration of carcinogen exposure, rather than a power function of tumor-host age. According to the second hypothesis, age-related progressive changes in the internal milieu of the organism provide an increasingly favorable environment for the initiation of new neoplasms and the growth of already existent but latent malignant cells (Anisimov 1983, 1987, 2003, 2009; Miller 1991; DePinho 2000). These mechanisms also include proliferative senescence, as the senescent cells lose the ability to undergo apoptosis, and produce substances favoring cancer growth and metastases (Campisi et al. 2001; Campisi 2003; Campisi and Robert 2014). The elucidation of the causes of an age-related increase in cancer incidence may be the key to a strategy of primary cancer prevention (Fig. 1).

Aging and Susceptibility to Carcinogenesis in Different Tissues

Animal experiments seem to confirm that age-related differences in the sensitivity to carcinogen in some tissues do exist. Thus, susceptibility to carcinogens decreases with age in the murine mammary gland, the small intestine and colon, the thyroid, and the ovarian follicular epithelium; it increases, by contrast, in the subcutaneous tissue, the cervix uteri, and the vagina. In other sites (the lung, hemopoietic tissues), it remains stable (for details see Anisimov 1983, 1987, 2009). For instance, female rats exposed to N-nitrosomethylurea (NMU) in doses of 10, 20, or 50 mg/kg at the age of 3 months developed mammary carcinomas and tumors of the kidney, ovaries, and colon. In contrast to young animals, the rats exposed to the same doses of the carcinogen at the age of 15 months showed a higher frequency of tumors of the corpus and cervix uteri following exposure to NMU and a lower frequency of mammary and intestinal adenocarcinomas and tumors of the ovary and kidney (Anisimov 1988). A comparison of the results with data on DNA alkylation, DNA synthesis, and O^6-methylguanine repair obtained in

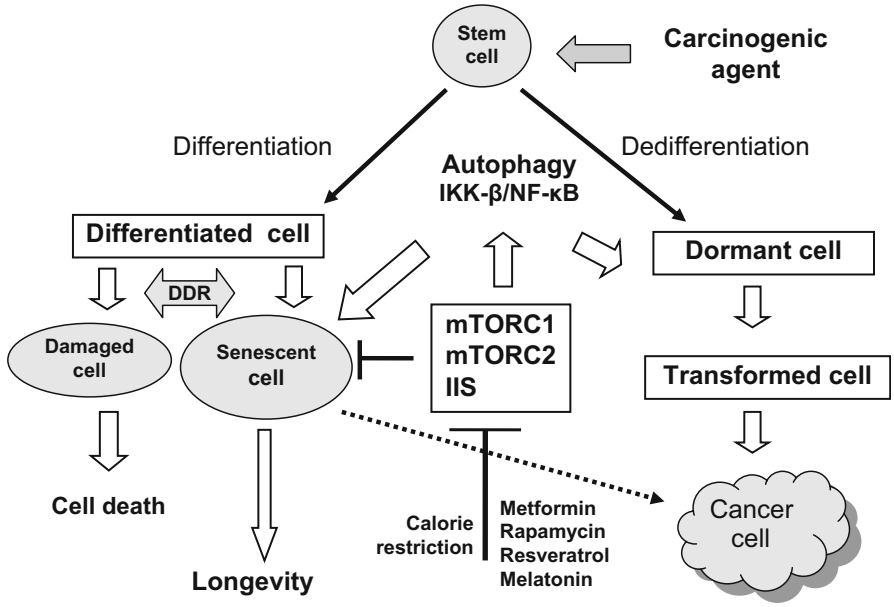

Fig. 1 Relationship between aging and carcinogenesis: the key role of insulin/IGF-1-like signaling (IIS) and mTOR signaling (From Anisimov 2013). DNA damage induced by environmental and endogenous factors (ROS, chemicals, ionizing radiation, ultraviolet, constant illumination, oncogenes, some diets, etc.) may lead to cellular senescence or cellular lesions which could be deleted by apoptosis or autophagy. The same agents can induce damages which are followed by neoplastic transformation thus leading to cancer. Metformin, rapamycin, and some other compounds with mTOR and IIS-inhibitory potential (resveratrol, melatonin) are able to modify both the aging and carcinogenesis

the same model suggests that age-related proliferative activity changes occurring in the target tissues in the mechanism of age play a critical role in modifying the effect on carcinogenesis. Obviously, there are no common patterns of age-related changes in DNA synthesis and repair or in the proliferative activity of different tissues with age.

This wide variation in experimental result can possibly be attributed to several factors, including those related to the experimental model and factors associated with the tumor host. Model-related factors involve the characteristics of different carcinogens (direct or indirect action, chemical structure, and the mechanisms of action), the route of administration, the exposure duration, the presence of local and systemic activity, and the time of observation. Host-related factors involve animal species, strain, sex, and age. The effective dose of an indirect carcinogen, requiring metabolic activation, may vary significantly in old and young animals, because the activity of the enzymes necessary for carcinogen activation in the liver and/or target tissue(s) may significantly decrease with age.

Critical factors that determine the susceptibility of a tissue to carcinogenesis include DNA synthesis and proliferative activity of that tissue at the time of carcinogen exposure and the efficacy of repair of damaged DNA (Tomasetti and Vogelstein 2015). The homeostatic regulation of cell number in normal tissues reflects a precise balance between cell proliferation and cell death. Programmed cell death (apoptosis) provides a protective mechanism from cancer by removing senescent, DNA damaged, or diseased cells that would otherwise potentially interfere with normal function or lead to neoplastic transformation (Hanahan and Weinberg 2011). Apoptosis and autophagy play a substantial role in many other aspects of aging and cancer, including control of the life span of most members of the immune complex and the rate of growth of tumors. P53-mediated apoptosis is suggested to act as a safeguard mechanism to prevent cell proliferation

induced by oncogene activation (Kinzler and Vogelstein 1997).

Being a component of two protein complexes, mTORC1 and mTORC2, serine/threonine protein kinase mTOR (mechanistic target of rapamycin) is a key enzyme of the mTOR-signaling pathway that regulates the maintenance of cellular homeostasis by coordinating transcription, translation, metabolism, and autophagy with availability of amino acids, growth factors, oxygen, etc. The activation of protein kinase mTOR by growth factors and nutrients suppresses autophagy and increases protein synthesis, thus increasing risk of cancer development, whereas mTOR inhibition increases longevity of mammals (Parkhitko et al. 2014; Laplante and Sabatini 2012). Administration of mTOR inhibitors rapamycin, rapalogs, or metformin increased life span of mice and reduced the tumor development (Harrison et al. 2009; Anisimov et al. 2010; Blagosklonny 2014; Anisimov 2015; Leontieva et al. 2015). It was shown that old mice have elevated mTORC1 signaling in hematopoietic stem cells (HSC) and that induction of mTORC1 by *Tac1* loss induces premature aging in HSC (Chen et al. 2009). Reducing mTORC1 with rapamycin restores HSC self-renewal and hematopoietic functions followed by improvement in immunity and increased life span of mice.

Age-related factors that limit susceptibility to carcinogens are tissue specific (Anisimov 1987). This conclusion explains, at least in part, both age-related changes in the susceptibility to carcinogenesis in target tissues and organ and tissue variability in the age distribution of spontaneous tumor incidence. This conclusion generates a critical question: Is aging accompanied by the accumulation of premalignant lesions in target tissues?

Aging and Multistage Carcinogenesis

Both carcinogenesis and aging are associated with genomic alterations, which may act synergistically in causing cancer (Hanahan and Weinberg 2011). In particular, age-related changes in DNA metabolism possibly favor cell transformation and cancer growth: genetic instability, DNA hypomethylation, and the formation of DNA adducts.

Genetic instability involves the activation of genes that are normally suppressed, e.g., cellular proto-oncogenes, and/or the inactivation of some tumor suppression genes (p53, Rb, etc.) (Kinzler and Vogelstein 1997; Hanahan and Weinberg 2011). DNA hypomethylation is a characteristic of aging, as well as of transformed cells. Hypomethylation, a potential mechanism of oncogene activation, may result in the spontaneous deamination of cytosine and consequent base transition, i.e., substituting the pair thymine, adenine. The accumulation of inappropriate base pairs may cause cell transformation by activating cellular proto-oncogenes. The different extent of DNA abnormalities among aging tissues accounts in part for the different susceptibility of these tissues to carcinogens (Catania and Fairweather 1991).

The damage caused by endogenous oxygen radicals is suggested to be a major contributor to both aging and cancer (Shigenaga et al. 1994). Endogenous oxidative damage to lipids and proteins increases with age. The level of one oxidized nucleoside, 8-hydroxy-2′-deoxyguanosine (oh8dG), in the DNA increased with age in the liver, kidney, and the intestine but remained unchanged in the brain and testes of rats. The urinary excretion of the nucleoside, by contrast, decreased in the rats with age. A variety of cellular defense systems are involved in protecting cellular macromolecules against the devastating action of oxygen-based radicals. They include antioxidant enzymes (Cu,Zn-superoxide dismutase (SOD), manganese-containing SOD, catalase, glutathione peroxidase, glutathione reductase, glucose-6-phosphate dehydrogenase), some vitamins (α-tocopherol, ascorbic acid), uric acid, and pineal indole hormone melatonin.

In the last decades, the importance of telomeres in aging has been highlighted. Telomeres are DNA sequences at the end of eukaryotic chromosomes in somatic cells. During cell replication, telomeres are preserved by the enzyme telomerase, a ribonucleoprotein enzyme that adds the telomere sequences TTAGGG to chromosome ends (Campisi et al. 2011; Blackburn et al.

2015). In the absence of telomerase, telomeres are shortened with each cell division. Loss of the distal region of telomeres correlates with the decline of the proliferative life span of cells both in vitro and in vivo. There are well-founded arguments suggesting that telomere shortening and reactivation of telomerase are important components of aging and carcinogenesis, respectively (Hanahan and Weinberg 2011).

There are evidences of an age-related accumulation of spontaneous mutations in somatic and germ cells (Vijg 2000; Adams et al. 2015). The accumulation with age of some spontaneous mutations or mutations evoked by endogenous mutagens can induce genome instability and, hence, increase the sensitivity to carcinogens and/or tumor promoters. Thus, the data available show that some changes in the structure and function of DNA are evolving with natural aging. The character of these changes varies in different tissues, causing uneven tissue aging. In turn, this leads to both age-related increases in spontaneous tumor incidence and age-related changes in susceptibility to carcinogens in various organs.

Carcinogenesis is a multistage process: Neoplastic transformation implies the engagement of a cell through sequential stages, and different agents may affect the transition between continuous stages (Schlessinger and Van Zant 2001). Multistage carcinogenesis is accompanied by disturbances in tissue homeostasis and perturbations in nervous, hormonal, and metabolic factors which may affect antitumor resistance. The development of these changes depends on the susceptibility of various systems to a carcinogen and on the dose of the carcinogen. Changes in the microenvironment may condition key carcinogenic events and determine the duration of each carcinogenic stage, and sometimes they may even reverse the process of carcinogenesis. These microenvironmental changes influence the proliferation rate of transformed cells together, the total duration of carcinogenesis, and, consequently, the latent period of tumor development. There is also evidence of age-related accumulation of cells at the latest stage of the multistage process of carcinogenesis. Numerous experiments support the results of this model.

Of particular impressive are experiments using skin transplants. Skin tumor promoter 12-O-tetradecanoylphorbol-13-acetate (TPA) failed to induce tumors in the skin of 2-month-old mice grafted to syngeneic animals of different ages but caused the same tumor incidence in the skin of 1-year-old donors irrespective of the recipient's age (Ebbesen 1985). These results indicate that the age of the target tissue determines susceptibility to late-stage agents more so than the age of the host.

In Tg.AC transgenic (v-Ha-ras) mice, skin tumor incidence and multiplicity were strongly age-dependent, increasing with advancing age of the experiment animal when first treated with TPA or exposed to wounding by UV light (Battalora et al. 2001). The authors suggest that natural developmental changes in keratinocytes are co-opted by the molecular mechanisms that regulate the induction of transgene expression, thus stimulating tumor formation in older Tg.AC mice.

The age-related accumulation of cells in advanced carcinogenic stages can also be demonstrated by other types of experiments. The mice model of hepatocarcinogenesis is very convenient for this purpose because of the availability of strains of animals with different susceptibility to hepatic carcinogenesis. In the liver of highly susceptible mice, the concentration of hepatocytes in the advanced stages of carcinogenesis increased early in life before exposure to experimental carcinogens. In the liver of F344 rats, the number of spontaneous proliferative foci is proportional to the animals' age. The incidence of proliferative foci and hepatic tumors induced by phenobarbital, carbon tetrachloride, or peroxisome proliferators in rodents is also a function of age (Ward et al. 1988).

Cellular Senescence and Carcinogenesis

In contrast to germ cells and certain stem cells, the majority of somatic cell types have a limited proliferative life span. This restriction may have evolved as a protective mechanism against cancer, although it may also cause the accumulation of cells at the end of their replicative life span that

may be responsible for the aging process and an increase in the susceptibility to carcinogenesis (Campisi 2003). The term "cellular senescence," originally defined as a series of cellular changes associated with aging, now refers more commonly to a signal transduction program leading to irreversible arrest of cell growth, accompanied by a distinct set of changes in the cellular phenotype. Senescence is a potent anticarcinogenic program, and the process of neoplastic transformation involves a series of events that allow cells to bypass senescence (Shay and Roninson 2004; Sicora et al. 2016). Although the relationships between cellular senescence and aging in vivo are not very clear yet, senescent cells were reported to accumulate in aging tissues: in human skin and liver (Dimri et al. 1995), in primate retina, and in some other tissues. Senescent cells were shown capable of stimulating the malignant progression of premalignant keratinocytes and mammary gland epithelial cells (Krtolica et al. 2001). Cellular senescence is controlled by the tumor suppressor proteins p53 and pRb. Inactivation of these proteins results in bypass of senescence. It is worthy to note that due to its essentially irreversible growth arrest and the requirement for p53 and pRb function, cellular senescence is considered a potent tumor suppressor mechanism. Numerous studies, primarily in human fibroblasts, suggest that telomere shortening is the primary cause of replicative senescence (Campisi 2003).

It is important that cellular senescence can be induced by a variety of extrinsic factors, such as X-ray irradiation, UV irradiation, H_2O_2, ectopic expression of certain oncogenes (Ras, Raf, ets2, E2F1), and tumor suppressors (p16, p14, p53). Cellular senescence may be one of the mechanisms by which cancer chemotherapy drugs work in vivo (Schmitt et al. 2002; Shay and Roninson 2004). Thus, the exposure to exogenic carcinogens can lead to accumulation of senescent cells which, in turn, can be anticarcinogenic factor and also can stimulate the malignization of precancerous cells in the target tissue.

Note that senescence is not an inevitable consequence of extended proliferation in a culture. Thus, rat Schwann cells appear to have the capacity for unlimited proliferation in vitro, whereas fibroblasts isolated from the same nerves undergo the classic replicative senescence seen in rodent fibroblasts. Some other normal rodent precursor cells (e.g., oligodendrocytes) have an unlimited proliferative capacity if cultured in conditions that avoid both the differentiation and activation of checkpoint responses that arrest the cell cycle. In contrast to fibroblasts, human mammary epithelial cells spontaneously escape senescence and generate genomic abnormalities that are required for the initiation of carcinogenesis.

Aging and Cancer Microenvironment

An important question related to the integral model of carcinogenesis concerns age-related changes in tissue microenvironment as these changes may favor or limit carcinogenesis in different circumstances (Liotta and Kohn 2001). Should aging tissues alter the environment in which tumor develops, the growth rate of transplantable tumors may vary with the age of the tumor recipient. These experiments bypass the effect of age on carcinogenesis itself and explore the role of age-related changes in the organism on the growth and progression of transformed cells. Evaluation criteria for such experiments should include tumor transplantability, the rate of tumor growth, and the survival time of tumor-bearing animals. The natural history of spontaneous tumors in humans (the rate of tumor doubling, metastazing potential) and the survival of cancer patients newly diagnosed at different ages provide information on the effects of age on tumor growth in humans. Available data both in experimental animals and in humans are contradictory and support different effects age has on tumor development (Anisimov 2006b). In general, an "age effect" is possible both in experimental and human malignancies. Tissue origin (histogenesis) and tumor immunogenicity are the principal factors determining age-related differences in tumor growth.

McCullough et al. (1994) observed that transformed rat hepatocytic cell lines were only weakly tumorigenic following transplantation into the livers of young adult rats. The tumorigenicity of

these cell lines increased progressively with the age of the tumor recipients. These results suggest strongly that the tissue microenvironment represents an important determinant in the age-related tumorigenic potential of transformed cells.

In recent years, it has become increasingly apparent that the senescence response is a complex phenotype, which has a variety of cell nonautonomous effects (Campisi et al. 2011). The senescence-associated secretory phenotype, or SASP, entails the secretion of numerous cytokines, growth factors, and proteases. The SASP can have beneficial or detrimental effects, depending on the physiological context. Among the detrimental effects, the SASP can disrupt normal tissue structures and function and, ironically, can promote malignant phenotypes in nearby cells. These detrimental effects in many ways recapitulate the degenerative and hyperplastic pathologies that develop during aging. It is worthy to note that many features of SASP are very similar with the cancrophilia syndrome proposed by Dilman (1994).

It is important to stress that in every tissue, the number of events occurring in the stem cell before its complete transformation is variable and depends on many factors, in particular the rate of aging of the target tissue and its regulatory system (s) (Anisimov 2009). This model is consistent with the analysis of the age-related distribution of tumor incidence in different sites in humans and laboratory animals. It must be emphasized also that old animals can be used as an adequate model for long-term assays for carcinogenicity of suggested weak carcinogens and/or tumor promoters.

Among most critical points in the mechanisms underlying the molecular and cellular basis of age-related cancer, an important role is played by the stroma (Elkhattouti et al. 2015). It was stressed that some components of senescent stroma, such as fibroblasts, contribute to create a tumor-promoting microenvironment through mechanisms including SASP and another stroma-derived factors. It was stressed that the ectopic expression of such transcription factors as OCT4, SOX2, KLF4, and cMYC (OSKM) in vivo, apart from inducing the reprogramming of a small population of cells, also induces damage and senescence in sufficient number of neighboring cells, with IL-6 being a critical mediator (Mosteiro et al. 2016). Thus, aging induces changes in molecular pathways that contribute in the initiation and/or clonal dominance of mutations in stem and progenitor cells. Cell-extrinsic factors affect stem cell maintenance and the selection of mutant stem cells and progenitor cells during aging of an organism (Adams et al. 2015).

Premature Aging Promotes Carcinogenesis

It is well known that some syndromes of untimely aging (progeria) are associated with an increased incidence of cancer (Lehmann 1985). Alongside with the classical progeria syndromes, some diseases are accompanied by disturbances that may be regarded as signs of intensified aging. For instance, the Stein-Leventhal syndrome (sclerocystic ovaries syndrome) occurs during puberty and is characterized by a bilateral sclerocystic enlargement of the ovaries, associated with a pronounced thickness of the ovary capsule. The enlargement forms a mechanical obstacle for the ovulatory rupture of a mature follicle. In these ovaries, follicular cysts and hyperplasia of theca tissue can be found. Patients have anovulation, sterility, hirsutism, hyperlipidemia, lowered glucose tolerance, hyperinsulinemia, obesity, hypertension, and increased incidence of breast and endometrial cancer (Dilman 1994). In rodents, the syndrome of persistent estrus, which normally completes the reproductive period of life, can be induced by several methods, including neonatal administration of sex steroids, exposure to some chemical carcinogens or to ionizing irradiation, housing under constant illumination, subtotal ovariectomy, orthotopic transplantation of an ovary into castrated animals, electrolytic lesion of anterior and/or mediobasal hypothalamus, etc. (Anisimov 1987). Regardless of the induction method, premature aging and a rise in tumor incidence have been observed in rats with persistent estrus (Anisimov 1987).

The induction of persistent estrus in rats exposed to chemical carcinogens (DMBA,

NMU) was associated with increased tumor incidence when compared to animals without persistent estrus exposed to a carcinogen alone (Anisimov 1987). These observations highlight the promoting effect of the persistent estrus syndrome on carcinogenesis.

Effect of an Exposure to Environmental Carcinogens on Aging and Life Span

The potency of carcinogenic and mutagenic agents to accelerate aging has been discussed for many years (Larionov 1938; Alexander and Connel 1960; Dilman 1971, 1994; Alexandrov 1982 Anisimov 1987, 2009). There are available data on the effects of carcinogens on aging at different levels of an integration: molecular, tissue, systemic, and organismal.

Exposure to various mutagenic agents, i.e., 5-bromodeoxyuridine, alkylating substances, carcinogenic polycyclic aromatic hydrocarbons, nitroso compounds, ionizing radiation, and light at night, decreases the life span of treated animals in direct proportion to dose and was considered as an acceleration of aging (Anisimov 2009).

Neonatal 7,12-dimethylbenz(a)anthracene (DMBA) administration decreased the mean life span of female mice from 608 to 297 days. Premature cessation of estrus function, graying of hairs, loss of weight, etc. were observed (Ohno and Nagai 1978). Dunjic (1964) noticed shortening of rat life span proportional to dose of Myleran and accompanied by such manifestations of old age as cataract and testicle atrophy. Female rats exposed to 3-methycholanthrene (MCA) manifested early discontinuation of estrous function and a number of hormonal shifts which have suggested intensified aging induced by the carcinogen (Anisimov 1987). There are data on smoking-induced life shortening of life span and acceleration of aging both in rodents and in human (Teramoto et al. 1993; Watanabe 2016). In mice exposed to radiomimetics (nitrogen mustard or triethylenemelamine), a decrease of life span was observed which correlated with all types of diseases associated with old age (Conklin et al. 1963). Acceleration of aging by ionizing radiation could serve for explanation of results obtained in studying "dose-effect" dependence in the action of irradiation (Alexandrov 1982).

DNA Damage in Aging and Carcinogenesis

One of the most advanced theories of aging is free radical theory proposed in 1956 by D. Harman (1998). This theory postulated that various oxidative reactions occurring in the organism (mainly in mitochondria) generate free radicals as by-product which cause multiple lesions in macromolecules (nucleic acids, proteins, and lipids), leading to their damage and aging. This theory explains not only the mechanism of aging per se but also a wide variety of age-associated pathology, including cancer. There are evidence that key mechanisms of both aging and cancer are linked via endogenous stress-induced DNA damage caused by reactive oxygen species. They include oxidative nuclear and mitochondrial DNA damage and repair and telomere shortening and telomere-driven cellular senescence and have been intensively discussed in a number of comprehensive reviews (von Zglinicki et al. 2001; Blackburn et al. 2015). It is worthy to note that chemically and radiation-induced carcinogenesis also are critically involved in the free radical processes.

The intensity of natural damages in DNA is very high, e.g., in a human cell, spontaneous depurinization takes place at a rate of up to 10,000 acts per day and spontaneous deamination of adenine and cytosine at a rate of hundreds of events per day. As a result, permanently working mechanisms of DNA repair have evolved. It turns out that in both of the most intensive natural mutation processes (depurinization and deamination), thymine is not present (mutations related to it are significantly more rare), and therefore the reparation schemes for thymine may have evolved less intensively (Lindahl 1993). Hence, if we want to induce uniformly distributed point mutations (and simultaneously to minimize damages in other structures) in laboratory animals, then it is meaningful to use analogues of thymine as a mutagen.

Some "in vitro" and "in vivo" effects of the thymidine analogue, 5-bromodeoxyuridine (BrdUrd), suggest that BrdUrd may be used to investigate the role of selective DNA damage both in carcinogenesis and in aging. BrdUrd is incorporated into replicating DNA in place of thymidine, and this effect is mutagenic (Morris 1991). In addition to the usual keto form, BrdUrd may assume an enol tautomeric form, which forms hydrogen bonds with guanine instead of adenine, the normal pair for thymidine and 5-bromouracil. In the absence of 5-bromouracil repair in rat DNA (Lindahl 1993), if BrdUrd is incorporated into DNA as the enol tautomer, base-pair substitution mutations are expected to occur (GC→AT and AT→GC transitions) during subsequent DNA replication (Morris 1991). Unlike purine analogues, BrdUrd is not involved in energy production or in cell signaling and interactions and hence can reach required levels of mutations while being less toxic than in the case of "spoiled" analogues of purines. This ability to induce uniformly distributed point mutations with a chosen intensity using BrdUrd is based on the fact that the number of mutations is linearly dependent on the concentration of BrdUrd. Assuming a fairly even level of BrdUrd incorporation, into the DNA of various tissues of neonatal rats and long-term persistence in them (Ward et al. 1991), cells with highest proliferative activity would be more likely to undergo malignant transformation. Exposure to BrdUrd had dramatic effects on cellular functions including cell differentiation, inactivation of regulatory genes or master switch, and proliferation. These changes in cellular function may favor tumor development.

In a series of experiments (Napalkov et al. 1989; Anisimov and Osipova 1992; Anisimov 1994), rats received subcutaneous injections of BrdUrd at 1, 3, 7, and 21 days of postnatal life at the single dose of 3.2 mg per rat. BrdUrd persisted for up to 49 weeks in all tissues studied immunohistochemically, especially in tissues with normal or low cell turnover. For cells with high turnover, few or no BrdUrd-labeled cells remained at 49 weeks (Ward et al. 1991). The exposure to BrdUrd was followed by the decrease in the mean life span of the animals of 38% in males and 27% in females and by the increase in the rate of aging (calculated according to Gompertz equation) in comparison with controls. The monitoring of estrus showed an acceleration of natural age-related switching off of reproductive function in female rats, due to disturbances in central regulation of gonadotropic function in the pituitary. The exposure of rats to BrdUrd was followed by signs of immunodepression, by increase in the incidence of chromosome aberrations and spontaneous tumors. The latency of these tumors was decreased. In offspring of rats neonatally treated with BrdUrd, the increased incidence of congenital malformation and of spontaneous tumors and accelerated aging were both observed. Neonatal exposure of rats or mice to BrdUrd was followed by the initiation of the neoplastic process and, consequently, by increased tissue susceptibility to "late-stage" carcinogens such as N-nitrosomethylurea (NMU), X-irradiation, urethane, estradiol benzoate, and persistent estrus syndrome. These data provided the evidence that a sole perturbation of DNA induced by BrdUrd contributed substantially to the initiation of tumorigenesis and to the acceleration of aging.

BrdUrd was found to induce in vitro flat and enlarged cell shape, characteristics of senescent cells, and senescence-associated beta-galactosidase in mammalian cells regardless of cell type or species (Suzuki et al. 2001). These results suggest that BrdUrd induced senescence-like phenotypic resemblance in both mortal and immortal mammalian cells and, possibly, activated a common senescence pathway present in both types of cells. It is important to stress that BrdUrd immediately induces premature senescence in normal cells and the senescence-like phenomenon in any type of immortal cells. It was shown also that BrdUrd immediately and dramatically induces senescence-associated genes in human cells.

The mathematical model of processes of aging and carcinogenesis in tissue based on the experimental data on in vivo exposure to BrdUrd has been considered (Butov et al. 2001). Modeling was carried out on the basis of the recurrent algorithms constructed on the stochastic equations in terms of semimartingale characteristics of the processes. The results confirm the conclusion that under BrdUrd treatment there is an accelerated

aging in tissues with proliferating cells and an increment of death from tumor growth. These results can serve as an indirect validation of the hypothesis about the influence of levels of tissue damages during mutagenesis and oxidative stress both on the rates of aging and on the rate of carcinogenesis. The abovementioned observation on in vitro effects of BrdUrd is in agreement with this conclusion.

Effect of Carcinogens on the Neuroendocrine System

It should be stressed that the most significant aftereffects induced by carcinogenic agents on supracellular levels are those produced on the central chains of the neuroendocrine system, the hypothalamus in particular. In certain hypothalamic nuclei, cells synthesize and secrete releasing or inhibiting hormones, which control secretion of pituitary hormones. In turn, hypothalamic peptidergic neurons are controlled by humoral signals and neurogenic stimuli, which enter the hypothalamus with blood and via afferent nervous tracts. Important roles of mediators and modulators between these signals are played by the biogenic amines (catecholamines, norepinephrine and dopamine, serotonin, γ-aminobutyric acid, etc.) in which the hypothalamic area is rich. With the information from internal and external media of the host, the hypothalamus coordinates the functions of the nervous and endocrine systems and eventually maintains constancy of the internal medium (homeostasis) of the host. The significance of the hypothalamus is so great that it is considered by some researchers as the "biologic clock" of aging (Dilman 1971, 1994).

Hypothalamic nuclei develop relevant morphological, biochemical, and functional changes in aging which tell eventually on the function of the endocrine and some of the other integrating systems of the organism. These changes result in an age-related increase of the threshold of sensitivity of the hypothalamus to inhibition by steroids (sex hormones, in the system of reproductive homeostasis, and glucocorticoids, in the system of adaptation to stress). According to Dilman (1994), this disturbance is a key one in the process of realization of the neuroendocrine program of development, aging, and formation of age-related pathology, including cancer.

Adult rats, exposed to single administration or chronic treatment with a variety of carcinogens, showed an elevated threshold of sensitivity of the hypothalamus to homeostatic inhibition via the mechanism of negative feedback (Anisimov 1987). Being noncarcinogenic for rats, anthracene or benzo(a)anthracene did not possess such property.

An age-related decrease of catecholamine level and amount of receptors to estrogens in hypothalamus as well as disturbances in the ratio of activity of adrenergic and serotoninergic brain structures plays a leading role in the mechanism of age-related elevation of hypothalamic threshold of sensitivity to inhibition by estrogens (Dilman and Anisimov 1979).

It is well known that hormonal imbalance, which develops in the first hours and days after carcinogen administration, is an important factor determining the appearance of mammary gland neoplasms under polycyclic aromatic hydrocarbon influence. In fact, ovariectomy performed immediately after DMBA administration suppresses mammary tumor development, while conducted 1 week after it, the ovariectomy does not prevent mammary carcinogenesis. Already in the first hours after DMBA or MCA administration to rats, an activation of neurosecretory elements in the hypothalamus nuclei was observed. Soon after the administration of polycyclic aromatic hydrocarbons, rats developed pronounced shifts in the function of the ovaries, adrenal glands, and thyroid gland. These data convincingly suggest an immediate influence of carcinogenic polycyclic aromatic hydrocarbons on the neuroendocrine system in rats, a possible triggering mechanism of which is their influence on the level of biogenic amines in the hypothalamus. There are data on different effects of chemical carcinogens on the level of biogenic amines in the hypothalamus of rats. Some of them effect predominantly the noradrenergic and dopaminergic structures (DMBA, DMH, and NMU), while others effect the serotoninergic (MCA) (Anisimov

1987). There could be a supposed influence of some carcinogens on the activity of MAO (2-AAF and NEU). It should be noted that such hepatocarcinogens as N-nitrosodimethylamine (DENA) and 2-AAF differently influence adrenoreceptors (Gurkalo and Pliss 1978). Despite the fact that the tested carcinogens produced different effects on the level of biogenic amines in the hypothalamus, practically all of them induced a general physiological shift – an increased level of hypothalamic threshold of sensitivity to homeostatic inhibition by estrogens.

Hypothalamic shifts, which develop in animals exposed to carcinogenic agents, lead to significant morphological and functional changes in the reproductive system. Thus, rats develop follicular cysts of the ovaries and persistent estrus in distant terms after irradiation or MCA treatment (Anisimov 1987). Similar changes on the hypothalamic level regularly switch off the reproductive period in female rats during natural aging (Dilman and Anisimov 1979; Aschheim 1976). Signs of accelerated development of age-related disturbances in the system hypothalamus-pituitary-adrenal glands of animals exposed to irradiation and some carcinogens have been described in numerous works (Alexandrov 1982).

Effect of Carcinogens on Carbohydrate and Lipid Metabolism

Hormone-metabolic shifts which develop in the organism during natural aging play an important role in the development of the tumor process. Among these shifts great importance is attributed to decreased tolerance to glucose, hyperinsulinemia, hypercholesterolemia, and hypertriglyceridemia (Dilman 1994).

Decreased glucose utilization, hyperinsulinemia, delayed rise of insulin level, and no elevation of serum IGF-I activity was observed in 14–16-month-old rats after glucose loading as compared to 3-month-old rats. At the same time, decreased sensitivity to insulin and low response of the level of free fatty acids to glucose loading were revealed in female rats of this age (Anisimov 1987).

In series of experiments, carbohydrate and lipid metabolism in rats exposed to different carcinogenic agents have been studied. A single or weekly administration of DMH during 1, 4, or 6 months did not cause changes in the blood basal glucose level. However, pronounced decrease of glucose utilization has been detected in a glucose tolerance test in 3 days after a single carcinogen injection (Anisimov 1987). Decreased tolerance to carbohydrates was revealed in rats in 1, 4, and 6 months after beginning weekly DMH administrations. A trend to elevated levels of serum cholesterol and triglycerides was traced in all experimental groups. The level of immunoreactive insulin in the serum of rats exposed to DMH during 6 months was observed to be higher than in the control group being investigated both after 18-h starvation and in 20 min after i.v. glucose loading. In rats subjected to chronic DMH administration (15 mg/kg of body weight × 15 times with weekly intervals), triglyceride level in the serum in 16 and 24 weeks of experiment was decreased by 18% and in 48 weeks when animals had developed colon tumors was increased by 33% (Windle and Bell 1982).

In the other experiment parameters of carbohydrate and lipid metabolism were studied in rats submitted to two i.v. administration of NMU in a dose of 50 mg/kg of body weight with a weekly interval (Anisimov 1987). Insulin level in the serum was significantly higher than other parameters in comparison with control 1 month past carcinogen administrations. However, in glucose tolerance tests, these rats manifested pronouncedly decreased glucose utilization and reactive hyperinsulinemia**.** The value of glycemia index was 1.4 times larger in rats exposed to carcinogen in comparison with control ones 1 h past glucose loading. Twice normal serum IGF-I activity was observed by that time in female control rats. In rats treated with NMU, the rise in somatomedin activity was not traced. Glucose tolerance tests revealed in rats submitted to NMU i.v. administrations disturbances of carbohydrate tolerance by latent diabetes mellitus typical of the old aged. Since this disturbance was found in the period prior to tumor appearance, it could be supposed to have been

conditioned by carcinogenic action and not by tumor influence on the organism (Anisimov 1987).

Considerable shifts in carbohydrate and lipid metabolism were revealed in rats exposed to DMBA or X-ray irradiation as well as in progeny of rats subjected to NMU or DES administration during pregnancy. In all the experiments, these disturbances were found in the period prior to neoplasm appearance. First of all there are disturbances in tolerance to carbohydrates, revealed in glucose tolerance tests, more or less pronounced hyperinsulinemia, and disturbances in regulation of the serum somatomedin activity. The level of serum cholesterol and triglycerides does not vary in some cases (Anisimov 1987).

Comparative evaluation of disturbances in neuroendocrine regulation occurring in the organism during aging and due to carcinogens gives an impression of earlier development and stronger pronouncement of age-related changes in radiation and carcinogenic effect without significant quality differences. Carcinogenic factors (irradiation included) are shown to cause in the organism a sharp transition to an older level and not acceleration of age-related changes (Alexandrov 1982). This transition is asynchronous and has different latent periods in various components of biological objects.

Effect of Carcinogens on Immune System

The tumor immunosurveillance hypothesis, first raised by P. Erhlich in 1909 and then refined by Burnet (1974), postulated that the immune system constantly surveys the newly developing tumors and, as long as it is effective, prevents the development of neoplastic disease. It was assumed that clinically evident tumors represent exceptions that slipped through the immunological net. At present it seems that immune defense mechanisms form the last barrier in organism natural mechanisms of protection against cancer and are probably less effective as compared with some other mechanisms operating at earlier stages of malignant tumor formation (Jakobisiak et al. 2003). The immunologic theory of aging, proposed 50 years ago by Walford (1969), suggests that the normal process of aging in man and in animals is pathogenetically related to faulty immunological processes. Since that time, research on immunological aging has undergone extraordinary expansion, leading to new information in areas spanning from molecular biology and cell signaling to large-scale clinical studies. Investigation in this area has also provided unexpected insights into HIV disease, many aspects of which represent accelerated immunological aging (Jakobisiak et al. 2003). It is worthy of note that the majority of chemical carcinogenic agents and ionizing radiation are immunosuppressors (Blankenstein and Qin 2003). It seems that metabolic immunodepression is one of the mechanisms of immunosuppressive effect of carcinogenic agents (Dilman 1994). Nikitina (1997) reported that an exposure to modulated electromagnetic fields induced by marine radio transmitters accelerated aging in seamen. Maintaining rodents at the constant illumination was followed by accelerated aging in reproductive, adaptation, and energy homeostases, development of metabolic syndrome, and other age-associated diseases, including cancer (Vinogradova et al. 2009; Vinogradova and Anisimov 2012).

Carcinogens as Promoters of Spontaneous Carcinogenesis

The data discussed above provide evidence that carcinogenic agents are able to accelerate aging. If this is the case, apart from the induction of neoplasms in target tissue(s), carcinogenic agents must increase the incidence of the tumors peculiar to a given strain of animal. Total incidence of spontaneous neoplasms (mammary fibroadenomas and fibromas, endometrial polyps, thyroid adenomas, adrenal cortex, and pituitary adenomas) in intact female outbred rats was 26%, and the mean latent period was equal to 738 days. Female rats aged 3 months were injected with NMU four or two times. As a result, apart from mammary adenocarcinomas and kidney, colon, and ovarian tumors, the benign tumors pertinent to control females not treated with the carcinogen were developed by

experimental animals in 38% and 25% of cases, respectively. The incidence of these tumors was the same as in control animals, but their mean latent period was equal to 295 days and 406 days, respectively. In other words, NMU-treated female rats developed benign tumors in endocrine glands and hormone-dependent organs much earlier than control ones (Anisimov 1981). Similar results were obtained in experiments involving a single injection of N-methyl(acetoxymethyl)-nitrosamine into 3-month-old female rats. Mean latent period of benign tumor development in the intact control and carcinogen-treated animals was 844 days and 516 days, respectively. It was shown the enhancement of spontaneous carcinogenesis in F344 rats treated with low (less than 10 ppm) dosages of NMU (Maekawa et al. 1984). Thus, there is some evidence on the promoting effect of intensified aging on carcinogenesis.

Effect of Geroprotectors on Aging and Carcinogenesis

The effects of factors or drugs that increase life span (geroprotectors) on spontaneous tumor development may provide important clues to the interactions of aging and carcinogenesis. About 20 substances were suggested as life span extension means (Anisimov 1987, 2006b; Spindler 2012; Blagosklonny 2014; Longo et al. 2015). The term *geroprotector* was introduced for such kind of substances. It seems rather fortunate because it means "defending from aging." Contrary to geriatric drugs which are prescribing to the elderly people, the treatment with geroprotectors should be used at young and adult age. Being suggested on the current knowledge on factors and mechanisms or theories of aging, these interventions in the aging process sometimes were followed some unfavorable effects.

The question of the safety of long-term use of these preparations including not only adverse effects but also the late effects, including cancer, is one of the priorities in this field. Other aspects of the problem related to observations on the age-related increase in cancer morbidity directly connected with the population aging (Anisimov 1987, 2009). That is why the evaluation of possible risk of the increase in cancer incidence should be taken into account when means of life extension will be recommended to practical use. The comparison of the data on the mechanisms of action of geroprotectors with its influence on the development of spontaneous and experimentally induced tumors permits to deepen our understanding of interactions between two fundamental biological processes – aging and carcinogenesis.

There are geroprotectors that extend the life span equally in all members of the population (these substances postpone the beginning of population aging), geroprotectors that decrease the mortality of long-living subpopulation leading to a rise in maximal life span (these substances slow down the population aging rate), and geroprotectors that increase the survival in short-living subpopulation without change of the maximal life span (in this case aging rate increases). Available data show a good correlation between the type of geroprotectors and the pattern of tumor development in the same population of animals. Geroprotectors of the first type do not influence the incidence of tumors but do prolong tumor latency. Geroprotectors of the second type are effective in inhibiting spontaneous carcinogenesis, prolonging tumor latency, and decreasing tumor incidence. Drugs of the third type can sometimes increase the incidence of cancer (Anisimov 1987, 2006).

The comparison of the data on the type of the slowing of mortality rate and the character of the antitumor effect of geroprotectors permits to suggest that the tumor incidence of a certain age is the function of the rate of aging (Anisimov, 1983, 1987, 2004). The calculations revealed a highly significant positive correlation between the rates of mortality of the rat populations studied and the rates of age-related increase of tumor incidence in these populations, while no positive correlation between mean life span and tumor incidence was found. These results led to the conclusion that the incidence of tumors and the rate of their age-related increase directly depend upon the rate of mortality of a population no matter if the animals were exposed to geroprotector or not. This dependence together with the data that

environmental factors which promote tumor growth (overfeeding, constant illumination, chemical carcinogens, ionizing radiation, etc.) may cause an acceleration of aging (Anisimov 1987, 2004, 2006b) suggests that the rate of mortality in these cases may be a function of the dose of carcinogenic agent.

In the framework of a multistage model of carcinogenesis, geroprotectors may both inhibit and enhance the passage of transformed cells through sequential carcinogenic stages. In general, the efficacy of geroprotectors in preventing cancer development decreases inversely with the age of exposure to the carcinogen. It is important to emphasize that geroprotectors of the second type delay aging by influencing the "main" regulatory systems of the organism (nervous, endocrine, immune). These effects delay the development of age-related changes in the microenvironment of cells exposed to carcinogens.

Geroprotectors may also be classified into two main groups according to their mechanism of action. The first group includes drugs that prevent stochastic lesions of macromolecules. The theoretical basis for using these drugs is provided for by variants of the "catastrophe error" theory, which regards aging as a result of the accumulation of stochastic damages. The second group includes substances that appear to delay intrinsic aging, i.e., programmed cellular aging.

Antioxidants are the most typical representatives of the first class of geroprotectors. Age of initial administration and doses of environmental carcinogens influence the geroprotective and tumor-preventing effects of antioxidants. The effectiveness of these substances increases when the initial administration occurs early in life and decreases with the dose of environmental carcinogen(s) to which the organism was exposed.

The second class of geroprotectors includes antidiabetic biguanides (phenformin and metformin), melatonin, and calorie-restricted diet. These factors influence the hormonal, metabolic, and immunological functions of the body, delaying age-related changes in these functions (Anisimov 1987, 2006, 2015). It was shown that melatonin is the most potent endogenous scavenger of free radicals in vitro and in vivo. Melatonin inhibits production of DNA adducts in carcinogen-exposed animals, protects chromosomes of human lymphocytes from radiation damages, enhances gap junctional intercellular communications in vitro, and prevents metabolic syndrome and spontaneous tumor development in rodents (Anisimov et al. 2006b).

The survival curves of human populations were noted to be more and more "rectangular." This is caused first of all by the decrease in infant and early mortality which is connected with tuberculosis and other infectious and non-infectious diseases. As a result, a significant increase in the mean life span of the human population occurred. Maximum human life span, however, has stayed the same for centuries. Thus, the changes in the shapes of the survival curves of human populations respond to the third type of aging delay according to the above-discussed classification. The changes of this type were shown experimentally and epidemiologically to be associated with an increase in tumor incidence. In other words, for the increase in mean life span achieved by the decrease in the mortality at early ages, mankind pay at later ages by an increased risk of having cancer or some other diseases of civilization like atherosclerosis or diabetes.

There are two strategies of development of the stem cell in an organism which could be realized in an organism. One strategy is the cellular differentiation and aging, and at least, in its individual death (apoptotic or necrotic). When factors of antiaging reach some limit of their compensatory possibilities to support tissue and functional homeostasis in life-important organs, the death of an organism as a whole has taken place. Another strategy of the stem cells in the circumstances of influence of exogenous or endogenous harmful factors could lead to its dedifferentiation, immortalization, and formation of a clone of neoplastic cells (Anisimov 1987, 2004, 2009). The simplified scheme presented allows to understand why drugs which prevent effects of some factors accelerating aging or, contrary, stimulate the antiaging factors, in a different way affecting homeostasis in tissues and in an organism as a whole, may promote or inhibit tumor development.

Further progress in preventive medicine is impossible without radical changes in the approaches to public health and to the prolongation of the human life span. In the burst of industrialization, urbanization, and increasing environmental pollution (including light pollution), one may hope only for a partial alleviation of the unfavorable effects on human health. The achievement of significant results in this field will require the solution of very complex scientific and technical problems as well as considerable economic expenses. It is probably true that even at present, changes in the life style, i.e., in dietary and sexual habits and in smoking and alcohol consumption, may be the most promising approach to achieving a decrease in cancer incidence and, hence, an increase in life span. It seems to become more clear that means which normalize the age-related changes in the hormonal status, metabolism, and immunity and thus slow down the realization of the genetic program of aging (not postpone aging, but slow down the rate of it) must be most effective in the protection from both premature aging and cancer. Among these means are mimetics of calorie restriction (e.g., metformin), melatonin, and some pineal peptides. The influences which protect from the initiating action of damaging agents (antioxidants and antimutagens) may be important additional means of accelerated aging prevention especially under conditions of an increased risk of exposure to environmental harmful agents.

Conclusion

Table 1 summarizes the data available in literature and obtained in experiments on some hormonal metabolic shifts in the organism and disturbances at tissue and cellular levels observed during natural aging and during carcinogenesis in vivo. It can be seen that there is a similarity between the shifts in aging and carcinogenesis. Carcinogens could be supposed to initiate a normal cell, interacting with its elements on the molecular level, on the one hand, and to produce diverse changes in the organism facilitating promotion and progression of tumor growth, on the other hand.

Table 1 Patterns of changes observed in an organism during natural aging and carcinogenesis at molecular, cellular/tissue, systemic/organism, and population levels of integration

Parameters	Aging	Carcinogenesis
Molecular level		
Free radical generation	Increases	Increases
DNA adduct formation	Increases	Increases
DNA repair efficacy	Decreases	Decreases
DNA hypomethylation	Increases	Increases
Genomic instability	Increases	Increases
Telomere length	Decreases	Increases[a]
Error protein synthesis	Increases	Increases
Mutation rate	Increases	Increases
Oncogene expression	Increases	Increases
p53 mutations	Increases	Increases
mTOR activity	Increases	Increases
Cell/tissue level		
Oxidative stress	Increases	Increases
Chromosome aberrations	Increases	Increases
Growth factor production	Deceases	Increases[a]
Proliferative activity	Decreases	Clonal proliferation[a]
Focal hyperplasia	Increases	Increases
Apoptosis	Increases	Decreases[a]
Autophagy	Increases	Decreases[a]
Angiogenesis	Decreases	Increases[a]
Bioenergetics	Decreases	Anaerobic glycolysis[a]
Cell-to-cell communication	Decreases	Decreases
Number of senescent cells	Increases	Increases
Latent (dormant) cell number	Increases	Increases
Systemic/organism level		
Melatonin circadian rhythm	Disrupted	Disrupted
Serum melatonin level	Decreases	Decreases
Hypothalamic biogenic amine level	Decreases	Decreases
Hypothalamic threshold of sensitivity to homeostatic inhibition by steroids	Increases	Increases

(*continued*)

Table 1 (continued)

Parameters	Aging	Carcinogenesis
Tolerance to glucose	Decreases	Decreases
Serum insulin level	Increases	Increases
Susceptibility to insulin	Decreases	Decreases
Insulin-like growth factor-1 (IGF-1) level	Decreases	Increases[a]
Low-density lipoproteins and cholesterol level	Increases	Increases
Serum glucocorticoid level	Increases	Increases
Fertility	Decreases	Decreases
T-cell immunity	Decreases	Decreases
Inflammoaging	Increases	Increases
Cancer risk	Increases	Increases
Population level		
Cancer incidence	Exponential pattern	Exponential pattern
Progeria	Acceleration	Increases
Exposure to 5-bromodeoxyuridine	Acceleration	Increases
Exposure to ionizing radiation	Acceleration	Increases
Exposure to constant illumination	Acceleration	Increases
Treatment with geroprotectors	Postponement	Prevents
Rate at the oldest age	Decreases in mortality	Decrease in incidence

[a]Related to clonally proliferating malignant cells

The incidence of cancer increases with age in humans and in laboratory animals alike, but the patterns of the age-related distribution of tumors are different for different tissues and different tumors. Aging may increase or decrease the susceptibility of different tissues to tumor initiation and usually facilitates promotion and progression of carcinogenesis. Aging may predispose to cancer by two mechanisms: tissue accumulation of cells in the late stages of carcinogenesis and alterations in internal homeostasis, in particular alterations in the immune and endocrine systems. Increased susceptibility to the effects of tumor promoters is found both in aged animals and aged humans, as predicted by the multistage model of carcinogenesis. Old animals should be included in standard protocols for the long-term assay for carcinogenicity, in particular, of compounds with suggested tumor-promoting activity. Strategies for cancer prevention must include not only measures to minimize exposure to exogenous carcinogenic agents but also measures to normalize age-related alterations in the internal milieu.

Abstract

Caloric restriction prolongs lifespan and healthspan in all model systems tested so far, including yeasts, worms, flies, mice, rats, and monkeys (Rhesus macaques). Caloric restriction also improves healthspan, including reducing cancer development in mice and Rhesus macaques. Nonetheless, chronic caloric restriction to prolong life or healthspan, including cancer prevention, is unlikely to be popular or widely adopted for human clinical use. As caloric restriction inhibits mTOR, the pharmacologic mTOR inhibitor, rapamycin, was tested in lifespan extension and clearly prolonged lifespan and healthspan in mice even when started late in life. Although the types and prevalence of cancer in control and rapamycin-fed mice were similar, cancer-related deaths were delayed in mice fed rapamycin, demonstrating potential cancer prevention. Rapamycin and related pharmacologic mTOR inhibitors, collective dubbed "rapalogues," are considered too dangerous for chronic human use for longevity extension or cancer prevention. Nonetheless, these data raise the interesting possibility that a pharmacologic intervention to suppress mTOR, or more specifically mTORC1, could prolong lifespan or healthspan in humans, including through cancer prevention, provided that a safe and effective agent for these purposes were identified. Many questions remain, including the specific mTOR-related pathway most appropriate for targeting, doses and schedules of specific agents for such purposes, and understanding specific mechanisms of action. The question arises as to whether rapalogues prolong life or delay aspects of aging by preventing cancer. This chapter will examine evidence to date and provide suggestions for major areas of needed research and possibilities for clinical trials and applications.

Keywords

Cancer prevention · Rapamycin · mTOR · DNA repair · Longevity

Introduction

Cancer treatments are generally less effective for advanced stage and metastatic cancers, and despite recent successes with cancer immunotherapy agents (Topalian et al. 2016), most advanced and metastatic cancers remain incurable. Thus, primary cancer prevention is an important cost-effective alternative to treatment and likely to be better tolerated compared with traditional treatment regimens in cancer-prone, aged hosts. Further, efficacious cancer prevention strategies will reduce the prodigious health impact of cancer based on the foregoing data and therefore could reasonably be expected to prolong human lifespan. Recent advances in understanding the contributions of mammalian target of rapamycin (mTOR) signaling pathway in longevity extension and cancer prevention have demonstrated the potential for concomitant lifespan extension and reduction in age-related debilities, defined as the healthspan. This chapter will provide evidence for mTOR suppression as a bona fide, feasible cancer prevention approach, which could also afford improved healthspan and longer lifespan. Improved healthspan could potentially help mitigate the cost impact of lifespan extension. However, because of the legitimate concerns for

potential adverse effects of mTOR inhibition in large, relatively healthy populations (Lamming et al. 2013), many aspects of this approach require careful and detailed consideration. Despite challenges, the potential to target mTOR signaling or related pathways as a cancer prevention strategy appears tractable and worthy of additional investigations.

Aging Is the Principal Risk Factor for Cancer

In some countries in Europe, 21% of the population is older than 60 years. This 60+ year old population is predicted to account for ~34% of the population by 2050 (United Nations 2011). Cancer is largely a disease of the elderly, and the primary risk for cancer is advancing age (Siegel et al. 2017; Hiller et al. 2017). Therefore, healthcare, long-term care, and welfare systems sustainability in many developed and developing nations hinge on outcomes of attempts to develop safe interventions to slow aging, compress overall morbidity/disability and increase healthspan in humans, as approximately 2 billion people on the planet are anticipated to be age 65 years old or older by 2050. It is currently estimated that worldwide cancer incidence will nearly double from 14.1 million cases per year in 2012 to 22.2 million cases per year by 2030, a projection based in large measure upon the growing elderly demographic (Bray et al. 2012). Approximately 60% of new cancer diagnoses occur in people 65 years or older with a staggering 70% of total cancer-related deaths occurring in this group (Berger et al. 2006). The total economic impact of cancer is hundreds of billions of dollars annually in the United States alone (Society 2012). Cancer is the second leading cause of death in the United States, just barely behind heart disease (https://www.cdc.gov/nchs/fastats/leading-causes-of-death.htm) and a leading cause of death worldwide in 2012, the date of most recent comprehensive statistics (http://onlinelibrary.wiley.com/doi/10.3322/caac.21262/full). Please also see ▶ Chap. 1, "Population Trends in Aging and Cancer."

Caloric Restriction Prolongs Life and Healthspan

It has been known since the 1930s that reducing caloric intake without engendering malnutrition can prolong life (Hursting et al. 2003; Mccay et al. 1989). The phenomenon of longevity extension from caloric restriction has been validated in yeasts, worms, flies, rodents, and Rhesus macaques as described in detail in ▶ Chap. 7, "Aging and Cancer Biology". Mechanistically, caloric restriction of 30–40% without malnutrition impairs accelerants of aging, including decreased metabolism, circulating serum hormones, growth factor levels, and the central energy-regulatory adenosine monophosphate-activated protein kinase/mTOR pathway. Recent analysis of the 2-year CALERIE (Comprehensive Assessment of Long-term Effects of Reducing Intake of Energy) trial conducted by the National Institute of Aging in young, nonobese adults demonstrated that chronic caloric restriction (11.7% on average) slowed biological measures of aging (Belsky et al. 2017). This trial employed multiple algorithms using pre-, middle-, and posttrial biomarkers including serum albumin, alkaline phosphatase, and C-reactive protein, among others, to compare chronological versus biological age. Of note, the authors found that the extent of caloric restriction was positively correlated to the slowed rate of biological age, both in participants experiencing $<10\%$ caloric restriction and in those experiencing $\geq 10\%$ caloric restriction versus the ad libitum dietary arm. Please see ▶ Chaps. 20, "Pharmacology of Aging and Cancer" and ▶ 23, "Biomarkers of Aging (With a Clinical Potential in Oncology)" for more details. Aside from providing longevity extension, there are many health benefits from moderate caloric restriction, such as increased physical capabilities and reduced chronic or age-related diseases and including reduced cancer incidence (Kenyon 2010; Brandhorst and Longo 2016; Colman et al. 2014; Hursting et al. 2003) (see ▶ Chap. 7, "Aging and Cancer Biology").

Caloric Restriction Prevents Cancer

A consistent and notable observation is that chronic caloric restriction specifically reduces cancer incidence across model systems, suggesting a conserved cancer prevention mechanism (Brandhorst and Longo 2016; Colman et al. 2014; Fontana et al. 2010; Hursting et al. 2003). The overall cancer-preventive effects of caloric restriction likely owe to the multitude of cellular changes that include metabolic adaptions in insulin-like growth factor-1, cortisol, Sirtuin1, and inflammatory signaling, as well as molecular alterations in phosphoinositol-3 kinase/Akt/mTOR, mitogen-activated proteiern kinase, and adenosine monophosphate-activated protein kinase signaling (Longo and Fontana 2010). One mechanism by which caloric restriction is thought to prevent tumorigenesis is through the reduction in insulin and insulin-like growth factor 1 signaling, which converges downstream at the metabolic regulatory sensor mTOR complex 1, or mTORC1 through insulin receptor substrate 1-mediated phosphoinositol-3 kinase/Akt activation. Decreased mTORC1 activity limits protein, DNA, and lipid synthesis, slows cellular proliferation, and stimulates the canonical autophagy pathway. Thus, caloric restriction could directly limit cellular transformation by reducing the increased cellular metabolic activity required for cancer progression. Other mechanisms involved in aging include the impact of oxidative stress which results from the aforementioned deregulated pathways and is described in more detail in ▶ Chap. 13, "Mitochondria, Oxidative Stress, Cancer, and Aging."

Notably, two independent studies conducted by the University of Wisconsin National Primate Research Center and the National Institute of Aging discerned different healthspan and lifespan outcomes from caloric restriction in the non-human primate model of Rhesus macaques. The 23-year National Institute of Aging study initially reported that caloric restriction did not improve survival in primates, By contrast, the University of Wisconsin study demonstrated that caloric restriction significantly improved both lifespan and healthspan in Rhesus macaques (Colman et al. 2009). A subsequent analysis comparing the two studies showed that although monkeys in the studies at the National Institute of Aging and University of Wisconsin were initiated on a 30% caloric restriction diet, there was a significant decline in food intake as the animals aged (Mattison et al. 2012). A conserved finding now appreciated is that a 30% caloric restriction diet in adult primates reduces age-related and all-cause mortality (Colman et al. 2014; Mattison et al. 2012). In the University of Wisconsin study, calorically restricted monkeys experienced a 50% reduced cancer incidence along with significantly decreased cardiovascular disease, brain atrophy, and glucose regulatory impairment. Further, the mortality rate due to age-related disease was 13% in the caloric restriction cohort versus 37% in the control group, suggesting that caloric restriction improves healthspan by preventing many age-associated pathologies. The biology underlying the prevention of such pathologies can be found in greater detail in ▶ Chaps. 15, "Respiratory Organ Aging and Cancer," ▶ 16, "Digestive Organ Aging and Cancer," and ▶ 17, "Musculoskeletal Aging, Sarcopenia, and Cancer."

Partial fasting is a less severe form of caloric restriction yet nonetheless protects against toxicities of chemotherapy, reduces cancer progression, and improves immune functions (Cheng et al. 2014; Parrella et al. 2013; Fontana et al. 2010; Levine et al. 2014). However, the overall health including immune state and diet of the elderly patient must be carefully considered before, during, and after cancer therapy regimens as these patients could be at increased risk for cachexia. See also ▶ Chaps. 26, "Frailty in Cancer Patients," ▶ 56, "Digestive Symptoms Control and Nutrition Issues in Older Cancer Patients," and ▶ 60, "Decision Making and Safety Issues in Older Cancer Patients." Fasting-mimicking diets vary in caloric composition and duration but can involve periods of fasting from 2 to 21 days and longer in some cases. The positive impact of partial fasting on human health parallels that of caloric restriction and includes reductions in cardiovascular disease, weight, neurodegenerative disorders, and cancer

incidence (Mattson et al. 2016). In particular, fasting cycles that restrict protein have shown much success in limiting aging-associated diseases such as Alzheimer's disease and multiple types of cancer, attributed in many studies to reductions in the insulin-like growth factor-1 signaling pathway that inhibits Ras/MAPK and phosphosinositol-3 kinase/Akt, and ultimately mTORC1. Fontana et al. demonstrated that diets ranging from 7% to 21% protein-restricted effectively inhibited castration-resistant prostate cancer and breast cancer growth in multiple mouse models through decreased serum insulin-like growth factor-1 and mTORC1 activity (Fontana et al. 2013). See also ▶ Chap. 20, "Pharmacology of Aging and Cancer."

Interestingly, a fasting-mimicking diet of 5 days per month for 3 months elicited profound improvements in healthy human participants, as the fasting-mimicking diet reduced body mass index, blood pressure, and serum insulin-like growth factor-1 and cholesterol among other biomarkers for aging and cancer (Wei et al. 2017). The fasting-mimicking diet alone or in combination with the chemotherapy drug doxorubicin delayed syngeneic 4T1 breast cancer and B16 melanoma progression in vivo in mouse models (Di Biase et al. 2016). This antitumor effect depends on stress-responsive heme oxygenase-1, which was decreased in fasting-mimicking diet cohorts compared with control diet-fed mice, resulting in increased lymphoid progenitor cells and $CD8^+$ T cells. Moreover, the fasting-mimicking diet, alone or in combination with chemotherapy, sensitized breast and melanoma tumors to increased cytotoxicity by $CD8^+$ T-cells.

Nonetheless, caloric restriction is not universally preventive, as cancers less responsive to this approach have been defined. For example, in a murine model of lung cancer, tumors with an activating *PIK3CA* mutation (and thus constitutive phosphoinositide-3 kinase signaling) were resistant to preventive effects of caloric restriction (Kalaany and Sabatini 2009). In this same study, similar lack of efficacy of caloric restriction was seen in a *PTEN*-null murine model of prostate cancer, where there was no reduction in the incidence of prostate intraepithelial neoplasia lesions in calorically restricted versus ad libitum-fed mice. Thus, activating phosphoinositide-3 kinase pathway mutations such as *PIK3CA* or loss of tumor-suppressive *PTEN* might not be prevented by caloric restriction. The type and intensity of caloric restriction also directly influence the amount of cancer prevention engendered in mouse models (Lee and Longo 2011). Thus, it could be possible to develop dietary regimens that effectively reduce cancer risk and which could be acceptable to large human populations. In contrast to caloric restriction, in vitro and in vivo studies demonstrate that presence of phosphoinositol-3 kinase pathway activating mutations (*PIK3CA*, *PTEN*) actually confers sensitivity to rapamycin and rapalogue everolimus except when *KRAS* mutations are present (Di Nicolantonio et al. 2010).

mTOR Promotes Signals Through Distinct mTORC1 and mTORC2 Complexes

The mTOR pathway has been linked to longevity extension in every organism model studied (Johnson et al. 2013), and health and longevity benefits of caloric restriction derive at least in part from mTOR suppression (Miller et al. 2014). mTOR signals integrate diverse and numerous internal and environmental cues (e.g., growth factors, nutrients, stress, energy) to regulate fundamental cellular processes (e.g., biosynthesis of macromolecules including lipids and proteins, autophagy, the cell cycle, and cell differentiation fates) (Laplante and Sabatini 2012). mTOR is the central catalytic protein present in two distinct complexes, mTORC1 and mTORC2, into which additional complex-specific proteins are integrated for full activation and downstream signaling specific to each complex (Laplante and Sabatini 2012). mTORC1 signaling is the pathway generally considered to extend longevity (Johnson et al. 2013) but likely also cooperates with other pathways and factors. For example, insulin and insulin-like growth factor signals, also related to longevity, can modulate mTORC2 which directly activates Akt by phosphorylation

of serine 473 and ultimately activates mTORC1. Further, Raptor knockout to ablate TORC1 signals extends *C. elegans* lifespan, while RNAi-mediated downregulation of the Rictor homolog *rict-1*, which inhibits TORC2 signals, will either increase or decrease *C. elegans* lifespan depending on the diet composition (Vellai et al. 2003; Soukas et al. 2009).

Rapamycin Extends Life in Mice

As caloric restriction inhibits mTORC1, in 2005, David Sharp at the University of Texas Health Science Center at San Antonio proposed to the Interventions Testing Program of the National Institute of Aging that the pharmacologic mTORC1 inhibitor rapamycin might also extend lifespan by replicating essential signals of caloric restriction without the actual dietary modulation. Rapamycin was selected as the proof-of-concept mTORC1 inhibitor because of its high mTORC1 specificity that has been validated in an extensive body of published literature, including in human clinical trials (Kennedy and Pennypacker 2014; Lamming et al. 2013), despite some known adverse effects (Soefje et al. 2011). See also ▶ Chap. 20, "Pharmacology of Aging and Cancer."

Pharmacologic mTOR inhibitors are characterized by distinct mechanisms of action, which include small-molecule inhibitors and second-generation mTOR kinase/dual mTORC inhibitors. Rapamycin and rapalogues are small molecule mTOR inhibitors that complex with the FK506-binding 12 kDa protein (FKBP12) through methoxy group crosslinking (Marz et al. 2013; Brown et al. 1994; Sabatini et al. 1994). The rapamycin-FKBP12 complex subsequently binds to the FKBP-rapamycin-binding domain on mTOR, itself already complexed with Raptor and mLST8, to block substrate access to the mTOR kinase active site cleft, rather than directly inhibiting the mTOR active site (Yuan and Guan 2016).

Thus, although rapamycin-bound FKBP12 disrupts mTORC1 kinase activity to inhibit mTORC1 (Zoncu et al. 2010), long-term rapamycin can inhibit mTORC2 signals depending on specific cells and conditions in vitro and in vivo (Sarbassov et al. 2006). Recent studies attempting to decipher the molecular and structural basis of rapamycin's differential inhibitory potential on mTORC2 have found that differences in signaling effects are related in part to the duration of treatment. Specifically, both short-term and long-term rapamycin treatments potentiate dephosphorylation of cytoplasmic complex 2 components Rictor and Sin1 but only long-term rapamycin exposure impairs assembly of the mTORC2 complex (Rosner and Hengstschlager 2008).

Aging biologist Randy Strong at the University of Texas Health Science Center at San Antonio suggested improving rapamycin delivery in mouse chow by encapsulating rapamycin in edible polymers for ease of chronic oral administration and enhanced bioavailability. This microencapsulated rapamycin formulation was developed as eRapa in mouse chow and used to deliver ~2.42 mg/kg/mouse/day of rapamycin for initial longevity studies (Harrison et al. 2009; Dao et al. 2015). The proprietary eRapa formulation has been used to deliver low, intermediate, and high doses of rapamycin for dose-response studies and have been shown to have improved tolerability in mice over unencapsulated rapamycin (Harrison et al. 2009; Miller et al. 2014). Chronic eRapa administration prolongs lifespan up to 30% in mice even when given late in life and improves healthspan with a dose dependence and propensity to extend female over male lifespan (Harrison et al. 2009; Miller et al. 2014). At present, rapamycin and related pharmacologic mTORC1 inhibitors, collectively dubbed "rapalogues," are considered too dangerous to be given widely to general human populations for health or longevity extension (Lamming et al. 2013). Nonetheless, these data raise the interesting possibility that a pharmacologic intervention to suppress mTOR, or more specifically mTORC1 signals, could be used in humans, provided that a safe and effective agent for this purpose were identified, and/or that specific at-risk populations could be identified to justify the risk of adverse effects. Please also see ▶ Chaps. 7, "Aging and Cancer Biology" and ▶ 21, "Drug Interactions in Aging and Cancer."

Pharmacologic mTOR Inhibition and Cancer Prevention

Recent data demonstrating that caloric restriction reduces cancer incidence through mTORC1 suppression has led to considerable interest in evaluating pharmacologic mTOR inhibitors for cancer prevention. In addition to known longevity extension effects of rapamycin, there is a compelling rationale to use pharmacologic mTOR inhibitors as anticancer agents as many cancers have oncogene-driven phosphoinositol-3 kinase/Akt/mTOR activation. However, the clinical efficacy of rapalogues as monotherapy for cancer treatment is modest in all cancers evaluated, due to their cytostatic rather than cytotoxic effects (Zoncu et al. 2011) among other considerations, which could result from multiple mechanisms of phosphoinositol-3 kinase pathway reactivation including phosphoinositide dependent kinase 1-mediated phosphorylation of Akt tyrosine 308 (Zou et al. 2016). Some of these limitations and off-target effects have been addressed by evaluating efficacy of combinatorial strategies of rapalogues plus chemotherapies and autophagy inhibitors, in addition to the development of second-generation dual mTORC inhibitors that inhibit both mTORC1 and mTORC2 and that have moved into human cancer treatment trials (Gupta et al. 2012).

As mTORC1 promotes protein translation and tumor cell growth through translational machinery proteins including 4EBP1 and S6K, inhibiting mTORC1 blunts tumor growth through metabolic and protein synthesis impairment (Laplante and Sabatini 2012). These actions therefore suggest consideration for mTORC1 inhibitors as plausible cancer prevention drugs.

In the seminal 2009 multisite study by Harrison et al., rapamycin delivered in eRapa markedly extended median and maximal lifespan in genetically diverse UM-het 3 mice, an effect attributed by authors to limiting the incidence or lethality of age-associated neoplasms (Miller et al. 2011). A median of 10% and 18% were increased in male and female lifespan, respectively. Cancers are the leading cause of death in UM-het 3 mice, accounting for 66–70% of all deaths, with lymphoma, hemangiosarcoma, and lung carcinoma the most common, and approximately equally represented in eRapa-fed and control-fed mice (Miller et al. 2011). However, in some cancers, such as liver, lung, and mammary carcinomas, time of death was delayed in eRapa fed versus control mice (841 versus 1006 days, 755 versus 1004 days, and 826 versus 1142 days, respectively) suggesting that eRapa could either delay cancer onset, reduce growth of cancers, or make the cancer more tolerable as potential longevity mechanisms. See also ▶ Chaps. 54, "Principles of Cancer Targeted Therapy in Older Adults" and ▶ 64, "Research Methods: Translational Research in Geriatric Oncology."

It has now been convincingly demonstrated that eRapa inhibits tumor development in distinct mouse models of spontaneous cancer in the setting of specific predisposing genetic defects. In $Apc^{Min/+}$ mice, their defect in Wnt/β-catenin promotes colon tumorigenesis. eRapa delivering 2.42 mg/kg rapamycin daily potently suppressed intestinal neoplasia in this model and extended the survival of these mice from a median of 174 days to that of normal BL6 mice at 974 days (Hasty et al. 2014). In another study, eRapa potently suppressed neuroendocrine tumors in $Rb1^{+/-}$ mice with heterozygous loss of the Rb tumor suppressor gene. $Rb1^{+/-}$ mice were fed eRapa delivering rapamycin at 2.42 mg/kg/mouse/day starting at 9 weeks of age had significant lifespan extension from 377 days to 411 days in females and 369–420 days in males as compared with the control-diet cohort. eRapa-fed mice had a significantly decreased incidence of thyroid tumors common in the $Rb1^{+/-}$ mice that could have improved their survival (Livi et al. 2013). See also ▶ Chap. 43, "Colorectal Cancer in Older Adults: Systemic Treatments."

In $p53^{+/-}$ male mice with heterozygous loss of the p53 tumor suppressor gene, 1.5 mg/kg/day rapamycin in drinking water reduced spontaneous cancer incidence and effectively extended mean lifespan by 10% (Komarova et al. 2012). By contrast, in a different study of $p53^{-/-}$ mice null for p53, eRapa delivering rapamycin at 2.42 mg/kg/mouse/day afforded no cancer prevention or survival extension (Christy et al.

2015), suggesting that rapamycin requires functional p53 for some of its cancer prevention activities. However, these two studies also differed in the specific mice tested and the type and dose of rapamycin used.

Rapamycin has been evaluated for efficacy in two murine models of Human papilloma virus E6/E7 gene-expressing anal cancer. Rapamycin 5 mg/kg/day in slow release pellets for 17 weeks effectively slowed tumor growth 2.5 fold in K14E6/7 mice (Stelzer et al. 2011). In another model of human papilloma virus E6/E7-driven squamous cell skin carcinoma, rapamycin treatment before topical skin application of the carcinogen dimethylbenz(a) anthracene resulted in robust decrease in squamous cell carcinoma development (Callejas-Valera et al. 2016). In a study of female A/J mice, lung adenocarcinoma was induced with the nicotine-associated carcinogen nitrosamine ketone (Patlolla et al. 2015). Early intervention (3 weeks postnitrosamine ketone) or late intervention (20 weeks postnitrosamine ketone) with diets containing 0, 8, or 16 parts per million rapamycin reduced lung adenocarcinoma development and also reduced adenomas that could progress to cancers. In early intervention, rapamycin prevented 26% (low dose) and 42% (high dose) of nitrosamine ketone-induced lung tumor formation. In late intervention, rapamycin prevented 31% (low dose) and 44% (high dose) of nitrosamine ketone-induced lung tumor formation. The authors observed a robust inhibition of p-mTOR, p-S6 K, PCNA, and other proteins. See also ▶ Chaps. 49, "Lung Cancer in Older Adults: Systemic Treatment" and ▶ 21, "Drug Interactions in Aging and Cancer."

Since many cancers arise in chronic inflammation (Demaria et al. 2010), rapamycin was tested as a cancer prevention agent in a model of carcinogen (dimethylbenz(a) anthracene) plus inflammation (12-O-tetradecanoylphorbol-13-acetate)-induced squamous cell skin cancer. BL6 mice were fed eRapa delivering rapamycin at 2.42 mg/kg/mouse/day or Eudragit control for 1 month. DNA damage was then initiated with 100 μg dimethylbenz(a) anthracene and tumors were promoted with 12-O-tetradecanoylphorbol-13-acetate, 25 μg/week for 24 weeks. In this model, initially benign skin papillomas eventually undergo malignant degeneration into squamous cell carcinomas after about 4 months. eRapa significantly reduced the development of benign papillomas and fully protected against their malignant degeneration. eRapa did not affect $CD45^{-}CD34^{+}CD49f^{mid}$ cancer initiating stem cells or affect major, known immune mediators of malignancy in this model, suggesting alternative cancer protective mechanisms (Dao et al. 2015).

Anecdotal evidence suggests that rapalogues could be safe and tolerable for effective cancer prevention in a high-risk population. For example, in human transplant recipients, mTOR inhibitor use correlated with reduced postkidney transplantation cancer rates (De Fijter 2017). However, these data derive from observational studies without defined mechanisms. These interesting observations merit additional follow up. See also ▶ Chap. 37, "The Evolving Role of Transplant for Older Adults."

Rapamycin and rapalogues are thought to blunt tumor growth by inhibiting mTOR signals, particularly mTORC1 directly in the cancer cells (Riaz et al. 2012). Nonetheless, in dimethylbenz (a) anthracene/12-O-tetradecanoylphorbol-13-acetate dermal carcinogenesis, eRapa did not affect p-mTOR serine 2448 in skin despite its potent capacity to inhibit benign skin neoplasia and malignant degeneration. There was evidence that eRapa inhibited mTORC1 signals as detected by Western blots for p-4E-BP1 and p-rpS6 in tumors and skin of dimethylbenz(a) anthracene/12-O-tetradecanoylphorbol-13-acetate-treated mice. Further, eRapa appeared to inhibit mTORC2 as detected by reduced p-Akt serine 473 (Dao et al. 2015). mTORC1 could be suppressed specifically in the skin cancer-initiating cell that drives carcinogenesis in this dimethylbenz(a) anthracene/12-O-tetradecanoylphorbol-13-acetate model (Affara et al. 2006), but this explanation is not supported by the finding that mTORC1 was not suppressed in

the benign papillomas and the numbers and proliferation of cancer initiating cells were not affected by eRapa (Dao et al. 2015). A different group of investigators used four applications of topical rapamycin prior to 12-O-tetradecanoylphorbol-13-acetate in dimethylbenz(a) anthracene/12-O-tetradecanoylphorbol-13-acetate carcinogenesis and found reduced p-mTOR and p-rpS6 (evidence for reduced mTORC1), and increased p-Akt serine 473 (evidence for increased mTORC2) in skin (Checkley et al. 2011), which could be due to effects of short-term rapamycin in this work versus chronic rapamycin in the prior study, or differences in oral versus topical rapamycin effects or rapamycin versus eRapa effects, among other considerations. The authors ascribed mTORC1 suppression as the mechanism of cancer prevention in this work.

In the $Apc^{Min/+}$ intestinal neoplasia model (Hasty et al. 2014), the rapamycin concentration in intestine after eRapa was ~7000-fold higher than skin rapamycin concentrations after the same eRapa dose in dermal dimethylbenz (a) anthracene/12-O-tetradecanoylphorbol-13-acetate carcinogenesis (Dao et al. 2015). Low skin rapamycin concentrations suggest that either these low levels suffice to suppress skin tumorigenesis, or that higher rapamycin concentrations in some other anatomic compartments affect immunity or other factors that control dermal carcinogenesis. Thus, more work on tissue delivery of mTOR inhibitors are needed, particularly to define the lower limits of drug that are still effective in cancer prevention, as such knowledge could help develop protocols using rapalogues with minimal adverse effect potential. See also ▶ Chap. 60, "Decision Making and Safety Issues in Older Cancer Patients."

mTOR Mediates Significant Immune Effects

mTOR has many notable immune effects such as controlling differentiation and function of conventional αβ T cells (Delgoffe et al. 2011; Powell et al. 2012) and regulatory T cells (Delgoffe et al. 2009), and rapalogues are generally considered immunosuppressive through reducing T cell interleukin-2 production that then blunts T cell activation. Nonetheless, recent reports show that rapalogues can improve -antigen-specific B cell (Keating et al. 2013) and T cell (Araki et al. 2009) immunity in virus infections in mice and improve vaccine responses in elderly humans (Mannick et al. 2014). See also ▶ Chap. 6, "Immunosenescence and Cancer Immunotherapy at Old Age: Basics."

eRapa was given to young (6 months old) or aged (19–22 months old) BL6 mice for 6 months without other interventions to assess immune effects of chronic mTOR suppression (Hurez et al. 2015). Many notable immune effects were seen in mice fed eRapa, but effects in young and aged mice, and between males and females were surprisingly similar for most immune outcomes studied. There was no major eRapa effect on regulatory T cell numbers or function in spleen, although regulatory T cell numbers were increased in Peyer's patches. There were few changes in myeloid cell and B cell numbers or composition. T cell numbers and Th1 immunity, which produces interferon-γ and is associated with anticancer immunity were reduced by eRapa. Some changes were also noted in Th2, Th9, Th17, Th22, Treg, and T-follicular helper T cell differentiation pathways. Notably, Th17 $CD4^+$ T cells producing IL-17, generally considered to be proinflammatory, were increased by eRapa. T cell PD-1 is a marker of poorly functional, exhausted T cells. eRapa reduced PD-1 expression in $CD4^+$ and $CD8^+$ T cells, and functional tests showed the $PD\text{-}1^+$ T cells from eRapa-fed mice were more functional than their counterparts from control-fed mice. eRapa also reduced expression of the Lag3 exhaustion marker in both $CD4^+$ and $CD8^+$ T cells. These changes are generally consistent with improved cancer immune surveillance and with the concept that rapamycin could prevent cancer through immunomodulation.

Immune Effects of Rapamycin in Cancer Prevention

Based on potential for rapamycin to boost cancer immune surveillance that prevents cancer, studies of potential immune effects of rapamycin in cancer were investigated. In the dimethylbenz (a) anthracene/12-O-tetradecanoylphorbol-13-acetate dermal carcinogenesis model, eRapa increased γδ T cell numbers and functions but not conventional αβ T cell numbers or functions in skin of BL6 mice. Despite almost 100% protection from cancer by eRapa in wild-type mice, δ TCR knockout mice specifically lacking only γδ T cells were entirely unprotected from dimethylbenz(a) anthracene/12-O-tetradecanoylphorbol-13-acetate dermal carcinogenesis by eRapa, demonstrating an important role for γδ T cells in eRapa protection against dermal carcinogenesis, at least in this model. Moreover, intratumoral injection of γδ T cells recovered from eRapa-treated but not control treated mice resulted in regression of established dimethylbenz (a) anthracene/12-O-tetradecanoylphorbol-13-acetate cancers. eRapa-mediated γδ T cell perforin was shown to be required to mediate tumor regressions. Cancer protection also required interferon-γ that induced the chemokine CXCL10 to recruit $CXCR3^+$ γδ T cells into the tumor. Thus, eRapa-mediated cancer protection depends on specific immune factors including γδ T cells, their perforin and host IFN-γ to recruit γδ T cells to skin (Dao et al. 2016). Such data suggest that underlying host immunity or rapamycin-induced immune effects can contribute to rapamycin cancer prevention, which could affect populations considered for potential trials, or suggest novel means to improve cancer prevention effects through other immune boosting agents. These investigators further showed that eRapa affected distinct γδ T cell subsets in mice. Human γδ T cell subsets differ from those in mice, so direct comparisons to humans cannot be made, but like mice, γδ T cells in humans are also tissue-specific, suggesting that rapamycin immune effects could differ in distinct organs or in distinct cancer types. Further, this study only examined young mice, and thus age effects on cancer prevention were not tested. As immune functions change with age (Mirsoian et al. 2014; Hurez et al. 2012; Hurez et al. 2015) (and see rapamycin has been shown to improve immune functions in age (Hurez et al. 2015), this concept bears further investigations.

Low-dose rapamycin also improved a cancer vaccine in a mouse cancer model (Pedicord et al. 2015) and improved T cell activation and immunotherapy in a mouse model of lymphoma and melanoma (Liu et al. 2017). Thus, rapamycin at low doses has significant antitumor effects through immune modulation, which could be useful in cancer prevention. However, rapamycin or caloric restriction could face limitations as effective immune interventions for the elderly if used at too high a dose (rapamycin) or intensity (caloric restriction) (Goldberg et al. 2015). The impact of either antiaging intervention was evaluated in BL6 mice for 60 days, following infectious challenge with West Nile Virus. Interestingly, rapamycin and caloric restriction have differential effects on thymic cellularity. Calorically restricted mice had a higher proportion of naive peripheral $CD8^+$ T cells but that did not translate into improved immune response to West Nile virus infection and could reduce survival in infection. Older mice on caloric restriction were more prone to West Nile virus infection and had reduced T cell function and thus an increased mortality rate compared with age-matched controls. Distinct mechanisms for caloric restriction versus mTOR inhibition to impair adaptive immunity in aged mice were found in this work.

Age-related adiposity promotes detrimental inflammation generally, and specifically in anticancer immunotherapy including through tumor necrosis factor-α-related pathways. Caloric restriction in aged mice reduced adiposity and tumor necrosis factor-α-driven inflammation during cancer immunotherapy that decreased immune treatment toxicity or anti-CD40 antibody plus interleukin-2 (Mirsoian et al. 2014). These data suggest that antitumor necrosis factor-α strategies could be used to mitigate potential toxicities of immunotherapies in aged humans or mitigate mTOR-driven cancer immune surveillance to prevent cancer. Limitations of this nicely done study are that while immunotherapy effects were

studied, more commonly used immunotherapy approaches (antibodies against PD-1, PD-L1, and CTLA-4) were not studied, nor were tumor-bearing mice studied. See also ▶ Chaps. 6, "Immunosenescence and Cancer Immunotherapy at Old Age: Basics" and ▶ 29, "Predictive Tools for Older Cancer Patient Management."

T cells and interferon-γ are major mediators of cancer immune surveillance (Mittal et al. 2014). Strikingly, RAG knockout mice lacking T or B cells and interferon-γ knockout mice derived very significant improvement in lifespan and healthspan when eRapa delivering rapamycin at 2.42 mg/kg/mouse/day was given from 2 months of age (Hurez et al. 2015), demonstrating that eRapa can improve lifespan in the absence of major cancer defense mechanisms and can improve health span even in the absence of major inflammation mediators.

Cancer Prevention Effects of Other mTOR Inhibitors

In addition to the demonstrated cancer prevention properties of mTOR inhibition through caloric restriction or rapalogues, metformin and aspirin also have noteworthy cancer prevention properties that might include mTOR inhibition as a mechanism. The widely used antidiabetic agent metformin inhibits hepatic glucose production through activation of the energy regulator adenosine monophosphate-activated protein kinase, which inhibits downstream mTORC1 signaling and thus mimics caloric restriction and rapalogues in this respect. In addition to its obvious utility for treating type 2 diabetes, metformin has therapeutic potential against human age-related pathologies by combatting inflammation, oxidative stress, and premature senescence (Novelle et al. 2016). These effects suggest that it could help prevent cancer (and other disorders, including Alzheimer's disease and Parkinson's disease (Markowicz-Piasecka et al. 2017)). See also ▶ Chap. 5, "Cellular Senescence and Tumor Promotion."

Recently, chronic low-dose dietary metformin was demonstrated to mimic caloric restriction or rapalogue administration and to extend both lifespan and healthspan in multiple mouse models. One study show a dose-dependent difference in metformin effects, where B6C3F1 and BL6 male mice were given either 0.1% (10.6 mg/kg/mouse/day, defined as low-dose) or 1% (high-dose) metformin for 30 weeks (Martin-Montalvo et al. 2013). Both cohorts of mice given lose-dose metformin had a 4 to 6% increase in mean lifespan, while the high-dose cohorts had an unexpectedly shortened lifespan associated with renal toxicity and lactic acidosis. The low-dose metformin-fed mice had improved healthspan evident by increased physical performance and body weight maintenance, and reduced ocular lens opacity, insulin, and cholesterol levels. Further, transcriptome analysis in this same study showed that low-dose metformin-fed mice had gene expression changes similar to calorically restricted mice in stress-response pathways, mitochondrial bioenergetics, glycolysis, and fatty acid metabolism. In particular, similar trends in decreased gene expression of serum amyloid protein expression (*SAA1*, *SAA2*) was found in livers of both metformin and calorically restricted mice, consistent with a reduced inflammatory response.

In a study of metformin as a cancer prevention agent, 9-week-old $Apc^{Min/+}$ mice received daily dietary metformin (250 mg/kg) or control chow for 10 weeks. Although there was no difference in the total number of intestinal polyps between metformin versus control diet mice, metformin significantly decreased polyp size and cell proliferation as assessed by BrdU staining. Moreover, metformin inhibited mTORC1 signaling as seen in blunted mTOR and S6K phosphorylation, leading to reduced protein synthesis, which could help explain reduced polyp size but not numbers.

The analgesic and nonsteroidal anti-inflammatory agent acetylsalicylic acid (aspirin) is a mainstay for prevention of multiple age-associated pathologies including colorectal cancer, cardiovascular disease, and stroke (Richman and Owens 2017). Salicylate, a plant-derived natural product from which aspirin is synthesized, allosterically activates adenosine

monophosphate-activated protein kinase by preventing dephosphorylation of T^{172} (Hawley et al. 2012). Aspirin is one of the most potent cancer prevention agents for colorectal cancer known and was recently shown to reduce 20-year risk of colorectal, stomach, gastrointestinal, and prostate cancers among other cancers – a benefit that increases proportional to the duration of aspirin intake (Rothwell et al. 2011). Salicylate activates adenosine monophosphate-activated protein kinase signaling, leading to inhibition of mTOR inhibition and induction of autophagic flux (Din et al. 2012). Additional studies are required to understand how aspirin prevents cancer to optimize its clinical uses.

Potential mTOR-Related Targets

Many life-extending interventions in model organisms including calorie restriction, adenosine monophosphate-activated protein kinase activation, insulin/insulin-like growth factor signaling inhibition, and possibly sirtuins work by reducing mTORC1 signaling (Johnson et al. 2013; Kennedy and Pennypacker 2014). These data suggest that these interventions are at least partially dependent on mTORC1 signals. However, downstream signaling consequences are not fully defined. 4E-BP1 and S6K are each downstream of mTORC1 and each have longevity extension effects. S6K deletion in yeast, flies, worms, and mice improves longevity (Johnson et al. 2013), and increased 4E-BP1 activity (a consequence of mTORC1 suppression) improves longevity in flies. Interestingly, rapamycin is generally unable to reduce mTORC1-mediated inhibition of 4E-BP1 phosphorylation as effectively as its capacity to inhibit other downstream mTORC1 targets. Thus, either 4E-BP1 activation is not a major longevity extension mechanism for rapamycin, or rapamycin longevity effects could be further improved by adding an agent specifically to activate 4E–BP1. Of note, 4E-BP1 is phosphorylated at multiple residues through mechanisms that could be both mTOR-dependent (at tyrosine 36/45) and mitogen-activated protein kinase pathway-dependent (at serine 64 and threonine 69) depending on the stimulus (Herbert et al. 2002). The cross-talk between the mitogen-activated protein kinase pathway and phosphoinositol-3 kinase/Akt/mTOR pathway has resulted in understanding that the mitogen-activated protein kinase pathway is activated in response to rapamycin or rapalogues in multiple preclinical and clinical studies (Mendoza et al. 2011). In particular, the mitogen-activated protein kinase pathway promotes mTORC1 activation independent of phosphoinositol-3 kinase/Akt signaling through multiple mechanisms, including activating eIF4B phosphorylation at serine 422 (Shahbazian et al. 2006) and mTORC1-activating Raptor phosphorylation at serine 8, serine 696, and serine 863 (Carriere et al. 2011). The impact of this alternative mTORC1 activation by mitogen-activated protein kinase pathway signaling has potential for evaluation of biomarkers to predict rapamycin efficacy or could become future drug targets in combination with rapamycin therapy. See also ▶ Chap. 54, "Principles of Cancer Targeted Therapy in Older Adults."

The details of eRapa-mediated signaling downstream of mTOR in cancer prevention are little reported. In studies of skin cancer prevention using eRapa in dimethylbenz(a) anthracene/12-O-tetradecanoylphorbol-13-acetate-induced dermal carcinogenesis, mTORC1 was not clearly inhibited in skin or the tumors there as detected by Western blotting for S6K and 4E-BP1phosphorylation (Dao et al. 2015). By contrast, topical rapamycin suppressed both mTORC1 and mTORC2 in this model (Checkley et al. 2011). At least in *C. elegans*, intact autophagy is also required, though not sufficient, for lifespan extension in response to TOR complex 1 inhibition (Hansen et al. 2008). Little is known in this regard for life extension in other models or in cancer prevention.

Finally, upstream mTOR modulators such as adenosine-monophosphate activated protein kinase (discussed above), the tuberous sclerosis complexes 1 and 2 and Rheb (Martin and Hall 2005) could be considered as druggable targets for cancer prevention.

Other mTOR Effects in Cancer Prevention

eRapa reduced the DNA damage that is critical to dimethylbenz(a) anthracene/12-O-tetradecanoylphorbol-13-acetate-induced carcinogenesis as demonstrated by reduced phosphorylation of H2AX, an indicator of double-stranded DNA breaks, and reduced mutation of the *HRAS* codon 61 that promotes carcinogenesis in this two-stage skin model (Digiovanni 1992). Thus, eRapa could prevent some cancers by reducing DNA damage. In this dermal carciongenesis model, when eRapa was delayed until after tumor initiation (DNA damage) with dimethylbenz(a) anthracene, protection from cancer was abolished, consistent with the concept that some eRapa protection in tis model could be from reducing DNA damage. Langerhans cells in skin promote carcinogenesis in the dimethylbenz (a) anthracene/12-O-tetradecanoylphorbol-13-acetate model by metabolizing dimethylbenz (a) anthracene to its active carcinogenic metabolite, but eRapa did not alter numbers of skin Langerhans cells (Modi et al. 2012). Nonetheless, it is possible that rapamycin could prevent cancer by altering the metabolism of carcinogens. See also ▶ Chap. 4, "Role of Cell Cycle Control, Checkpoints, and DNA Repair Mechanisms in Stem Cells and Changes with Aging and Cancerogenesis" A detailed understanding of metabolic effects and other cancer prevention effects of mTOR inhibition or of rapalogues will help define optimal patient populations most likely to benefit from cancer prevention using mTOR inhibitors.

Adverse Effects of mTOR Inhibitors

Rapalogues can generate significant adverse effects in murine models and humans, including but not limited to metabolic dysfunction (e.g., insulin resistance, hyperinsulinemia, hyperglycemia), hematopoietic lineage defects (e.g., defective proliferation of specific bone marrow cells) interstitial pneumonitis, and other adverse toxicities including mucositis and rash (Soefje et al. 2011). The majority of human data on rapamycin adverse effects have been obtained in sick patient populations, not from healthy individuals. Thus, data on adverse rapalogue effects in generally health populations as would be studied in longevity extension or cancer prevention trials are largely unknown. Everolimus (RAD001) is a rapalogue with mTORC1 inhibitory properties similar to rapamycin but with better pharmacokinetics. In addition to its use as an immunosuppressant for transplant patients, everolimus is FDA-approved to treat kidney, breast, and neuroendocrine tumors of gastrointestinal or lung origin and is being evaluated in a multitude of cancer treatment clinical trials. In a study of everolimus in elderly humans to improve influenza vaccine efficacy, low doses (about 20% of typical pharmacologic doses) were relatively well-tolerated, with relatively few adverse effects (Mannick et al. 2014). The primary endpoint of improving influenza vaccine efficacy was achieved in this study, demonstrating the potential for improved immune function during aging. See also ▶ Chap. 27, "Geriatric Interventions in Oncology."

Further, as rapamycin adverse metabolic effects are largely attributed to inhibiting mTORC2 (Lamming et al. 2012), it could be feasible to mitigate adverse metabolic effects by specifically inhibiting mTORC1, without loss of clinical efficacy. RTB101 is a drug developed by resTORbio that inhibits S6K and 4E-BP1 activation but not the whole mTORC1 pathway when used at low doses. Everolimus plus RTB101 synergistically inhibits mTORC1 without inhibiting mTORC2. In a trial of influenza vaccine efficacy in the elderly, RTB101 at 10 mg/day plus everolimus at 0.1 mg/day, both given orally, improved influenza vaccine efficacy better than either agent alone. Significant adverse events of the drug combination included diarrhea, nausea, mouth ulcers, and rash. Hyperglycemia and hyperlipidemia were worse with everolimus alone versus everolimus plus RTB101. Nonetheless, the combination was generally well tolerated and is moving forward clinically.

A recent panel of longevity experts met in Erice, Sicily, to discuss moving specific agents into human longevity trials. After much discussions that culminated in vetting an extensive list of

gene targets and drugs, the group selected dietary mimetics of chronic dietary restriction (e.g., fasting cycles, protein restriction), drugs to inhibit the growth hormone/insulin-like growth factor-1 axis or the mTOR-S6K pathway and drugs to activate adenosine monophosphate-activated protein kinase and sirtuins or anti-inflammatory agents as most promising for human trials on healthspan extension (Longo et al. 2015). Many of these approaches also have cancer prevention potential. Thus, clinical data on cancer prevention from these trials is possible.

Closing Thoughts

Much data suggest that the mTOR signaling pathway is a drug discovery target not only for longevity extension but also to prevent cancers, which could secondarily improve lifespan or healthspan. Rapamycin is a proof-of-concept agent for this concept and might not ultimately be optimal for general cancer prevention in humans owing to toxicity concerns (Lamming et al. 2013). Notably, there has been concern for immunosuppression. However, rapalogues are often combined with other immunosuppressive agents and therefore its specific effects in humans are not fully understood. However, rapalogue cancer prevention benefits in selected high-risk populations (such as those with familial adenomatous polyposis at extremely risk for early colon cancer) could outweigh risk concerns and justify use in such selected populations.

Currently, studies of rapamycin effects in normal humans are not reported in detail. There is new data showing that rapalogues augment immunity to pathogens (Havenith et al. 2013; Keating et al. 2013) and boost vaccine immunity in elderly humans (Mannick et al. 2014), consistent with beneficial immune effects. Work showing that eRapa prevents cancer in spontaneous tumor models (Hasty et al. 2014; Livi et al. 2013; Komarova et al. 2012) and in models of inflammation-driven cancer (Dao et al. 2015, 2016; Saha et al. 2015), extends lifespan to normal in $Apc^{Min/+}$ mice (Hasty et al. 2014) and greatly improves lifespan and healthspan in highly immunodeficient RAG KO, and interferon-γ KO mice (Hurez et al. 2015) is inconsistent with rapamycin mediating detrimental immunosuppression and supports further studies of rapalogues and agents targeting mTOR signals as cancer prevention agents.

Mechanisms for rapamycin-mediated cancer prevention are likely complex and multifactorial and could include improved cancer immune surveillance, immunostimulation, delayed biological aging, increased autophagy, or reduced DNA damage, among other considerations. See also ▶ Chap. 6, "Immunosenescence and Cancer Immunotherapy at Old Age: Basics." As mechanistic details are better understood, additional drugs or targets could be identified for cancer prevention. Such information will help determine optimal use of agents and optimal populations for clinical testing. eRapa longevity extension effects also include sex differences (females generally derive greater longevity benefits versus males), and mechanisms are shown to differ from those mediated by caloric restriction (Miller et al. 2014). Thus, the hunt for additional drugs to intervene in mTOR-mediated effects on longevity and cancer prevention continues.

Abstract

Two ubiquitous calpains (extremely calcium-dependent, neutral, cytoplasmic cysteine proteases) and their endogenous inhibitor – calpastatin – form the calpain-calpastatin system (CCS). Activity of the CCS is implicated in the processes of proliferation and apoptosis of many human cell types. We have demonstrated a necessity of resting activity of the CCS for adequate proliferative response of nonmalignant T lymphocytes, as well as the reduction of amounts and activities of the CCS proteases in the elderly. On the other hand, we have also shown that hyperactivity of the CCS protects chronic B-cell leukemia (B-CLL) cells from apoptosis and possibly

induces their excessive proliferation. As the B-CLL is the typical leukemia of old age, and relatively frequently transforms into the tumor (lymphoma) growth, it was interesting to analyze the existing data on overall role of the CCS in the processes of proliferation, apoptosis, aging, and malignant transformation of human lymphoid cells. This chapter summarizes these data.

Introduction: Basic Characteristics of Lymphoid Malignancies

Any malignancy derived from cells belonging to whatever stage of lymphopoiesis, whether in the bone marrow or in periphery, is considered to be a lymphoid neoplasm. These lymphoid neoplasms in general, as well as those more typical for the elderly, are clinically divided into lymphoid leukemias and lymphomas. While the first are delocalized, i.e., growth of malignant cells occurs initially in the bone marrow from which they may spread via blood to organs which they infiltrate, the latter are more typical tumors, which can develop in the lymphatic organs or elsewhere. In fact, the malignancy belonging to lymphoid neoplasms' group is now considered a leukemia if it tends to affect circulating cells only, a lymphoma if it tends to produce tumors, and a lymphoma/leukemia if it exhibits both these features together (Swerdlow et al. 2016).

Lymphomas are broadly divided into Hodgkin lymphoma (HL) and non-Hodgkin lymphomas (NHLs) while leukemias – mostly for clinical reasons – into the acute lymphoblastic leukemias (ALLs) and chronic lymphocytic leukemias (CLLs).

HL is now considered (despite its variegated clinical and pathomorphological forms) to be derived from some developmental stage of the B lymphocyte (likely from the germinal center (GC) lymphocytes), which not only proliferates but also differentiates into disease-characteristic cells, namely, Reed-Sternberg and LP cells. Agewise, the peak incidence of Hodgkin lymphomas is observed in 15–35-year-olds, and a secondary incidence peak is seen around the age of 55 (Caporaso et al. 2009).

On the other hand, NHLs form a large group of lymphoma subtypes, which substantially differ in both their clinical features and cellular origin and in susceptibility to therapy. They can be broadly divided into B-cell and T-cell lymphomas and other, not specified, lymphoproliferative disorders. Lymphopoiesis is very complex, and multiple stages are distinguished in the development of each phenotypically distinct form of lymphocytes. Thus, B-cell lymphomas can be further divided into five main types: diffuse large B-cell, mantle cell, marginal zone, follicular, and Burkitt lymphomas. What makes the NHLs more relevant to the topic of this chapter is their incidence rates, which rise steeply from age 50 to 54, and peak in the 85–89 age group for both sexes (Smedby and Hjalgrim 2011; Fisher and Fisher 2004).

Common characteristics of all lymphoid leukemias and lymphomas have on one hand very high proliferation rate corresponding to high mitotic indexes and resulting in potential tumor/total cell mass doubling time between 40 and 100 h; this indicates that most cells in these tumors are cycling at any time (Lang et al. 1980). This was long ago confirmed by quantitation of cells expressing the Ki-67 antigen characterizing the non-resting (i.e., dividing) cells; depending on the clinical grade of lymphoma, proportion of Ki-67-positive blasts may reach even 70% (Baird 1993; Cooperman et al. 2004). Similar proportions of Ki-67+ lymphocytes are only seen in the germinal centers of reactive lymph nodes and undergo reduction with pathogen elimination.

On the other hand, growing of each lymphoid neoplasm does not stem from higher-than-healthy proliferation rates only. Another reason for their rapid accumulation is decreased or even fully eliminated susceptibility to undergo apoptosis. This finding is true for Hodgkin lymphomas,

non-Hodgkin lymphomas, and lymphoid leukemias (Mani and Jaffe 2009; Kunkalla et al. 2013; Packham et al. 2014; Mikosik et al. 2015; Witkowski et al. 2002). Major molecular mechanisms involved in apoptosis abrogation in lymphoid neoplasms include increased expression of anti-apoptotic and pro-survival molecules on one hand and decreased expression of pro-apoptotic species on the other (Tacke et al. 2004; Ito et al. 2004; Dadi et al. 2012).

Calpains, Calpastatin, and Their Roles in Cellular Survival, Proliferation, and Apoptosis

Every eukaryotic cell possesses multiple proteolytic enzymes either freely floating in cytoplasm or attached to or embedded in intracellular organelles (lysosomes) or forming specific macromolecular machines (proteasomes). Their roles range from total degradation of proteins and peptides to amino acid "building bricks" through limited cleavage into smaller and larger peptides with specific functions to a limited modulating proteolysis, where only a (usually regulatory) part of a protein is clipped off to change the substrate properties and functions. Ultimate "scissors" yielding free amino acids can be found as amino- and carboxypeptidases in the cytoplasm as well as in lysosomes. The enzymatic activities contained in the lysosomes mostly deal with the extracellular substrates brought inside the cell by the process of endocytosis (in the innate immune cells culminating as phagocytosis of bacteria and certain own cells); another facet of lysosomal activities is their participation in autophagy – a process where intracellular organelles (e.g., mitochondria) are contained in actively formed intracellular vesicles which then fuse with lysosomes, allowing for recycling of molecules building an organelle and recuperation of some energy (Anding and Baehrecke 2017). Also the proteasomes, which require "tagging" of the proteins to be targeted and degraded by their binding with a number of ubiquitin molecules (polyubiquitination), serve to degrade the intracellular proteins (including obsolete, used-up, and misfolded). However, they do not convert the digested proteins to their amino acid components. Rather, the product of intraproteasomal proteolysis is the range of peptides with the length from 3 to 22 amino acids which, in order to yield free amino acid "bricks," require further proteolysis by cytoplasmic peptidases. Still, proteasome function, as well as that of derived immunoproteasomes, is indispensable, as they provide each cell with the capability to present antigenic epitopes to the cytotoxic lymphocytes. Thus, some of these proteasome-derived peptides (typically 8–10 aa long) may directly be loaded onto MHC Class I complexes and serve as epitopes to be recognized by the T-cell receptors on CD8+ cells. Stimulation with gamma interferon leads to exchange of certain components within the proteasomes which converts them to immunoproteasomes, capable to manufacture the presentable epitopes at much higher rate than proteasomes and with average lengths more suited for binding in the MHC Class I "groves" (McCarthy and Weinberg 2015; Neefjes et al. 2011).

Calpains: General

Calpains (calcium-dependent, neutral, cytoplasmic cysteine proteases) form a (currently) 15-member family of cytoplasmic endopeptidases with very specific properties and list of intracellular substrates. Since their discovery in 1964, they draw broad attention of scientists as the only protease group so strongly dependent on contact with Ca^{2+} (Ono and Sorimachi 1824; Ono et al. 2016). Some of these enzymes are relatively ubiquitous (including calpains numbered 1, 2, 5, 7, and 10), while the activity of others is apparently limited to specific tissues (Potz et al. 2016; Baudry and Bi 2016). Another evolutionary approach divides the calpain family into typical or classical (1, 2, 3, 8, 9, 11, 12, 13, 14) and atypical (5, 6, 7, 10, 15, 16); this approach is based on structural similarities within both groups and differences between them (Baudry and Bi 2016). Major structural difference between the classical and nonclassical calpains is their structural elements required to bind Ca^{2+}, so-called EF-hands; while the classical

calpains exhibit a penta-EF-hand type of calcium binding domain, it is lacking in atypical calpains. Of the former, calpains 1 and 2, also known as μ- and m-calpain, respectively, and sometimes called "conventional," were so far detected in practically all vertebrate (including human) tissues tested, so they are the most ubiquitous of the whole family (Ono et al. 2016). Catalytic subunits of the conventional calpains are coded by the CANP1 and CANP2 genes, respectively. Unlike the rest of the family, conventional calpains are uniquely characterized by one more feature: they contain common, small (30 kD) regulatory subunit coded by a separate gene *CAPNS1*.

Calpain Substrates

As mentioned above, calpains act by cleaving the substrate proteins at (or in coordination with) specific, relatively unique sites. For a relatively long time, these sites were described as enriched in proline, glutamic acid, serine, and threonine, otherwise known as PEST sequences, flanked by the arginine and lysine (Perrin and Huttenlocher 2002; Tompa et al. 2004). In fact, predictions of proteins to be the calpain substrates were made based on the abundance and location of the PEST domains. One such example is the IκB molecule, which contains such PEST domain and is degraded by calpain (Shumway et al. 1999). More recently, deeper analysis of calpain chemistry, structures of catalytic sites, as well as novel bioinformatics approaches including the machine learning had yielded many more potentially cleaved amino acid sequences (Sorimachi et al. 2012; DuVerle et al. 2011). Interestingly enough, the authors of the cited paper suggest that in the biological settings, that less probable sites may actually be cleaved with equal or even more effectiveness than the "strong" ones. This observation would greatly increase the list of potential and real targets of the proteolytic activity of calpains in the cells. Indeed, it was recently stated that the conventional calpains alone are capable to cleave more than 40% of the peptide bonds of most polypeptides, at least when their proteolytic activities are studied in vitro.

Currently there are about 200 of them known (Piatkov et al. 2014). However, based on the abovementioned machine learning and other analyses, it is suggested that the total number of cellular substrates for calpains 1 and 2 may exceed 1000 (Ono and Sorimachi 1824). The list includes many proteins that are involved in transduction of signals leading to either proliferation or apoptosis of many cell types. Thus, it includes cyclins (especially cyclin D1, found to be increased in centrocytic lymphomas), surface growth factor/mitogen receptors including the Egfr, membrane (receptor), and cytoplasmic kinases, including PKCα and PKCγ, as well as calmodulin kinase IV (CAMK-IV), calcineurin inhibitor DSCR1, IGF-binding protein Igfbp2, and proto-oncogenes (e.g., c-myc and ras) (Piatkov et al. 2014; Moretti et al. 2014; Choi et al. 1997). An interesting group of calpain substrates are the transcription factors and their regulators, notably c-fos, c-jun, p53, β-catenin, and IκB. The latter is a very well-known negative regulator of NFκB, preventing it from entering the nucleus and releasing it after being phosphorylated by a specific activation-dependent kinase IKK. Discovery of susceptibility of IκB to calpain cleavage suggests an alternative path to NFkB activation in the cells responding to stimulation by building an appreciable calcium signals (Lopatniuk and Witkowski 2011). Also cohesin, a protein necessary for maintenance of the fidelity of chromosome cohesion and segregation during mitosis, is on the calpain substrates' list (Rao et al. 2001).

Movement of the cells, including the lymphocyte transmigration from the vessels and into the tissues, requires calpain-mediated, spatially and temporally controlled cleavage of cytoskeletal proteins, including ankyrin, talin, vimentin, cortactin, troponin T2, and dystrophin (Piatkov et al. 2014; Franco and Huttenlocher 2005). Proteolysis by calpains plays many other roles as well, including their major functions in the brain and muscle (Piatkov et al. 2014; Lopatniuk and Witkowski 2011; Sorimachi and Ono 2012).

Excessive calpain-dependent cleavage of activator of Cdk5 cyclin-dependent kinase occurring in the neurons activates the kinase which in turn hyperphosphorylates the tau protein leading to its misfolding and formation of

neurofibrillary tangles, typical for tauopathies including Alzheimer's disease.

Calpains cleave calcium channels, including the ryanodine receptor and the NMDA receptor, as well as voltage-gated Ca^{2+} channels (Piatkov et al. 2014). On the other hand, they do cleave also the membrane calcium-dependent ATPase (calcium pump, PMCA) molecules.

Also the list of known calpain substrates directly involved in the positive or negative regulation of apoptosis is relatively long and includes both the pro-apoptotic proteins like Bak, Bid, caspases 3, and 9 and the anti-apoptotic proteins including Bcl-2, Bcl-XL, and Bfl-1 (Piatkov et al. 2012, 2014; Lopatniuk and Witkowski 2011). Interestingly, at least in the case of Bcl-XL, the actual target of calpain-dependent destruction is its deamidated form; this happens upon DNA-targeting chemotherapy, e.g., of follicular lymphoma (Dho et al. 2013).

Calpain Action on Target Proteins

Calpains belong to the group of proteases which can be characterized as modulative, rather than hydrolytically degrading their targets. As was said above, calpains cleave their targets in relatively specific, predefined sites. The result of such limited (modulative) cleavage may be either inactivation of target protein (e.g., IκB, above) or its activation (e.g., PKC) (Sessoms et al. 1992).

It was recently demonstrated that calpain activities yield protein fragments that bear destabilizing N-terminal residues. By recognizing proteins that are having these structurally destabilizing N-terminal residues, calpains generate their fragments tagging them for further proteasomal destruction (Piatkov et al. 2012, 2014; Brower et al. 2013; Varshavsky 2012). In this way, calpains may protect the cellular proteome from errors (improperly constructed proteins) that could affect cell functions by decreasing intracellular concentration (and thus activities) of properly built ones. This would be pro-survival, both in the case of normal and malignant cells.

On the other hand, some target proteins may be variably cleaved and initially "only" modulated in order to yield them active or inactive in a specific intracellular context but later finally degraded. This double-edged activity includes, for instance, the caspase 3. Thus, "initial" events of calpain-dependent cleavage activate the caspase but at the same time yield it more prone to further calpain-dependent, now degrading, events or to proteasomal degradation. That way calpain activity may be pro-apoptotic or anti-apoptotic, depending on spatiotemporal considerations of this activity in a specific cell type.

A Puzzle Regarding Calpain Activity In Vivo

It was shown that calpains are activated (at least in vitro) solely by relatively high (micro- to millimolar for calpain-1 and -2, respectively) concentrations of calcium ions and by presence of (membrane) phospholipids which, in fact, reduce their need for Ca^{2+} (Ono and Sorimachi 1824; Lopatniuk and Witkowski 2011; Saido et al. 1992).

The limiting factor, potentially preventing them from being constantly active in the cells, was considered to be the intracellular concentration of Ca^{2+} ions which in most resting cells remains at around 100 nM, only to be brought to a few μM during activation. This is also true for the lymphoid cells where "calcium signals" observed within seconds to minutes of the onset of stimulation by a mitogen or antigen rarely exceed 1–2 μM. This should be sufficient for activation of calpain-1 (μ-calpain), but clearly not m-calpain, described as requiring millimolar Ca^{2+} for activity. Still, both calpains were found in the lymphocytes and their activities demonstrated (Lopatniuk and Witkowski 2011; Mikosik et al. 2007, 2013, 2016). One explanation that was proposed was that contact with membrane phospholipids decreases the calpains' need for Ca^{2+} (Saido et al. 1994; Tompa et al. 2001). Also, while the *average concentrations* of Ca^{2+} in resting and activated lymphocytes, usually measured by flow cytometry with the use of calcium-sensitive fluorochromes, are as mentioned above, the *local concentrations*, e.g., in the vicinity of periodically opening CRAC channels, may be much higher and approach multi-micromolar at least for the short moments. This way also a necessary

condition of calpain activation in the lymphoid cells, i.e., relatively high concentration of Ca^{2+} available for binding by the enzyme molecules, would become possible not only during early moments of stimulation as proposed earlier but also in resting state. In fact, we have recently demonstrated a significant activity of both μ- and m-calpain in resting human peripheral blood lymphocytes (Mikosik et al. 2016). This proteolytic activity was coupled with equally conservative transcriptional activities of both calpains (CANP1 and CANP2, respectively). This finding seems understandable if one considers that the *resting*, at least semipermanent calpain activity in unstimulated lymphocytes, serves some physiological purpose. In fact we have demonstrated in the same paper that specific inhibition of calpains prevents the T cells from proliferation and cytokine secretion upon stimulation in vitro and shown that these effects may be at least in part due to modified (decreased) levels of phosphorylated NFκB, p56lck, and phospholipase Cγ in the cells in which the calpains were inhibited before the beginning of stimulation (Mikosik et al. 2016). Our interpretation of these findings is that the observed, constitutive activity of calpains is necessary to maintain a non-zero level of T-cell readiness for the rapid initiation of the immune response (proliferative and secretory) to antigens.

Considering the above, including the ubiquitous calpain substrates' list encompassing multiple molecules of extreme importance for cellular proliferation, apoptosis, and other functions, as well as their permanent constitutive activity in the human lymphoid cells at rest, one can easily perceive that this activity must be in a very precarious, dynamic balance. Otherwise such an activity, if unleashed, would greatly affect multiple functions of the lymphoid cells, ultimately leading to two possible outcomes. One would be their early apoptotic death, especially during early response to activation. It is tempting to say that possibly the well-known activation-induced cell death (AICD) happening to many stimulated T cells in vitro and possibly in vivo is dependent on this pro-apoptotic calpain activities, especially because the dependence between AICD extent and Ca^{2+} concentration in stimulated lymphocytes was observed (Sarin et al. 1994; Ruiz-Vela et al. 1999). The second one, more to the topic of this chapter, would be the calpain activity-dependent pro-survival, anti-apoptotic activities which could in principle lead to either accumulation of excessive numbers of active T cells, possibly leading to some autoimmune reactivity and pathology, or to the promotion of lymphoid malignancy. Along with the latter notion, we have repeatedly shown that excessive activity of calpains protects malignant lymphocytes from apoptosis, both in the case of acute lymphoblastic leukemia typical for children and for chronic B-cell leukemia of the elderly (Mikosik et al. 2015; Witkowski et al. 2002).

Thus, if allowed to, the calpains would either cleave the proteins that are necessary for adequate pre-proliferative signaling and for mitosis itself or induce apoptosis by cleaving-off, e.g., the inhibitory parts (peptides) of the effector caspases or, eventually, prevent apoptosis by cutting these caspases and other relevant proteins to non-functional pieces. In fact, all these activities are seen in some clinically relevant conditions, like muscular dystrophy and Alzheimer's disease, where the main problem is cell degeneration, or, on the other hand, protection from apoptosis by the token of removing the effector caspases and possibly other pro-apoptotic factors mentioned above, as in case of ALL and B-CLL leukemias.

What is maintaining the precarious and so important balance between the necessity of some calpain activity in the lymphocytes even at rest, and the danger of its excess? It is now accepted that due to their involvement in cellular life-and-death decisions, the activity of calpains requires multiple safety valves. One of these is the requirement for really high (near-millimolar) Ca^{2+} concentration for the activity of m-calpain, as without it the active site of the enzyme assumes an inactive conformation and is inaccessible for potential targets (Ono et al. 2016). Although we did see it even in resting T cells, and interpreted as occurring in the close vicinity of the opening CRAC channels, it was never as potent as that of μ-calpain, despite the fact that the actual cellular amounts of both proteases were comparable (Mikosik et al. 2016). Another "safety valve" feature is the existence of the unique, specific, equally ubiquitous

cytoplasmic inhibitor of calpain activity, the calpastatin (Wendt et al. 2004; Goll et al. 2003; Friedrich and Bozoky 2005). Calpastatin accompanies the calpains in all human cells tested so far, including the lymphocytes, and their relative concentrations seem to be in a stoichiometric equilibrium. Calpastatin is activated (and starts performing as an inhibitor of calpain activity) only upon modulative cleavage by active calpain, for which it is a substrate; in this way some activity of the enzyme can occur before calpastatin is activated (Lopatniuk and Witkowski 2011; Piatkov et al. 2014; Wendt et al. 2004; Goll et al. 2003; Friedrich and Bozoky 2005). Finally, both active and resting (inactive) calpains 1 and 2 are the substrates for their own activity; thus initially the activation of some calpain molecules makes possible the activation of others by cleaving some parts of both the large and small (regulatory) subunits; later, autodegradation takes over and amounts of active enzymes are reduced (Ono and Sorimachi 1824; Lopatniuk and Witkowski 2011; Piatkov et al. 2014). So, there is strong built-in mechanism modulating the CCS complex. It is becoming clear now why we had observed constitutive transcription of the genes for both calpains (CANP1 and 2) and for calpastatin (CAST) in resting T cells. On one hand, the appreciable activity of calpains in the resting cells was likely evolutionarily selected for as beneficial for the speed of the response, and so, on the other, it had to be maintained in the system where active enzymes are disappearing "from own hands."

Calpains and Aging

By the token of being modulatory for so many important cellular proteins involved in proliferation and apoptosis, i.e., the two major cellular functions greatly affected by advanced age, calpains must have been perceived as potential element of the cellular aging machinery. Considering that in most if not all aging and senescent cells, their proteostasis, i.e., maintenance of functionally relevant proteins at adequate qualities and quantities, is impaired, calpains became one of the master molecules of interest for cellular gerontologists. However, so far the papers studying their role in human aging concentrate on their involvement in aging-associated neurodegeneration (especially Alzheimer's and Parkinson's diseases), sarcopenia (muscular wasting of the old), and some chronic inflammatory states, notably atherosclerosis and its consequences – the cardiovascular problems (Pinto et al. 2017; Nixon 2003). On the other hand, the involvement of calpains in aging of human immune (lymphoid) cells, with their dwindling bursts of proliferative and secretory activities upon antigen stimulation and long periods of rest, is so far studied only fragmentarily. At the beginning of this century, our group had shown that the amount and total activity of both μ- and m-calpains decrease in the peripheral B lymphocytes of old individuals (Witkowski et al. 2002). We had extended these observations more than a decade later, demonstrating that amounts of all three members of the calpain-calpastatin system, i.e., μ- and m-calpain and calpastatin, decrease significantly in peripheral blood T and B cells of elderly in their 60s and 70s and remain high in these cells coming from the oldest old, i.e., centenarians (Mikosik et al. 2013). These quantitative changes were not associated with known shifts of the proportions of major subpopulations within the T cells (including the naïve and memory, as well as these expressing CD28 versus these that did not). As we did show recently in a paper already cited above, at least for the peripheral blood T cells, the resting (constitutive) calpain activity is necessary for adequate buildup of proliferative response to stimulation and cytokine production (Mikosik et al. 2016). Our as yet unpublished data suggest that the actual calpain activities (measured by flow cytometry in living cells, rather than total available activities in cell lysates) are also changing in the lymphocytes of old individuals, albeit differentially for various populations. Maintenance of sufficient resting calpain and calpastatin amounts in old lymphoid cells requires increased levels of transcripts of all three genes, CANP1, CANP2, and CAST (Witkowski, unpublished), which stresses the

importance of calpain activity in the lymphocytes for supporting their functioning in the aging environment.

Complex Relations Between CCS Hyperexpression and Hyperactivity as Likely Mechanisms of Apoptosis Escape and Increased Proliferation in Lymphoid Neoplasms

Ubiquitous calpains' activity is implicated in multiple human pathologies, including atherosclerosis, Alzheimer's disease, cardiovascular disorders, Parkinson's, muscular dystrophies, cataracts, and many others; the effect of – presumably excessive – calpain activity is described as at least aggravating, or even causative, to the extent that calpain inhibitors are presently contemplated and tested as therapeutic candidates (Ono et al. 2016). Cancers are no different, and excessive calpain activity is proposed as causative or aggravating for a score of them (Ono et al. 2016). This activity prevents apoptosis and increases basic autophagy levels in cancer cells, helping their survival under stress (including chemotherapy) (Shi et al. 2013). By interfering with cytoskeleton and adhesion molecules, as well as by stimulating neovascularization, calpain activity facilitates cancer cell migration and invasiveness. However, both the cited paper and other ones bring up that calpain activities may also act as preventive, by stimulating cancer cell apoptosis and/or inhibiting their protective autophagy (Ono et al. 2016; Moretti et al. 2014; Tan et al. 2006). In the latter case, calpains do it by cleavage of G protein Gsα, which leads to high levels of cAMP inhibiting the autophagy (Williams et al. 2008).

As was mentioned above, calpains affect the amounts and activities of multiple proto-oncogenes and transcription factors. On the other hand, their own activity is augmented by activation of Src, Jun, Fos, Myc, k-Ras, and other oncogenes during oncogenic transformation of many cell types. While this may be pro-survival, the increase of calpain activities in v-Myc – transformed cells – is the strongest and pro-apoptotic (Carragher et al. 2004). On the other hand, more recently Li et al. had reported that in model transgenic E1-myc B-cell lymphoma cells, activation of c-Myc is parallel with constitutive activation of (mostly) μ-calpain and pro-survival or anti-apoptotic, thus promoting or sustaining the tumorigenesis (Li et al. 2012). One possibility is that calpains can cleave and degrade c-Myc, defusing its pro-apoptotic action in these cells (Small et al. 2002; Conacci-Sorrell et al. 2010, 2014; Conacci-Sorrell and Eisenman 2011). In the cited paper, caspase 3/7 inhibitors protected cells from death induced by calpain inhibitor, suggesting that calpain activity generated a pro-survival signal for this lymphoma and its lack resulted in caspase-dependent apoptosis (Li et al. 2012).

Interestingly enough, we did see the constitutive activity of both μ- and m-calpains in perfectly normal human peripheral blood T cells; it is possible then that also in these cells the pro-proliferative effect is associated with calpain-dependent decrease in c-myc activity; transition from normal to malignant (lymphoma) lymphocyte would – in this case – be hypothesized more as a continuum (Fig. 1) (Mikosik et al. 2016).

As already cited in this chapter, we have demonstrated increased amounts and activities of both (especially μ-) calpains in the malignant cells of acute B-lymphoblastic leukemia (B-ALL) and in chronic B-cell leukemia of the aged. Inhibition of calpains in these cells in vitro induced their significant apoptosis (Witkowski et al. 2002). In fact, induction of apoptosis of multiple human B-cell and T-cell lines, including RAMOS, DAUDI, NALM-6, JURKAT, and MOLT-3 by in vitro treatment with calpain inhibitors, was already demonstrated in the year 2000 (Zhu and Uckun 2000). However, other authors who assessed the activity of calpains in adult **T**-cell leukemia (one of the very severe forms of leukemia) found that m-calpain was significantly downregulated in these cells (Ishihara et al. 2013). Still, one cannot just suppose that B-cell-derived malignancies exhibit increased calpain activities, and T cell-derived malignancies do not. An example (and proposed mechanistic, molecular explanation) of the reciprocal situation (effects of calpain activity in T-cell lymphomas) is described below.

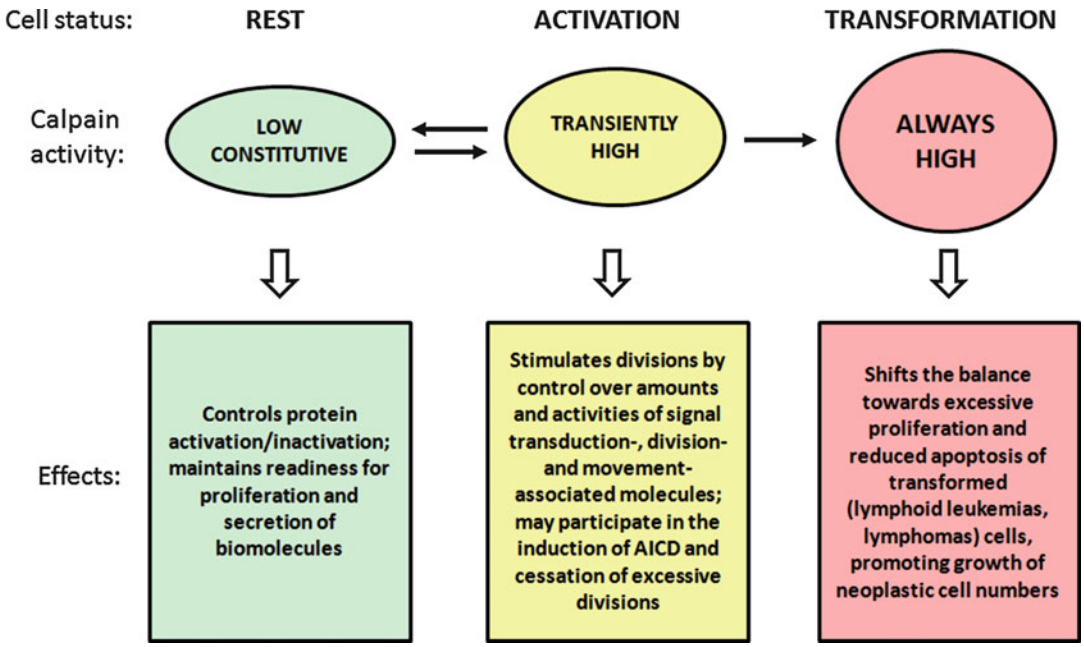

Fig. 1 Hypothesis: Continuity and roles of various activities of calpains in lymphoid cells depending on cell status (rest, activation, transformed (leukemic, lymphomatic)). *AICD* activation-induced cell death

Thus, primary cutaneous T-cell lymphomas (CTCL) form a heterogeneous group of non-Hodgkin lymphoma (NHL). Mycosis fungoides (MF) is the most common form of CTCL and is usually of relatively benign nature. A less common variant of indolent CTCL is the CD30-positive anaplastic large cell lymphoma. Finally, the Sezary syndrome (SS) is an aggressive, leukemic form of CTCL (Mitchell and John 2005).

It is known for some time that cutaneous T-cell lymphoma cells exhibit the aberrant expression of so-called Stat-3γ and Stat-5γ proteins (Hendry and John 2004). These two proteins are nothing more than the C-terminally truncated Stat-3 and Stat-5 transcription factors. At the time of writing the cited paper (2004), it was not known that calpains are in fact producing such C-terminal fragments, which now is an established knowledge, pertinent also for truncated, C-terminal fragments of Stat-3 and Stat-5 (Piatkov et al. 2014; Mitchell and John 2005). In fact the latter was demonstrated already in 2002 but only for human blood platelet STATs (Oda et al. 2002). These fragments may be constitutively activated and provide pro-survival, anti-apoptotic signals (Hendry and John 2004). Constitutive activation of Stat-3 and Stat-5 was demonstrated for both the mycosis fungoides and Sezary syndrome cells (Mitchell and John 2005; Zhang et al. 1996).

Also in human B-cell lymphomas (e.g., Burkitt lymphoma), the activity of calpain is proposed to be anti-apoptotic due to interfering with the amount and activity of the effector caspase 3. These lymphomatic cells can be induced to apoptosis by calpain inhibition, similarly to our observations of acute and chronic B-cell leukemias (Li et al. 2012). Activated, membrane phospholipid-bound calpains were also found in the cells of active mantle cell lymphomas (MCL), especially in their leukemic phase (Boyd et al. 2009). Authors of this paper suggest that this calpain activity in MCL is elevated and constitutive and likely provides the pro-survival or pro-proliferative and anti-apoptotic signals.

Finally, earlier studies on immortalized B cells in vitro (WEHI-231) had shown that they maintain constitutively active NFκB (p50-c-Rel heterodimer) due to continual degradation of

IκBα, sensitive to calpain inhibition (i.e., executed by calpain) (Shumway and Miyamoto 2004).

Conclusion

Concluding, very unique properties of ubiquitous calpains, including their substrate list predisposing them for regulation of proliferation and apoptosis of practically every cell type studied as well as their actual pro-proliferative, anti-apoptotic activity observed even in resting normal lymphocytes and augmented in leukemic/lymphomatic ones, put calpains high on the list of known and potential therapeutic targets in lymphoid leukemias and lymphomas. Still, published data concerning the role of modified calpain activities in the lymphoma pathogenesis are fragmentary and warrant necessity for more thorough and detailed studies.

Abstract

Lymphoma and aging interplay may be firstly considered from an epidemiologic point of view, as the incidence of lymphoma – and notably diffuse large B-cell lymphoma (DLBCL) – increases with age. In addition, its histopathogenic subcategories develop an age-dependent repartition – with less frequent germinal center-derived DLBCL and more activated B cell ones. Finally, some specific entities have been specifically described in an aged population, like EBV DLBCL, leading to specific biologic explanatory hypotheses.

This review aims at summarizing current data (i) on the impact of age on the mutation burden leading to lymphomagenesis, (ii) on defects in cancer surveillance associated with age, (iii) on the impact of clonal restriction in the hematopoietic system, (iv) on the specific lymphoma entities associated with age and particularly EBV DLBCL of the elderly, and finally (v) on the treatment perspectives based on this interplay.

Keywords

Lymphoma · Aging · Senescence · Immunosenescence · Telomere · EBV DLBCL of the Elderly

Abbreviations

3′UTR	3′ untranslated region
ABC	Activated B-cell-like (lymphoma)
AID	Activation-induced deaminase
ATLL	Adult T-cell leukemia/lymphoma
BCR	B-cell receptor
DDR	DNA damage response
DLBCL	Diffuse large B-cell lymphoma
DSB	Double-strand breaks
EBV	Epstein-Barr virus
FL	Follicular lymphoma
GC	Germinal center
GEP	Gene expression profiling
HR	Homologous recombination
hTERT	(Human) telomerase reverse transcriptase
MCL	Mantle cell lymphoma
MLBCL	Mediastinal large B-cell lymphoma
MZL	Marginal zone lymphoma
NHEJ	Nonhomologous end joining
RAG	Recombination-activating gene
SHM	Somatic hypermutation
TCR	T-cell receptor
VH	Variable locus of Ig heavy chain

Introduction

Lymphoma – and particularly diffuse large B-cell lymphoma – can be partly considered as age-related, since its incidences increase with age until 90 years, reaching at this age 0.45‰ in men compared to 0.12‰ at the age of 60 in women (Monnereau et al. 2013). The cumulative incidence of DLBCL increases from 0.13% (in men) and 0.09% (in women) before 39 years to, respectively, 1.77% in men and 1.4% in women after 70 years (Maartense et al. 1998; Siegel et al. 2012; Edwards et al. 2005; Howe et al. 2001). Around half of DLBCL cases occur after 60 years and 40% after 70 years (Morton et al. 2006). Considering other histologic forms of lymphoma, median age at diagnosis is 65 years for FL and 70 years for MCL.

Aside from epidemiologic relationships, some biologic pathways have been proposed to explain the link between lymphoma development and aging.

Indeed, lymphoma pathogenesis is at the crossroads of physiologic processes at high risk of mutagenesis (e.g., B-cell processing itself) and depends on alterations of genetic and immune surveillance and microenvironmental dysfunctions, all being correlated with age (Sarkozy et al. 2015).

This review aims at summarizing current data (i) on the impact of age on the mutation burden leading to lymphomagenesis, (ii) on defects in cancer surveillance associated with age, (iii) on the impact of clonal restriction in the hematopoietic system, (iv) on the specific lymphoma entities associated with age and particularly EBV DLBCL of the elderly, and finally (v) on the treatment perspectives based on this interplay.

Lymphomagenesis and Age: The Role of the Mutation Burden

Lymphomagenesis Process Is Long and Implies Several Steps

B-cell NHL development is closely related to normal B-cell development and maturation. Each lymphoma entity corresponds to a normal cell counterpart in the B-cell lineage. Balanced translocations that involve the immunoglobulin genes (Ig) and an oncogenic partner are frequent and often correspond to the primary oncogenic events resulting in the overexpression of oncogenes. Nevertheless, such events are not sufficient since multiple additional mutation hits may be needed to induce the lymphoma phenotype, according to a multistep process. As such successive mutation hits need time, they are expected to accumulate with aging.

Mutations Related to B-Cell Processing

During normal B-cell development, in the pro-B cell, the V(D)J Ig segment recombination into the variable region of the BCR is mediated via RAG 1 and 2 recombinases leading to DNA double-strand breaks (DSB) at specific recombination signal sequences in the bone marrow. These breaks lead to the activation of the DNA damage response (DDR) pathway, notably the non-homologous end-joining (NHEJ) system. RAG 1/2 is also able to produce DSB in "off-target" sites as oncogenes. Experiments in mice showed that errors in NHEJ can lead to translocation, as t(11;14) or t(14;18) (Guidos et al. 1996). However, full development of a cancer phenotype depends on the blockade of *p53*. Nevertheless, these events are not sufficient: mice bearing only t(11;14) as single mutation do not develop lymphoma (Lovec et al. 1994). In the human context, almost 70% of healthy individuals present normal circulating B cell with t(14;18), and only few will transform into true lymphoma (Roulland et al. 2006). Thus additional mutations are necessary for lymphoma development and may depend on other steps of B-cell processing, as class switch recombination (CSR) and somatic hypermutation (SHM). SHM and CSR correspond to programmed DNA damage occurring in the germinal center (GC), depending on activation-induced deaminase (AID) (Stavnezer et al. 2008). Recent data showed that AID is induced by exogenous DNA damage, leading to enhanced base excision repair (Tepper et al. 2016). Moreover AID can lead in vitro and in vivo to off-target mutations, notably in oncogenes, as well as lymphoma-associated chromosome translocations (Robbiani et al. 2009). Finally, AID was shown to be expressed at high levels in lymphoma subtypes with an ongoing mutation process (Lenz et al. 2007; Roulland et al. 2011).

Nevertheless, in spite that time may impact the accumulation of mutations related to B-cell processing, the exact impact of age on RAG1/2 function and on AID off-target mutations is currently unknown.

The Mutation Burden Is Time-Dependent and Leads to Aging and Cancer

According to the Nobel laureate Peter Medawar mutation burden theory (1952), natural selection does not delete mutations with no detrimental effect on species reproduction (Medawar 1952). Such mutations can accumulate with time and participate to aging phenotype. As the development of lymphoma requires multiple mutational events to deviate from normal B-cell development, age-related genomic and epigenomic instability may participate to this multistep process.

Accordingly, experimental data suggest age induces DNA damage accumulation, notably in the stem cell compartment, in turn leading to dysfunctions in different mechanisms regulating genomic integrity (Rossi et al. 2007; Rübe et al. 2011). Age-related accumulation of reactive oxygen species (ROS) might accelerate DNA damage. In addition, the genetic instability associated with the B-cell processing might synergistically promote DNA abnormalities leading to

lymphomagenesis (Gosselin et al. 2009). Blood-derived sequence data of 2728 individuals from the Cancer Genome Atlas showed that 2% of blood cells contain mutations, the rate reaching 5–6% in patients over 70 years. In 83% of these cases, these mutations implied 19 hematological cancer-associated genes (as *ASXL1, DNMT3A, JAK2, TET2, TP53*, etc.). Blood-specific mutations increase with age, some of them being able to initiate hematopoietic stem progenitor cell clonal expansion. Such clonal expansions are proposed to be a contributing factor to the development of hematological malignancies in the elderly (Xie et al. 2014).

In another large-scale whole-exome sequencing analysis of peripheral blood from 17,182 persons without overt hematological malignancies, 160 genes known to be recurrently mutated in hematological cancers displayed a high rate of somatic mutations, with a frequency significantly rising with age. Interestingly, the presence of somatic mutations correlated both with an increased risk in future development of hematological cancer and with all-cause mortality (Jaiswal et al. 2014).

Thus the accumulation of mutation appears both as an age-related event and as premalignant events that may preclude clonal hematological expansion and overt hematological malignancy.

The Epimutation Burden

During cell differentiation, gene expression is regulated by both transcription factors and chromatin architecture. Classically the chromatin is called euchromatin when it is open to transcription and heterochromatin when it is silenced. Heterochromatinization's main characteristics imply cytosine methylation and histone H3 trimethylation. Genome-wide analysis of DNA methylation showed that age is associated with a general hypomethylation, the hypermethylation of CpG islands, an accumulation of heterochromatin, and its mislocalization. The concept of epigenetic drift has been proposed to describe the accumulation of small changes in DNA methylation during aging. These marks correspond to stochastic errors appearing during the transfer of epigenetic marks during replication (Issa 2014). Such errors accumulate in the most proliferative organs as hematopoietic stem cells and spleen but also the gastrointestinal tract (Maegawa et al. 2010; Beerman et al. 2013). Mutations arising in aging stem cells predominantly affect the epigenetic regulation machinery and may participate to clonal HSC expansions with aging and therefore in hematological malignancy development (Welch et al. 2012).

Similarly, some lymphoma mutation hotspots affect chromatin protein genes (Xie et al. 2014): histone methyltransferases such as *EZH2* and *MLL2*, histone demethylases including *UTX* and *JMJD2C*, and histone acetyltransferases including *CBP* and *p300*. Thus, large-scale modifications of DNA methylation and histone acetylation pattern have been proposed as specific hallmarks of NHL (Shaknovich and Melnick 2011). For example, in a RNA-sequencing study (Morin et al. 2010), 32% of DLBCL and 89% of FL cases had somatic mutations in *MLL2*, a histone methyltransferase, and 11.4% and 13.4% of DLBCL and FL cases, respectively, had mutations in *MEF2B*, a calcium-regulated gene that cooperates with CREBBP and EP300 in acetylating histones.

The Impact of Telomere Shortening

During normal aging, the gradual loss of telomeric DNA in dividing somatic cells due to the "end replication problem" contributes to replicative senescence (Gilson and Géli 2007). Importantly, this telomere length dynamics plays an important signaling role in determining cell fate during aging and cancer (Ye et al. 2014). Indeed, telomere shortening contributes to a mitotic clock leading to replicative senescence, considered an important tumor-suppressive mechanism. Moreover, recent data demonstrated that dysfunctional telomeres induce p53-dependent and p53-independent apoptosis to compromise cellular proliferation and inhibit tumor formation (Wang et al. 2016). At the same time, it contributes to tissue exhaustion and loss of heterogeneity

in organs with a high proliferative rate, and particularly in the hematopoietic system, contributing to age-related dysfunctions and finally to expansions of dysfunctional clones (Falandry et al. 2014a). During cancer development, on one hand, telomerase activation in precancerous cell may lead to their immortalization and is shown in 90% of solid tumors (Kyo et al. 2008). On the other hand, telomere shortening may lead to the induction of DNA damage response (DDR) that may induce pathologic chromosomal recombination through homologous recombination (HR) and/or nonhomologous end-joining (NHEJ) pathways (Hackett and Greider 2002). Any defect in the telomere-binding protein complex (containing TRF1, TRF2, POT1, TIN2, TPP1, and RAP1), also known as the shelterin complex, may also lead to DDR signaling. In aging mice, a gene dosage reduction of Trf1 and/or Tin2 telomere-binding proteins induced DNA damage, precancerous hyperplastic nodules, and T- and B-cell lymphoma (Hartmann et al. 2016).

In the specific context of hematologic malignancies, a recent review has synthetized the different telomeric pathways dysregulated during hematologic malignancies, depending on the oncogenic triggers (Ropio et al. 2016). When telomerase activation is an early event, cancer cells are characterized by long telomeres, as in virus-driven malignancies. In other cases, telomere activation may be a late event, and cancer cells may have short telomeres. Telomerase activation depends mainly on hTERT expression, the reverse transcriptase enzymatic subunit of telomerase as it is its limiting factors, the other subunits being generally produced in excess. Increased expression of hTERT may be driven by genetic mechanisms (*hTERT* amplification, translocations, or point mutations in *hTERT* gene or promoter) as well as epigenetic ones (methylation of DNA, demethylation of CpG islands, acetylation or methylation of histones) or posttranscriptional regulation (mutation of 3′UTR of hTERT gene, action of micro-RNAs). During virus-driven lymphoid malignancies, telomerase is precociously activated either directly (like Tax in HTLV-1-driven ATLL) or indirectly (like HBZ in HTLV-1- or LMP-1 for EBV-driven malignancies) by viral oncoproteins. However, little is known about the impact of age on these regulation pathways.

Age-Related Dysfunction of Anticancer Surveillance

Age is associated with a decline in different organ functions. Among these, the decline in immune surveillance against tumors, but also against infectious diseases, shown to participate to the expansion of some lymphomas, as well as the decline in microenvironment-associated functions or in DNA damage response pathways may participate to hematological malignancy triggering.

Immunosenescence Links Chronic Infection to Cancer Development

Immunosenescence corresponds to the different changes in the immune system associated with age (Franceschi et al. 2000). It includes dysfunctions in B cells and T cells (less naive CD8+ cells, decrease in T-cell repertoire and functionality, less regulatory T cells, more memory T cells) (Maue et al. 2009) as well as dysfunctions in innate immunity associated with a pro-inflammatory profile called inflammaging. The observed phenotype associates a decrease in adaptive immunity and a chronic stimulation of innate immunity (Franceschi et al. 2000). It affects immune responses to infection and to cancer cells and leads to a decrease in vaccine response (Goodwin et al. 2006; Goronzy and Weyand 2013). Thus aging induces an increase in infectious disease (Hadrup et al. 2006), chronic inflammation disorders and autoimmunity, as well as cancer (Fulop et al. 2013). T-cell populations are unbalanced, leading to a "restricted T-cell response" in which mature and senescent CD8+ T cells proliferate instead of naive T cells. In elderly patients T-cell responses are often restricted (9–20%) or monoclonal (15–50%) (Dojcinov et al. 2011). Such epitope-specific repertoires promote sensitivity to infections (Hakim and Gress 2007; Messaoudi

et al. 2006) and consequently infection-linked diseases. In the elderly EBV promotes clonal reactive B-cell hyperplasia and specific forms of DLBCL called EBV + −DLBCL (see below). In turn, Wang reported that chronic infection with CMV and EBV altered the B-cell immune repertoire (Wang et al. 2014a). Such age-related decrease in B-cell repertoire is associated with a decreased survival in older patients (Gibson et al. 2009). Moreover, an "immune-risk profile" has been described in epidemiological studies, which is characterized by deep hallmarks of immunosenescence related to a chronic CMV infection and correlates with a poor outcome in older patients (Pallis et al. 2014).

Considering NHL pathogenesis, chronic infections were shown to promote B lymphomagenesis either directly – via lymphotropic oncogenic viruses (EBV, HHV8, HTLV1; Suarez et al. 2006) – or indirectly via a chronic inflammation. Indeed, epidemiological correlations have been demonstrated between chronic inflammation and MALT MZL (mucosa-associated lymphoid tissue marginal zone lymphomas): *Helicobacter pylori* in the stomach, *Campylobacter jejuni* in the small intestine, *Chlamydia psittaci* in the ocular adnexal gland, or *Borrelia burgdorferi* in the skin. Moreover, chronic HCV infections lead to an increased risk to develop MZL or DLBCL (Zucca et al. 2014). A pathophysiologic scenario has been proposed, involving a chronic antigenic stimulation by microbial pathogens and/or autoantigens. In HCV, the nonstructural viral protein NS3/4A induces BCR activation (Dai et al. 2016).

In spite of the absence of any specific correlation between age and infection-related lymphomageneses, one might consider immunosenescence as one of the drivers of the relationship between age and lymphoma.

Microenvironment and Immunity Change with Age

Most NHL display a biased *IGVH* repertoire, supporting the concept of an antigen-driven BCR selection and stimulation (Hadzidimitriou et al. 2011). Some NHL exhibit restricted or "stereotyped" *IGVH* complementarity-determining region 3 (CDR3) sequences within the BCR suggesting a specific antigen (Ag) stimulation (Darzentas and Stamatopoulos 2013). Thus, as raised in the context of chronic infection, continuous exposure to specific antigens in a specific microenvironment seems to trigger lymphomagenesis.

Senescence Modifies Tumor Cells and Their Microenvironment

Cellular senescence induces, in response to DNA damage signaling, a permanent growth arrest and resistance to apoptosis. Senescent cells display specific properties, both intrinsically via cell-autonomous pathways and extrinsically via cell-nonautonomous pathways. At the cell-autonomous level, they are characterized by a cessation of proliferation and cell cycle arrest. At the cell-nonautonomous level, they display a specific secretory pattern, including pro-inflammatory cytokines and growth factors, also called SASP (senescence-associated secretory phenotype).

Senescence may be activated in response to telomere shortening either due to replication after a stereotyped number of divisions (replicative senescence) or to DNA damage (premature senescence). Such DNA damages may be due to inappropriate expression of oncogenes, exposure to endogenous or exogenous toxins, or oxidative stress. Thus, senescence acts as a tumor suppressor mechanism and as the first barrier to malignant transformation and proliferation. Senescence is also associated with the induction of quiescence in some tissue compartments, as the hematopoietic system, thus allowing a genome protection by minimizing DNA replication-induced errors and the accumulation of mutations (Rossi et al. 2005). Two major tumor suppressor pathways participate to this phenotype, p53 and p16INK4a-pRB (Campisi 2005), and are frequently dysfunctional in different lymphoma subtypes.

The oncosuppressive properties of senescence are raised by the existence of a high number of senescent cells in preneoplastic lesions (Falandry

et al. 2014b). In Hodgkin lymphoma, the expression of p16INK4a and p21CIP1/WAF is correlated with a better prognosis (Calio et al. 2015).

Nevertheless, senescence also contributes to the aging phenotype and paradoxically to lymphoma development by inducing inflammatory background.

Indeed, senescent cells also display a specific secretion pattern known to have both auto- and paracrine properties and able to impact their microenvironment through an increased expression of secreted proteins including pro-inflammatory cytokines and growth factors (Bavik et al. 2006). This secretion profile, called senescent-associated secretory phenotype (SASP) or senescence-messaging secretome (SMS), was reported in fibroblast and epithelial cells (Coppé et al. 2008). This cell-nonautonomous mechanism induces changes in the neighboring cells with increase proliferation and degenerative defects on non-senescent cells (Liu and Hornsby 2007). All these phenomena play a dual role in oncogenesis by promoting tumor clearance with the activation of innate immunity against cancer cells but also by favoring cancer development and invasiveness of premalignant cells, thanks to this pro-inflammatory phenotype (Coppé et al. 2008; Xue et al. 2007). Finally, the pro-inflammatory phenotype induced by senescence can also provoke an increase in chronic inflammatory diseases and autoimmune disorders, considered as an important risk factor for lymphoma (Zucca et al. 2014; Morton et al. 2014).

Age Induces Defects in the DNA Damage Response Pathway

In response to DNA damage, the repair mechanisms are known to induce errors, with a level depending on the proofreading pathways, and introduce both mutations and epimutations. The increased burden of (epi)mutations in aged tissues favors cellular degeneration and participates to the aging phenotype. Moreover, it may induce uncontrolled cell proliferation and finally both a progressive decline in organ function and an increased cancer risk (Campisi 2003). For example, many progeroid syndromes such as ataxia-telangiectasia, Werner syndrome (Cheng et al. 2008), Hutchinson-Gilford progeria syndrome, and restrictive dermopathy (Pereira et al. 2008) have defective DDR and genomic instability and induce a premature aging phenotype and an increased frequency of cancer and lymphoma.

During B-cell commitment, the mutational load is heavy. Lymphomagenesis is closely related to DDR pathway and more particularly to NHEJ since RAG and AID induce either on- or off-target mutations that induce the activation of DDR pathway. Errors in this DDR may promote the accumulation of genetic abnormalities and/or translocations.

Therefore, age-related decline and dysfunction in DDR participate to the accumulation of genetic abnormalities in B cell and the development of lymphoma.

Age-Related Clonal Restriction

During aging, stem cell capacities for proliferation and differentiation are impaired, eventually leading to defects in the clearance of damaged cells and ultimately to cancer progression. Indeed, two cell extrinsic properties of stem cells participate to the protection against cancer: on one hand, proliferative competition allows the selection of undamaged cells from the global pool of stem cells; on the other hand, damaged clones are inhibited (Bondar and Medzhitov 2010). Aging is associated with both a loss of proliferative competition and an impaired immune clearance of senescent cells (Ju et al. 2007; Wang et al. 2014b; Janzen et al. 2006). The accumulation of DNA damage restricts the stem cell pool, thus contributing to the enhanced selection of premalignant clones (Porter et al. 2011).

According to Issa's model of aging, epigenome effects on stem cell function (Issa 2014), toxic exposures, environment, and chronic inflammation can favor stochastic errors in DNA methylation that play a key role in the progressive restriction of the HSC pool, resulting in a growth advantage of some stem cell and exhaustion of others. This stem cell pool restriction may favor

both clonal proliferation/expansion of premalignant clones and exhaustion of normal differentiated cells. Finally, HSC-bearing mutations will be selected, and their clonal advantage will contribute to lymphoma development.

Thus, in HSC, the systematic elimination of defective germinal cells during aging leads to tissue exhaustion and eventually to loss of proliferative selection and finally to clonal selection.

Considering lymphopoiesis, aging is associated with low-grade inflammatory processes. The chronic stimulation of effector T cells and memory T cells induces both a restriction of repertoire diversity and a progressive expansion of oligoclonal T cells, particularly CD8+, CD27-, CD28-, CD45RA+, and CD57+ (Monnereau et al. 2013). B-cell receptor repertories also dramatically decline with age in parallel with clonal expansion of B cells in vivo.

Specific Entities of Lymphoma in the Elderly

Age-Related Molecular Specificities in DLBCL

Even if DLBCL histological characteristics do not differ significantly between age groups, their molecular abnormalities display age-related specificities. With age, the repartition between the three different prognostic molecular signatures identified in gene expression profiling (GEP) studies – namely, the germinal center (GC), the activated B-cell (ABC) lymphoma, and the mediastinal large B-cell lymphoma (MLBDL) – is changing (Rosenwald et al. 2002). The MLBCL, which has a profile similar to Hodgkin lymphoma (Savage et al. 2003), is mostly seen in younger patients; patients developing GC-DLBCL are 8 years younger than patients developing ABC-DLBCL (Mareschal et al. 2011). Elderly patients present more frequently unfavorable genetic features (Klapper et al. 2012): more frequent ABC-DLBCL subtype, BCL2 expression, and an increased genomic complexity. The relationship between age and genetic complexity appears more as a continuum corresponding to the "age evolution model" concept: whatever being their molecular subtype, older patients' lymphomas bear a higher mutation load, related to the stochastic risk of acquiring genetic aberrations with age. A logistic regression analysis revealed a significant association between increasing age and some molecular characteristics: the ABC signature; the BCL2 protein expression; the absence of IRF4 translocations; gains in 1q21, 18q21, 7p22, and 7q21; as well as changes in 3q27 including abnormalities affecting the BCL6 locus. In this cohort, ABC subtype, BLC2 expression, and age were independent prognostic markers. In contrast and after adjustment on age, other genetic markers associated with age such as IRF4 break; 1q21+, 18q21+, 7p22+, 7q21+, and 3q aberrations; or genetic complexity lost their significant prognostic impact. Interestingly, a ATMKO.CD3εKO mouse model reconstituted the phenotypic characteristics of ABC-DLBCL, leading to the hypothesis that ATM pathway defects could participate to these aggressive lymphomas.

EBV DLBCL of the Elderly

In 2008, an additional entity was included in the WHO classification of tumors of hematopoietic and lymphoid tissue: "EBV-positive DLBCL of the elderly" is defined as an EBV-positive clonal B-cell proliferation in a patient older than 50 years and in the absence of any other primary or secondary immune disease. Except these characteristics, no single morphological or phenotypical feature was identified to distinguish them from other lymphoproliferations (Balague Ponz et al. 2009; Oyama et al. 2003; Park et al. 2007; Oyama et al. 2007). The spectrum of EBV+ B-lymphoproliferative disease is wide, from simple reactive hyperplasia and nodal and extra-nodal polymorphic lymphoproliferative diseases to real DLBCL. Most EBV+ DLBCL cases have a post-GC phenotype, an aggressive evolution with poor OS, on the contrary to classical Hodgkin lymphoma also encountered in the elderly (Asano et al. 2009). The postulated pathogenic mechanism

implicates immunosenescence and the reduction in T-cell repertoire that may contribute to decreased immune surveillance (Dojcinov et al. 2011). The GEP of EBV+ versus EBV- DLBCL of the elderly have been compared (Kato et al. 2014), and the prominent gene characteristic of EBV+ DLBCL included inflammation and inflammatory-related genes, particularly the activation of Janus kinase-signal transducer and activator of transcription (JAK-STAT) and NF-kB pathway activation. This activation seems to be based on the EBV+ tumor cells and not on the inflammatory background (Montes-Moreno et al. 2012).

Lymphoma, Senescence, and Therapeutic Options

Future therapeutic targets may include senescence pathway modulation. Cumulative data favor the use of immunomodulation in lymphoma. Lenalidomide therapeutic effect acts through the antilymphoma T-cell response. Therapeutic immunomodulation of the T-cell response can also be achieved by inhibition of the PD-1/PD-L1/2 receptor/ligand axis or the KIR-HLA matched inhibitory axis in NK cells.

Therapy-induced senescence (TIS), known to be a major contributor during antilymphoma treatment, illustrates how premature senescence can have anticancer properties. However and as aforementioned, senescent cells may also promote cancer proliferation and invasion. Consequently, the elimination of the senescent cells should be integrated in future therapeutic strategies. Based on this rationale, Dörr (Dörr et al. 2013) developed a mouse lymphoma model exploiting senescence-related metabolic reprogramming. This model is more sensitive to blocking glucose utilization or autophagy that induces a caspase-mediated apoptosis also called senescence-induced hypercatabolic targeting or synthetic lethal metabolic targeting.

Finally, telomerase represents another pathway for future therapeutic interventions: gene expression differs between normal cells and lymphoma cells, suggesting that targeting telomerase could be envisioned with manageable side effects. This possibility is in development in solid tumors (Harley 2008).

Conclusion

Accumulating time has a major impact on the hematopoietic lineage, explaining the very complex interplay between age and lymphomagenesis. It favors the accumulation of mutations and epimutations, related both to the high proliferative turnover of these cells and also to their high sensitivity to exogenous as well as endogenous mutational events, related to BCR and TCR processing. It induces the accumulation of senescent cells, both through replicative and premature senescence. It favors, during time, clonal restriction, leading both to tissue exhaustion and an immunologic dysfunction and eventually to the selection of pre-tumoral clones. It favors the accumulation of memory B and T cells, contributing to the immunosenescence and to the inflammaging phenotypes, both contributing to chronic infection and inflammation. These pathways contribute to an increased incidence of lymphoproliferative disorders in the elderly, with specific genetic characteristics. They are also good candidates for the development of future therapies.

Aging of Natural Killer Cells in Acute Myeloid Leukemia

11

Beatriz Sanchez-Correa, Rafael Solana, and Raquel Tarazona

Contents

Abstract

Aging is associated with changes in the immune system involving both adaptive and innate immunity. Immunosenescence refers to the deterioration of the immune system function associated with aging. Natural killer (NK) cells are innate lymphoid cells specialized in killing tumor cells as well as virus-infected cells without the requirement of prior sensitization. NK cells are also involved in regulating immune function as they produce several cytokines and chemokines. NK cell immunosenescence affects the frequency,

phenotype, and subset distribution of human NK cells. A decreased expression of activating receptors is observed in the elderly that may contribute to the decline of NK cell function. It has been proposed that the failure of tumor immunosurveillance may be partly responsible for the age-associated increase in cancer incidence.

Acute myeloid leukemia (AML) is a disease of older adults with a median age at diagnosis usually over 65 years old. NK cells in AML patients show a reduced expression of several activating receptors that impair NK cell function. Low level of expression of activating receptors such as NKp46 has been correlated with disease progression and patient survival.

KIR-HLA class I receptor-ligand mismatch is associated with a graft versus leukemia effect in haploidentical hematopoietic stem cell transplantation supporting the role of NK cells in AML control. Thus, NK cell-based immunotherapy emerges as a novel treatment for AML patients. However, a better understanding of age-associated changes on NK cell phenotype and function is required to delineate adequate therapeutic strategies in older AML patients.

TriKE	Trispecific killer engager
ULBP	UL-16 binding protein

Introduction

Acute myeloid leukemia (AML) is a hematologic disorder usually diagnosed in older adults (Klepin et al. 2014; Thomas 2015; Isidori et al. 2013). Age-associated changes in the immune system, referred to as immunosenescence, are observed in both the adaptive and the innate immune system. Immunosenescence limits the immune response to pathogens or tumor cells. Age induces changes in the frequency, phenotype, and function of different subpopulations of immune cells, including natural killer (NK) cells (Gayoso et al. 2011; Solana et al. 2014). NK cells belong to the family of innate lymphoid cells (ILC). ILC contribute to tissue repair, lymphoid homeostasis, and defense against infections. NK cell are cytotoxic ILC specialized in monitoring cell transformation by virus and tumors and exert different effector functions such as natural cytotoxicity, antibody-dependent cell-mediated cytotoxicity (ADCC), and cytokine production (Vacca et al. 2016).

AML patients frequently show changes in the phenotype and function of NK cells that compromise NK cell recognition and killing of leukemic blasts. These alterations are even more important in elderly AML patients because of age-associated immunosenescence (Sanchez-Correa et al. 2011, 2012).

Recently, immunotherapy is showing remarkable potential against cancer. NK cell-based immunotherapy is becoming a promising approach for the treatment of AML patients. Adoptive therapy using autologous or allogeneic NK cells expanded in vitro and checkpoint blockade of inhibitory receptors together with the use of agonist antibodies to stimulate activating receptors or NK cells engagers binding an activating receptor and a tumor antigen are emerging areas of research for the design of new therapeutic strategies based on NK cells (Shin and Ribas 2015; Chester et al. 2015; Borrego et al. 2016). In this context, a better understanding of the effect of age on NK cell function is necessary to improve the efficiency of NK cell-based immunotherapy in older AML patients (Tarazona et al. 2017; Sanchez-Correa et al. 2016).

Natural Killer Cells

NK cells are derived from a lymphocyte progenitor and represent a prototypical member of the ILC family. NK cells are included into group 1 of ILC family together with ILC1 (Spits et al. 2016). NK cells display cytotoxic capacity as well as regulatory functions by cytokine production. Traditionally, human NK cells are defined as lymphocytes that lack CD3 and express CD56 and/or CD16. Different NK cell subsets can be distinguished on the basis of CD56 and CD16 expression. In peripheral blood, a low percentage (≈10%) of NK cells are $CD56^{bright}CD16^{-}$ representing a more immature NK cell subset in comparison with the major $CD56^{dim}CD16^{+}$ NK cell subset (≈90%). NK cell subsets display different effector functions, thus, $CD56^{bright}$ NK cells have mainly an immunoregulatory role mediated by the secretion of cytokines, whereas $CD56^{dim}$ counterpart are cytotoxic cells (Moretta et al. 2014). An additional minor subset correspond to $CD56^{-}CD16^{+}$ NK cells, this subset was initially described in HIV-1 infected patients (Tarazona et al. 2002; Mavilio et al. 2005), hepatitis virus infection (Gonzalez et al. 2009), and to some extent in healthy individuals (Campos et al. 2014b).

NK cells monitor cell surfaces of autologous cells for an altered expression of major histocompatibility complex (MHC) class I molecules and stress markers. NK cell-mediated cytotoxicity is controlled by a repertoire of inhibitory and activating receptors expressed on their surface (Fig. 1a). MHC class I-specific receptors are the major inhibitory receptors acting as sensors of healthy cells since tumor transformation and viral infection frequently lead to diminished expression of MHC class I molecules. NK cell activation requires signaling through activating receptors whose ligands are frequently expressed on tumor and viral infected cells (Waldhauer and Steinle 2008).

MHC Class I-Specific Receptors

Killer immunoglobulin-like receptors (KIR) are type I transmembrane glycoproteins belonging to the Ig superfamily with two or three Ig-like domains. KIR include both inhibitory and activating receptors. Inhibitory KIR have long cytoplasmic domains containing immunoreceptor tyrosine-based inhibitory motifs (ITIM) that recruit protein tyrosine phosphatases required for mediating inhibitory function. In contrast, activating KIR have a short cytoplasmic tail and associate to the adaptor protein DAP-12 that contains immunoreceptor tyrosine-based activation motifs (ITAM). KIR binds human leukocyte antigen (HLA)-A, -B, and -C molecules which are expressed on almost all healthy nucleated cells and protect them from NK cell attack (Campbell and Purdy 2011; Thielens et al. 2012).

The CD94/NKG2 C-type lectin-like receptors family is composed by different NKG2 members that form disulfide-linked heterodimers with an invariant CD94 chain. Several members have been described with either inhibitory (CD94/

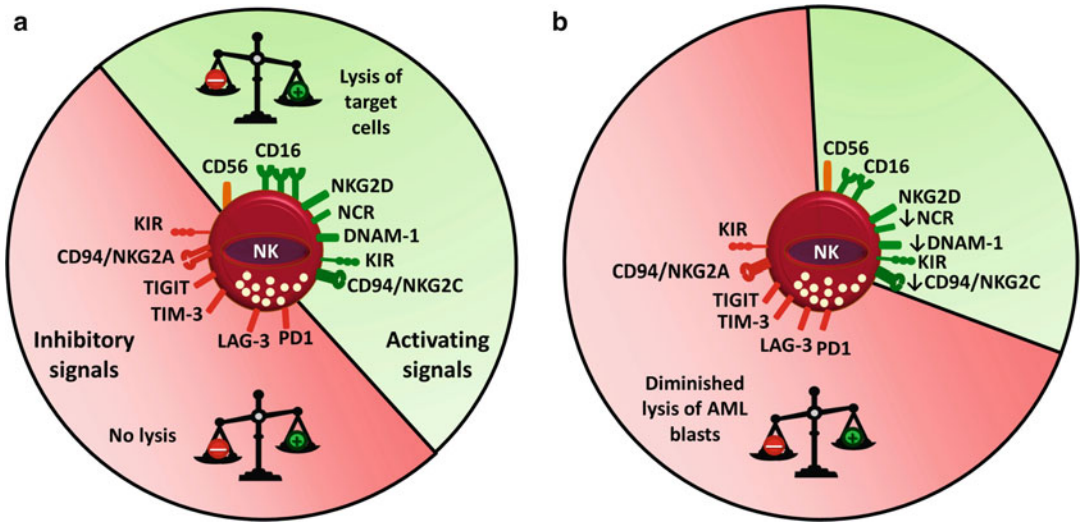

Fig. 1 Human NK cell receptors in healthy and AML patients. (**a**) NK cell activation against target cells is regulated by the balance of signals mediated by an ample set of inhibitory or activating surface receptors. NK cell receptors interact with their ligands on target cells and signal NK cells to preserve healthy cells (shift the balance to inhibition) or attack cells undergoing tumor or virus transformation (shift the balance to activation). (**b**) A reduced expression of several NK cell activating receptors has been observed in AML patients shifting the balance to inhibition and contributing to leukemic blast escape from NK cells

NKG2A, CD94/NKG2B) or activating (CD94/NKG2C, CD94/NKG2E) function. These receptors are expressed on NK cells and in a subset of T cells. CD94/NKG2 receptors recognize as ligands the nonclassical HLA class I molecule HLA-E in humans and Qa-1b in mice (Borrego et al. 2006).

Non-MHC Class I-Specific Inhibitory Receptors

Several receptors recognizing ligands other than MHC class I molecules have been described to play a relevant role in NK cell activation and consequently represent novel immune checkpoints for cancer immunotherapy. TIGIT (T-cell immunoreceptor with Ig and ITIM domains) acts as an inhibitory receptor on T and NK cells. TIGIT binds nectin and nectin-like molecules CD112, CD113, and CD155 (PVR).

The role of CD155 expression on cancer immunosurveillance has been well characterized since it binds different receptors with opposite functions (Martinet and Smyth 2015). CD155 is also a ligand for CD96 (TACTILE) a receptor expressed on human T cells, NK cells, and a subset of B cells. CD96 is also found highly expressed in AML, T-cell acute lymphoblastic leukemia (T-ALL), and myelodysplastic syndromes (Blake et al. 2016a). Human but not mouse CD96 contains within the cytoplasmic tail an YXXM motif similar to that found in activating receptors (Meyer et al. 2009). In addition, both human and mouse CD96 contains cytoplasmic ITIM-like motifs that may be involved in inhibitory signaling after receptor engagement (Martinet and Smyth 2015). It has been described that human CD96 interacts with CD155 on target cells promoting cell adhesion (Fuchs et al. 2004). In contrast, $CD96^{-/-}$ mice showed resistance to lung metastases and fibrosarcoma induction suggesting that CD96 may act as an inhibitory receptor. In this model, antibody blocking of CD96 showed a reduction of lung metastases further supporting its inhibitory function (Chan et al. 2014). In murine tumor models, anti-CD96 blockade demonstrated to be more effective when combined with anti-CTLA4 or anti-programmed death protein 1 (PD-1) (Blake et al. 2016b).

The inhibitory receptor PD-1 represents a key checkpoint in T-cell activation, and recently its role in NK cell activation has been highlighted. PD-1 mediates functional exhaustion of both T cells and NK cells. PD-1 ligand 1 (PD-L1) is expressed in lymphoid and nonlymphoid cells as well as in tumors. Thus, control of the PD-1 pathway may circumvent tumor escape not only from T cells but also from NK cells (Benson et al. 2010).

Lymphocyte activating gene 3 (Lag-3 or CD223) is an inhibitory receptor expressed on activated NK cells and T cells. Lag-3 structure resembles that of CD4 coreceptor and binds to MHC class II molecules and LSECtin, a member of the DC-SIGN family of molecules (Triebel et al. 1990; Xu et al. 2014; Anderson et al. 2016). Lag-3 associates with CD3/T-cell receptor (TcR) complex suppressing T-cell activation (Hannier et al. 1998). Lag-3 is considered a novel immune checkpoint molecule to activate anti-tumor T cells (Perez-Gracia et al. 2014). In addition, Lag-3 and PD-1 act synergistically regulating T-cell function (Okazaki et al. 2011). Further studies will be needed to understand the involvement of Lag-3 on NK cell activation.

T-cell immunoglobulin and mucin domain 3 (Tim-3) is expressed on all mature $CD56^{dim}$ NK cells and is induced by cytokines on $CD56^{bright}$ NK cells (Gleason et al. 2012; Ndhlovu et al. 2012). Tim-3 interaction with its known ligand Galectin-9 (Gal-9) has shown to mediate both inhibitory and activating signals. Thus, in healthy individuals Tim-3 engagement with its ligand Gal-9 triggers interferon (IFN)-γ secretion acting as a costimulatory receptor (Gleason et al. 2012), whereas in advanced melanoma Tim-3 blockade reversed NK cell exhaustion and improves NK cell function ex vivo (Da Silva et al. 2014). Cross-linking of Tim-3 with antibodies also suppressed NK cell-mediated cytotoxicity (Ndhlovu et al. 2012) suggesting that Tim-3 regulation of NK cell function depends on the context in which NK cell activation occurs. In addition to Gal-9, other ligands have been identified for Tim-3 including phosphatidyl serine, high mobility group protein B1 (HMGB1) and Ceacam-1 (Anderson et al. 2016). Tim-3 has been also shown to be expressed on leukemic stem cells on all types of AML by French-American-British (FAB) classification with the exception of acute promyelocytic leukemia (M3). Thus, Tim-3/Gal-9 represents an important autocrine loop promoting leukemia progression that may become a target for treating AML (Kikushige et al. 2015).

Activating Receptors

Activating NK cell receptors belong to different families including MHC class I-specific activating KIR and CD94/NKG2C. Among the activating receptors CD16, a low-affinity receptor for the Fc portion of immunoglobulin G plays an important role in ADCC. Upon recognition of antibody coated target cells, CD16 signaling activates NK cells to release their cytotoxic granules containing perforin and granzymes. Other activating receptors recognize stress-related ligands on tumor and virus-infected cells. Thus, NKG2D is a member of the NKG2 C-type lectin-like receptors. NKG2D is expressed on NK cells, $CD8^+$ and subsets of $CD4^+$ T cells, NKT cells, and γδ T cells. NKG2D forms homodimers and associates with DAP10 adaptor protein in humans, whereas in mice associates with DAP10 or DAP12. This receptor recognizes a large repertoire of ligands encoded by several genes, some of them polymorphic. In humans, NKG2D ligands are the major histocompatibility complex class I-related chain A and B (MICA and MICB) and the UL-16 binding proteins (ULBP, also known as RAET1, retinoic acid early transcript 1) with six functional proteins described so far. In general, NKG2D ligand induction is attributed to cellular stress and ligands are usually not expressed on healthy cells. The expression of one or more NKG2D ligands is observed in cancer cells and virus-infected cells. NKG2D ligand expression regulation is a complex process involving transcriptional, post-transcriptional, and post-translational mechanisms (Lanier 2015).

Natural cytotoxicity receptors (NCRs) were identified as major activating receptors eliciting cytotoxicity and cytokine production by NK cells. Three members of this family of receptors have

been described named NKp46 and NKp30 that are constitutively expressed by NK cells and NKp44 that is induced after activation. Although originally NCRs were thought to be NK cell specific receptors, different studies have demonstrated that NCRs can also be expressed on other innate lymphoid cells as well as in some T-cell subsets (Hudspeth et al. 2013). The identity of NCR ligands remains in part elusive. NCRs recognize pathogen-associated molecules as well as stress-related molecules on cell surface. Hemagglutinin (HA) protein from influenza and vaccinia virus is recognized by NKp46 and Sendai and Newcastle virus can be recognized by NKp46 and NKp44 (Mandelboim et al. 2001). NCRs also recognize intracellular bacteria and parasites (Mavoungou et al. 2007). Other NKp44 ligands include heparan sulfate and the cellular ligands mixed lineage leukemia 5 (MLL5). The proliferating cell nuclear antigen (PCNA) has been described as an inhibitory ligand for NKp44 (Horton and Mathew 2015). The human leukocyte antigen-B-associated transcript 3 (BAT3) was identified to interact with NKp30 triggering tumor lysis and cytokine release by NK cells (Pogge et al. 2007). B7-H6, a member of the B7 family of receptors, was also identified as a ligand for NKp30 (Brandt et al. 2009).

Physiologically relevant splice variants of NKp30 and NKp44 have been recognized (Siewiera et al. 2015). Whereas NKp30a and NKp30b engagement triggers NK cell activation, signaling through NKp30c isoform inhibits NK cell function. HA and pp65 a component of human cytomegalovirus (CMV) can inhibit NK cell function by binding to NKp30c (Arnon et al. 2005; Pende et al. 1999). Splice variants of NKp44 are associated with survival in AML patients (Shemesh et al. 2016). Cytokines in the local microenvironment may regulate alternative splicing of the NCRs (Siewiera et al. 2015).

DNAX accessory molecule 1 (DNAM-1), also known as CD226, was initially described as an adhesion molecule promoting cytotoxicity by $CD8^+$ T and NK cells. Further studies on DNAM-1 function demonstrated its function as an activating receptor. DNAM-1 ligands are the poliovirus receptor (CD155) and nectin-2 (CD112) that are associated with DNA damage-induced conditions such as oncogenic transformation or viral infections. CD155 expression is also observed in T cells after antigen-induced proliferation (de Andrade et al. 2014). AML blasts express DNAM-1 ligands CD112 and CD155 (Sanchez-Correa et al. 2012; Sanchez-Correa et al. 2011). It is of interest to note that CD155 binding to the receptors TIGIT and CD96 may counterbalance DNAM-1-mediated NK cell activation (Martinet and Smyth 2015).

Cancer, Aging, and Immunosenescence

Age is considered a risk factor included in almost all studies of cancer epidemiology. Cancer can be considered an age-related disease as the incidence of most cancers increases with age (White et al. 2014). It is estimated that the incidence of cancer would undergo an increasing trend in the future because of the increment of life expectancy around the world.

The age-associated deterioration of the immune system known as immunosenescence can be, at least in part, responsible of the higher incidence of several types of cancer in the elderly. Immunosenescence negatively affects both adaptive and innate immune responses reducing tumor immunosurveillance in the elderly (Fulop et al. 2013; Derhovanessian et al. 2008). On the other hand, a decline in the immune response has been described in cancer patients that mirror, at least in part, those changes observed in healthy elderly individuals (Sanchez-Correa et al. 2011, 2016; Poschke et al. 2012; Tarazona et al. 2017). This process termed "early immunosenescence" or "cancer-induced immunosenescence" can be detected as early as the onset of tumorigenesis limiting immunotherapy efficacy (Poschke et al. 2012).

Many factors contribute to immunosenescence including exposure to chronic pathogens throughout life. Latent infection by CMV constitutes a major driving force of T-cell immunosenescence. CMV can also induce changes on NK cells in young, middle-aged, and old individuals (Campos et al. 2014b, 2015). CMV infection associates

with inflammation, frailty, and mortality in the elderly (Pawelec et al. 2012) and lower responses to influenza vaccination and higher risk of influenza complications (Frasca et al. 2015). In contrast, in young individuals CMV-seropositivity associates with increased multifunctionality of $CD8^+$ T lymphocytes in response to Staphylococcal enterotoxin B (SEB) (Pera et al. 2014) and improved response to influenza vaccination (Furman et al. 2015). The determination of CMV serostatus should be considered in all studies addressed to analyze the immune system, in particular in those clinical situations in which a high percentage of patients are elderly.

NK Cells and Aging

The phenotype and function of NK cells is altered in the elderly (Campos et al. 2014b, 2015). Human NK cell immunosenescence is characterized by a redistribution of NK cell subsets showing a reduction of immature $CD56^{bright}$ NK cells and the accumulation of $CD56^{dim}$ NK cells (Gayoso et al. 2011; Solana et al. 2014).

It has been proposed a dynamic turnover model for NK cell subsets. $CD56^{bright}$ NK cells are more immature and proliferate and differentiate into $CD56^{dim}$ NK cells (Lutz et al. 2011). In the elderly, there is a decreased input of new $CD56^{bright}$ NK cells that is compensated by an increased proportion of $CD56^{dim}$ and $CD56^-CD16^+$ cells that may represent long-lived NK cells (Lutz et al. 2011; Campos et al. 2014a, b; Solana et al. 2014). The role of intrinsic factors such as cytokines (IL-15) and extrinsic factors, such as CMV, in the generation of long-lived, memory-like, NK cells has been suggested (Lopez-Verges et al. 2011, 2014). The analysis of NK cells according to age and CMV seropositivity has shown that aging affects the percentage and subsets of NK cells (Campos et al. 2014b, 2015; Solana et al. 2014).

NK cell function is also altered in the elderly; a reduced per-cell cytotoxicity is observed that is associated with a decreased expression of activating NK cell receptors (Gayoso et al. 2011; Campos et al. 2014b, 2015; Solana et al. 2014). The expression of NKp30, NKp46, and DNAM-1 activating receptors on NK cells is diminished in elderly healthy donors (Campos et al. 2014b, 2015). In contrast, the expression of NKG2D and CD244 (2B4) is preserved in the elderly (Mariani and Facchini 2003; Gayoso et al. 2009) as well as the expression of the Fc receptor CD16 and ADCC function (Solana and Mariani 2000; Lutz et al. 2005). An increased expression of CD57 and NKG2C on NK cells is associated with CMV serostatus (Campos et al. 2014b, 2015; Lopez-Botet et al. 2014). CMV seropositive young donors had a reduced expression of NKp30 compared to CMV seronegative young donors, whereas CMV seropositivity does not alter the expression of DNAM-1 and NKp46 on NK cells (Campos et al. 2014b, 2015).

NK Cell Receptors and Their Ligands in Patients with Solid Tumors

As summarized above, NK cells constitute the major component of the innate immune response involved in the recognition and elimination of cancer cells. It is generally accepted that evasion from immunosurveillance is one of the hallmarks of cancer (Hanahan and Weinberg 2011), and it has been demonstrated that tumor cells use different strategies to avoid NK cell recognition and lysis. Thus the increased expression of inhibitory receptors on NK cells or their ligands on the tumor cells has been demonstrated in patients with different solid tumors such as nasopharyngeal carcinoma (Butsch et al. 2005), neuroblastoma (Keating et al. 2015), or lung cancer (Al Omar et al. 2011). The interaction of NK cell-activating receptors with their ligands on tumor cells from different lineages is required for NK cell-mediated cytotoxicity (Casado et al. 2009; Morgado et al. 2011; Garcia-Cuesta et al. 2015; Boerman et al. 2015; Shiraishi et al. 2016). As a mechanism to escape NK cell immunosurveillance, NK cells from patients with solid tumors frequently show a decreased expression of activating receptors such as NKG2D, NCRs, or DNAM-1 (Shiraishi et al. 2016; Al Omar et al. 2011). In addition, the ligands for these NK cell-activating receptors can

be expressed by tumor cells, but they can be released from the tumor cell surface. These released isoforms can interact with the activating receptor leading to altered function. It has been found that the serum levels of the NKG2D ligand ULBP-2 inversely correlate with the survival of melanoma patients (Paschen et al. 2009). In a similar way, a soluble form of B7-H6, the NKp30 ligand, can be detected in neuroblastoma patient sera. In these patients, elevated serum levels of B7-H6 inhibited NK functions in vitro and correlated with downregulation of NK-p30 on NK cells, as well as with bad prognosis after treatment due to bone marrow metastasis and chemoresistance (Semeraro et al. 2015a, b). Taken together these results support the relevance of the interactions between NK cell-activating receptors and their ligands in cancer immunosurveillance.

NK Cells in AML Patients

NK cells from AML patients had impaired effector functions showing reduced NK cell degranulation, TNF-α, and IFN-γ production against autologous blasts and K562 cells (Stringaris et al. 2014). The analysis of NK cell-activating receptors in AML patients has demonstrated a decreased expression of several activating receptors (Fig. 1b). The expression of NKp46 and NKp30 is diminished in AML patients compared to age-matched healthy donors and may be related to patient outcome (Fauriat et al. 2007; Sanchez-Correa et al. 2011, 2012). Thus, preserved expression of NKp46 was correlated with survival of AML patients (Fauriat et al. 2007). DNAM-1 expression is also diminished in AML patients and CD112 expression on blasts inversely correlates with DNAM-1 expression on NK (Sanchez-Correa et al. 2011, 2012). It has been suggested that chronic exposure to ligands on tumor cells is responsible of the decreased expression of NCR and DNAM-1 in AML patients (Fauriat et al. 2007; Sanchez-Correa et al. 2011, 2012).

Paired receptor-ligand interactions between DNAM-1, TIGIT, and CD96 receptors sharing the same ligands are relevant in the context of tumor immunity (Martinet and Smyth 2015). In AML patients, the axis DNAM-1/TIGIT/CD96/CD155 shifts the balance to inhibition over activation due to the reduced expression of DNAM-1.

A lower expression of CD94/NKG2C and CD16 is also observed in AML patients compared to age-matched healthy donor. In contrast, the expression of the activating receptor NKG2D is conserved on NK cells from AML patients (Sanchez-Correa et al. 2011). However, a limitation for NKG2D-mediated activation of NK cells in AML patients is the lower expression of NKG2D ligands on AML blasts compared to solid tumors such as melanoma (Sanchez-Correa et al. 2011; Casado et al. 2009).

NK Cells in Elderly AML Patients

Elderly AML patients have a poor prognosis due, among others, to higher incidence of drug toxicity, overexpression of genes associated with drug resistance, higher frequency of poor risk cytogenetic abnormalities, and comorbidities. Age itself constitutes an independent prognostic factor for AML (De Kouchkovsky and Abdul-Hay 2016; Heiblig et al. 2017). Recent advances in the treatment of AML have led to significant improvements in outcomes for younger patients. However, the prognosis in the elderly AML patients is poor, and treatment options remain limited for the majority of older patients (Appelbaum et al. 2006).

The study of NK cells in AML patients according to age showed a decreased expression of NKp46 in elderly AML patients compared to healthy elderly donors suggesting that both age and AML may contribute to the diminished expression of activating receptors on NK cells (Sanchez-Correa et al. 2012). Due to the high prevalence of CMV in the elderly, CMV-related changes on NK cells can also facilitate leukemic blast escape. Thus, it has been proposed that chronic antigenic stimulation by CMV and tumors is additive leading to immune exhaustion reducing adaptive immune responses to new antigens and also diminishing immunological memory (Fulop et al. 2013). On the other hand, the

deleterious participation of CMV infection in tumor immunosurveillance is supported by the finding of CMV-induced downregulation of both MHC class I and class II molecules on infected cells limiting adaptive immune responses. In addition, CMV blocking of MICB and ULBP1/2 expression on cell surface avoids NKG2D-mediated activation of NK cells and costimulatory signals for T cells. In addition, tumor growth factor (TGF)-β1 secreted by CMV-infected cells also promotes immunosuppression in the tumor microenvironment (Michaelis et al. 2009). The question of how the effect of aging, CMV, and cancer is cumulative requires further analysis.

Because many AML patients are elderly at diagnosis, immunosenescence may impair NK cell function and allow AML blast escape from NK cell-mediated immunosurveillance restraining the exit of NK cell-based immunotherapies (Sanchez-Correa et al. 2016; Tarazona et al. 2017).

NK Cell-Based Immunotherapy in AML Patients

The discovery of NK cell spontaneous cytotoxicity, originally demonstrated in vitro against leukemia cell lines, together with the clinical benefits observed in KIR-ligand mismatched allogeneic stem cell transplantation support the pivotal role of NK cells against leukemia and consequently their exploitation in immunotherapies. Evidence for graft-versus-leukemia (GVL) effect mediated by NK cells was observed in both murine models and in clinical studies with haploidentical donor transplants where the presence of alloreactivity was correlated with higher survival rates (Ruggeri et al. 2002). KIR-ligand mismatch was demonstrated to be responsible for the GVL effect mediated by NK cells. Interestingly, NK cells do not induce graft versus host disease (GVHD) and also can decrease GVHD mediated by T cells by targeting recipient's antigen presenting cells. As a result, NK cells exert their cytotoxicity preserving healthy cells, and in contrast to T cells, tumor control can be achieved in the absence of GVHD (Rezvani and Rouce 2015).

Recent advances on the integration of NK cell activating and inhibitory signals highlight that NK cell-based immunotherapies are feasible for the treatment of cancer. NK cell-based immunotherapy includes adoptive immunotherapy with ex vivo-expanded NK cells or NK cell lines such as NK-92. A major limitation for adoptive NK cell immunotherapy is the failure of transferred NK cells to persist and expand in vivo. Thus, NK cell engineering to express chimeric antigen receptor (CAR) has shown great promise in preclinical settings. CAR-engineered NK cells are advantageous compared to CAR-engineered T cells due to their shorter life span that may diminish side effects. In addition, strategies directed to increase ADCC, modulate activating receptor expression and redirect NK cytotoxicity toward tumor cells by using recombinant antibody constructs also constitute new approaches to control cancer (Rezvani and Rouce 2015). The use of bispecific or trispecific killer engagers (BiKE and TriKE respectively) containing single-chain variable fragments directed to CD16 to trigger NK cells, anti-CD33 to bind leukemia blasts, and in the case of TriKE a modified IL-15 crosslinker have shown to induce NK cell-mediated killing of blasts and to promote survival and in vivo expansion of NK cells in a xenograft murine model of AML (Vallera et al. 2016). Finally, checkpoint blockade constitutes a novel alternative for NK cell-mediated therapies against tumors (Tarazona et al. 2017; Carotta 2016; Blake et al. 2016b).

During the last decade, a valuable number of NK cell-based clinical trials for leukemia have been developed (Table 1). However, the inclusion of elderly AML patients in clinical trials is very limited. NK cell transfer is feasible and safe and its effect can be improved by selection of optimal donors, ex vivo or in vivo stimulation of infused NK cells by cytokines, use of antibodies to induce ADCC, checkpoint blockade by antibodies directed to inhibitory receptors such as KIR, and by the use of CAR-engineered NK cells (Handgretinger et al. 2016). Monitoring NK cells in AML patients, in particular in elderly patients, is important in order to stratify patients at diagnosis and to evaluate NK cell status after standard chemotherapy and immunotherapies.

Table 1 NK cell-based clinical trials for leukemia

Category	Strategy	Start date-completion	Conditions	Phase	Age	Identifier/ references
Autologous NK cells	Autologous NK cells & Bortezomib	2008–2018	Hematological malignancies (MM, CML, CLL and SLL) and solid tumors	1	18–70	NCT00720785
Allogeneic NK cells	Haploidentical NK cells	2004	Refractory AML and solid tumors	1		(Miller et al. 2005)
	Haploidentical KIR-ligand mismatched NK cells	2005–2009	AML	1	>18	NCT00799799 (Curti et al. 2011)
	Haploidentical KIR-ligand mismatched NK cells	2006–2014	AML and MDS	1	≤70	NCT00402558 (Lee et al. 2016)
	Haploidentical NK cells & aldesleukin post HSCT	2005–2011	High risk AML	1/2	18–70	NCT00303667
	Haploidentical NK cells post HSCT	2007–2015	Hematologic malignancies	2	≤120	NCT00526292
	NK cells post HSCT	2008–2017	Hematologic malignancies	1/2	All	NCT00789776
	NK cells post HSCT	2009–2013	Advanced cancer (solid and hematologic)	1/2	15–75	NCT00823524
	Haploidentical NK cells & TcRαβ-depleted cells from the same donor	2011–2019	High risk AML and MDS	2	18–75	NCT01370213
	Haploidentical NK cells expanded by K562mb15-41BBL	2014–2018	Acute leukemia and MDS	1	6–80	NCT02123836
	Haploidentical NK cells & IL-15	2015–2019	Relapsed/refractory AML	2	>18	NCT02395822
	UCB NK cells (PNK-007) & IL-2	2016–2019	Relapsed/refractory AML	1	18–70	NCT02781467
	UCB NK cells post UCB transplant in C2C2 patients	2016–2020	Hematologic malignancies	2	18–80	NCT02727803
	non-HLA matched NK cells & ALT803	2016–2019	Hematologic malignancies and other tumors	1	>18	NCT02890758
	Haploidentical NK cells & IL-2	2015–2020	High risk Elderly AML	2	≥60	NCT02229266
	Haploidentical NK cells & ALT803	2017–2020	Relapsed/refractory AML	2	18–70	NCT03050216
	CNDO-109 (CTV-1 leukemia cell lysate)-activated haploidentical NK	2012–2016	AML in CR1	1/2	>18	NCT01520558
	Haploidentical NK cells	2010–2012	Relapsed/refractory AML	2	>2	NCT01106950 (Bachanova et al. 2014)

(*continued*)

Table 1 (continued)

Category	Strategy	Start date-completion	Conditions	Phase	Age	Identifier/ references
	Cytokine induced memory-like haploidentical NK cells	2014–2020	AML and MDS	1	>18	NCT01898793
	Cytokine induced memory-like NK cells post HSCT	2017–2022	Refractory AML	2	>18	NCT02782546
NK cell line	NK92 cells	2005–2012	Hematologic malignancies	1	>18	NCT00990717
	Neukoplast™ (NK92)	2014–2016	Relapsed/refractory AML	1	>18	NCT00900809
CAR-NK	(α-CD7-CAR-NK92)	2016–2018	Hematologic malignancies	1/2	>18	NCT02742727
	α-CD33 CAR-NK92 cells	2016–2018	Relapsed/refractory AML	1/2	3–80	NCT02944162

Checkpoint blockade	α-KIR (IPH2101)	2007–2013	Elderly AML in CR	1	60–80	NCT01256073
	α-KIR (IPH2102)	2012–2016	Elderly AML in CR	2	60–80	NCT01687387
	α-KIR (IPH2102, lirilumab) & Rituximab	2015–2021	Relapsed/refractory or high risk leukemia (CLL, SLL)	2	>18	NCT02481297
	α-NKG2A (IPH2201, monalizumab) & ibrutinib	2015–2019	Relapsed/refractory CLL	1/2	>18	NCT02557516

AML Acute myeloid leukemia, *CLL* chronic lymphocytic leukemia, *CML* chronic myelogenous leukemia, *CR* complete remission, *MM* multiple myeloma, *MSD* myelodysplastic syndromes, *SLL* small lymphocytic lymphoma, *UCB* umbilical cord blood

NK cells from elderly AML patients in first remission were evaluated in a clinical trial (NCT00540956) to determine the evolution of NK cell receptors after chemotherapy and the kinetics of NK cell recovery of cytotoxic function. The effect of the immunomodulatory drug lenalidomide on NK cells in AML patients was also evaluated in a clinical trial (NCT02525250). In AML patients previously treated with IL-2, the relationship between NK cell cytotoxicity against leukemia cells and the outcome was analyzed (NCT00896701). To our knowledge, results from these clinical trials have not yet been published.

Adoptive transfer of allogeneic NK cells post HSCT or in nontransplant scenarios has demonstrated to be superior to whole lymphocyte infusions (Suck et al. 2016). Infused NK cells can persist and expand in vivo and can be used for the treatment of leukemia (Miller et al. 2005). In a phase I study (Dutch Trial Register NTR2818), the feasibility, safety, and toxicity of the infusion of allogeneic umbilical cord blood NK cells following an immunosuppressive preparative regimen in nontransplant eligible elderly AML patients was evaluated. NK cell transfer was safe and could induce or sustain remission in elderly AML patients.

NK cell alloreactivity was assessed after infusion of KIR-ligand mismatched NK cells. Elderly AML patients, in first complete remission, received haploidentical KIR ligand-mismatched NK cells in combination with IL-2. The results suggested that infusion of high numbers of NK cells was associated with prolonged disease free survival (Curti et al. 2011; Curti et al. 2016).

The use of NK-92 cells transduced with CAR is under study in clinical trials directed at the treatment of hematological malignancies (NCT02742727, NCT02944162, NCT02892695). The NK-92 cell line can be expanded in vitro under good manufacturing conditions highlighting its potential for immunotherapy.

Recently, two clinical trials using anti-KIR in elderly AML patients in complete remission have been performed to analyze the safety and tolerability of IPH2101 (NCT01256073) and the efficacy of IPH2102 as maintenance treatment (NCT01687387). Other inhibitory receptors such as TIGIT, Lag-3, and Tim-3 represent novel checkpoints for both T and NK cell-based immunotherapy.

Conclusions

Immunotherapy represents a promising approach to induce cancer immunity. Recent progress in our understanding of NK cell biology has allowed the development of novel NK cell-based immunotherapies for the treatment of leukemia. Adoptive transfer of autologous or allogeneic ex vivo expanded or NK cells, CAR-engineered NK-92 cells, or checkpoint blockade of inhibitory receptors combined with NK cell engagers are novel areas of research on NK cell-based immunotherapy against cancer.

Nowadays, translational research on NK cells is moving to the forefront of cancer immunotherapy. The detrimental effect of immunosenescence on the clinical success of immunotherapy should be considered. In addition, strategies directed to overcome immunosenescence in cancer patients may constitute a new avenue for future directions in leukemia treatment.

Hematopoietic Stem Cell Aging and Malignant Hemopathies

12

Michele Goodhardt, David Garrick, Luan Dang, Adriano Salaroli, and Dominique Bron

Contents

Abstract

The probability of developing cancer, primarily malignant hemopathies, increases with age. This complex relationship between cancer and aging has been extensively studied; cellular senescence, a protective mechanism in response to DNA damage, can induce permanent growth arrest and resistance to apoptosis. Chronological age also favors the accumulation of genetic and epigenetic changes that are

important contributing factors in the complex pathogenesis of cancer. Indeed recent studies have highlighted the role of epigenetics and, in particular, a decline in heterochromatin integrity as important factors contributing to the loss of stem cell function during HSC aging in premature aging syndromes. Furthermore, impairment of cancer prevention pathways and the clonal restriction of hematopoietic stem cells observed with age may also contribute to the increased frequency of malignant transformation. However, at present our understanding of the process of aging is far from complete, and many open questions are currently under investigation. This chapter will focus on the complex multistep interplay between aging and the higher incidence of malignant hemopathies.

Keywords

Aging · Elderly · Tumor suppressor genes · Malignant hemopathies · Hematopoietic stem cell · Epigenetics · Senescence · DNA damage repair

Introduction

Though not a disease per se, aging is a complex phenomenon that progressively leads to organ dysfunction and represents a major risk factor for chronic diseases and primarily cancers. Cellular senescence is a major contributor to this biological process.

Since adult stem cells are responsible for maintaining tissue homeostasis, an attractive hypothesis is that age-related degenerative changes may be due to an alteration in tissue stem cells, particularly the hematopoietic stem cells (HSCs), with progressive waning of our immune defenses. Concomitant genetic and epigenetic modifications are observed in all malignant hemopathies leading to activation of oncogenes or loss of tumor suppressive genes.

This chapter will thus focus on the accumulation of mutations, epigenetic changes, and age-related clonal hematopoietic cell expansion. These age-related events decrease anticancer immunity and alter the DNA damage response pathway. This complex multistep interplay ultimately favors a higher incidence of cancer in the aging population.

Senescence: A Dual Phenomenon

Cellular senescence is thought to be one of the major molecular processes in biological aging. It serves primarily as a protective mechanism to shut down damaged cells and force them into a state of irreversible growth arrest (Ben-Porath and Weinberg 2004, 2005). Various triggers can induce cellular senescence including telomere erosion, irreversible DNA damage, lysosomal stress, unresolved unfolded protein response (UPR), oncogene activation, or reactive oxygen species (Sharpless and Sherr 2015). The induction of senescence in a damaged cell protects the organism from abnormal cell growth that could lead to cancer, because it prevents the cell from reentering the cell cycle in response to mitogenic or oncogenic stimulation and uncontrolled proliferation and dissemination. Senescence is believed to be an evolutionarily selective mechanism designed to preserve the integrity of a young organism during its reproductive period.

Senescence is induced by the upregulation of several genes, which are primarily CDKN2A (p16/INK4A/ARF), TP53, and RB (retinoblastoma gene). A fourth gene, CDKN1A (p21/WAF1/CIP1) also plays a role in the induction of growth arrest but is a less reliable senescence marker because the growth arrest it induces is more transient (Sharpless and Sherr 2015; Vandenberk et al. 2011). CDKN2A is a complex gene that encodes two distinct proteins, p16INK4a and p14ARF. Their locus has a complex architecture containing two separate promoters that can generate transcripts with distinct first exons followed by common second and third exons. p16INK4a is encoded by exons 1α, 2, and 3. It functions as a cyclin-dependent kinase inhibitor of the cell cycle by inhibiting the activity of the cyclin-dependent kinase complex "cyclinD/CDK4/CDK6" thereby blocking pRB phosphorylation and the passage from G1 into S (Serrano

et al. 1993; Rocco and Sidransky 2001). The alternate reading frame product, p14ARF, is encoded by the second first exon, exon 1β, located upstream from exon 1α together with the same second exon as p16INK4a in a different reading frame (Rocco and Sidransky 2001; Haber 1997). p14ARF functions by preventing p53 degradation, thereby allowing p53-mediated apoptosis or cell cycle arrest.

P53 and related proteins, p63 and p73, are key factors in the DNA damage response (DDR). Members of this family are directly involved in the induction of cell cycle arrest, necessary for cellular repair. Alternatively, they promote cell death when there is prolonged or irreparable DNA damage. They also take part in a direct task by modulating the expression of core factors involved in DNA repair processes or direct interactions with them (Nicolai et al. 2015). TP53, a tumor suppressive gene (TSG) first described 50 years ago, belongs to the group of "gatekeeper" genes typically involved in elimination or arrest of damaged cells.

PTEN is another potential candidate involved in senescence (Ortega-Molina and Serrano 2013). An established tumor suppressor gene, PTEN is often mutated in human tumors (Cantley and Neel 1999). Transgenic mouse models have highlighted its role in the aging process as well (Ortega-Molina et al. 2012; Garcia-Cao et al. 2012). Two mouse models with systemic PTEN overexpression under normal regulatory controls have, in addition to reduced adiposity and metabolic changes, higher median and maximal lifespans that are independent of PTEN's tumor suppressor function. Downregulation of the nutrient-sensing IIS (insulin/insulin-like growth factor signaling) pathway has been shown to be an important modulator of longevity across evolution. The observation that PTEN overexpression in mice extends their life-span adds further evidence to this paradigm.

A remarkable feature of senescent cells is the increase in protein secretion, including proinflammatory cytokines and growth factors (Bavik et al. 2006). This phenotype, known as senescent-associated secretory phenotype (SASP), induces changes in the microenvironment that increase proliferation and degenerative defects of non-senescent cells, thereby favoring the development of tumors such as lymphoma or myeloma (André et al. 2015; Coppé et al. 2008; Xue et al. 2007).

This seems to be a high price to pay for senescence as a protection mechanism. In exchange for the integrity of our organism early in life, senescent cell accumulation throughout the body causes biological aging in later life. An in vitro finding that senescent cells accumulate with increased population doublings until the majority of the culture has reached replicative senescence was an important observation. This led to the hypothesis that as senescent cells accumulate in an organism coupled with their lack of regenerative capacity, there is a failure of organ homeostasis and functions and consequent tissue aging (Jeyapalan and Sedivy 2008). Senescent cells have been identified in vivo, in various tissues from different organisms including mice, primates, and humans (Herbig et al. 2006; Jeyapalan et al. 2007; Dimri et al. 1995; Satyanarayana et al. 2003; Molofsky et al. 2006). There have also been studies, mostly in the skin, providing evidence that frequency of senescent cells increases with age (Herbig et al. 2006; Jeyapalan et al. 2007; Dimri et al. 1995; Ressler et al. 2006). The detection of signs of senescence at specific sites in age-related pathologies further suggests there is a link between cellular senescence, aging, and chronic diseases (Fenton et al. 2001; Matthews et al. 2006; Minamino et al. 2002; Price et al. 2002).

What Have We Learned from Progeroid Syndromes?

Many progeroid syndromes such as ataxia telangiectasia (ATM gene (=TSG) mutation and severe depletion of ATM protein), Werner syndrome (mutation of the WRN gene leading to genetic instability) and Hutchinson-Gilford progeria syndrome, and restrictive dermopathy (mutation in the LMNA gene involved in chromatin structure) (Cheng et al. 2008; Pereira et al. 2008) cause genomic instability due to defective

DNA repair. They present as a premature aging phenotype associated with an increased incidence of cancer. In these patients, damage in DNA integrity results from poor DNA repair, telomere shortening, chromosome instability, altered intercellular communications, and senescent environmental loss of apoptosis-regulating genes.

Among TSG, the TP53 gene codes for p53 protein which is an important regulator of the cell cycle (DNA repair, growth arrest, and apoptosis) and can be described as the "guardian" of the genome. p53 is usually low in normal cells but can be upregulated by DNA damage and other types of stress. TP53, located on chromosome 17 (17p13.1), is frequently mutated in progeroid syndromes and many patients with malignant hemopathies (Whibley et al. 2009).

The trade-off between cancer and aging has been nicely illustrated in murine experiments where TP53 was manipulated to investigate its effects on the aging process and cancer development. Mice with one allele of TP53 knocked-out died mainly of cancer. If however they escaped from cancer, they had a longer life-span than their normal counterparts, demonstrating that decreased senescence limits aging. Mice transfected with a constitutively active allele of TP53 had a greatly reduced cancer incidence but had signs of premature aging. If mice were armed with an extra allele of TP53, but under normal controls (i.e., not constitutively activated), they did not display this enhanced aging phenotype but did have improved tumor clearance (Donehower 2002; Donehower et al. 1992; Garcia-Cao et al. 2002; Maier et al. 2004; Tyner et al. 2002).

Hematopoietic Stem Cell Aging

A large body of evidence indicates that many important aspects of hematopoietic aging may be driven by age-associated changes in the functional properties of hematopoietic stem cells (HSCs). Paradoxically, this multipotent stem cell population that is responsible for the lifelong maintenance of the hematopoietic system increases in both number and frequency with age (Garrick et al. 2015). However, the HSCs that accumulate with time in elderly individuals, like in aged mice, demonstrate a poorer long-term engraftment capacity, clonal restriction, as well as a myeloid-biased differentiation output (Kuranda et al. 2011; Pang et al. 2011; Jan et al. 2017).

Clonal Expansion of Hematopoietic Stem Cells

The analysis of blood-derived sequence data from 2,728 individuals in the cancer genome ATLAS revealed mutations in 2% (up to 6% if they were older than 70 years). Among these mutations, 83% were divided among 19 hematological cancer-associated genes (DNMT3A, TET2, JAK2, ASX11, TP53, etc.). These common mutations are likely to initiate clonal expansion of HSCs in the elderly and may thus be responsible for the increased rate of leukemias and lymphomas observed in this age group (Xie et al. 2014a). This was confirmed on a large series of 17,182 samples, recently published by J. Aiswal (Jaiswal et al. 2014a), where somatic mutations in 160 genes that are characteristically mutated in hematological cancers had an increased incidence of mutation in older individuals.

Role of Epigenetics in Hematopoietic Stem Cell Aging

Recent studies have indicated that one important factor contributing to age-associated changes in HSC function is alterations in the epigenetic state and chromatin structure of HSC. The term epigenetic refers to changes to gene transcription and other DNA-templated processes (including DNA damage repair and replication) which are not due to alteration of the underlying DNA sequence. Recent findings implicating epigenetic changes in the aging of human HSC as well as genome-wide epigenomic studies carried out in mouse models are outlined below.

One of the most frequently studied epigenetic marks is the methylation of cytosine residues in double-stranded DNA to produce 5-methyl cytosine (5meC). This mark is associated with

repressive chromatin structure and transcriptional silencing. Profiling of murine HSC has revealed that the DNA methylome is surprisingly stable during aging, although specific localized changes (both hypo- and hypermethylation) are observed (Beerman et al. 2013; Sun et al. 2014; Taiwo et al. 2013). These localized changes in DNA methylation appear to have little direct effect on the expression of underlying genes, many of which encode lineage determining factors which are not normally expressed in the HSC themselves. These results suggest that alterations in DNA methylation may not give rise to functional changes in the stem cell population per se but may impact upon downstream cell fate decisions during differentiation (Beerman et al. 2013). Conditional knockout experiments in mice have indicated that the enzymes that catalyze DNA methylation, and in particular the de novo DNA methyltransferases Dnmt3a and Dnmt3b, play a critical role in regulating HSC self-renewal versus differentiation decisions (Challen et al. 2011, 2014). Consistent with this, it has been shown that the expression of all three DNA methyltransferases (Dnmt1, Dnmt3a, and Dnmt3b) is decreased with age in mouse HSC (Beerman et al. 2013; Sun et al. 2014). HSCs from aged mice also exhibit decreased expression of members of the 10–11 translocation (Tet) family of 5meC deoxidases, which are involved in the process of active DNA demethylation (Sun et al. 2014). In humans, exome sequencing studies of peripheral blood have revealed that aging is also associated with the acquisition of somatic mutations in genes affecting global DNA methylation patterns (primarily DNMT3A and TET2) (Jaiswal et al. 2014b; Genovese et al. 2014; Xie et al. 2014c). These mutations appear to confer a proliferative advantage on HSC, resulting in eventual dominance of the mutant stem cells and clonally restricted hematopoiesis. As these age-associated mutations observed in healthy aged individuals mirror those that are detected in malignant conditions, it is thought that these dominant HSC clones constitute a preleukemic pool in which the accumulation of secondary mutations eventually leads to the emergence of myeloproliferative disorders and myeloid leukemias.

Aside from DNA methylation, another important form of epigenetic information is a range of different covalent modifications that can occur on histone proteins and which alter the structure and accessibility of the underlying chromatin, thereby affecting DNA-templated processes including gene transcription (Kouzarides 2007). HSC aging is associated with altered expression of a number of histone-modifying proteins and regulators of chromatin structure (Beerman et al. 2013; Sun et al. 2014; Rossi et al. 2005; Chambers et al. 2007; Djeghloul et al. 2016), and knockout mouse models for several of these activities exhibit HSC and hematological defects (Djeghloul et al. 2016; Hidalgo et al. 2012; Xie et al. 2014b; Lee et al. 2015). Consistent with these observations, epigenomic profiling of mouse HSC by ChIP-seq has revealed that aging is associated with widespread but subtle changes in the distribution of several key histone modifications (Sun et al. 2014). In particular, HSC aging is associated with an increase in both the number and especially in the breadth of peaks of enrichment of trimethylation of lysine 4 of histone H3 (H3K4me3), a mark associated with transcriptional activation. A strong correlation was observed between augmentation in H3K4me3 at gene promoters and age-associated increases in gene expression. Among the sites most affected by these changes, there was an enrichment for genes associated with HSC self-renewal and loss of differentiation capacity, suggesting that these epigenetic changes could be an important factor contributing to the accumulation of HSC and impaired differentiation which is observed with age (Sun et al. 2014). A net increase was also observed with age in the size and strength of peaks of enrichment of trimethylation of lysine 27 of histone H3 (H3K27me3), a repressive histone modification laid down by the PRC2 Polycomb complex. There was also an increase in the number of so-called bivalent chromatin domains (marked by both H3K4me3 and H3K27me3), a signature which indicates a state of transcriptional priming for subsequent rapid activation (Bernstein et al. 2006). Changes in the global levels of other active (acetylation of lysine 16 of histone H4; H4K16ac) and repressive (trimethylation of

lysine 9 of histone H3; H3K9me3) histone modifications have also been observed with age in both human and mouse HSC (Djeghloul et al. 2016; Florian et al. 2012a).

Loss of Heterochromatin

More recently, studies of human HSC aging as well as epigenetic studies in patients with premature aging syndromes have highlighted the role of heterochromatin alterations as a driver of aging (Djeghloul et al. 2016; Zhang et al. 2015). Heterochromatin domains are regions of compacted chromatin that are generally refractory to transcription. The formation of heterochromatin is critical for many aspects of nuclear biology, including the regulation of gene expression, repression of genomic repeat elements, maintenance of genome stability, as well as centromere and telomere function (Peters et al. 2001; Grewal and Jia 2007; Schoeftner and Blasco 2009; Bulut-Karslioglu et al. 2014). One of the initial steps in the formation of heterochromatin is the trimethylation of lysine 9 of histone H3 (H3K9me3), a repressive histone modification that serves to recruit the HP1 family of heterochromatin proteins as well as other chromatin-modifying factors, that together cause chromatin condensation and gene silencing. Relative to those of young individuals (35 years), human $CD34^{+}CD38^{-}$ HSCs, isolated from the elderly (>70 years), show a global decrease in the levels of H3K9me3 and decreased expression of the histone H3K9 methyltransferase SUV39H1 (Djeghloul et al. 2016). Similar changes occur with age in murine HSC, leading to reduced HP1 binding and resultant heterochromatin decondensation. That this decline in heterochromatin is likely to be functionally important in driving the changes observed in HSC during aging is supported by the observation that inhibition of SUV39H1 in HSC from young individuals reduced their B-cell output, while enforced expression of SUV39H1 enhanced the capacity of HSC from elderly individuals to generate B cells and attenuated the age-associated myeloid bias (Djeghloul et al. 2016). Decline in expression of SUV39H1 in human HSC with age is associated with increased expression of the microRNA miR-125. This miR targets the SUV39H1 transcript via a conserved 8-mer recognition site within the 3′UTR. Interestingly, miR-125 is the homologue of lin-4, one of the first microRNAs to be implicated in the control of life-span and aging in *C. elegans* (Boehm and Slack 2005). The groups of John Dick and Gerald de Haan have recently shown that increased expression of miR-125 leads to enhanced HSC self-renewal (Wojtowicz et al. 2016). In this way, the increased expression of miR-125 observed with age could lead to clonal expansion of HSC similar to that resulting from mutations in DNMT3A and TET2 in elderly individuals (Pang et al. 2017). Further, miR-125 is a known oncomir, implicated in a number of myeloid and lymphoid leukemias (Shaham et al. 2012). Together these observations suggest that the increase in miR-125 observed in HSC with age may contribute to the expansion of preleukemic stem cell clones and enhanced susceptibility of the elderly to myeloproliferative neoplasms and other hematological malignancies (Sant et al. 2010).

A more relaxed chromatin resulting from an age-associated loss of heterochromatin is predicted to lead not only to deregulation of gene expression but also to increased DNA damage and genome instability. Indeed, it has been shown that aging of human $CD34^{+}38^{-}$ HSC is associated with upregulated expression of human endogenous retroviral elements as well as satellite II repeats (Chambers et al. 2007). Upregulation of the same repeats is observed in HSC from young individuals in which decreased expression of SUV39H1 is experimentally induced by overexpression of miR-125. Similarly activation of repeat elements is observed in hematopoietic progenitors of Suv39h1-null mice. Together these results indicate that the age-associated decline in SUV39H1 expression and resultant disruption of heterochromatin observed in human and mouse HSC leads to derepression of genomic repeat elements, including endogenous retroviruses. As dysregulation of genomic repeats has been postulated as an important factor driving genomic instability and transcriptomic changes that contribute

to oncogenesis (Tufarelli et al. 2013), it is possible that the age-associated decline in the SUV39H1/heterochromatin axis is an important factor contributing to the accumulation of DNA damage observed in HSC with age and the predisposition to hematopoietic malignancy observed in elderly individuals (Beerman 2017).

Malignancies: Not Only an Accumulation of Mutations

As described for myelomas and lymphomas, genomic and epigenomic instability, which requires multiple abnormal genetic events, has a major role in the development of malignant B cells. Chronological age itself favors the accumulation of genetic alterations that contribute to tumorigenesis. Aging is associated with the release of reactive oxygen species (ROS) and their accumulation can induce oncogenic mutations, as reported by Gosselin et al. (2009). Age-related defects in cancer protection, including altered immune clearance of premalignant or malignant cells, provide another explanation for cancer occurrence.

Accumulation of DNA damage, primarily in the stem cell compartment, increases with age thereby deregulating the mechanisms that control genome integrity (Rübe et al. 2011). Successive mutations that individually do not have significant detrimental effects can accrue over time, promoting aging and through cumulative abnormal genetic events lead the cell to deviate from normal development. As described above, the protective mechanisms of cellular senescence that occur in response to DNA damage can be bypassed by some genetic changes that favor cellular evolution toward malignancy.

Even small epigenetic changes can lead to significant alterations in expression patterns (either directly through the loss of regulatory controls or indirectly by additive effects), ultimately leading to transcriptional changes, cellular degeneration, or uncontrolled proliferation of stem cells. Taken together, this DNA damage prepares the ideal ground for cancer development. In addition to genetic and epigenetic mutations, alterations to the surrounding microenvironment play a key role in cancer development. When a senescence program is activated the cells express a specific phenotype (SASP). These senescent cells produce inflammatory mediators (IL-6, IL-7, IL-8, MIP3a), angiogenic factors (VEGF), and growth factors (IGFBP, HGF, etc.), with the probable dual purpose of maintaining permanent growth arrest while attracting immune cells to eliminate these irreversibly damaged cells. Unfortunately, the active secretion of biological mediators (SASP) has harmful bystander effects on the stromal cells in the microenvironment. There is experimental evidence confirming the hypothesis that malignant cells surrounded by senescent cells have measurably more rapid growth (Capparelli et al. 2012).

In the HSC microenvironment, mesenchymal stromal cells (MSC) are major partners in cell differentiation, cell growth, and cell survival. Our studies have shown that MSC from patients with multiple myeloma (MM) overexpress the β-galactosidase marker associated with senescence and are larger and characterized by reduced proliferative capacity. We also found a reduction in the capacity of osteoblasts to differentiate and their immunomodulatory properties. Overall, these observations support the hypothesis that the HSC microenvironment does play a role in cancer development. It is also worth noting that our studies have shown that current treatment of MM (thalidomide, lenalidomide, bortezomib) is capable of partially reducing the abnormal release of factors such as VEGF, GDF-15, and DKK1 and restoring proliferative and osteoblastogenic capacity (André et al. 2013).

Lymphomagenesis and Lymphomas

During normal B-cell development in the bone marrow, recombination of VDJ Ig segments (variable region of the BCR) is mediated by the RAG-1 and RAG-2 recombinases, which provoke DNA double-stranded breaks (DSB) at a specific recombination signal sequence. These breaks stimulate the DNA damage repair (DDR) pathway and particularly nonhomologous end joining

systems (NHEJ). In mice, different studies have shown that errors in NHEJ can lead to translocations such as t(11–14) or t(11–18) that together with P53 dysfunction can underlie lymphoma development. Furthermore, activation-induced cytidine deaminase (AID) transgenic mice that do not express P53 inconsistently develop lymphoma (Muto et al. 2006). This supports a multistep process for age-related oncogenesis that includes genome mutation, epigenomic changes, and DDR deficiency. In humans, approximately 70% of healthy individuals carry the t(14–18) translocation, but they do not develop non-Hodgkin's lymphoma (NHL) (Roulland et al. 2006).

Gene expression is controlled at many levels, including epigenetic mechanisms that govern chromatin architecture and regulate transcription via cytosine methylation and histone acetylation. In NHL, somatic mutations are frequently observed in chromatin-modifying proteins such as the histone methyltransferases (EZH2 and MLL2), histone demethylases (UTX and JMJD2C), and histone acetyltransferases (CBP and P300) suggesting that epigenetic changes play an important role in the etiology of this disorder (Morin et al. 2010).

In addition to the accumulation of mutations, age is associated with a decline in immune surveillance due in part to decreases in the T- and B-cell repertoire. The homeostatic nature of the adaptive immune response suggests that as humans age replicative stress from multiple rounds of proliferation during antigen-specific responses begins to take its toll. Immune responses to DNA damaged cells and pathogens would therefore be less efficient. Wang et al. (2014) reported that chronic infection with CMV and EBV can alter the B-cell immune repertoire. In addition, although not fully understood, persistent viral infections (CMV, EBV, Herpes simplex and Zoster) lead to an increase in the CD8+ T-cell population, characterized by a higher resistance to apoptosis (Fulop et al. 2013). One hypothesis is that dysfunctional CMV-specific CD8+ T cells accumulate resulting in a restriction of the T-cell repertoire and increased susceptibility to infection and cancer. This "inflamm-aging" is discussed elsewhere in detail by T. Fulop and G. Pawelec (Wang et al. 2014). Profound immune-senescence associated with chronic CMV infection also correlates with poor outcome. In addition, EBV-associated clonal reactive B-cell hyperplasia and EBV+ DLBCL are more common in the elderly. Other bacterial or virally associated lymphomas have also been reported to be more frequent in older populations (Zucca et al. 2014).

Acute Myeloid Leukemia

Among malignant hemopathies, acute myeloid leukemia (AML) has been extensively investigated in terms of cytogenetic and molecular changes, most frequently observed in older patients. The median age of AML patients is indeed 69 years (National Cancer Institute. SEER Cancer Statistics Review (CSR) (1975–2011)), and older patients have a higher rate of poor prognostic factors such as high-risk cytogenetics. Reliable data on cytogenetic and age have been recently published (Juhl-Christensen et al. 2012). However, because of several new mutations described during the last decade, only the recent literature can be analyzed. A major comprehensive review is reported by U. Creutzig et al. who analyzed two large cohorts of pediatric (n = 1,192) and adults (n = 4,372) patients (1–100 years old), among four countries (Germany, Austria, Czech Republic, and Switzerland) (Creutzig et al. 2016). Her analysis confirms that older patients are carrying a higher proportion of unfavorable cytogenetic abnormalities, with the exception of infant below 2 years old who express 45% of 11q23 (MLL) aberrations (Creutzig et al., 2016; Mrozek et al. 2012; Bacher et al. 2005). Interestingly, these genotypes seen in infants are different from older adults; indeed, the frequency of 11q23/MLL abnormalities decrease from infancy to young adults and is rarely detected in older patients (Creutzig et al. 2016). These observations suggest a different mechanism of AML pathogenesis in the infants.

NMP1 and CEPBA mutations are correlated with favorable outcome, and the occurrence decreases above 60 years old (Creutzig et al. 2016). Chromosome 5 and 7 monosomies,

carrying a poor prognosis, increase in the oldest age group. Patients whose AML is characterized by monosomal karyotype (MK) defined as two or more autosomal monosomies or one monosomy combined with structural abnormalities have a 2 year OS of only 7 (Perrot et al. 2011).

Complex karyotypes increase continuously (up to 28%) in the oldest group and are significantly related to aging (Juhl-Christensen et al. 2012). These complex aberrations indicate multiple genetic – including epigenetic – events during lifetime, changes that contribute to the development of AML (Galm et al. 2006; Chen et al. 2010). It could be due to carcinogens but also to genetic error in cell division (Bleyer 2002). Indeed, it has been demonstrated by several groups that clonal hematopoietic stem cells (HSC) accumulate mutations by aging (Welch et al. 2012). These mutations can target DNA repair genes, telomerase gene, and complex aberrations leading to ring chromosomes (Gisselsson et al. 2004; Nicklas 1997; Obe et al. 2002). Epigenetic changes – such as methylation of P15 and RARB2 – are more frequent in older adults (Juhl-Christensen et al. 2012). The CBF abnormalities (t(8–21); t(15–17); inv16) represent less than 5% of patients above 70 years old (Creutzig et al. 2016). Altogether, unfavorable cytogenetics increases with age in AML patients, leading to worse outcome. This observation was already made in 2009 by D Grimwade and B Juliussen (Grimwade et al. 2001; Juliusson et al. 2009).

On the other hand, survival rates for specific risk groups also decrease with increasing ages; i.e., in a British study analyzing more than 600 AML patients older than 65 years, the relapse rate of patients carrying t(8–21) or inv 16 was 70% (vs 56 in younger population). These abnormalities seem thus associated with a less favorable outcome in older patients (Cancer and Leukemia. Group et al. 2006).

Similarly, NPM1+ and FLT3-ITD ^{neg} genes in older patients (65+) do not carry the same favorable prognosis as in younger population. The 2 year OS was only 19% in two trials (Ostronoff et al. 2013; Cornelissen et al. 2012). Finally, a poor outcome is observed in all specific risk groups, and the possible bias of dose-reduced chemotherapy and/or comorbidities in this older population could also play a role in the poor outcome of elderly AML patients (Keplin et al. 2014; Bron et al. 2016).

The Future

Aging of HSCs has long been thought to be an intrinsically irreversible process. Recent studies, however, indicate that the functional decline of aged HSCs can be reversed by pharmacological intervention targeted to specific age-altered signaling pathways or epigenetic modifications. Such restorative interventions hold promise for treatment of many age-related diseases, including sarcopenia, heart failure, and neurodegeneration (Djeghloul et al. 2016; Bron et al. 2016; Geiger et al. 2013; Florian et al. 2012b).

This chapter highlights the complex multistep interplay between aging, epigenetic and genetic changes, and alterations in the microenvironment which contribute to tumor development in the hematopoietic system. Further investigation of these interrelationships promises to advance our fundamental understanding of malignant hemopathies and to lead to novel and better-targeted therapeutic approaches.

Abstract

In human cells, the main source of reactive oxygen species (ROS) and oxidative stress are mitochondria, the organelles where oxidative phosphorylation take place. Although ROS are an inevitable by-products of respiration, they do not necessarily have detrimental effects; low doses of ROS can have beneficial effects on cells, and their production can be finely regulated in mitochondria. Increasing ROS levels and products of the oxidative stress, which occur in aging and age-related disorders, are related to progressive dysfunction of mitochondria, due to damage to mitochondrial DNA or to oxidation and damage of mitochondrial proteins, and are also present in cancer. This chapter focuses on the regulation of ROS production in mitochondria and on the mechanisms that lead to its dysregulation in aging and cancer.

Mitochondria · mtDNA · ROS · Aging · Cancer

Introduction: The Role of Mitochondria in Oxidative Stress

Structure and Functions of Mitochondria

Mitochondria are organelles broadly conserved in almost all *Eukarya*. Energy metabolism, β-oxidation of fatty acids, mitochondrial matrix calcium homeostasis, amino acids metabolism, heme- and iron-sulfur (Fe-S) cluster biogenesis, control of cell death, steroid synthesis, and hormonal signaling are processes in which mitochondria play a fundamental role.

The structure of the mitochondria consists of two membranes, the outer and the inner (OMM and IMM, respectively), which occasionally come together to form junctional complexes or contact sites, interspersed with the intermembrane space. The IMM encloses the mitochondrial matrix and forms a large number of invaginations, named *cristae*, which increase the IMM surface area. The protein composition of the compartments is different: in the outer membrane, porins are the most represented proteins, while the inner one, largely impermeable and the main barrier between cytosol and the mitochondrial matrix, contains proteins involved in mitochondrial fusion, transport of nuclear-encoded proteins, oxidative phosphorylation (OXPHOS), iron-sulfur cluster biogenesis, protein synthesis, and transport of mitochondrial DNA-encoded proteins. The intermembrane space is characterized by the presence of a large number of proteins, which play major roles in cell physiology, in mitochondrial energetics, and in cell death (Galluzzi et al. 2012).

Consistently with the hypothesis of their bacterial origin, mitochondria, along with chloroplasts, are the only organelles with their own DNA. Mitochondrial DNA (mtDNA) is a small circular double-stranded DNA molecule of 16,569 bp, present in multiple copies in the mitochondrial matrix. The replication of mtDNA is performed many times and independently from the cell cycle. Interestingly, mtDNA encodes only a fraction of the proteins that are fundamental for mitochondrial function, while the vast majority of proteins are encoded in the nucleus and transported to mitochondria. The strands distinguish for their nucleotide composition: the heavy strand (H-strand) is guanine rich, whereas the light strand (L-strand) is cytosine rich. It contains 37 genes: 13 of these encode for proteins, which are all components of the electron transport chain (ETC), while the remaining genes encode 22 mitochondrial tRNA and 2 rRNA molecules. Mutations in mtDNA are likely to cause alterations of the encoded protein and compromise the ETC function. Thus, the frequent mtDNA mutations

observed in a variety of human cancers are thought to contribute to respiratory malfunction in cancer cells (Carew and Huang 2002).

The morphology of this organelle is not always the same and, rather, it differs in different cell types and organism. Mitochondria could appear as small, bean-shaped compartments dispersed throughout the cytosol, or they could form elongated tubules or a single, highly branched reticulum. The main reason of these differences resides in the continuous growth, fission, and fusion of the mitochondria throughout the life of a cell. Many key regulators of fusion and fission have been identified. Mitofusin 1 and 2 (MFN 1/2) and optic atrophy 1 (OPA1) are the three GTPase proteins that regulate the process of fusion (Cipolat et al. 2004). On the other hand, the GTPase proteins that regulate mitochondrial fission are FIS1 (mitochondrial fission protein 1) and DRP1 (dynamin-related protein 1). Notably, in the fusion process, mitochondrial content is unavoidably intermixed but electrical conductivity is maintained throughout the mitochondria (Hoppins 2014).

Mitochondria play a key role in energy metabolism and, particularly, in glucose metabolism. This can be splitted in three major stages: glycolysis, citric acid cycle, and ETC. While glycolysis occurs in the cytosol, the last two steps take place in the mitochondria.

The ETC is formed by a series of protein complexes responsible for the OXPHOS process. It is organized in five multisubunit enzymes embedded in the mitochondrial inner membrane, namely complex I, II, III, IV, and V. These complexes are also indicated as NADH dehydrogenase, succinate dehydrogenase, ubiquinol-cytochrome c reductase, cytochrome c oxidase, and F1F0-ATP synthase, respectively. In addition, two diffusible factors that function as electron shuttles within the mitochondrial intermembrane space take part to the system: coenzyme Q, a lipophilic quinone, and cytochrome c (cyt c), a hydrophilic heme protein localized on the external surface of the inner membrane (Galluzzi et al. 2012). Mitochondrial complexes do not exist as physically separate entities within the IMM but rather co-assemble into higher-ordered structures referred to as "supercomplexes" or, otherwise, "respirasomes" (Genova et al. 2008).

All these complexes form the ETC that transfer electrons from a donor, for example, reduced NADH accumulated during metabolic processes to an acceptor, molecular oxygen (O2), thus reducing it to water. The free energy decrease accompanying electron transfer is exploited to create an electrochemical gradient by proton translocation from the matrix to the intermembrane space. The proton gradient is then used as a source of energy to synthesize ATP from adenosine diphosphate (ADP) and inorganic phosphate (Pi) by the F1F0-ATP synthase complex or complex V. The synthesized ATP is moved to the cytoplasm in exchange with ADP by the ATP/ADP translocase.

The proton gradient is kept because of the impermeability of the IMM. However, mitochondria can increase its permeability to ions and solutes, which weigh less than 1500 Da, through a well-known process called mitochondrial permeability transition (PT). This can has a crucial role in regulating many different cellular processes, including Ca^{++} storage and programmed cell death. Permeability transition pore (PTP) is the high-conductance channel at the center of this process, formed probably by assembly of different proteins, including dimers of F1F0-ATP synthase, and regulated by several factors (for example, calcium ions, adenine nucleotides, and reactive oxygen species, ROS) (Bernardi et al. 2015). In particular, Ca^{++} is an essential permissive agent for PTP but alone is not enough for the permeability transition (Bernardi 1999).

Mitochondria as a Source of Reactive Oxygen Species

The mitochondrial metabolism is oxidative and it lead to the production of highly reactive and unstable oxygen, which in turn can oxidize different molecules and form ROS (Ray et al. 2012) and/or radical nitrogen species (RNS) (as reported in Table 1). Not only mitochondria produce ROS, as they are generated intracellularly in different compartments through multiple mechanisms, but

Table 1 Main reactive oxygen species and reactive nitrogen species relevant for aging and cancer

Name	Formula	Formation/chemical reaction	General function	References
Reactive oxygen species				
Singlet oxygen	O_2	From O_2 by xanthine oxidase	DAMAGE (DNA: G to T transversion due to 8-oxodG generation; inactivation of PTP)	Salet et al. (1997), Kudryavtseva et al. (2016)
Superoxide anion	O_2^-	One-electron reduction of oxygen by flavins, quinones, and others. From NO synthase, xanthine oxidase and NADPH oxidase	DAMAGE; SIGNALING (MAPK, ERK, Akt kinase)	Powers et al. (2010)
Hydrogen peroxide	H_2O_2	Dismutation of superoxide anion	DAMAGE; SIGNALING ($p66^{shc}$ through cyt c; Akt kinase)	Giorgio et al. (2005), Numajiri et al. (2011)
Hydroxilic radical/anion	OH/OH^-	From H_2O_2 in presence of Fe^{++}	DAMAGE (very short in vivo half-life, high reactivity)	Sies (1993)
Reactive nitrogen species				
Nitric oxide	NO	NO synthases (nNOS, iNOS, and eNOS)	DAMAGE (apoptosis and necrosis); SIGNALING (src tyrosine kinases, PI3K-Akt, MAPK)	Adams et al. (2015)
Peroxynitrite Peroxynitrose acid	$ONOO^-ONOOH$	From superoxide reacting with nitric oxide	DAMAGE; SIGNALING (cGMP, PKG in neurons and smooth muscle)	Klotz et al. (2002)
Nitrogen dioxide	NO_2	From NO and O_2	DAMAGE	Patel et al. (1999)
Dinitrogen oxide	N_2O_3	From NO and O_2	DAMAGE (nitrosation)	Patel et al. (1999)

they are the main site of ROS generation. Singlet oxygen (O_2), superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), nitric oxide (NO), hydroxyl radical ($OH^•$), and hydroxyl ion (OH^-) are the mitochondrial-derived ROS (mtROS). Among RNS, nitric oxide (NO), peroxynitrite and peroxynitrose acid ($ONOO^-$ and ONOOH, respectively), nitrogen dioxide (NO_2), and dinitrogen oxide (N_2O_3) are the most common. The condition of oxidative stress occurs when a disturbance in the balance between the production of ROS and antioxidant defenses arises.

An important node linking mitochondria to cell metabolism is NO (Brown 2003), as it inhibits respiration at cytochrome c oxidase, and S-nitrosothiol inhibition of mitochondrial complex I causes a reversible increase in mitochondrial H_2O_2 production (Borutaite and Brown 2006). Indeed, flavin mononucleotide (FMN) may become a major source of ROS production after complex I destabilization (Fato et al. 2009), and a reasonable hypothesis is that FMN becomes exposed to oxygen when complex I is dissociated from complex III, in keeping with the idea that dissociation of the supercomplexes causes conformational changes that enhancing reactivity of individual complexes with oxygen (Dudkina et al. 2005).

Lipid peroxidation, carbonylation of proteins, and DNA damage are the three basic ways through which oxidative stress could lead to cell injury and damage. Lipid peroxidation affects cell membranes and other lipid structures. The oxygen released after β-oxidation of lipids is reduced to water through the ETC. At the same time, lipid radicals and water can be produced after oxidation

of lipids with efficient ROS initiators, particularly hydroxyl radical and perhydroxyl radical (HO_2•). This is the initial reaction of lipid peroxidation. Afterwards, the lipid radical reacts directly with molecular oxygen and produces a lipid peroxyl radical, an unstable molecule, that can react with itself or it can combine with fatty acid to form a lipid hydroperoxide and different lipid radicals. These molecules can react with oxygen again to produce another lipid peroxyl radical, creating the chain reaction of lipid peroxidation. Lipid hydroperoxides (LOOHs), the intermediate products, are dangerous for cells, because they can disturb membrane structure. Other dangerous products are toxic and mutagenic aldehydes, malondialdehyde (MDA), and 4-hydroxynonenal/4-hydroxy-2-nonenal (HNE) (Michiels and Remacle 1991).

Protein carbonylation is a process that leads to the formation of reactive ketones or aldehydes, highly reactive with 2,4-dinitrophenylhydrazine (DNPH), with the final effect to form hydrazones (Suzuki et al. 2010). Primary and second protein carbonylation can be distinguished: in the first type of carbonylation, side chains of lysine, arginine, proline, and threonine residues undergo an oxidative reaction that produces DNPH detectable protein products (Levine 2002). The addition of aldehydes produced by lipid peroxidation, as mentioned above, to the proteins is typical in the second type of carbonylation. The result of this reaction is the formation of DNPH derivatizable protein products (Grimsrud et al. 2008). Carbonylated protein can be used easily as biomarkers of oxidative stress, since their relative early formation and the relative stability of carbonylated proteins. The most common assay reveals the stable dinitrophenyl hydrazine product, after the derivatization of the carbonyl group with DNPH (Dalle-Donne et al. 2003).

ROS and products of lipid peroxidation can also have an effect on both genomic and mtDNA. Double- and single-strand breaks, intra- and interstrand DNA crosslinks, DNA-adduct formation, and DNA base and deoxyribose modifications are the DNA damage types that can be caused by them. The DNA double-strand breaks cause severe genetic mutations leading to various disorders and tumor progression (Zhou and Elledge 2000). Repairing in time can avoid damages caused by single-stranded breaks. Otherwise, even these breaks cause serious lesions and their contribution to many human diseases becomes possible (Caldecott 2008).

MtDNA results to be directly exposed to oxidative stress and mtDNA mutations occur due to replication errors and to accumulated damage (Park and Larsson 2011). The consequence is that mtDNA damage are more than a half higher and more extensive compared to nuclear DNA. MtDNA has no histones and presents a limited repertoire of DNA repair pathways (Larsen et al. 2005). For these reasons, authors formulate a hypothesis, still being discussed in different fields of research (aging and cancer, for example (Cheng and Ristow 2013; Shokolenko et al. 2014)), that contemplate a vicious circle, described later.

It is important to note that, although mitochondrial ROS are potentially able to damage cellular macromolecules, their production is not necessarily a negative process. Indeed, it has been widely demonstrated that the release of ROS by mitochondria is not simply a collateral effect of OXPHOS, but it is a finely regulated process that is used to control many physiological cell processes, including apoptosis and cell proliferation.

For example, redox events become crucial in the regulation of the PTP (Bernardi et al. 2015). Oxidation of matrix pyridine nucleotides and dithiols, along with dithiols reagents, favor PTP opening. Moreover, using reducing agents can reverse the effect, whom can be blocked using 1-chloro-2,4-dinitrobenzene, with a possible involvement for matrix glutathione. Again, quinones regulate PT and oxidation of succinate causes an augment in ROS production and PTP opening, while rotenone exerts as inhibitor for both effects. Interestingly, F1F0-ATP synthase can be transformed in Ca^{++}-dependent channel, similar to PTP in terms of electrophysiological properties, upon oxidative stress in mammals, yeast, and *Drosophila* (Bernardi et al. 2015). Finally, it has been observed that increased ROS production, due to mitochondrial dysfunction, provokes damage to neurons in Alzheimer's

disease, after the formation of the PTP (Rao et al. 2014).

Mitochondria can actively promote the production of ROS. The most important factor known to regulate ROS production in mitochondria is the protein 66^{shc} ($p66^{shc}$). It is one of three isoforms encoded by ShcA locus with the weight of 66 kDa and is a crucial redox signaler. It is similar to other two isoforms at molecular level, $p46^{shc}$ and $p52^{shc}$, having the same Src homologues type two domain, the phosphotyrosine binding domain and a region glycine and proline rich. An interesting and additional CH region at its N-terminus constitutes the peculiarity of $p66^{shc}$. From functional point of view, $p66^{shc}$ differs from the other two isoforms. While $p42^{shc}$ and $p52^{shc}$ are activators of Ras signaling pathway, $p66^{shc}$ causes a negative effect on this pathway (involving also MAPK and Fos) (Migliaccio et al. 1997; Pacini et al. 2004).

$P66^{shc}$ exerts its main function increasing ROS levels through three mechanisms: a decrease in ROS scavenging, an augment in the activity of membrane oxidases, and a leakage in ETC. It has also been observed that hydrogen peroxide produced by $p66^{shc}$ in the mitochondria, through a mediating action on the electron transfer from reduced cyt c to molecular oxygen, leads to the PTP opening and, in turn, to the rupture of mitochondrial integrity and release of proapoptotic factors and, finally, activation of apoptotic cascade. Notably, $p66^{shc}$ knockdown animal models revealed important results. In fact, these animals display a decreased amount of ROS, suggesting a role of $p66^{shc}$ in the regulation of redox balance and oxidative stress levels. Moreover, levels of systemic and intracellular oxidative stress decrease in KO organisms (Trinei et al. 2002; Napoli et al. 2003; Francia et al. 2004). Again, $p66^{shc-/-}$ cells resist more to apoptosis induced by several factors, such as UV radiation, growth factor deprivation, and others (Migliaccio et al. 1999; Orsini et al. 2004; Pacini et al. 2004). Even a link with p53 pathway exists; indeed, $p66^{shc}$ half-life results increased when cells undergo a p53-dependent apoptotic stimulation. Therefore, it appears clear that $p66^{shc}$ assumes a central role in regulating redox levels and, in turn, programmed cell death pathways. Other roles for $p66^{shc}$ has been reported in insulin-induced gene expression, while PTEN (phosphatase and tensin homolog) and other phosphatases inhibiting insulin signaling result to be inactivated by oxidation (Lee et al. 2002b; Trinei et al. 2009).

Mitochondrial Stress Response

In the presence of excessive ROS, mitochondrial components can be severely damaged. Thus, mitochondria are provided with many defense mechanisms to counteract these detrimental effects. In particular, three different and correlated levels exist for the degradation of oxidized mitochondrial components: mitochondrial proteases, mitochondrial unfolded protein response (UPRmt), and mitophagy. Mitochondrial proteases are enzymes which share the same location (exclusively in mitochondria or both in mitochondria and cytosol). Degradome is the result of the collectivity of mitochondrial proteases and is defined as the complete set of proteases acting in mitochondria. Authors proposed to divide the human mitochondrial proteases (25 already identified) in three main categories, depending on their location, function, and structural characteristics. Three subcategories for each main category exist, based on the different catalytic site: cysteine, metallo-, and serine proteases. Notably, next to the first group, which groups classical enzymes and, thus, named intrinsic mitochondrial proteases, the second group contains the pseudo-mitochondrial proteases, and the third group encase the transient mitochondrial proteases.

Proteases of the first group, localized in mitochondria or both in cytosol and mitochondria, present two functions: protein processing from cytosol to mitochondria, removing the mitochondria import signals and, on the other hand, quality control, leading misfolded and/or damaged proteins to degradation. The Lon protease (LONP) family is the most widespread family of ATP-dependent mitochondrial proteases, which are highly conserved throughout all phylogenetic kingdoms. LONP is fully included in the downstream pathways involved in energy metabolism, like SIRT1

and PGC-1α. Although the majority of LONP is soluble within the mitochondrial matrix, it is also found in mitochondrial nucleoids with the roles in mtDNA maintenance (Lu et al. 2003). LONP shows several crucial properties, which include: binding and hydrolyzing of ATP and protein substrates (for example, misfolded and oxidatively damaged proteins for quality control or other proteins as a regulatory mechanism), chaperoning, and mtDNA binding (Pinti et al. 2015). Importantly, LONP is upregulated by oxidative stress (Pinti et al. 2010, 2011)

Pseudo-mitochondrial proteases lacks some crucial residues for catalytic activity and they intervene only in regulation on the activity of homologue proteases, or they display complete different functions, as in the case of UQCRC1 and 2 (cyt b-c1 complex subunit 1 and 2), component of the ETC. The name of the third group members come from their capacity to translocate to mitochondria only under specific conditions (autophagy and apoptosis, mainly), in order to perform additional proteolysis. Despite of this fine categorization, mitochondrial proteases, normally, do not have only one role. In fact, majority of them displays overlapping activity. However, seven main functions have been identified: processing, quality control, mitochondrial biogenesis, stress responses, mitochondrial dynamics, mitophagy, and apoptosis (Quiros et al. 2015).

Mitochondrial unfolded protein response (UPRmt) is a retrograde stress response that contemplates the activation of several transcription factors, C/EBPβ (CCAAT-enhancer-binding protein β) and CHOP (C/EBP homolog protein) as principal actors, which leads to the upregulation of chaperones, such as Hsp60, Hsp10, Hsp70 (heat shock protein 60, 10, and 70, respectively), and CLPP (caseinolytic mitochondrial matrix peptidase proteolytic subunit). Collectively, they have a fundamental prevention action to avoid accumulation of misfolded proteins in mitochondria.

Mitophagy is a highly specific form of macroautophagy that targets dysfunctional mitochondria, with a clear role in maintaining the energy homeostasis and in the adaption to nutrient stress (Liesa and Shirihai 2013). This process presents shared components with autophagy but also comprises distinct and specific traits. Mitochondrial proteases, such as LONP, PARL (presenilin associated rhomboid like), USP30 (ubiquitin specific peptidase 30), and HtrA2 (high temperature requirement protein A2), gained prominent position in interaction of known regulators of mitophagy (Quiros et al. 2015). Two types of mitophagy exist on the basis of the molecular pathways and the activating stimuli. The first contemplates a PINK1/Parkin-dependent pathway. Normally, PINK1 (PTEN-induced putative kinase 1) translocates into the mitochondrial inner membrane, it undergo a cleavage by PARL, and, finally, a degradation by proteases within the mitochondria (Jin et al. 2010). As a consequence of mitochondrial membrane depolarization, PINK1 remains at the outer membrane of mitochondria and associates with the TOM20 (translocase of outer membrane 20) complex. This leads to the recruitment of Parkin (or PARK2, Parkin RBR E3 ubiquitin protein ligase), which is phosphorylated in its ubiquitin-like domain. Thus, E3 ligase activity of Parkin is promoted and, after further polyubiquitination, the p62/SQSTM1 adaptor proteins are recruited and Parkin interacts with LC3 (microtubule associated protein 1 light chain 3 alpha) (Bjorkoy et al. 2009). Finally, this complex is degraded by the autophagic machinery. The second type is mediated by a PINK1/Parkin-independent pathway. BNIP3 (BCL2 interacting protein 3) and NIX (BCL2 interacting protein 3 like) are two OMM proteins, with a BH3 domain which interacts with BCL2 proteins, that regulate mitophagy (Bellot et al. 2009; Ding et al. 2010). The activation of this pathway is mediated by hypoxia inducible factors (HIFs), transcription factors composed by the α and β subunit, expressed when the supply of oxygen is low. (Schwarten et al. 2009). Recently, the adaptor protein FUNDC1 (FUN14 domain-containing protein 1) has been discovered as a mitophagy receptor, which is regulated by ULK1 (Unc-51 like autophagy activating kinase 1) phosphorylation (Liu et al. 2012). The mechanism is similar to that described for BNIP3 and NIX and is mediated by HIF1α (hypoxia inducible factor 1 alpha).

Mitochondria and Oxidative Stress in Aging

The Mitochondrial Free Radical Theory of Aging

During years, a number of aging theories have been proposed, and the mitochondrial free radical theory of aging (MFRTA), proposed by Harman, has been the most important one for several decades. Harman proposed that aging is the result of the accumulation of damage caused by free radicals generated as by-products during normal metabolism (Harman 1956). The observations that constitute the foundations of this theory are: (a) the decline in mitochondrial function, observed during aging, causes an increase in the mtROS production, (b) several ROS-scavenging enzymes decrease their activity as a consequence of aging processes, (c) mtDNA accumulates mutations during aging, and (d) this causes an impairment in ETC functions, leading to a further increase in ROS production and, finally, to an accumulation of oxidative damage in DNA, proteins and lipids, establishing a vicious circle. Therefore, it appears clear that mitochondria play a crucial role in the oxidative stress mechanisms that drives the aging process.

However, data from different authors raised doubts on MFRTA, particularly focused on the role of mtDNA mutations and mtROS in aging and, more, on the way through mitochondria and signaling pathways that regulate longevity are linked (Vina et al. 2013). A linear dose-response relationship exists between the increasing amounts of ROS and the oxidative stress and, therefore, the aging process. However, a beneficial role of ROS as redox signaling molecules has been demonstrated by several authors. Thus, mtROS are thought to exert a double-edge sword effect; while high levels of ROS cause cellular damage and to promote aging, low levels may improve defense mechanisms by inducing an adaptive response. This concept has been named mitochondrial hormesis (Ristow and Schmeisser 2014). Deficiencies in mitochondrial function, organelles that are fully integrated into the cell, may alter nuclear gene expression, inducing an adaptive response (Yun and Finkel 2014).

Concerning mtDNA mutations, ex vivo and in vivo observations argue against the order of events that occurs in MFRTA and points to a crucial role of mtDNA mutations in stems cells as a crucial event for the aging process. First experimental evidence was obtained by the creation of a mouse that is homozygous for a mutation that leads to the expression of a proofreading-deficient catalytic subunit of mtDNA polymerase, called mtDNA mutator mouse (Kujoth et al. 2005). It shows extensive mtDNA mutagenesis and a range of phenotypes reminiscent of naturally occurring aging (anemia, hair loss, hearing loss, etc.). It has been suggested that, in this murine model, the instability of ETC subunits can be due to the high number of mtDNA point mutations. (Edgar et al. 2009). The elevated levels of mtDNA mutagenesis affects stem cells, in terms of both quantity and quality, and interfere with the maintenance of the quiescent state, fundamental for reconstitution capacity and long-term sustenance of somatic stem cells. The premature onset of an aging phenotype in mtDNA mutator mouse could be due to the early onset of dysfunction of somatic stem cells (Ahlqvist et al. 2012). Again, it has been observed that most somatic mutations in mtDNA mutator mice occur as replication errors during development and do not result from damage accumulation during adult life (Ameur et al. 2011). How the increased mutation rate in this murine model results in early-onset dysfunction of somatic stem cells still being discussed. However, neural progenitor cells recover their self-renewal ability, after the treatment with the antioxidant N-acetyl cysteine (Ahlqvist et al. 2012). Hence, it implies that alterations in cellular redox state or ROS levels, even mild, become important for the regulation of somatic stem cell function.

Indeed, numerous studies show that mitochondrial metabolism is important in mediating longevity through nutrient-sensing pathways and dietary restriction. The effects of reduced nutrient availability (also defined CR, caloric restriction) on longevity are very complex and include many organs and different pathways. Although the exact

underlying mechanisms remains unknown, it has been observed that CR extends life span in several species, even mammals, and determine an improvement in the health status of rodents and primates (Kaeberlein et al. 2007; Colman et al. 2009). It has been proposed that the inhibition of signaling pathways regulated by mitochondria-derived ROS, as a consequence of the reduction of metabolic rate and oxidative damage, finally determines an antiaging effect (Dai et al. 2012). The nutrient-sensitive pathways TOR (target of rapamycin) and IIS (insulin/IGF-1 signaling) become fundamental in the regulation of aging in various animal models (Selman et al. 2009), through the activation of the common downstream effector ribosomal protein S6 kinase (S6K). Among the characteristics of the S6 K knockout mice, ameliorated age-related pathology, life span extension, and gene expression changes, similar to those observed under CR, are very interesting and they confirm the key role of S6 K. Interestingly, it seems that AMPK (AMP-activated protein kinase) could be the link between the three molecules mentioned above. In fact, AMPK, that regulate the activity of TORC1 (mammalian homolog TOR complex 1), increases its activity after the loss of S6 K (Selman et al. 2009). This increase has been observed, only in worms, even when IIS is altered. Such alteration causes an elevated cellular AMP/ATP ratio that activates AMPK. The consequence is an induction of a metabolic shift, with an increased respiration, transiently increased ROS production and, finally, a life span extension (Zarse et al. 2012). Therefore, it seems that the common mechanism through AMPK, shared by impaired IIS and CR, contemplate a role for ROS at physiological levels, whom act as signaling molecules to induce mitochondrial metabolism and, in the end, to trigger a health-promoting metabolism (Zarse et al. 2012). Thus, the ETC itself, along with TOR kinase and AMPK, could be crucial in mediating longevity. However, further experiments are needed, especially to determine whether changes in mtROS production or, instead, a cellular bioenergetics deficiency could clear up the role of mitochondrial dysfunction to different age-related diseases.

Additionally, a number of studies also show that SIRTUIN1 (SIRT1) and PPARγ coactivator 1 alpha (PGC-1α) have a precise role in this process: the activation of the first one during CR leads to an increase in mitochondrial biogenesis and respiration in mice and rats, further activating PGC-1α, its downstream effector (Cohen et al. 2004). Importantly, it should be noted that PGC-1α is involved in increasing mitochondrial function on demand by activating the expression of certain nuclear genes in different tissues (Lee et al., 2002) and this means that it does not intervene on the basal mitochondrial biogenesis. In summary, all that is mentioned above suggests that the improvement in mitochondrial function is responsible, at least partly, for the beneficial effects of CR on longevity.

Impairment of Mitochondrial Stress Response During Aging

As described previously, mitochondrial proteases are deeply involved in quality control and alterations at this level can lead to mitochondrial dysfunction, one of the nine hallmark of aging process. Several authors reported that mitochondrial proteases and in particular LONP, HtrA2, PARL, and CLPP, assume crucial role in aging (Cipolat et al. 2006; Maltecca et al. 2008; Gispert et al. 2013; Kang et al. 2013).

In yeast cells, lack of Pim1, the genes that encodes yeast Lon protease, results in premature aging cells, with a shorter replicative life span, increased cytosolic levels of oxidized and aggregated proteins as well as decreased proteasome activity (Erjavec et al. 2013). On the other side, the constitutive overexpression of LONP in *Podospora anserina* has several beneficial effects: a decrease in levels of carbonylated and carboxymethylated proteins, an increase in the resistance to exogenous stresses, and an extension of the lifespan (Luce and Osiewacz 2009).

In rodent models, LONP expression and activity decrease with age, causing the accumulation of oxidized and carbonylated proteins in the matrix and a decrease in the activity of mitochondrial aconitase (Bota et al. 2002). CR and, partially,

exercise training (in association with the mitochondrial biogenesis) has the effect to rescue the reduction described above in muscle cells (Lee et al. 1999). This explains why LONP can be included in the downstream pathways involved in energy metabolism (Guarente 2008).

Decreased mtDNA levels, mtRNA and protein expression, increased oxidative stress, and increased accumulation of oxidatively modified proteins are all index of an exponential decline of mitochondrial capacity, which characterizes aging phenotype (Lanza et al. 2008). Unavoidably, even mitochondrial quality control decrease with aging (Friguet et al. 2008). Relevantly, LONP, essential component of this system, presents lower levels and activity in skeletal muscle of the old mice, if compared to young mice (Bota et al. 2002). Moreover, different authors observed an increase in LONP levels but not in its activity; in aged rat hearts (Delaval et al. 2004), the possible explanation could be given by the progressive accumulation of inactive LONP, probably because of oxidative damage that hit LONP directly (Hoshino et al. 2014).

Since the presence of mitochondrial dysfunction within hallmarks of aging, it appears clear that UPRmt can play a role in aging process. Indeed, augment of activity of UPRmt permits to preserve mitochondrial functionality, and although not alone, it promotes longevity. Next to the UPRmt, it is likely that multiple pathways and different actors take part in the response to stressors. At least in worms, ATFS-1 (activating transcription factor associated with stress 1), transcription factor involved in mitochondria-to-nucleus communication during UPRmt, gained prominent role in regulation of response to oxidative stress. In fact, it regulates chaperones and glycolysis genes and, more interestingly, it acts directly on the OXPHOS gene promoters. Again, OXPHOS complex assembly and function is guaranteed with a balanced ATFS-1 accumulation, suggesting the importance of this gene in respiratory recovery process (Nargund et al. 2015). Moreover, UPRmt likely intervenes in maintaining high levels of NAD^+. Increased NAD^+ levels, which can be induced also by pharmaceuticals, improve functionality in mitochondria, and, at the end, leads to longevity. When the transcription of gene involved in the cycle returns to normality, a restore of normal levels occurs and UPRmt ends its action (Lin and Haynes 2016).

Important findings of reduced adiposity in $p66^{shc}$-KO organisms suggest that this protein can have relevant effect on the lifespan (Berniakovich et al. 2008). Obesity, cardiovascular diseases, and diabetes are typical of the aging phenotype. Moreover, the metabolic syndrome, among other characteristic traits, contemplates oxidative stress and this is a contributor to the aging process. Researchers suggest that reduced oxidative stress in $p66^{shc-/-}$ animals could reduce adiposity and, in turn, extend lifespan (Bluher et al. 2002; Berniakovich et al. 2008). On the other hand, it has also been reported a strong counterselection of $p66^{shc-/-}$ organisms, if compared to wild type, when they live in outdoor environment, with food competition and cold temperature exposition. Defects in fat accumulation, thermoregulation, and reproduction are typical of the KO animals. This suggests an evolutionary selection of $p66^{shc}$ in order to refuel energy metabolism. Hence, the beneficial or harmful role of $p66^{shc}$ seems to depend on the specific life conditions of the organism (Giorgio et al. 2012).

Besides mitochondrial proteases and UPRmt, also the third macroprocess which deeply regulate mitochondrial function, mitophagy, is crucial for aging process. In fact, it has been observed a gradual accumulation of mitochondria in several tissues of aged *Caenorabditis elegans*. They observed the same effect of aging on mitochondria in young individuals that undergo the depletion of BEC-1, homolog of the mammalian general autophagy regulator Beclin 1 (BECN1). Therefore, inhibition of autophagy leads to a defect in mitochondria degradation and a subsequent accumulation during aging. DCT-1 protein acts as its mammal homologues, BNIP3 and NIX, functioning as mitophagy receptors and interacting with LGG-1, homolog of the mammal LC3 (the autofagosome membrane-associated protein), for the removal of mitochondria (Palikaras et al. 2015).

DCT-1 plays a key role in the control of mitophagy, in order to maintain mitochondrial homeostasis and to increase the survival under stress condition, as a downstream effector of PINK1 and PDR-1 (*C. elegans* homologues for PINK1 and Parkin observed in mammals). Thus, mitophagy-deficient animals display pronounced mitochondrial dysfunction, sensitivity to various stressors and abrogation of different life span-prolonging interventions in *C. elegans*. Mitochondrial dysfunction, sensitivity to various stressors, and absence of interventions that target a prolongation in the life span are hallmarks of mitophagy-deficient animals. Notably, they present activation of SKN-1, homolog of NFE2L2 (nuclear factor, erythroid 2 like 2), that causes the accumulation of damaged mitochondria. This activation follows oxidative stress conditions and encourages the expression of important mitochondrial biogenesis genes, as its mammalian homologues.

Therefore, a fine coordination exists between mitochondrial biogenesis and mitophagy, in order to regulate the quantity and quality of mitochondrial population and allows cells to intervene on their mitochondrial content after the exposure to stress conditions or change in cellular metabolic state. DCT-1 and SKN-1 and, presumably their homologues in mammals, become nodal elements in this pathway. Particularly, SKN-1 might be a sort of central rheostat of homeostasis in mitochondria, promoting detoxification and cell survival after sensing mitochondrial damage. After the disruption of this fine and vital balance between mitochondrial biogenesis and mitophagy, functional deterioration of biological systems, promotion of cell death, and increase in mitochondrial mass occur, as observed during aging and in several pathologic conditions (Fan et al. 2008; Vafai and Mootha 2012).

Mitochondria and Oxidative Stress in Cancer

Mitochondrial dysfunction, caused by mtDNA mutations or mitochondrial enzyme defects, perturbs bioenergetics of the cells, supporting the metabolic reprogramming observed in cancer, and can trigger changes which ultimately promote cancer transformation, through the release of metabolites, calcium, or ROS.

Research from past three decades revealed the strong and complex link between oxidative stress and cancer. Complexity can be primarily explained by the several ROS produced and their properties, (chemical nature and reactivity, half-life, ability to diffuse in the cellular and intercellular compartments, among others). Furthermore, molecular targets and pathways affected by ROS are difficult to be identified. Last but not least, ROS has a dual role, with a biologically active function or a toxic effect depending on the concentration. The ratio between ROS production and detoxification performed by antioxidant systems (Hernandez-Garcia et al. 2010) is crucial in determining the beneficial or toxic effects. Scavenging antioxidant natural compounds can contribute to this detoxification effects and has been widely proposed as anticancer molecules among which quercetin revealed excellent, although the intracellular availability of glutathione is sine qua non condition for its activity. Interestingly, quercetin shows also a direct and proapoptotic effect in tumor cells and, again, it intervenes in blocking growth of several human cancer cell lines (Gibellini et al. 2011, 2015a).

Oncogenes, Mitochondria, and ROS: A Complex Interplay

Transformation, growth promotion, and malignant progression are three fundamental steps which characterize cancer pathogenesis. A huge number of genes, molecules, and pathways take part to these three steps, and ROS strongly interact with most of them, in different compartments.

Transformation characterizes for the loss of control of proliferation and deregulated apoptosis, with the formation of the tumor. Oncogenes or oncosuppressor genes are genes that undergo mutations which lead to alterations in cell cycle and apoptosis and excessive proliferation. Afterwards, tumor starts to grow and to increase its volume and cell number. Insufficient or abnormal

angiogenesis and inflammatory status typically occur at this step, with the formation of areas of hypoxia and the activation of inflammatory reparative response (IRR) as a consequence, respectively. On one side, unavoidably, this promotes ROS production, suggesting a central role for hypoxia and ROS as regulators of tumor cell adaption (survival, growth, motility, invasion, metastasis, metabolic changes, and resistance to chemotherapy). On the other side, classical and physiological IRR contemplates ROS as important players in both defensive and reparative mechanisms. In several cases, even the direct influence by ROS in nonphysiological IRR lead to the acquisition of many hallmarks of malignancy by tumor cells.

Several oncogenes and oncosuppressors have been shown to regulate mitochondrial functions and ROS production by this organelle and, not surprisingly, they have been shown to promote carcinogenesis, at least in part, through metabolic reprogramming and alterations of mitochondrial functions.

Among oncosuppressors, p53 protein is a principal actor, since its several functions in maintaining genomic integrity (Vousden and Lu 2002). Wild-type p53 regulates transcription and activation of numerous target genes, directing cells to cell cycle arrest, senescence, or apoptosis (Liu and Chen 2006). The precise and specific cellular outcomes of p53 activation are determined by the capability to differently activate its effectors among which proteins and noncoding RNA. A complex interplay exists between ROS and p53. Treating human cells with hydrogen peroxide and performing microarray analysis, authors found that, among the highly H_2O_2 responsive genes, one-third of them are targets of p53 (Desaint et al. 2004); moreover, p53-dependent DNA repair is favored by nuclear oxidative stress (Ueno et al. 1999). ROS intervene in triggering p53 activation (figuring as upstream signal) and, at the same time, in mediating apoptosis (as a downstream signal). Moreover, p53 can modulate cellular ROS status with a direct control on the expression of pro- and antioxidant genes or, less directly, intervening in cellular metabolic pathways.

Different covalent posttranslational modifications (ubiquitylation, phosphorylation, etc.) act on the stability and activity of p53. Particularly, ROS play a role in phosphorylation through kinases, such as p38α MAPK (mitogen activated protein kinase) (Bragado et al. 2007), ATM (ataxia-telangiectasia mutated protein) (Kurz and Lees-Miller 2004), and ERK (extracelluar signal-regulated kinases) (Persons et al. 2000), although these pathways are shared with genotoxic stresses, such as UV light (Bode and Dong 2004; Kurz and Lees-Miller 2004; Moiseeva et al. 2006). Instead, ubiquitylation represents the major turnover pathway for p53: cysteine residues of p53 can suffer oxidative modifications, due to ROS, and conformation changes could occur, affecting the stability of p53, favoring ubiquitylation and, finally, proteasome degradation.

DNA-binding activity of p53 is abolished after the treatment with oxidizing reagents, but this activity can be replenished by using antioxidants (Sun et al. 2003; Velu et al. 2007). Moreover, thioredoxin (TRX) and other redox proteins influence and modify p53 activity (Ueno et al. 1999; Seo et al. 2002; Hanson et al. 2005; Seemann and Hainaut 2005), although their effectors still partially unknown.

Important research shows a decrease in p53 binding to GADD45 (growth arrest and DNA damage-inducible 45) when p53 is oxidized in a specific cysteine residue, but authors do not observe any decrease in p21 binding (Buzek et al. 2002). Notably, GADD45 proteins take part to the regulation of numerous cellular functions, including DNA repair, cell cycle control, and senescence, besides to present proapoptotic activities (Tamura et al. 2012). P21 (or Cip1/Waf1) is an inhibitor of Cdk 1 and Cdk2 (cyclin-dependent kinase 1 and 2). It causes the arrest of the G1-S transition and G2-M transition after DNA damage, enabling the repair processes. Furthermore, it induces replication and stress-induced premature senescence. Binding to caspase 3 and to ASK1 and JNK (apoptosis signal-regulating kinase 1 and c-Jun N-terminal kinase, respectively, two apoptosis kinase), it display also antiapoptotic activity (Cmielova and Rezacova 2011). This confirms the relationship

between ROS and p53, suggesting that redox modification represents a possible mechanism for target gene selection.

$P66^{shc}$ in cancer displays numerous functions, correlated to the metabolism of cancer cells. This protein cause the damp of growth factor signaling, leading to a suppressive effect on tumor metabolism. Mammalian TOR (mTOR) and S6K program a shift in metabolism, with increased glycolysis and favoring anabolic metabolism, when $p66^{shc}$ is silenced (Soliman et al. 2014; Lebiedzinska-Arciszewska et al. 2015). This shift causes a decrease in mitochondrial ROS production and drives the metabolism in a biosynthetic direction. Indeed, $p66^{shc}$ inhibits mTOR, cell growth, and glucose metabolism (Soliman et al. 2014) and, moreover, it acts as a sensor of glucose, amino acids, and insulin, regulating mTOR/S6K pathway. Therefore, $p66^{shc}$ guarantees a specific link between ROS, mTOR/S6K and nutrients and, particularly, it seems that it can translate nutrient availability into mitochondrial ROS production. $P66^{shc}$, and p53, display altered expression, associated with augmented cell proliferation and metastatic potential, in cancer cells and in cancer stem cells (Veeramani et al. 2008). Thus, a leading role for $p66^{shc}$ for autophagy and programmed cell death on the basis of the bioenergetic profile represents a concrete hypothesis. Finally, it has taken into account that $p66^{shc}$ favors also the acquisition of resistance properties by these cells, with roles in carcinogenesis and self-renewal (Sansone et al. 2007; Beltrami et al. 2013).

Notably, upon oxidative stress, serine residues of $p66^{shc}$ are phosphorylated, inducing conformational changes, which lead to the binding with prolyl isomerase 1 (Pin1) (Galimov 2010). As a consequence, $p66^{shc}$ moves in the intermembrane mitochondrial space, where determines cyt c oxidation, that, in turn, provokes H_2O_2 levels increase and impairment in mitochondrial calcium buffering, favoring mitophagy (Giorgio et al. 2005). On the other side, the absence in the cytosol of $p66^{shc}$ interrupts its normal activity, leading to a raise in lipid and protein injury and in autophagosome assembly.

PTEN, main regulatory member of the signaling cascade that promotes cell survival through activation of PI3K/Akt (phosphatidylinositol-4,5-bisphosphate 3-kinase/protein kinase B) pathway, intervenes, upon normal condition, decreasing Akt transduction. This leads to an augment in apoptosis and a reduction in cell survival, proliferation, and migration (Griesser et al. 2009). When ROS production results increased, in particular H_2O_2, PTEN undergoes a reversible inactivation, making it ineffective on Akt transduction, promoting cell survival (Numajiri et al. 2011). Moreover, ROS induce direct and adaptive modifications on Akt, increasing the nuclear export of FoxO1 (Forkhead box protein 1) and, in the end, leads to the synthesis of TRX reductase, important antioxidant enzyme. Thus, a counterattack to ROS increase and enhancement in Atg (autophagy related proteins) activity are guaranteed.

The importance of FoxO family is not limited to that mentioned above. In fact, FoxO3 promotes the activation of BECN1, Atg12, Atg4, and LC3, promoting, at last, autophagy. Furthermore, BNIP3 increases its activity, as an effect of FoxO3 action, leading to augment in autophagosome complex activity and in mitophagy (Mammucari et al. 2007). Finally, FoxO3 provokes an increase in PI3K activity, which in turn determines increase in Akt activity. Therefore, the nuclear export of Foxo1 is favored and this promotes autophagy in mammals cells (Zhou et al. 2012).

It has been observed that ROS intervene also in regulating Atg family activity. Particularly, Atg4 suffers a decrease in its activity, after the augment of H_2O_2 levels. Consequently, it does not remove arginine residue on Atg8 and this impedes the binding and the activation of Atg8 by Atg7. The first one stills free and it conjugates to autophagosome (Scherz-Shouval et al. 2007).

Another crucial regulator of mitochondrial functions and ROS is SIRT3 (SIRTUIN 3). It is a nuclear-encoded, mitochondrial deacetylase that regulates the function of several mitochondrial proteins involved in oxidative phosphorylation, fatty acid oxidation, the urea cycle, and the antioxidant response system (Xiong et al. 2016).

SIRT3 acts as an oncosuppressor in several types of cancer, including breast, colorectal, hepatic, lung, and gastric cancers. Accordingly, its loss promotes carcinogenesis, through the increase intracellular ROS levels and HIF1α stabilization which in turn promotes the switch to an aerobic glycolytic metabolism, the so-called Warburg effect (Finley et al. 2011). In most tumors, HIFs, HIF1α in particular, display high activity even if pseudohypoxia, instead of hypoxia, occurs. This particular condition contemplates HIF stabilization upon normoxia. HIFs and their downstream effectors are targets of several antitumor agents. To cite a few, PX-478 acts decreasing HIFs levels both in vitro and in vivo, while bevacizumab targets VEGF (vascular epithelial growth factor), a downstream effector of HIFs (Tennant et al. 2010).

At last, it is important to underline the link between ROS and HIFs in autophagy and mitophagy signaling processes. Whether normoxia conditions are guaranteed, PHD (prolyl hydroxylase containing-domain) enzyme hydroxylates HIF1α subunits, causing the ubiquitination of the latter one by pVHL (E3 ubiquitin ligase von Hippen-Lindau protein). This mechanism goes out when hypoxia occurs. Nonhydroxylated HIF1α subunits does not undergo ubiquitination and they can operate favoring transcription of VEGF, COX4-2 (cyt c oxygenase 2), and others. Importantly, presence of HIF1α leads to the stabilization and regulation of BNIP3, which binds BCL2 and, in turn, leaves BECN1 free. This protein triggers mitophagy and a reduction in number of mitochondria occurs (Zhang et al. 2008). ROS intervene at pVHL level, avoiding HIF1α ubiquitination and stabilizing it. However, it has taken into account that this model fits only in mild hypoxia conditions.

Mitochondrial Proteases, Oxidative Stress, and Cancer

As mentioned above, different mitochondrial proteases assume prominent roles in the regulation of mitophagy. Particularly, LONP seems to be fundamental in cancer. Indeed, several tumor cell lines present higher expression levels of LONP, such as colorectal (Gibellini et al. 2014b) or mammary epithelial cancer cells, either at RNA and protein levels. Increasing expression leads, at mitochondrial level, to changes in organelle architecture and functionality, which deeply increase the resistance to stress conditions typical of tumor microenvironment. To name one example, upon hypoxic condition, upregulation of LONP by HIF1α occurs, determining the degradation of cyt c oxidase 4-1 subunit and favoring the assembly of COX4-2, cited previously, that gives better chances for the adaption of cancer cells to the hypoxic environment (Aksam et al. 2007). Moreover, switch from respiration to glycolysis, proliferation, and transformation cells are favored when LONP is ectopic overexpressed. In the same nude mice model, even migration and metastasis formation result increased (Quiros et al. 2014). Again, NDUFS8 (NADH:ubiquinone oxidoreductase core subunit S8) of complex I undergoes an upregulation in its expression, after LONP overexpression in different tumor cell lines (293T, OEC, to cite a few), probably determining an impairment in complex I assembly and, finally, leading to an increase in ROS production. Authors proposed that cell proliferation is promoted by ROS production, through MAPK (p38, ERK1/2, and JNK) and Ras-ERK signaling, with the important evidence that LONP overexpression drives oncogenic transformation. This overexpression drives also another type of transformation, the epithelial-mesenchimal transition, or EMT. Particularly, E-cadherin, N-cadherin, Vimentin, and Snail result to be increased in their expression as a consequence of LONP overexpression, which even enhance cell migration through MMP-2 matrix metallopeptidase 2). Interestingly, N-acetyl cysteine, antioxidant molecule, inhibits EMT, suggesting a probable cause-effect relationship between ROS generation and LONP-induced EMT (Cheng et al. 2013).

LONP confirms to be linked to numerous pathways, since even SIRT3 causes deacetylation of LONP in colorectal cancer cells, as a posttranslational mechanism (Gibellini et al. 2014a). The importance of SIRT3, as a regulator of mitochondria integrity and function in cancer, is sustained

by a lot of works from many authors (Gibellini et al. 2014a). Probably, this is due also to the ability of SIRT3 to regulate LONP activity and, in turn, to regulate the switch from respiration to glycolysis, to regulate citric acid cycle proteins, or to regulate the degradation of damaged proteins as a consequence of oxidative stress. This explains, at last, the high resistance of tumor cells to stressors typical of the tumor environment.

Notably, it has been clearly demonstrated that LONP can be fundamental for the cell survival upon conditions of excessive stress load, since administration of two triterpenoids, CDDO and CDDO-Me, which inhibits LONP expression, leads to depolarization, increased mtROS, alterations in mitochondrial morphology and mitochondrial dynamics proteins, increased levels of protein carbonyls in mitochondria, and intrinsic apoptosis (Gibellini et al. 2015b).

Unfolded and misfolded proteins represent common trait in tumor environment. A recent study revealed high correlation between LONP expression and Hsp60, Hsp10, Hsp70, and CLPP expression (Wu et al. 2014b), principal components of the UPRmt machinery. Moreover and importantly, LONP is included in the category of proteases activated by CHOP, along with heat shock proteins. LONP cannot be included in the UPRmt machinery, but it shows relevant proteolytic activity in the mitochondrial stress response (Gibellini et al. 2016). In addition, downregulation of LONP causes increased starvation-induced autophagy (Gibellini et al. 2014b) and accumulation of PINK1, as already cited as essential regulator of mitophagy (Jin and Youle 2013). PINK1 degradation is promoted by LONP, in the mitochondrial matrix of *Drosophila*, avoiding healthy mitochondria undergo mitophagy (Thomas et al. 2014).

The essential function of chaperones is to de novo fold protein or to refold misfolded proteins (Voos 2013). LONP shows also important chaperon-like functions. As observed in yeast and humans, LONP takes part in the assembly of mitochondrial membrane complexes (Quiros et al. 2014). Although precise targets of LONP still unknown, recent study investigated on LONP binding partners NDUFS8, Hsp60, both cited above, and mtHsp70 (mitochondrial heat shock protein 70) (Kao et al. 2015).

Mitophagy, Oxidative Stress, and Cancer

Dysregulation of mitophagy is now considered as an etiological factor in tumorigenesis (Chourasia et al. 2015b). Particularly, inhibition of this process is fundamental for tumorigenesis, whereas functional mitophagy likely is requested for tumor progression. Naturally, ROS figure as principal actors in regulating autophagy and mitophagy, through oxidative modification in proteins directly involved in the autophagy machinery or in signaling pathways that enhance autophagy and mitophagy.

The Parkin gene, located at chromosome 6, represents a fragile site, highly susceptible to genetic mutations. In fact, many tumors, which include lung, melanoma, gliomas, and colon cancers, presents this kind of mutations (Veeriah et al. 2010; Lee et al. 2016). Besides, Parkin knockout animals and cell lines show increased tumorigenesis (Matsuda et al. 2015). This suggests a possible tumor suppressive role for Parkin gene (Dehennaut et al. 2013). Parkin knockout mice are prone to spontaneous hepatic tumors, while various cell models show increased tumorigenesis.

Hypoxia, and a consequent activation of HIF1α, is a hallmark of the microenvironment of solid tumors. This is a clear a helpful condition for cancer stem cells and potentiates cancer progression and metastasis (Semenza 2016). Whether mitophagy inhibition occurs in tumorigenesis because of Parkin mutations, vice versa, during cancer progression and metastasis, mitophagy displays an increase through BNIP3. Excessive mitochondrial damage derived from tumorigenesis could lead to a decrease in fitness of cancer cells and the apparent contradiction would be explained. Using other words, increase in mitophagy observed in tumor progression could represent a sort of adaptive response acted by tumors, in order to increase survival.

The role for BNIP3 in both tumorigenesis and tumor progression still, almost apparently, controversial and not clearly elucidated. A list of studies investigates on its protumorigenic role, highlighting, for example, reduced cell migration and vascular mimicry with a remodeling of the cytoskeletal actin, after BNIP3 knockdown in melanoma cell line (Maes et al. 2014). On the contrary, recent findings displayed antitumorigenic properties for BNIP3 and its possible role as a tumor suppressor gene (Chourasia and Macleod 2015). To name one example, BNIP3 loss, and consequent mitophagy defects, results in increased metastasis in a mammary tumor rodent model (Chourasia et al. 2015a). It has taken into account that BNIP3 can undergo alternative splicing of exon 3, determining the formation of a truncated splice variant that presents prosurvival and, as a consequence, protumorigenetic properties (Gang et al. 2015). This finding can be useful to elucidate the dichotomial role observed for BNIP3.

Concerning FUNDC1, its role in hypoxia-induced mitophagy has been well established (Wu et al. 2014a), but further studies are needed in order to establish whether FUNDC1 has also a key role in cancer mitophagy.

KRAS is commonly mutated in several type of cancer, such as lung, colorectal, and pancreatic (Chan et al. 2003; Karachaliou et al. 2013; Quiros et al. 2014). Mutations present in the form of a single nucleotide substitution, finally leading to the hyperactivation of this proto-oncogene (Flemming 2013). Consequently, it activates the proliferative pathway, involving PI3K, and it upregulates GLUT1 (solute carrier family 2 member 1), moving the metabolism to an aerobic glycolysis profile (Kerr et al. 2016), alias Warburg effect (Lunt and Vander Heiden 2011; Quiros et al. 2014). Consistently with these issues, autophagy determines the augment of malignancy of tumors with oncogenic transformation of KRAS (Kim et al. 2011). Interestingly, shift from adenoma and carcinoma to oncocytoma, a more benign and rarer form, has been observed in mouse model that presents KRAS G12D mutation, after loss of Atg7. Oncocytoma displays an increase in number of dysfunctional mitochondria. It seems that mitophagy has a different role in KRAS-mutated tumors, since it appears to increase malignancy, instead of inhibits it, as seen previously in other models of cancer.

Conclusions

Aging and carcinogenesis are multistep processes whose hallmarks have been progressively defined in the last 40 years. Among other features, both processes are characterized by alterations of metabolism, in which mitochondrial dysfunctions play a direct, central role.

DNA mutations or arrangements, genomic instability, impairment of protein functions and proteostasis, altered metabolic and signaling pathways are features present both in aging and in neoplastic transformation. ROS, normally produced by mitochondria, may cause all these phenomena and determine a progressive deregulation of cell functions, which in turn could induce further mitochondrial dysfunctions and increase in ROS production.

Thus, a deeper comprehension of the fine regulation of ROS production in physiological aging, or in pathological conditions related with aging, such as chronic inflammatory diseases or neurodegenerative diseases could also help to better comprehend the dysregulation of metabolic processes observed in cancer, and to pave the way for the identification of new therapeutic targets for cancer.

George E. Taffet

Contents

Abstract

Normal aging, from maturity to senescence, is accompanied by a large number of physiologic, organ, biochemical, and molecular changes. In the unchallenged state, at homeostasis, age-related decrements in function from these changes are few in part because reserves are used to maintain homeostasis. When challenged, whether by diseases, environment, medications, etc., those age-related changes become apparent. These changes lead to increased vulnerability with aging, called "homeostenosis." Rather than the reserves disappearing with age, the reserves are invoked in the older person just to maintain homeostasis. Therefore, less are available to respond to disease or medication or other challenge. Broadly this pattern is seen in the cardiovascular system, the hematological system, and the renal system, and elsewhere. When there are essentially no reserves available for challenges, when any challenge overwhelms them, that is frailty. Additionally, aging can modify the impact, presentation, and natural history of any illness. This is because the substrate, the aging person, more than the disease pathophysiology, has been modified. In any given person, the system where the reserves are the least may be the most likely to fail with any challenge. For example, in older patients with dementia, delirium may be the presenting symptom for a urinary tract infection, gastrointestinal bleed, or myocardial infarction; the weakest link fails first. Understanding homeostenosis helps one to understand the apparent vulnerability of the elderly that are in our care.

Introduction

While aging produces changes at the physiologic, organ, biochemical, and molecular levels, the general increase in vulnerability that may accompany aging and drives the increases in adverse responses to therapy, increases in complications after procedures, and increases in mortality after challenges, is the theme of this chapter. The diminution in the physiologic reserves or functional capacity over time is considered a characteristic hallmark of aging. Some of the changes are specifically relevant to oncologists and are discussed in detail elsewhere (see ▶ Chaps. 57, "Exercise and the Older Cancer Survivor," ▶ 60, "Decision Making and Safety Issues in Older Cancer Patients," ▶ 54, "Principles of Cancer Targeted Therapy in Older Adults," ▶ 56, "Digestive Symptoms Control and Nutrition Issues in Older Cancer Patients," ▶ 59, "Integrating Geriatric Oncology into Clinical Pathways and Guidelines," ▶ 62, "The Older Cancer Patient: Religious and Spiritual Dimensions," ▶ 52, "Principles of Radiation Therapy in Older Adults," ▶ 61, "Improving Communications with Older Cancer Patients," and ▶ 51, "Principles of Cancer Surgery in Older Adults"). Aging leads to increased mortality for many cancers, and increased frequency and severity of adverse effects in response to many chemotherapeutic agents and other interventions.

But aging also leads to slower growth of some tumors, famously for laboratory scientists, the B16 melanoma line. This line, possibly dependent upon host immune responses for robust growth, produces lower growth and longer survival in old mice compared to young ones (Ershler et al. 1984). Similarly poor angiogenesis has been implicated (Pili et al. 1994). That is the age-related decrease in the ability to develop new blood vessel limits tumor growth (Pili et al. 1994). So age-associated changes in both humoral and local host factors might contribute to the behavior of a transplanted tumor into an old host compared to a young one (Anisimov 2006). Geriatricians frequently see breast cancers and lung cancers that seem to follow a protracted or indolent course (Kaesberg and Ershler 1989). So not all aging phenomenon are directly harmful.

Homeostenosis

The overall goal of this chapter is to discuss the increased vulnerability with aging, called "homeostenosis." For this chapter, aging is post-developmental, ranging from maturity to senescence. Homeostenosis has direct implications on therapeutic choices for older people and toxicities they experience (Sawhney et al. 2005; Sehl et al. 2005). The concept of homeostenosis in aging is not new. The famous physiologist Walter Cannon described it in the quote below (Cowdry and Allen 1939). Figure 1 graphically displays one model of homeostenosis. In the unchallenged state, at homeostasis, age-related decrements in function are few. Things like vital signs, cardiac output, and activities of daily living are unchanged by age. When challenged, whether by diseases, environments, medications, etc., the impact, presentation, and natural history of diseases are modified with age. This is because the substrate, the aging person, more than the disease pathophysiology, has been modified.

> Homeostasis is not affected to any marked degree (with aging) . . . When subjected to stress, . . . (older people) are revealed as being more and more narrowly limited in their ability to preserve uniformity of the internal environment.
>
> Walter Cannon, in Cowdry and Allen (1939).

In the figure, challenges are displacements (arrows) off the baseline, away from homeostasis, and larger challenges are larger arrows, and they require greater physiologic reserves to bring the person back to homeostasis. The "precipice" is any clinical sign or symptom, including death, such as ill enough to have a cardiac arrest or for hospital admission. The precipice can be

nonspecific, presentations such as confusion or incontinence, etc. Overall, the loss of physiologic reserves with aging brings the individual closer to the precipice. The area where a person is able to bring themselves back to homeostasis decreases with aging. This has the appearance of a stenotic valve, thus homeostenosis. Furthermore, frailty is the extreme condition, where challenges of small magnitude lead to loss of homeostasis, and frailty and the inability to maintain homeostasis increases the risk of death (Kane et al. 2012).

This paradigm fits most practitioners' experiences, but direct evidence can be seen by examining the physiologic scores as deviation from normal which are components of the "APACHE" severity of illness scales used in many ICUs. The APA, the acute physiologic assessment, gives an increasing number of points for increased deviation from normal values for 12 variables (Knaus et al. 1985; Zimmerman et al. 1998). The variables include heart rate, blood pressure, oxygenation, blood pH, electrolytes, hematocrit, white count, and creatinine (Knaus et al. 1985). At homeostasis, a normal person, independent of age, will have an APA score close to or equal to zero. Younger patients (mean age, 59 years) who experienced a cardiac arrest had significantly higher (by 20%) APA scores than the older group (mean age, 75) (Beer et al. 1994). The precipice, here having a cardiac arrest, is closer to homeostasis for the older person than for the younger one. In practice, the creators of the APACHE severity of illness scales recognized this and the scales give "bonus points" for age (Zimmerman et al. 2006). Therefore, the total scores between the younger and older groups that arrested were not different (Beer et al. 1994).

The physiologic reserves have not "disappeared," with age as suggested in Fig. 1, but they are unavailable to the older person to maintain homeostasis. A primary contributor to the lack of physiologic reserves is that older persons are actively employing some of those reserves just to maintain homeostasis in the unstressed state. In the elderly, as in youth, maintaining homeostasis is a dynamic, active process. The reserves appear depleted not because they have disappeared with age, but because they in are already in use as shown in Fig. 2. For illustration, examples from the cardiovascular system – heart rate, cardiac hypertrophy, metabolic pathways, and diastolic function – will be shown below, because the data provide an ample molecular, biochemical, and physiologic foundation to show how reserves are invoked at rest to maintain homeostasis.

Homeostenosis in the Aging Cardiovascular System

Resting heart rate does not change with age. In contrast, maximum heart rate attained with exercise or pharmacological manipulation decreases progressively. Healthy, highly screened individuals in the Baltimore Longitudinal Study give a

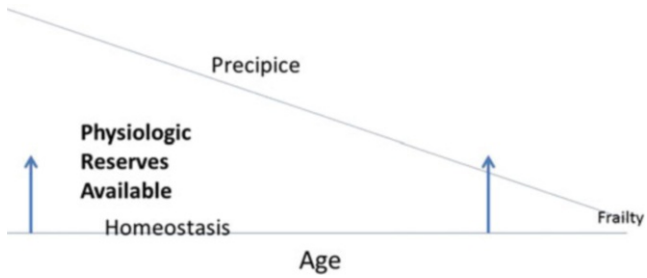

Fig. 1 Standard schematic of homeostenosis. With age, the older person's capacity to bring themselves back to homeostasis after a challenge decreases. Challenges to homeostasis are arrows off the baseline. Larger challenges require greater reserves. Aging brings the precipice closer to individual because of the loss of physiologic reserves. The precipice can be death or ill enough to have a cardiac arrest or for hospital admission or the appearance of common and protean symptoms, such as confusion, weight loss, falls, or incontinence

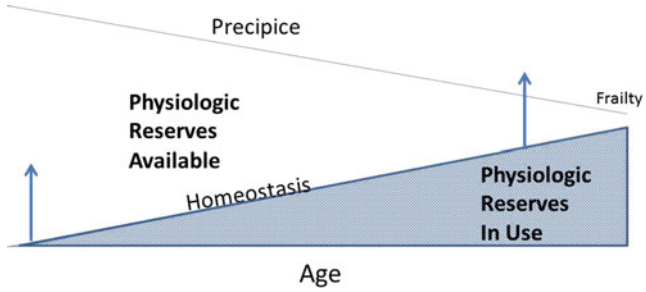

Fig. 2 Revised homeostenosis. Maintaining homeostasis is a dynamic process and older persons are actively employing reserves to accomplish this. The available reserves look like they have disappeared because they are already in use by the old heart (or other organ or system) to compensate for primary age-related or other changes. Nevertheless, there are few reserves available for subsequent challenges

regression equation of $208-(0.95 \times \text{age})$ for maximum heart rate attained with exercise (Fleg et al. 1995). Some suggest that women have lower maximum heart rates in youth than men and show a less steep decline with age than this equation predicts. The decrease in maximum heart rate is due to a number of factors. First, primary aging decreases in the intrinsic heart rate (the heart rate in the absence of sympathetic and parasympathetic stimulation) from 120–130/min to less than 80 (Craft and Schwartz 1995; Christou and Seals 2008). As there is no difference in resting heart rate with age, the extent of parasympathetic tone, slowing heart rate, is decreased at rest (Craft and Schwartz 1995). Removal of vagal, parasympathetic tone is the first mechanism invoked to increase heart rate with exercise. This is less effective for the elderly because vagal tone is already diminished at rest. The observed attenuated heart rate response of healthy elders to administration of atropine is consistent with the decreased vagal tone (Craft and Schwartz 1995). The attenuated response to lysis of parasympathetic tone is added to an age-related decrease in sympathetic, beta-adrenergic heart rate response that results in the overall decreased maximal heart rate in exercise (Craft and Schwartz 1995; Christou and Seals 2008). Thus reserves used by the young to attain high maximum heart rate with exercise are already partially invoked to maintain adequate resting heart rate in the elderly (Fig. 2).

Similarly, reserves used in youth to maintain homeostasis in response to increased systemic pressure are reduced in the old in part because they are already in use. When younger adult male rats (9 months) have blood pressure increased experimentally by constricting the aorta, there is a 40% hypertrophy of the left ventricle, increasing wall thickness. This same increase in afterload results in only trivial increase in left ventricular mass in older rats (18 months of age) (Isoyama et al. 1987). As would be expected, older rats already have hypertrophy, thicker left ventricular walls, and higher mass (Isoyama et al. 1987). Older people, even in the absence of hypertension or other disease also have left ventricular hypertrophy with age (Cheng et al. 2010; Hung et al. 2017).

With exercise and the accompanying increased heart rate, young persons increasingly use left atrial systole to increase left ventricular filling (Channer and Jones 1989). The hypertrophy described above decreases early diastolic filling. In the elderly, the compensation is used at rest to maintain ventricular filling, contribution of atrial systole to diastolic filling increases from 10% to 15% at age 20 to almost 50% at age 80 (Kuo et al. 1987; Kitzman et al. 1991).

The hypertrophy includes myocyte and non-myocyte components. Evidence of myocyte hypertrophy in aging, by examining myocyte size, is seen in reports of 25% in increased myocyte length and 50% or more increases in myocyte width (Strait and Lakatta 2012). Ventricular myocytes from older persons and animals are larger; the myocyte hypertrophy is in response to uncertain stresses.

The molecular response to increased afterload is also attenuated in these old hearts, little

induction c-jun and c-fos, immediate early response genes and skeletal actin, which precedes cardiac actin (Takahashi et al. 1992). Atrial natriuretic peptide (ANP), a marker for myocyte hypertrophy, was increased significantly after banding in the young heart but was already very high in the old heart at rest and was not increased further in response to afterload (Isoyama et al. 1987; Takahashi et al. 1992). The increased left ventricular mass, wall thickness, and molecular markers all provide evidence that the old heart has already invoked the hypertrophic response and it is no longer available for subsequent challenges.

Other changes with aging in the cardiovascular system and elsewhere follow the paradigm described above. Older persons are frailer, more likely to cross a given "precipice" after a stress, not only because they have lost some reserves because of aging, but because they are already utilizing reserves to compensate for those lost just to maintain homeostasis. The older person is more likely to drown when thrown a brick not because they are unable to swim, but because they are already treading water. For all these examples, the apparent loss of physiologic reserves in aging reflects the use of compensatory reserves available for challenges in youth just to maintain homeostasis in the elderly and the magnitude of that use of compensatory reserve is called allostatic load.

Allostatic Load and Aging

Is there any evidence that the state of using compensatory reserves, the extent of the allostatic load, is in itself bad? MacArthur Study of Aging data and a long series of papers from Seeman and McEwen support the concept that the presence of invoked compensation in healthy elders is associated with worse outcomes (Seeman et al. 1997). Of community dwelling people, aged 70–79, only 7% had no evidence of compensation and the lack of compensation was associated with highest level of function over the next few years. Seeman's measures of this activation, allostatic load, were not perfect, but broadly reflected the activity of sympathetic nervous system, immune system, or hypothalamic–pituitary–adrenal axis. Those with high allostatic load had decreased physical and cognitive function at 2-year follow-up (Seeman et al. 1997). If over the next 2 years, the allostatic load decreased, the cognitive and physical function was better than for those where the load increased or did not change (Karlamangla et al. 2006). This suggests efforts to disengage reserves may decrease vulnerability.

Invoking compensatory mechanisms has the additional effect of constraining the complexity of many variables. Heart rate variability decreases with aging, and this constriction of heart rate may be due to decreased parasympathetic tone and possible activation of the sympathetic nervous system while at rest (Lipsitz and Goldberger 1992). A similar constriction is seen in blood pressure variability. The decrease in variability may correspond with the ongoing activation of compensatory reserves.

It then is possible that low levels of nonharmful challenge may be beneficial. Masoro and colleagues believe that one mechanism by which caloric restriction lengthens life is through the low-intensity, nonharmful stress produced by the decreased availability of calories (Masoro 2006). This concept, hormesis, suggests that persistent, harmless stresses, such as caloric restriction or radiation, may be good for us; larger stresses may be harmful (Masoro 2006; Demirovic and Rattan 2013). The beneficial effects of methionine or tryptophan restriction may also be via this mechanism (Masoro 2006).

Homeostenosis and Altered Presentation of Disease in the Elderly

The precipice shown in the figures also helps explain the altered, nonspecific, presentations of disease that characterizes the elderly. Delirium or altered mental status is a very common presentation of a wide variety of illnesses in the elderly, from urinary tract infection to gastrointestinal bleeding. In some individuals, where the "anti-confusion reserves" are exhausted, delirium may be their presentation for almost all their illnesses

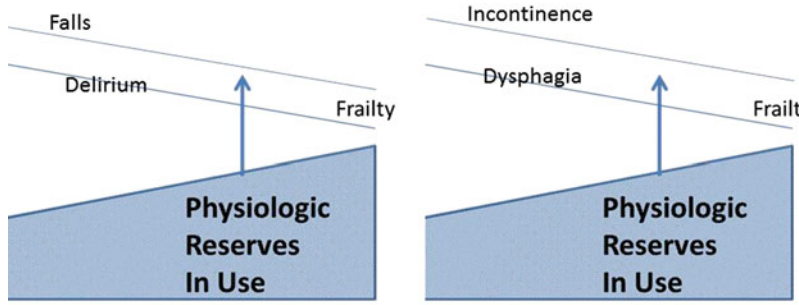

Fig. 3 Altered presentation of illness. Altered presentations may be another manifestation of homeostenosis. With age, different precipices may approach homeostasis at differing rates and different reserves may be invoked differentially so that small challenges cross different precipices. In this case, the same challenge results in new onset of incontinence for one individual and confusion in another

(Fig. 3). In that individual, homeostasis and the delirium precipice lie very close to each other, any challenge crosses the precipice. Another individual may present with incontinence as their catch-all presentation. The extent that any precipice approaches homeostasis may determine whether that threshold is crossed by a given challenge. This phenomenon may be relatively common in frail older people because the systemic responses to these differing illnesses may be similar, involving cytokines, catecholamines, etc. It means that one needs to have a broad differential for the nonspecific presentations in the elderly patient.

The increased frequency of falls in response to challenge fits this model perfectly. Decreases in recognition of thirst, baroreceptor sensitivity, arterial compliance, cardiac compliance (and greater dependence on cardiac filling to maintain cardiac output), renal sodium conservation, plasma volume, vasopressin response to standing, and renin, angiotensin, aldosterone levels all contribute to increase the propensity to fall with postural change in the older person in the absence of illness. That is the precipice representing falling gets closer to homeostasis with age. With illness, dehydration or other perturbation occurs and falls ensue. Many of the problems with medications in the elderly, once attributed to altered pharmacodynamics, may be explained by this apparent depletion of physiologic reserves. Falls are the nonspecific presentation of a wide number of underlying processes.

The lines representing the precipices are unlikely to be straight in reality, because none of the processes are necessarily linear. For example, the rate of loss in muscle mass increases with increasing age and the loss of lower extremity strength also follows this same pattern.

The concept of homeostenosis also allows understanding of, therapeutic nihilism, the idea that treating older people has no yield. Indeed, the opportunity for treatment focused only at a disease to benefit a patient is limited by the length of the arrow displacing them from homeostasis. We verbalize this as “a little COPD exacerbation” in the older person. The lesser opportunity for “cure” creates a greater impetus for prevention or active treatment. Additionally, treatment directed at the depleted or activated reserves can be considered.

Summary

Physiologic reserves appear to be lost with age leading to an intolerance of challenges to homeostasis. Some of those reserves have not disappeared but are invoked to maintain homeostasis. Nonspecific presentations of illness in elderly may reflect their individual homeostenosis. Frailty is, in part, the extreme where the older person is continuously expending reserves to compensate for existing chronic disease and primary age changes. Providing ways to improve the resilience of the elderly may lead to rich rewards. Interventions that increase longevity, but do not prevent homeostenosis, may lead to longer years of disability and dependence.

Abstract

Lung aging begins in the third decade, initiating a gradual decline in maximal pulmonary function that continues throughout the remainder of life. Lung aging may mimic obstructive and restrictive lung diseases. Lung parenchyma loses elasticity via alveolar wall and mesenchymal degradation and distortion, similar to emphysema. Muscles of respiration become sarcopenic and weaken, while the

thorax contorts due to osteoporotic vertebral fractures, all of which manifest as a restrictive lung function pattern. Chronic obstructive pulmonary disease (COPD) and idiopathic pulmonary fibrosis (IPF) and their pathogenesis may be related to accelerated cellular aging. Chronic lung disease impacts cardiopulmonary fitness, which can lead to decreased physical exertion and resultant frailty.

Lung cancer incidence also increases with age and is increased in older adults with COPD and IPF. Lung cancer is the leading cancer-related cause of death in the world. Most lung cancer in the USA is attributable to smoking. Globally, indoor air pollution is also a significant risk factor. Approximately 85% of lung cancer is non-small cell lung cancer (NSCLC), and adenocarcinoma is the predominant histologic type. Depending on stage at diagnosis, treatment options can include surgical resection, medical therapy (e.g., chemotherapy, driver mutation-targeted agents, and immunotherapy), and radiation therapy (photon or proton). Best care practices mandate that multidisciplinary teams formulate treatment plans to optimize care. Comprehensive geriatric assessments are useful decision-making tools and may improve survival while limiting treatment toxicity. Surgical resection impacts postoperative lung function, so preoperative evaluations must include pulmonary function testing with additional cardiopulmonary testing as indicated. Early palliative care interventions should be a cornerstone of medical management in advanced lung cancer.

Introduction

Lung function peaks in the third decade of life, and then begins to slowly decline, precipitated by degradation of lung parenchyma, weakening of respiratory muscles, and distortion of the thorax. The natural history of chronic lung disease may mimic chronic obstructive pulmonary disease, due to air trapping (increased residual volume) and decreased forced expiratory volume in one second (FEV_1). However, respiratory muscles weakness and restriction of the thoracic cavity may counteract some of these obstructive changes on pulmonary function testing.

Chronic obstructive pulmonary disease (COPD) and idiopathic pulmonary fibrosis (IPF) are prototypical chronic lung diseases of aging. Not only does prevalence and incidence of both diseases rise with age, but the pathogenesis of each overlaps with hallmarks of aging, such as shortened telomeres, defective DNA repair, genomic instability, cellular senescence, stem cell exhaustion, and mitochondrial dysfunction. Emerging evidence suggests that individuals with chronic lung disease experience physiologic aging that outpaces chronologic aging, therefore they are disproportionately burdened with geriatric syndromes such as frailty.

The prevalence of lung cancer is increased with COPD and IPF. Lung cancer is the deadliest of all cancers in the USA and causes substantial morbidity and mortality for aging populations. Given the increasing prevalence of lung cancer with age, understanding lung aging is an important element of caring for these patients. This chapter will discuss lung aging, chronic lung disease, lung cancer screening, and the nuances of caring for geriatric patients with lung cancer.

Recent guidelines recommend initiating low-dose computed tomography (LDCT) lung cancer screening in select at-risk populations with smoking exposures. These new guidelines are altering clinical practice particularly for geriatric patient populations, as screening targets patients between ages 55 and 80 years, and Medicare now pays for annual screening in select populations. Primary care physicians must decide how to incorporate lung cancer screening into their care of geriatric patients and use shared-decision making to determine when to stop screening.

When lung cancer is suspected, a multidisciplinary team including primary care

providers, geriatricians, pulmonologists, oncologists, and thoracic surgeons helps to shape the management plan for geriatric patients. Geriatric populations are heterogeneously resilient to the risks of cancer treatment; some high-risk subgroups are burdened with decreased physical function, disability, multimorbidity, and/or geriatric syndromes (including falls, incontinence, and polypharmacy). It is essential that providers appropriately risk-stratify patients to make the complex decisions required in care planning, so to avoid overtreatment of high-risk groups and undertreatment of resilient groups.

Lung Aging

Lung aging begins in the third decade of life, far earlier than what could be described as a "geriatric" age. Understanding lung aging, therefore, mandates an understanding of the embryologic underpinnings of the respiratory system (Bush 2016). Lung development first begins at week 3 of embryologic development, when the lung bud develops from the foregut (Burri 2006). By week 4, the lung bud has divided into two bronchial buds. Primitive alveolar sacs develop at approximately 16 weeks and proliferate. At 24 weeks, more alveoli have developed and the epithelium is thin enough for respiration, at which time the type 2 pneumocytes begin to produce surfactant. The lungs continue to develop throughout postnatal life, by increasing the size and number of respiratory bronchioles and alveoli until approximately age 8. Lung aging, the gradual decline of maximal lung function, begins just 20 years later (Janssens et al. 1999; Janssens 2005; Meiners et al. 2015).

Aging incites structural and functional changes throughout the respiratory system, including the thorax, muscles of respiration, bronchioles, and alveoli. The elasticity of lung parenchyma deteriorates, impeding bronchiole patency, alveolar integrity, and the alveolar/capillary interface. Muscles of respiration, including the diaphragm, intercostal muscles, and other accessory muscles, gradually lose muscle mass with age (called sarcopenia) and may functionally weaken (Cruz-Jentoft et al. 2010). The thorax, including the spinal column and rib cage, contorts due to osteoporotic vertebral body fractures and resultant kyphosis, hampering the lungs' expansion (Leech et al. 1990).

There are several objective assessments of respiratory organ aging. Such tools include lung volume measurements (by body box plethysmography or single breath helium dilution) **(**Fig. 1a**)**, airflow measurements (by spirometry), gas exchange capability (via diffusing capacity of the lung for carbon monoxide (DLCO)), respiratory muscle strength (by maximal inspiratory and expiratory pressure), exercise testing (6-min walk testing, shuttle walk testing, and cardiopulmonary exercise testing), and oxygenation measures (by arterial blood gas or pulse oximetry) (Table 1). Lung volumes are measured in liters, and these values are reported along with "predicted" values based on height, age, and gender (Quanjer et al. 1993).

Age-related changes in airway and alveolar structure impede air egress, which decreases forced expiratory reserve volume in one second (FEV_1) particularly as compared to the total forced expiratory reserve volume (FVC), consistent with airflow obstruction **(**Fig. 2a–c**)** (Schmidt et al. 1973). These changes mimic chronic obstructive pulmonary disease (COPD). Alveolar distortion impairs gas exchange which decreases the DLCO. Pathologically, enlargement of the alveolar structure with age may appear similar to emphysema, though typically without the same degree of alveolar wall destruction (Janssens et al. 1999).

Lung volume changes with age vary between individuals. Airflow obstruction causes air trapping and an increased residual volume (RV), which is the volume of air remaining in the lungs after maximal exhalation **(**Fig. 1b**)**. Total lung capacity (TLC) may stay constant or shrink due to chest wall restriction from thorax distortion or respiratory muscle weakness (Enright et al. 1994). Therefore, the outcome of pulmonary function testing will vary depending on an individual's burden of aging-related lung function changes.

Respiratory muscle strength	MIP, MEP
Exercise testing	
Low technology	6-min walk, shuttle walk, stair climb
High technology	Cardiopulmonary exercise testing (VO_2)

TLC total lung capacity, *FRC* functional residual capacity, *RV* residual volume, *FEV_1* forced expiratory volume in 1 second, *FVC* forced expiratory volume, *DLCO* diffusing capacity of the lung for carbon monoxide, *paO_2* partial pressure of oxygen, *SpO_2* pulse oximetry, *pCO_2* partial pressure of carbon dioxide, *MIP* maximal inspiratory pressure, *MEP* maximal expiratory pressure, *VO_2* maximal oxygen consumption

Chronic Lung Diseases and Aging

Chronic lung diseases such as COPD, IPF, combined pulmonary fibrosis and emphysema (CPFE), asthma, and the newly described asthma-COPD overlap syndrome (ACOS) can impact quality of life and mortality of geriatric patients. General primary or specialty pulmonary

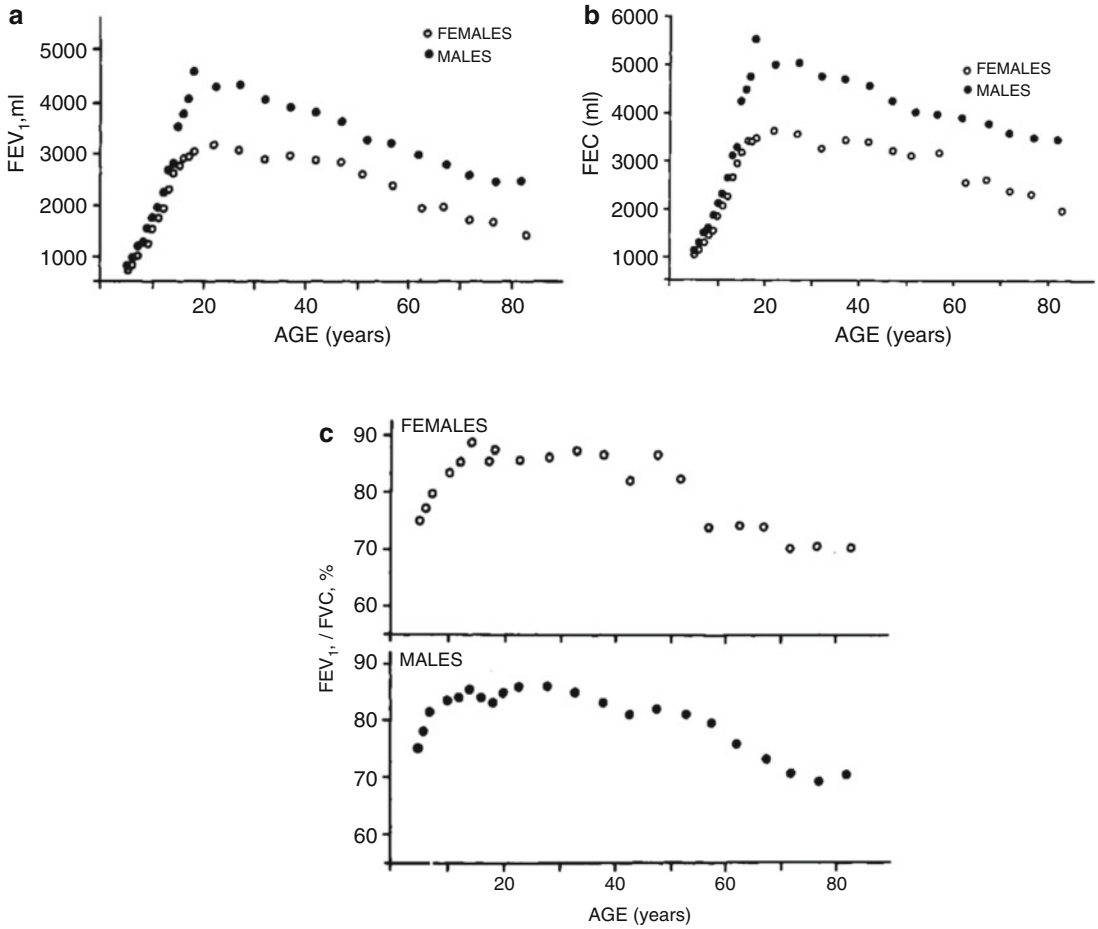

Fig. 2 (**a**) Mean forced expiratory volume in 1 second capacity (FEV_1) values by age 5–94 years. (**b**) Mean forced vital capacity (FVC) values by age 5–94 years. care for patients with chronic lung disease should include an assessment of pulmonary function (as described above), physical function (as measured by low-technology exercise testing and oxygenation), appropriate maintenance and rescue inhaler prescriptions, supplemental oxygen when indicated, and meticulous preventive care (including influenza and pneumococcal vaccination). Pulmonologists are increasingly recognizing the impact of aging on caring for patients with chronic lung disease and incorporating geriatric assessments into their care (Singer et al. 2016; Castriotta et al. 2010; Fried et al. 2012a).

Dyspnea or shortness of breath is a common complaint in geriatric populations and a frequent reason for referral to pulmonary subspecialists. Dyspnea can occur for a multitude of reasons, including cardiopulmonary impairment (e.g., congestive heart failure), neuromuscular diseases (e.g., amyotropic lateral sclerosis), and psychological distress (e.g., anxiety). Dyspnea complaints should receive a comprehensive evaluation, as detailed in the 2012 American Thoracic Society consensus statement, which includes a thorough history and physical examination to narrow the broad differential diagnosis and

Table 2 Clinical dyspnea scales

determine further testing (Parshall et al. 2012). In a study of home-dwelling elderly individuals (aged 70 and older), the prevalence of dyspnea by the modified Medical Research Council scale (mMRC) (Table 2) was 32.3% (95% CI 30.3–34.3%) (Ho et al. 2001).

Dyspnea also appears to be related to mortality. In a cohort study of elderly family practice patients, dyspnea at baseline evaluation was significantly associated with death at 8-year follow-up (Huijnen et al. 2006). Some experts suggest that dyspnea be considered a geriatric syndrome. In an analysis of the 4413 community dwelling people in the Cardiovascular Health Study, moderate to severe dyspnea (Miner et al. 2016) was associated, expectedly, with cardiopulmonary impairments such as low FEV_1 or left ventricular function. Surprisingly, dyspnea was also associated with anxiety/depressive symptoms, inability to perform a chair stand, and grip weakness.

COPD is the third leading cause of death in the USA and fourth in the world (NCHS 2016; WHO 2016). Most patients with COPD have a history of personal or second-hand smoking (GOLD 2017). In countries with significant air pollution, such as from indoor solid-fuel use, COPD causes an even higher burden of mortality. For example, in China, COPD is the second leading cause of death due to high rates of smoking and indoor air pollution (Lin et al. 2008).

COPD is characterized by progressive airflow obstruction, defined by the Global Initiative for Chronic Obstructive Lung Disease (GOLD) criteria as an FEV_1/FVC ratio $< 70\%$ (actual) and a forced expiratory volume (FEV_1) $< 80\%$ (predicted) (GOLD 2017). Traditionally, COPD staging depended solely on FEV_1 impairment, but now dyspnea symptoms and exacerbation history are included in staging. The Body-Mass Index, Airflow Obstruction, Dyspnea, and Exercise Capacity (BODE) Index can assist in predicting 4-year survival (Celli et al. 2004). Patients may have the chronic bronchitis (mucous production and increased airway resistance) and/or emphysema (impaired gas exchange and increased air trapping) subtypes of COPD.

COPD mimics the natural history of normal lung aging (Macnee 2016; Mercado et al. 2015). An emerging debate is challenging the traditional paradigm of COPD pathogenesis as solely attributable to accelerated lung aging and suggests that a subset of patients may be predisposed to develop COPD due to abnormal lung development but normal lung aging. In 1977, Fletcher and Peto presented what would become the conventional model of COPD pathogenesis. Their epidemiological description of "British disease," so-called due to the high prevalence of COPD in Britain, suggested that gradual age-related lung function decline can be accelerated by smoking in some individuals (Fletcher and Peto 1977).

A 2015 study by Lange and colleagues contested the traditional model as the only path to COPD pathogenesis. In their review of spirometry and outcomes from three large cohort studies, the Framingham Offspring Cohort, the Copenhagen City Heart Study, and the Lovelace Smokers Cohort, the authors showed that some patients

who develop obstructive lung disease may have failed to achieve normal lung function before experiencing normal age-related lung function decline (Lange et al. 2015). Risk factors in childhood and early adolescence, such as parental smoking (particularly intrauterine exposure by the mother), a family history of asthma, and/or a personal history childhood asthma, or respiratory infections, may predispose an individual to obstructive lung disease (Bush 2016).

Clearly, there is heterogeneity within the COPD patient population, and as a result, the rate at which FEV_1 declines in COPD is highly variable between patients. Data from a 2011 study by Vestbo et al., that followed 2163 patients over a 3-year period, found a mean (± standard error) rate of decline of 33 (±2) ml per year (Vestbo et al. 2011). Notably, patient subgroups experienced different rates of decline, with higher rates in current smokers compared to nonsmokers (21 ± 4 ml), those with emphysema compared to those without emphysema (13 ± 4), and those with bronchodilator reversibility compared to those without reversibility (17 ± 4 ml). These findings demonstrate that the clinical course of COPD is variable and difficult to predict.

Caution must be exercised before conferring COPD diagnoses on elderly individuals. Remember that normal lung aging mimics COPD **(**Figs. 2a–c**)**, yet patients may not be symptomatic and medical therapy for COPD has not been studied to "treat" normal lung aging. In a study of 208 asymptomatic never-smoker individuals over age 70 who underwent spirometry, 35% were found to qualify for stage 1 COPD by the GOLD criteria (Hardie et al. 2002). Further evidence from 2025 individuals aged 65–100 years old found airflow limitation in 28.2 per 1000 person-years when using the GOLD criteria (Luoto et al. 2015). The number of patients classified as having airflow limitation decreased to 11.7 per 1000 person-years when an age-dependent predicted lower limit of normal (LLN) value was used instead. Increasingly, experts suggest modifying diagnostic criteria to be based on standard deviations from the median (called spirometric z scores) (Vaz Fragoso et al. 2015) or LLN criteria for older patients.

Idiopathic pulmonary fibrosis (IPF), an interstitial lung disease of unknown etiology, is far less prevalent than COPD though similar aging-related changes are implicated in its pathogenesis. The incidence and prevalence of IPF increases significantly with age, male gender, and history of tobacco use (Raghu et al. 2006). Two-thirds of patients with IPF are over 60 years old at time of presentation, with a mean age at diagnosis of 66 years (Fig. 3).

In IPF, aberrant wound healing and resultant pathogenic fibrosis causes progressive lung destruction. Pulmonary function testing reveals small lung volumes and a restrictive lung disease pattern. There is typically a normal or high FEV_1/FVC ratio due to increased elastic recoil in the lungs. There is no cure for IPF, though two new recently approved medications, pirfenidone and nintedanib, slow the progression of IPF (King Jr et al. 2014, Richeldi et al. 2014). End-stage IPF may be treated with lung transplant. Median survival following diagnosis is 2.5–3.5 years and approximately 40,000 people die per year of IPF just in the USA (Blackwell et al. 2013; Ley et al. 2011), though this data was reported prior to use of antifibrotic agents.

Combined pulmonary fibrosis and emphysema (CPFE) is an increasingly recognized disease state that combines pathogenic features of COPD and IPF. Pulmonary function testing may approach normal due the balanced deficits of lung restriction and obstruction (Jankowich and Rounds 2012). Therefore, the diagnosis is often made radiographically or on pathology. Median survival is slightly higher than IPF, ranging from 2.1 to 8.5 years.

Asthma in the elderly often mimics COPD and is under recognized and undertreated (Skloot et al. 2016). Patients 65 years and older have the highest rates of asthma deaths and second highest rate of asthma hospitalizations as compared to other age groups. Further, the natural history of lung aging, such as decreased elastic recoil, can further exacerbate asthma symptoms making the disease more challenging to treat. The asthma-COPD overlap syndrome (ACOS), like CPFE, identifies a unique subset of older patients with an overlapping asthma and COPD phenotype.

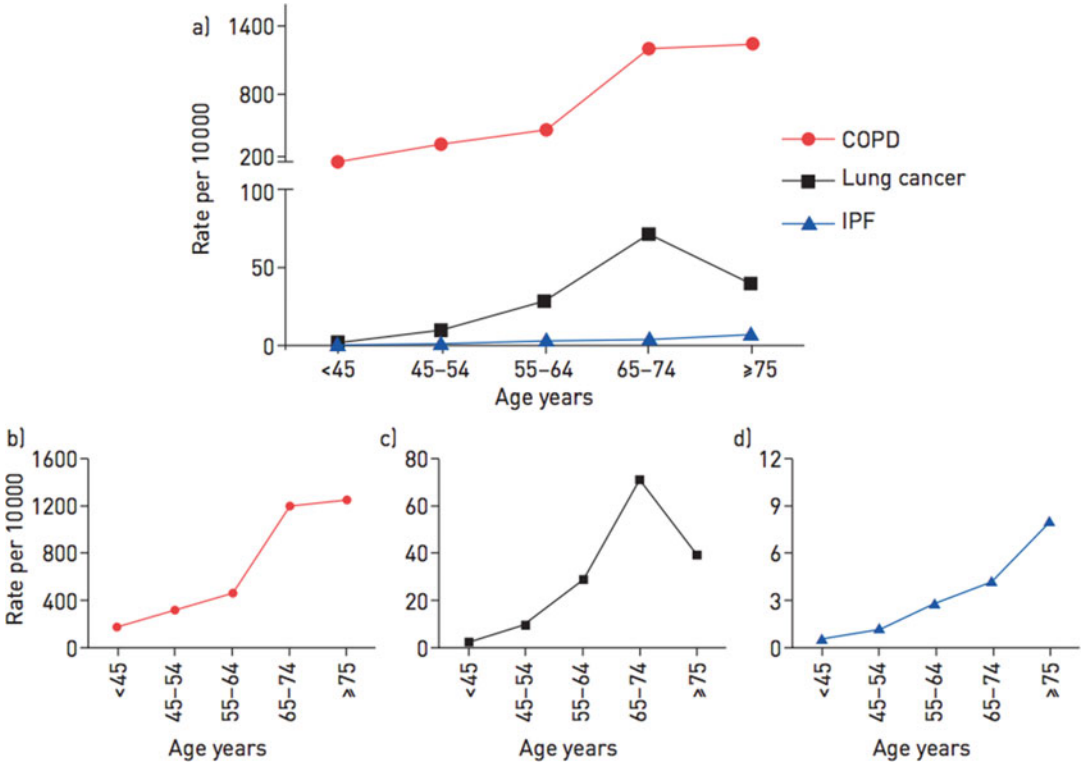

Fig. 3 The all-gender incidence rates of chronic obstructive pulmonary disease (COPD), lung cancer, and idiopathic pulmonary fibrosis (IPF) according to age in the USA. (Reproduced with permission from the European Respiratory Society ©. European Respiratory Journal. 2015;45(3):807–827. https://doi.org/10.1183/09031936.00186914)

(Postma and Rabe 2015). One study estimated the prevalence of ACOS in individuals with COPD at 17.4%, and noted increased dyspnea, wheezing, respiratory-related quality of life by the St. George' Respiratory Questionnaire (SGRQ) and reduced physical activity, as compared to nonoverlap COPD patients (Miravitlles et al. 2013).

Primary care for patients with chronic lung disease can be complex (Fried et al. 2012b). These patients often have multiple comorbidities such as arthritis, osteoporosis, congestive heart failure, and depression (Schnell et al. 2012). One study noted a prevalence of four or more comorbid conditions in over half of patients with moderate to very severe COPD (Vanfleteren et al. 2013). Comorbid conditions such as gastroesophageal reflux and cardiac dysfunction can exacerbate asthma and COPD (Hanania et al. 2011; Le Jemtel et al. 2007). The guideline-based management of multiple comorbid conditions, when taken together, may offer contradictory advice or be financially or logistically impractical to undertake (Boyd et al. 2005).

Chronic Lung Diseases and Frailty

Patients with COPD are more likely to be frail. Frailty is a phenomenon of impaired physiologic reserve and resilience, first described by the Cardiovascular Health Study in 2001, through the creation of the Fried Frailty Phenotype (FFP) (Fried et al. 2001). The FFP is an aggregated score of five assessments: grip strength, walk speed, weight loss, exhaustion, and physical activity level. Fried's original study revealed that a frailty phenotype was significantly associated

with COPD even when adjusted for age. Lahousse et al. confirmed these findings through a study of community-dwelling individuals, finding that those with COPD by spirometry were more likely to be frail by FFP (10.2%) as compared to those without COPD (3.4%) ($p = 0.001$) (Lahousse et al. 2016). Frail patients with COPD had a mortality rate three times that of nonfrail patients with and without COPD. The authors noted that frailty predicted mortality better than FEV_1 or other comorbidities.

Not surprisingly, frailty is highly prevalent in patients seen in outpatient pulmonary clinics. In 2016, Mittal and colleagues described a frailty prevalence of 18% and prefrailty prevalence of 64% in pulmonary outpatients (Mittal et al. 2016). Fried frailty phenotype assessments can be arduous to complete, so the authors used easily collected ambulatory data such as 100 feet gait speed, as frailty surrogates. They defined slow gait speeds as less than 60 m/min, finding that this was 95% sensitive and 34% specific to predict frailty. Gait speed may be an adequate frailty screening tool in an outpatient pulmonary clinic and could suggest referral to a geriatric clinic.

Spirometric impairment, even without diagnosed lung disease, impacts mortality. Vaz Fragoso and colleagues discovered that, among participants aged 65–80 years in the Cardiovascular Health Study, mortality was highest in those with both frailty and respiratory impairment (adjusted hazard ratio, 3.91, 95% CI, 2.93–5.22) as compared to those with and without frailty and/or respiratory impairment alone (Fragoso et al. 2012).

Sarcopenia, the phenomenon of muscle loss with age, has been described in individuals with COPD. Jones et al. applied the European Working Group on Sarcopenia in Older People (EWGSOP) criteria to 622 outpatients with COPD and found a 14.5% (95% CI 11.8–17.4%) prevalence of sarcopenia, which was associated with age and COPD severity (Jones et al. 2015). In an evaluation of the exercise capacity and muscle strength of 41 patients with COPD, Gosselink et al. found that lung function and peripheral muscle strength were significantly related to exercise capacity in these patients (Gosselink et al. 1996). Pulmonary rehabilitation, a pillar of chronic lung disease management, improves sarcopenia (Jones et al. 2015).

End-stage lung disease can be treated with single or double lung transplant in appropriate candidates, and transplant centers are examining the role of geriatric assessments in further evaluating transplant candidates. While the current lung allocation score incorporates some candidate characteristics (e.g., 6-min walk distance and functional status) accumulating evidence about global functional impairment in patients with severe lung disease suggests the utility of frailty and sarcopenia assessment tools for transplant candidates (Egan et al. 2006). A 2015 study of listed lung transplant candidates showed a high burden of frailty by FFP (28%) and Short Physical Performance Battery (SPPB) (10%) (Singer et al. 2015). Frailty was significantly associated with lung transplant delisting, disability, and death.

Lung Cancer and Aging

Lung Cancer Epidemiology and Risk Factors

Lung cancer is the leading cause of cancer-related deaths for both men and women in the USA. Until recently, lung cancer screening was not standard of care, and most patients presented with late stage disease. As a result, the 5-year survival of all stages of lung cancer from 2006 to 2012 was 17.7% (Howlader et al. 2016). The median age of lung cancer patients at time of diagnosis is 70 years old, and lung cancer is most frequently diagnosed between 65 and 74 years. Men, particularly African American men, face the highest burden of lung cancer diagnoses and death. In the USA, the incidence of lung cancer began to decline in the late 1980s for men, though it did not decline for women until the 2000s (ACS 2016). Lung cancer costs in the last year of life are the highest compared to other types of cancer (Mariotto et al. 2011).

Non-small cell lung cancer (NSCLC) comprises about 85% of all lung cancers (ACS 2016). Adenocarcinoma is the most frequently

identified histologic type of NSCLC and accounts for approximately 40% of all lung cancers. The frequency of adenocarcinoma declines with age, while the frequency of squamous cell carcinoma increases (ACS 2016). In the USA, 80% of lung cancer deaths are attributed to smoking (ACS 2016). Other lung cancer risk factors include second-hand smoke exposure, smoke from indoor burning of coal and wood for cooking and heating, air pollution, radiation therapy (e.g., for Hodgkin lymphoma or breast cancer), and environmental/occupational carcinogens (e.g., radon) (Darby et al. 2005; Pope III et al. 2002; Fontham et al. 1994; Travis et al. 2002).

The pathogenesis of chronic lung diseases such as COPD and IPF have cellular "hallmarks of aging" that overlap with those found in malignant lung cancer cells. Similar pathogenic features include shortened telomeres (Morla et al. 2006), defective DNA repair (Caramori et al. 2011), genomic instability, cellular senescence/stem cell exhaustion (Chilosi et al. 2013), metabolic alterations such as mitochondrial dysfunction (Mora et al. 2017), and epigenetic changes (López-Otín et al. 2013; Mercado et al. 2015; Pardo and Selman 2016; Macnee 2016; Vancheri et al. 2010) (Fig. 4).

Lung cancer is more prevalent in those with COPD and IPF compared to patients without chronic lung disease. In a 2009 study of patients with lung cancer, COPD prevalence by all GOLD stages was significantly higher than age/sex/smoking exposure matched-controls (50% compared to 8%) (Young et al. 2009). COPD appeared to confer a sixfold greater risk of developing lung cancer compared to participants without COPD. Emphysema on computed tomography (CT) scan is an independent risk factor for lung cancer. In a 2007 study of 1166 individuals undergoing lung cancer screening with low radiation-dose CT, the incidence of lung cancer was 25.0 per 1000 person-years in those with emphysema vs. 7.5 per 1000 person-years in those without emphysema (De Torres et al. 2007) (Fig. 5).

Patients with IPF also have higher rates of lung cancer. In a retrospective study of patients with CPFE, IPF, and emphysema, patients with CPFE were found to have the highest risk of lung cancer (adjusted hazard ratio of 4.62, 95% CI 1.58–13.55) as compared the emphysema group (Kwak et al. 2014). The IPF group also had an increased risk of lung cancer as compared to the emphysema group (adjusted HR 4.15, 95% CI 1.03–16.78).

Lung Cancer Screening

Until recently, there was no standardized lung cancer screening practice supported by strong evidence. In 2011, the National Lung Screening Trial Research Team published a randomized, prospective study of 53,454 participants who received either three annual screenings with low-dose computed tomography (LDCT) or single-view posteroanterior chest radiography, from 2003 to 2004 (Team 2011). At the end of the study, the LDCT group had fewer deaths related to lung cancer (247 deaths per 100,000 person-years) versus the chest radiography group (309 deaths per 100,000 person-years). All-cause mortality in the LDCT group was significantly reduced by 6.7% (95% CI 1.2–13.6; $p = 0.02$) as compared to the chest radiography group. A follow-up analysis of the data suggested that LDCT screening could prevent approximately 12,000 lung cancer deaths per year in the USA (Ma et al. 2013).

This data must be interpreted with an understanding of the greatest drawback of increased lung cancer screening: falsely positive tests leading to increased invasive diagnostic procedures and anxiety about test results. The 2011 screening study found a high false positive rate in both the LDCT group (96.4%) and the chest radiography group (94.5%). Further analyses of the same study population have demonstrated higher false positive rates in participants 65 years or older (Medicare-eligible) as compared to those less than 65 (Pinsky et al. 2014). More false-positive screening exams resulted in more invasive procedures to pursue diagnosis. Importantly, participants who underwent invasive procedures experienced a relatively low complication rate in both age groups, that was not significantly different (9.8% in <65 group and 8.5% in ≥ 65 group). However, the older participants had a higher prevalence of cancer and higher positive predictive

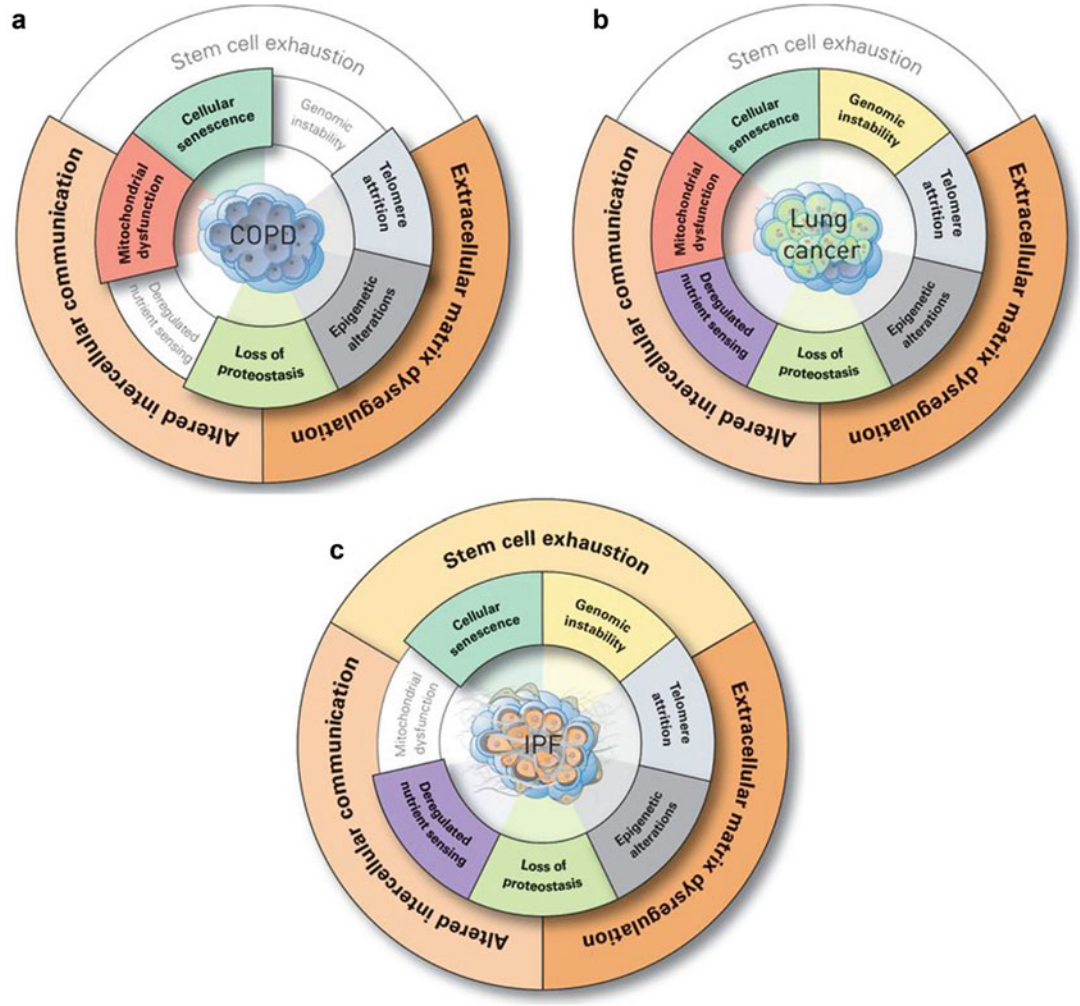

Fig. 4 The predominant hallmarks of aging in (**a**) chronic obstructive lung disease, (**b**) lung cancer, and (**c**) idiopathic pulmonary fibrosis. (Reproduced with permission from the European Respiratory Society ©. European Respiratory Journal. 2015;45(3):807–827. https://doi.org/10.1183/09031936.00186914)

value (4.9% vs. 3.0%) as compared to the group under age 65.

The findings from the National Lung Screening Trial Research Team study led the United States Preventive Task Force (USPSTF) to give a grade B recommendation for annual lung cancer screening by LDCT. This recommendation applies to adults aged 55–80 years with a 30 pack-year smoking history and current smoking behavior, or smoking cessation within the last 15 years. They suggest that screening should continue until a patient has not smoked for 15 years (Moyer 2014).

The intent of the screening practice is to identify early-stage resectable lung cancer. Therefore, annual screening should cease if a patient's life expectancy is limited by comorbidities or the patient is unwilling to have curative lung surgery or radiation treatment. In 2015, the Centers for Medicare and Medicaid Services began covering LDCT lung cancer screening as a preventive service benefit (Medicare and Services 2015).

The American College of Radiology (ACR) has suggested a standard method for evaluating LDCT, called the ACR Lung CT Screening Reporting and Data System (Lung-RADS)

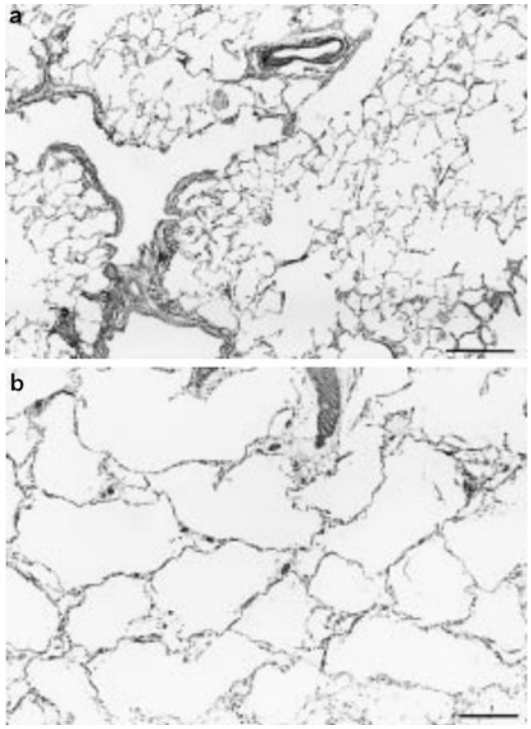

Fig. 5 (**a**) Lung parenchyma from a 29-year-old individual with no history of smoking; (**b**) lung parenchyma from a 100-year-old nonsmoking individual. The alveolar spaces are markedly enlarged as compared to the younger individual in panel a. (Hematoxylin and eosin stain; internal scale bar = 280 mm (**a**); 250 mm (**b**)). (Reproduced with permission from the European Respiratory Society ©. European Respiratory Journal. 1999;13(1):197–205)

(Mckee et al. 2016). Suggested categorization for screening LDCTs along with management recommendations is summarized in Table 3. The ACR's guidelines were retrospectively applied to the National Lung Screening Trial group's method of approaching nodules and demonstrated a decreased false positive rate (12.8% vs. 26.6%) but a lower sensitivity (78.6% vs. 93.8%)(Pinsky et al. 2015).

Some lung cancers are found incidentally on radiographic imaging obtained for other reasons. The Fleischner Society has published guidelines for managing incidentally discovered pulmonary nodules in nonimmunocompromised patients over 35 years (Macmahon et al. 2017). These recommendations stratify risk by nodule type (solid versus subsolid) and further by size (by average diameter) and pretest probability for lung cancer (Table 4).

The guidelines for management of incidental pulmonary nodules should not be used to interpret lung cancer screening LDCT studies, primarily because the pretest probability for lung cancer is higher in the preselected lung cancer screening group. A predictive calculator tool may assist in estimating a nodule's probability of malignancy (Mcwilliams et al. 2013). Increased risk is ascribed to individuals with older age, female sex, a personal history of emphysema, and a family history of lung cancer. Nodule characteristics that impart additional risk are larger size, spiculation, semisolid components, and upper lobe location.

Lung Cancer Diagnosis

Outside of screening or incidental findings, physicians may infrequently suspect lung cancer based on clinical signs or symptoms. However, patients do not typically develop symptoms suggestive of lung cancer until late in the disease course. Symptoms can include cough, chest pain, hemoptysis, clubbing, weight loss, and fever (Spiro et al. 2007). When lung cancer is suspected based on clinical symptoms, one should proceed to chest radiography or contrast-enhanced CT scanning.

If lung cancer is suspected by imaging, the patient may have either a biopsy to obtain tissue for pathologic evaluation and staging, or if radiographic characteristics strongly suggest an early stage cancer (stage IA), proceed directly to surgical resection for diagnosis and curative management. The most commonly used staging system is the TNM (tumor/node/metastasis) classification produced by the American Joint Committee on Cancer (AJCC), recently updated to an 8th edition in 2017 (Tables 5 and 6) (AJCC 2017).

There are two steps of staging lung cancer. First, patients are clinically staged prior to invasive procedures, to determine the best next step. Clinical staging should begin with contrast-enhanced CT imaging of the chest and upper abdomen and brain imaging (Silvestri et al. 2013).

Table 3 LDCT grading and management

Category	Description	Findings	Recommendation
0	Incomplete	Cannot evaluate (poor study, need prior imaging)	Additional images needed (or compare to prior)
1	Negative	No nodules or nodule(s) with benign calcifications	Annual LDCT
2	Benign appearance/ behavior	*Solid nodule(s)*: < 6 mm or new <4 mm *Part-solid nodule(s)*: <6 mm total on baseline screen *Non-solid nodule(s)*: < 20 mm or ≥ 20 mm and unchanged Category 3 or 4 without change for ≥3 months	
3	Probably benign	*Solid nodule(s)*: ≥6–8 mm at baseline or new 4 mm to <6 mm *Part-solid nodule(s)*: ≥6 mm total, solid component <6 mm or new <6 mm total *Non-solid nodule(s)(ground glass)*: ≥20 mm baseline or new	6 month LDCT
4A	Suspicious	*Solid nodule(s)*: ≥8 – < 15 mm baseline or growing <8 mm or new 6 – <8 mm *Part-solid nodule(s)*: ≥ 6 mm with solid component ≥6–8 mm or new/growing <4 mm solid component *Endobronchial nodule*	3 month LDCT, may use PET/CT if ≥8 mm solid component
4B		*Solid nodule(s)*: ≥ 15 mm or new/growing and ≥8 mm *Part-solid nodule(s)*: Solid component ≥8 mm or new/growing solid component ≥4 mm	Chest CT with or without contrast, PET/CT and/or tissue sampling
S	Significant – other	Add on to 0–4 coding	No specific recommendation
C	Prior lung cancer	Add on to 0–4 coding

The evidence for use of whole body positron emission tomography (PET) or PET/CT scans to stage is mixed, and staging decisions should not be made based on PET/CT scan alone. Staging consensus guidelines suggest synthesizing radiographic data to guide tissue biopsy planning (Travis et al. 2011; Murgu 2015). A PET/CT scan may help guide clinicians to biopsy lymph nodes (via endoscopy or mediastinoscopy) or to proceed directly to surgery for resection and surgical/pathologic staging (Schmidt-Hansen et al. 2014).

The second step of lung cancer staging is pathologic staging, either surgical with mediastinal lymph node dissection or nonsurgical lymph node sampling. If Stage IB, II, or III is suspected, the preferred diagnostic and staging modality is endobronchial ultrasound with transbronchial needle aspiration (EBUS-TBNA), particularly for centrally located lesions or paratracheal lymph node biopsies. The EBUS-TBNA procedure allows for safe, moderately invasive tissue diagnosis, typically under general anesthesia, with on-site cytologic evaluation (Yasufuku et al. 2005). A 2014 study of 451 patients showed that the risk of complication rates among patients $\geq$70 years was similar to patients <70 years (5.1% vs. 8.7%, respectively, $p = 0.13$), in spite of worse performance status in the older patients ($p < 0.001$) (Evison et al. 2014).

If cancer is diagnosed during the EBUS-TBNA procedure, the disease is further staged during the same procedure by obtaining tissue from contralateral lymph nodes that could "up-stage" the

disease and alter treatment plans. If biopsies from the EBUS-TBNA procedure are negative or inconclusive, and clinical suspicion of regionally advanced disease is high, the patient proceeds to mediastinoscopy or thoracoscopy for regional nodal assessment (Rivera et al. 2013). When lesions are peripheral, the yield by bronchoscopy decreases, and alternative diagnostic methods such as CT-guided transthoracic needle aspiration or video-assisted thoracic surgery (VATS) may be useful. If stage IV lung cancer is suspected based on distant metastases, a more readily available metastatic tissue sample may be obtained, such as from pleural fluid or a superficial lymph node. No matter the diagnostic modality, adequate tissue must be obtained for histologic type and molecular analysis.

Non-Small Cell Lung Cancer

Making Treatment Decisions

Lung cancer treatment planning requires a multidisciplinary approach that integrates expert recommendations from medical oncologists, medical and radiation oncologists, pathologists, thoracic surgeons, pulmonologists, primary care doctors, and geriatricians (Spira and Ettinger 2004). Lung cancer stage along with comorbidities, lung function, and physiologic status informs treatment recommendations that can include surgical resection, single agent chemotherapy, doublet chemotherapy, immunotherapy, targeted driver mutation therapies, radiation, and/or palliative care. Oncologic treatment planning for elderly patients with NSCLC is nuanced, as providers must synthesize guideline-based recommendations with patient preferences and assessments of global function (Gajra and Jatoi 2014).

Traditionally, risk-stratification prior to oncologic treatment interrogated patient fitness for treatment using the Eastern Cooperative Oncology Group (ECOG)/World Health Organization (WHO) score, a 0–5 scale of health symptoms and disability, or the Karnofsky method, a 0–100 scale with more discrimination in disability description (Table 7) (Karnofsky et al. 1948; Oken et al. 1982). The Comprehensive Geriatric Assessment (CGA) has, over the over the last several decades, gained popularity as a more comprehensive risk-stratifying tool for elderly patients with cancer (Extermann and Hurria 2007).

The components of a CGA can vary based on the practice of the administering provider, but typically include a thorough assessment of activities of daily living (ADLs), instrumental activities of daily living (IADLs), comorbidities, functional-based assessments (e.g., 6-min walk test and grip strength), mental health, cognition, nutritional status, social support, and medications/polypharmacy (Table 7). In particular, the CGA adds additional risk information to traditional performance status measures, which often miss IADL disability. For example, a 2005 study of 566 elderly patients with advanced NSCLC found that pretreatment assessments of quality of life and IADLs were associated with improved prognosis (Maione et al. 2005). Assessments of ADLs and comorbidities, the central elements of the Karnofsky and ECOG/WHO scores, did not correlate with prognosis.

These studies support the notion that chronologic age alone should not determine treatment planning. Instead, treatment decisions should be made based on physiologic age, using CGAs such as the Elderly Selection on Geriatric Index Assessment (ESOGIA) (Corre et al. 2016). Treatment-related toxicity can be predicted using the Cancer and Aging Research Group tool (CARG) (Hurria et al. 2011) or Chemotherapy Risk Assessment Scale for High-Age Patients (CRASH) (Extermann et al. 2012) tools (Table 7).

Early-Stage NSCLC (Stages I and II)

Early stage lung cancer increases in prevalence with age. In 2005, a large retrospective analysis of 14,555 patients with early-stage NSCLC in the Surveillance, Epidemiology, and End Results (SEER) database revealed that the prevalence of stage I NSCLC increased from 79% in patients less than age 65 compared to 87% in patients older than age 75 (Mery et al. 2005). Five-year relative survival for localized lung cancer is 55% (ACS

2016), but true pathologic stage I NSCLC may have five-year survival of approximately 80% (Cerfolio and Bryant 2009). However, lung cancer is infrequently diagnosed at a localized stage (16%) (ACS 2016), which is the basis for more aggressive lung cancer screening.

Surgery is the first-line treatment for early-stage lung cancer (stages I and II) (Table 8). If a patient has a potentially resectable lung cancer, multidisciplinary teams perform presurgical risk assessments, to identify patients at high-risk for surgical complications. While age has historically been used as a crude risk-stratification method, recent surgical guidelines by American (Brunelli et al. 2013) and European (Brunelli et al. 2009) societies recommend against using age cut-offs to make surgical decisions. In fact, approximately one-third of lung-resection candidates are over 70 years old. Instead, if a patient has potentially surgically resectable cancer, the patient should be further risk-stratified with appropriate preoperative testing including lung function assessments (Table 1) and evaluation of other comorbidities (Table 7).

Table 8 Suggested non-small cell lung cancer treatment by clinical stage[a]

Stage I and IIA (Local): Lungs only, without lymph node extension
Surgical resection with mediastinal lymph node dissection (if clinical stage IA, may proceed directly to resection for diagnosis, staging, and curative intent surgery)
+/− adjuvant chemotherapy
SABR +/− chemotherapy if inoperable
Stage IIB–IIIA (N0–1) (Regional): Lung and nearby lymph nodes
Preoperative mediastinal staging to determine eligibility for surgical resection
Adjuvant chemotherapy
SABR +/− chemotherapy if inoperable
Stage IIIA(N2)–IIIB (Locally advanced): Extension to central ipsilateral lymph nodes **or** to central contralateral lymph nodes/above clavicle
Role of surgery and neoadjuvant chemotherapy controversial, consider resection if noninvasive tumor and N2 disease eradicated with induction chemotherapy
N3: Definitive chemotherapy and radiation
Stage IV (Metastatic): Extension to both lungs, pleural space, or extrapulmonary site
Early palliative care
Targeted therapies if indicated (ALK, EGFR, ROS1, PD-L1)
Chemotherapy
Immune checkpoint inhibitors
Radiation targeting metastases
Stereotactic radiosurgery for limited brain metastases

Adapted from AJCC seventh edition staging (Goldstraw et al. 2007) and NCCN Clinical Practice Guidelines in Oncology (Version 5.2017): https://www.nccn.org/professionals/physician_gls/f_guidelines.asp. Consult guidelines for addition, nuanced detail

SABR sterotactic ablative therapy

[a]Recommend consultation with multidisciplinary team including medical oncologist, thoracic surgeon, radiologist, pathologist, and geriatrician. Treatment plan may be altered by discrepancy between pathologic stage and clinical stage or patient risk-assessment/treatment tolerability

Surgical resection of lung cancer will impact lung function, so presurgical evaluations must include an objective assessment of pulmonary function to calculate predicted postoperative (ppo) FEV_1 and DLCO, which is based on the number of functional segments to be removed (Brunelli et al. 2013). Regardless of lung disease, all patients should have a DLCO assessment in addition to spirometry, because ppoDLCO is strongly correlated with pulmonary complications, even in patients without COPD (Ferguson et al. 2009). Further, testing of a patient's exercise tolerance is pursued if questions remain about a patient's ability to tolerate the surgery, including low technology exercise testing such as 6-min walk testing, shuttle walk or stair climbing, and high technology exercise testing such as cardiopulmonary exercise testing (Table 9).

Interrogating preoperative lung function and calculating ppo lung function is essential to a careful assessment of projected surgical morbidity and mortality. Ferguson et al. demonstrated that, in 854 patients who underwent major lung resection, ppoFEV1 and ppoDLCO were significantly associated with mortality (HR 1.06, 95% CI 1.01–1.12, $p = 0.03$; HR 1.06, 95% CI 1.01–1.12, $p = 0.02$, respectively) (Ferguson et al. 2014). Additionally, the morbidity and mortality (including noncancer mortality) associated with a low ppoDLCO increases with age (Eguchi et al. 2016).

Frailty is an independent risk factor for postoperative complications, length of hospital stay, and discharge to skilled or assisted living facilities in older patients (Makary et al. 2010). Frailty in patients referred for lung cancer surgical resection is under recognized. A 2017 study by Beckert et al. found, in a prospective cohort study of 125 patients referred to an academic thoracic surgical clinic for thoracic surgical procedures, that

Table 9 Presurgical cardiopulmonary assessments

PPO lung function	Further testing	Risk assessment
$FEV_1 > 60\%$ and DLCO >60%	Not indicated	**Low risk**
FEV_1 or DLCO 30–60% predicted	"Low technology" exercise test (e.g., stair climbing or shuttle walk)	**Low risk** if stair climbing altitude >22 m or shuttle walk distance >400 m
FEV_1 and/or DLCO <30% predicted	"High technology" exercise test (e.g., cardiopulmonary exercise test)	**Low risk** if VO2 peak >20 ml/kg/min (or 75% predicted) **High risk** if VO2 peak <10 ml/kg/min (or 35% predicted)

Adapted from Brunelli et al. (2013)
PPO postoperative lung function, *FEV_1* forced expiratory volume in 1 second, *DLCO* diffusing capacity of the lung for carbon monoxide, *VO2* peak oxygen consumption

12% were frail and 57% were prefrail based on an adapted Fried's phenotypic frailty assessment (Beckert et al. 2017).

Various presurgical assessments of physical robustness have been explored in an effort to achieve greater precision in presurgical risk stratification. Tsiouris et al. created an 11-item modified frailty index (mFI) adapted from the Canadian Study of Health and Aging Frailty Index, a 70-item scale that predicts survival using preoperative data from the National Surgical Quality Improvement Program (NSQIP) (Tsiouris et al. 2013). Items in this index included functional status and co-morbidities (e.g., diabetes, COPD, and cardiovascular disease). The authors found that morbidity and mortality increased as mFI increased in patients who had undergone an open lobectomy. This study suggests that an objective approach to assessing preoperative frailty may improve upon single-organ assessments.

Sublobar resection may not improve long-term survival when compared to lobectomy; however, this has not been demonstrated prospectively. In 2014, Shirvani et al. retrospectively analyzed patients with early-stage NSCLC undergoing curative surgical therapy (mean age 75 years, $n = 9093$) in the SEER database. Most (79.3%) patients underwent lobectomy, while 16.5% underwent sublobar resection and 4.2% underwent stereotactic ablative radiotherapy (SABR) (Shirvani et al. 2014). Unadjusted 90-day mortality was highest for patients who underwent lobectomy (4.0%) as compared to the other two groups (sublobar resection, 3.7%, $p = 0.79$; SABR, 1.3%, $p = 0.008$). However, 3-year unadjusted mortality was lowest for patients who underwent lobectomy (25.0%) as compared to the other two groups (sublobar resection, 35.3%, $p < 0.001$; SABR, 45.1%, $p < 0.001$). Propensity score matching between sublobar resection and lobectomy groups demonstrated worse survival for the sublobar resection groups.

When comorbidities or patient preferences contraindicate surgical resection of an early stage tumor, other options include observation/best supportive therapy or SABR (Table 8). Median survival without surgical resection in patients with early stage disease is poor, with one estimate suggesting survival of 14.2 ± 2.37 months (Mcgarry et al. 2002). In Shirvani et al.'s study, a propensity score-matched analysis of SABR and lobectomy groups, showed a similar overall survival, suggesting that SABR is indicated in patients who cannot tolerate surgical risk (Shirvani et al. 2014). Further, a pooled analysis of two small randomized trials comparing SABR to surgical resection suggests that the two treatments may be equally effective, and that SABR may be preferred in individuals with multiple comorbidities (Chang et al. 2015). In 55 patients with T1 or T2 tumors, stereotactic body radiation therapy without resection had a 3-year local control rate of 90.6% (95% CI, 76.0–96.5%) and a local-regional control rate of 87.2% (95% CI, 71.0–94.7%). The median survival was 48.1 months, with a 55.8% survival rate at 3 years (Timmerman et al. 2010).

Adjuvant therapy with postoperative cisplatin-based doublet chemotherapy for stage

IIA to IIIA is standard of care (Pisters et al. 2007). A 2004 study of 1867 patients treated with cisplatin-based adjuvant chemotherapy following surgical resection showed 44.5% survival at 5 years as compared to 40.4% in the observation group ($p < 0.03$) (Group 2004). Cuffe et al. examined the Ontario Cancer Registry to assess the benefit of adjuvant chemotherapy on older age groups (<70, 70–74, 75–79, and ≥80) (Cuffe et al. 2012). This analysis found benefit of adjuvant chemotherapy in all age groups except for those ≥80 years. The main concerns with using cisplatin-based doublet therapy in older adults are the adverse side effects of renal and ototoxicity, requiring intravenous hydration pre- and postinfusion. It is also highly emetogenic, requiring adequate antiemetic support. Risk stratification taking organ function, social support, transportation, and medication management into account prior to selection of cisplatin is mandatory to prevent severe toxicity. Carboplatin is often substituted for cisplatin for high-risk older adults.

Locally Advanced NSCLC (Stage III)

Concurrent chemoradiation is indicated for curative-intent treatment of locally advanced NSCLC: stage IIIA medically inoperable or stage IIIB (Bezjak et al. 2015). However, for more frail, high-risk older adults, sequential chemotherapy followed by radiation is also an option. The 5-year relative survival rate for regionally advanced lung cancer is 28% and for distant metastatic lung cancer is 4% (ACS 2016). Surgical resection and neoadjuvant chemotherapy are controversial in patients with stage III, N2 cancers. In some centers, patients with adequate performance status and acceptable surgical risk proceed to surgery if the tumor is noninvasive and the N2 disease is completely resectable. Other centers recommend presurgical eradication of N2 disease with induction chemotherapy before proceeding to surgery (Van Meerbeeck et al. 2007; Albain et al. 2009).

There is limited strong, prospective evidence to guide surveillance of patients who have undergone curative intent therapy. Current guidelines suggest that patients who have undergone surgical resection of NSCLC have a follow-up chest CT every 6 months for 2 years, then yearly (Colt et al. 2013). When surveillance becomes yearly for the curative-intent cohort, it mimics the screening suggested for eligible patients in the new lung cancer screening guidelines (Table 3). Just as is suggested in the screening cohort, providers should reevaluate patient wishes to continue surveillance when comorbidities or functional status alter patient preferences to undergo further cancer work-up or therapy, if disease recurrence is identified on imaging.

Metastatic NSCLC (Stage IV)

Most lung cancer is diagnosed at an advanced, metastatic state of disease. Currently, the treatment for advanced NSCLC is expanding rapidly and includes targeted treatments and immunotherapy in addition to traditional chemotherapy, the original mainstay of treatment for advanced disease. All metastatic lung cancer biopsy specimens should undergo molecular marker testing for the EGFR mutation, anaplastic lymphoma kinase (ALK) rearrangement, or ROS1 translocation (Lindeman et al. 2013), to determine if driver mutation-targeted therapies can be used. In a small study of 32 patients (median age 80 with NSLC and the EGFR mutation) treated with the EGFR tyrosine kinase inhibitor erlotinib, this drug was well-tolerated and had similar efficacy (56.3% response rate) as compared to a prior study of a mixed-age cohort (58.1% response rate) (Rosell et al. 2012; Inoue et al. 2015). The most frequent adverse event was skin-related toxicity. A separate study of erlotinib versus placebo in 731 patients compared outcomes based on age (<70 years or ≥70 years). The older age group had similar survival as compared to the younger group but experienced more severe (grade 3/4) toxicity. For ALK positive tumors, ALK tyrosine kinase inhibitors (e.g., crizotinib or ceritinib) are superior to standard chemotherapy (Solomon et al. 2014; Shaw et al. 2014). Tumors with the

ROS1 rearrangement should be treated with crizotinib (Bergethon et al. 2012).

Immunotherapy utilizing checkpoint inhibitors such as programmed death-1 (PD-1) inhibitors is beginning to emerge as an important pillar of treatment in NSCLC. PD-1 inhibitors have a survival benefit as compared to first-line platinum-based doublet chemotherapy or second-line chemotherapy after treatment failure with doublet therapy. Two pivotal studies in 2015 demonstrated increased overall survival in patients treated with the PD-1 inhibitor nivolumab, as compared to docetaxel, in previously treated, advanced squamous-cell NSCLC regardless of PD-L1 expression (Brahmer et al. 2015) and previously treated, advanced nonsquamous NSCLC (Borghaei et al. 2015). Reck et al., in 2016, then demonstrated superiority of the PD-1 inhibitor pembrolizumab as compared to platinum-based chemotherapy, in untreated NSCLC (both squamous and non-squamous), in which at least half of the tumor cells were PD-L1 positive but ALK and EGFR negative (Reck et al. 2016). Progression-free survival was 10.3 months in the pembrolizumab group as compared to 6.0 months in the chemotherapy group. Importantly, overall survival was significantly longer in the group treated with pembrolizumab (HR 0.6, 95% CI 0.41–0.89, $p = 0.005$). Six-month survival was 80.2% for those treated with pembrolizumab compared to 72.4% in the chemotherapy group. Additionally, there were fewer treatment-related adverse events in the pembrolizumab group. Though promising, these results have yet to be replicated in large population-based studies. As clinical trials include younger, healthier adults, evidence of improved overall survival and decreased toxicity among frail older adults is needed.

Cytotoxic platinum-based chemotherapy is the first-line treatment for the majority of advanced NSCLC without a molecular mutation with a targeted therapy (Table 8). Standard chemotherapy consists of two agent (doublet) therapy with a platinum agent (e.g., cisplatin or carboplatin) plus a second agent (e.g., docetaxel, paclitaxel, gemcitabine, etoposide, irinotecan, or vinorelbine) (Masters et al. 2015). Several studies have shown efficacy of chemotherapy treatment in elderly patients with lung cancer. A 2011 multicenter study of 451 patients aged 70–89 years with locally advanced or metastatic NSCLC and good performance status (WHO performance status 0–2) found that platinum-based doublet chemotherapy improved survival (10.6 months) compared to monotherapy (6.2 months) with vinorelbine or gemcitabine (Quoix et al. 2011). The patients who underwent doublet chemotherapy experienced significantly more side effects, particularly cytopenias and neuropathy.

Histologic subtyping of NSCLC helps determine the preferred first-line cytotoxic chemotherapy agents. A study by Scagliotti and colleagues in 2008 found a significant survival benefit for patients with squamous cell carcinoma treated with cisplatin/gemcitabine (10.8 months) versus cisplatin/pemetrexed (9.4 months) (Scagliotti et al. 2008). In patients with adenocarcinoma, treatment with cisplatin/pemetrexed is preferred (12.6 months compared to 10.9 months). High-grade cytopenias were significantly higher with cisplatin/pemetrexed treatment.

Bevacizumab, an antibody that inhibits vascular epithelial growth factor A (VEGF-A), improves survival in patients with metastatic non-squamous NSCLC, in combination with platinum-based doublet therapy (Sandler et al. 2006). Data supporting its efficacy in elderly patients has been inconclusive, and increased adverse events (including death) appear to be significantly higher (Ramalingam et al. 2008). Therefore, the increased risk in older populations may outweigh potential benefits. Bevacizumab is not used in squamous cell lung cancer due to the increased risk of serious hemorrhagic events.

Even when patients cannot have surgical resection either due to advanced disease, risk stratification by performance status and CGA remains important, as chemoradiation therapies carry risk of serious toxicities. Elderly patients are a potentially vulnerable patient population to experience treatment-related toxicities, and oncologists have struggled with both overtreatment and undertreatment when caring for individuals with NSCLC (Presley et al. 2016). A 2010 retrospective study of the SEER Medicare database

revealed that many elderly patients with advanced NSCLC do not receive chemotherapy in spite of survival benefits in those who do (Davidoff et al. 2010).

The first evidence that undertreatment impairs patient quality of life came in 1999, when the Vinorelbine Italian Study Group presented data that, in patients over age 70 with stage IV or IIIB NSCLC ineligible for radiotherapy with good performance status, treatment with six 21-day cycles of vinorelbine (a vinca alkaloid) significantly improved survival (Group 1999).Cognitive function was better in the vinorelbine group, and they reported less pain and dyspnea. They did report worse constipation, nausea/vomiting, hair loss, and peripheral neuropathy.

Elderly patients are an at-risk group with potentially more comorbidities and functional impairments that can impact chemoradiation tolerance. Hurria et al. found that 53% of older adults experienced at least one grade 3–5 toxicity during the course of treatment across cancer types and stages (Hurria et al. 2011). A 2015 retrospective study of the SEER registry demonstrated a significant burden of toxicity on elderly patients (70 years or older) with advanced NSCLC undergoing therapy (Kale et al. 2017). Patients with stage IIIB had a nearly sixfold increase in toxicities with chemoradiation compared to those who received no treatment. The most common toxicity was esophagitis. Stage IV patients had a nearly fourfold increase in toxicities with chemotherapy, most commonly neutropenia. This study was limited by the lack of analysis by chemotherapy agent or doublet versus singlet therapy.

Rarely, chemotherapy agents and radiation therapy can cause toxicity to the lungs directly, which can include pneumonitis or acute respiratory distress syndrome (Read et al. 2002; Parashar et al. 2011). Pulmonologists crowd source and catalog treatment-related lung toxicity at www.pneumotox.com (Camus et al. 2013). Checkpoint inhibitor-related pneumonitis is an uncommon but highly morbid complication of use that is rising in prevalence with increased use of these agents. Pneumonitis is estimated to occur in 5% of patients, with onset ranging from 9 days to 19.2 months following treatment (Naidoo et al. 2017).

Improvements in risk stratification, to limit toxicities while maximizing therapy benefit, are ongoing. A 2016 study by Corre et al. assigned patients with advanced NSCLC (median age 77 years, n = 494) to chemotherapy regimens based either on performance status or CGA (Corre et al. 2016). In the standard arm, patients were assigned based on performance status; if PS $\leq$ 2 and age $\leq$ 75, patients received carboplatin-based doublet chemotherapy, and if PS =2 or age > 75 they received docetaxel. In the CGA group, "fit" patients received carboplatin-based doublet, "vulnerable" patients received docetaxel, and "frail" patients received best supportive care. In summary, patients assigned to treatment based on CGA experienced significantly less treatment toxicity, with similar overall survival and treatment failure free survival.

Joint decision-making with patients is important. Discussions should include careful counseling about expected toxicities including the likelihood of functional or cognitive impairment. Projected toxicities may influence a patient's advanced care planning more than risk of death (Fried et al. 2002). Treatment-related toxicities in older patients receiving chemotherapy can be predicted using the CRASH (Extermann et al. 2012) or CARG (Hurria et al. 2011) calculators (Table 7). Risk calculators for both targeted treatments and immune checkpoint inhibitors are needed.

Finally, palliative care should be a cornerstone of caring for patients with metastatic (stage IV) lung cancer (Table 8). In addition to improving symptom control, palliative care can also increase survival. A revolutionary study by Temel and colleagues in 2010 demonstrated that, in patients with metastatic NSCLC, an early palliative care intervention led to increased median survival compared to standard care (11.6 vs. 8.9 months p = 0.02 (Temel et al. 2010). On average, patients who received early palliative care had received less aggressive care than the standard treatment group (33% vs. 54%, p = 0.05) and noted better quality of life and less depression and anxiety. The

palliative care intervention consisted of guideline-based visits with a dedicated palliative care team, including board-certified palliative care advanced practice nurses and physicians, who met with the patient at least monthly and attended particularly to "physical and psychosocial symptoms."

Lung cancer-related symptoms are wide-ranging and can be debilitating. A frequent lung cancer symptom is dyspnea due to cancer-related etiologies that include pneumonia, pulmonary emboli, metastatic pleural effusions, or superior vena cava syndrome. Care teams can track dyspnea symptoms using clinical dyspnea scales (Table 2). Other symptoms include sequelae of metastases (e.g., bone pain and neurologic impairment), depression, anxiety, insomnia, and fatigue (Simoff et al. 2013). Rarely, airway-esophageal fistulas and paraneoplastic syndromes can occur. Palliative care teams experienced in treating these symptoms are invaluable partners in patient care.

Other Lung Malignancies

Small Cell Lung Cancer

Small cell lung cancer (SCLC) is an aggressive neuroendocrine malignancy comprising about 15% of all lung cancers (ACS 2016). Unlike NSCLC, the malignant cells are characterized by rapid growth and initial sensitivity to chemotherapy and radiation that later becomes resistant to treatment (Rudin et al. 2015). It is strongly associated with a history of smoking. Classic staging for SCLC uses the Veterans Administration system of limited or extensive stage disease, though the AJCC TNM staging system is recommended due to improved prognostic discriminatory power (Micke et al. 2002; Jett et al. 2013). In limited stage disease, the cancer is localized to the ipsilateral hemithorax and regional lymph nodes. Extensive disease includes any spread beyond, such as distant metastases. Staging should be performed radiographically (head MRI/CT and PET) as well as invasively (EBUS or mediastinoscopy) if patients are being considered for curative intent surgical resection.

In stage I disease, which is uncommon, adjuvant chemotherapy should be administered following surgical resection. In limited stage disease, early chemotherapy with radiotherapy is recommended. The foundation of treatment is combination chemotherapy, typically including a platinum agent (e.g., carboplatin or cisplatin) (Rudin et al. 2015). Whether a patient has limited or extensive stage disease, prophylactic cranial irradiation is indicated. However for older adults, cranial irradiation can cause acute, subacute, and long-term impairments to cognition, a particularly pertinent side effect for elderly populations (Robbins et al. 2012).

A 2011 retrospective study of chemotherapy tolerability in the Netherlands looked at 368 patients with limited stage SCLC and 577 with extensive stage SCLC, all 75 years old or older (Janssen-Heijnen et al. 2010). Many patients (48%) did not receive chemotherapy for a wide range of reasons, including poor performance status or patient preference. Up to 75% of all patients undergoing chemotherapy developed a serious toxicity and two-thirds could not complete treatment. Survival is extremely limited without chemotherapy treatment, so even patients with impaired performance status are typically treated (Pelayo Alvarez et al. 2009).

Other Neuroendocrine Tumors, Mesothelioma, and Pulmonary Metastases

Less common malignancies of the respiratory system include malignant mesothelioma and other lung neuroendrocrine tumors such as carcinoid (bronchial neuroendocrine) tumors and large cell neuroendocrine carcinoma. Large cell neuroendocrine carcinoma, like small cell lung cancer, has a poor prognosis and 5-year survival across all stages is approximately 35.3% (Fasano et al. 2015). Treatment can include surgical resection in early stage disease, with adjuvant chemotherapy.

Bronchial neuroendocrine (carcinoid) tumors are indolent tumors that have increased in incidence since the 1980s. Age 60 or greater strongly

predicts mortality (Perez et al. 2007). Localized disease is typically managed with surgical resection and data on adjuvant chemotherapy is mixed. Metastatic disease is treated with first with a somatostatin analog, with everolimus as second-line therapy. Cytotoxic chemotherapy if everolimus fails to control disease. A complication of carcinoid tumors is carcinoid syndrome, which can be treated with somatostatin analogs (e.g., octreotide) (Pavel et al. 2011).

Mesothelioma is an asbestos-associated malignancy, that presents insidiously (Van Zandwijk et al. 2013). The average age of diagnosis is over age 60, implying a disproportionate burden of disease on elderly patients. The average overall survival is 7 months. Malignant mesothelioma is typically treated with two-agent platinum-based chemotherapy. Surgical debulking can palliate symptoms. Radiotherapy is a cornerstone of palliative treatment, both to control symptoms and prevent relapse following surgery. Pleurodesis can be useful to manage recurrent malignant effusions.

The lung and pleural space is a frequent site of metastatic disease from non-lung primary cancers, including breast, colon, ovarian, bladder, and melanoma (Nguyen et al. 2009). In addition to chemotherapy or radiation to treat these metastatic lesions (Rusthoven et al. 2009), further palliative management may be indicated. Interventional pulmonologists can assist with palliative management using stent placement or laser therapy to treat endobronchial lesions or bronchial compression from surrounding tumor (Cavaliere et al. 1996). Pleurodesis or long-term indwelling pleural catheters may be used to manage malignant pleural effusions (Van Meter et al. 2011).

Conclusion

Maximal pulmonary function declines with aging, beginning in the third decade of life (Table 10). The natural history of lung aging involves progressive decline in lung elasticity leading to increased lung volumes and an obstructive spirometric pattern. Respiratory muscle weakness and changes to the architecture of the thorax can concomitantly cause a restrictive pulmonary function pattern. When evaluating pulmonary function testing in the geriatric patient, one must consider the natural history of lung changes so as to avoid overdiagnosis of lung disease.

Chronic obstructive pulmonary disease has been described as a disease of accelerated aging, though recent evidence indicates that a subset of affected patients has abnormal lung development with normal lung aging. Both COPD and IPF share pathogenic cellular features in common with lung cancer, including telomere attrition, defective DNA repair, genomic instability, cellular senescence, stem cell exhaustion, and mitochondrial dysfunction.

Lung cancer is the deadliest malignancy in the USA, and its prevalence increases with age. Non-small cell lung cancer is the most common of lung cancer and adenocarcinoma is the most common histologic type. Depending on the stage at diagnosis, treatment options for NSCLC can include surgical resection, single agent chemotherapy, doublet chemotherapy, immunotherapy, targeted driver mutation therapies, and/or radiation.

For early-stage NSCLC that amenable to surgical resection, patients must have presurgical pulmonary function testing with calculation of predicted postoperative lung function. Depending

Table 10 Key points

Lung aging begins in the third decade of life
COPD, IPF, and lung cancer share pathogenic cellular features, including telomere
Attrition, defective DNA repair, genomic instability, and cellular senescence
Lung cancer is the deadliest of all malignancies
Screening for lung cancer is recommended for high-risk patients (age 55–80 with $\geq$30 pack-year smoking history)
Comprehensive geriatric assessments prior to treatment limit toxicities and may improve survival
Early palliative care should be initiated for all patients with stage IV lung cancer

on the FEV_1 and/or DLCO, patients may require "low technology" (e.g., stair climbing or shuttle walk) or "high technology" (e.g., cardiopulmonary exercise testing) to determine their cardiopulmonary fitness for surgery. Frailty is under recognized, and frail patients have more surgical complications. Adjuvant chemotherapy can improve outcomes.

First-line treatment for advanced NSCLC is driver mutation-targeted therapy if eligible, against ALK, EGFR, ROS1, and/or PDL-1. Most patients do not have these mutations, so doublet platinum-based therapy is their first line treatment. Single-agent or no chemotherapy is reserved for patients with poor performance status or high-risk as determined by a Comprehensive Geriatric Assessment. In metastatic NSCLC, palliative care must be a cornerstone of best supportive care. Given the profound burden of lung cancer on geriatric patients, pretreatment global functioning should be evaluated for risk-stratification and to guide treatment decisions. Traditional risk-stratification relied on assessing performance status with either Karnofsky or ECOG/WHO tools. Variations of the Comprehensive Geriatric Assessment are gaining ground as methods for risk-stratifying patients prior to cancer treatment. Risk stratification based on CGA can lead to decreased treatment toxicity with similar or improved survival.

Avoiding undertreatment in fit elderly patients and overtreatment in vulnerable subgroups remains the shared goal of clinical partnerships between primary care providers, geriatricians, medical oncologists, thoracic surgeons, and pulmonologists. As evidence accumulates about how best to assess pretreatment global fitness, physicians must adopt a shared-decision making strategy, incorporating patient preferences into treatment decisions.

Abstract

Digestive cancer is extremely frequent and is the third cause of cancer in both sexes. Prevalence is mainly in older adults with more than half of the incidence above 75 years, and diagnosis in the elderly is done at more advanced stages.

Management is complex with intensive treatments combining all available anticancer modalities of treatment depending on stage: major surgery, radiotherapy, chemotherapy, radio-chemotherapy, targeted therapy, etc. Comprehensive geriatric assessment is an essential step in this population to assess the feasibility of available treatments and the possible supportive care. So geriatric status (frail or robust) influences the final treatment decision.

If specific recommendations of management have been elaborated for older adults in colorectal cancers, efforts need to be made to produce management guidelines for other digestive cancers.

Keywords

Digestive cancers · Aged · Geriatric oncology · Management · Treatment · Geriatric evaluation

Introduction

Digestive cancers represent a high burden of morbidity and mortality worldwide. Colorectal cancer (CRC) is the third most commonly diagnosed cancer, with 1.36 million of cases after lung and breast cancers. Liver cancer (745,000 deaths per year) and stomach cancer (723,000 deaths per year) are the second and the third, respectively, causes of death by cancer after lung cancers worldwide (Ferlay et al. 2015).

Most digestive cancers occur in an elderly population. For example, in Europe, 70% of CRCs occur in patients aged above 65 years old and 46% in patients aged above 75 years old (Institut de veille sanitaire 2018). This high prevalence is similar in other digestive cancers: 23.8% for esophageal cancers, 46.1% for gastric cancers, 27.6% for liver cancers, and 37.1% for pancreatic cancer (Institut de veille sanitaire 2018).

One critical issue facing medical science concerns the aging population. This often vulnerable group poses significant challenges with regard to address its healthcare needs.

Indeed, these patients have more often comorbid conditions and are more often diagnosed at a later stage of cancer than in younger patients

(Vercelli et al. 2000). As a result, management strategy should be adapted to the incidence of adverse treatment reactions such as morbidity and mortality (Colorectal Cancer Collaborative Group 2000).

Impact of Age on the Management Strategy of Digestive Cancers

The core principles of oncology in treatment and management of digestive cancers are similar in an older population. Given the lack of data in elderly patients, specific therapeutic strategies are difficult to establish. This population is often underrepresented in clinical trials due to their comorbidities, disability, and physiological changes (Aparicio et al. 2016a).

Because the elderly population is often more heterogeneous, chronological age is not a relevant marker for measuring healthy aging. The patient's physiological age should be ideally evaluated through a comprehensive geriatric assessment (CGA) (Caillet et al. 2014; Extermann et al. 2005) as recommended by the International Society of Geriatric Oncology (SIOG).

Comprehensive geriatric assessment evaluates functional status, mobility, comorbidities, polypharmacy, nutritional status, cognitive function, emotional status, and social support based on validated geriatric scales. The purpose of this evaluation is to identify healthy patients from vulnerable patients to adapt cancer treatment. Evaluating the benefit-risk ratio in treating older patients allows a more tailored approach between a recommended treatment and the best supportive care.

Moreover, contraindication for surgery is evaluated as well as the risk of adverse outcomes of chemotherapy. Therapeutic decision-making in an older population should take into account the nature and the extension of the tumor as well as an integrative geriatric approach where quality of life is preferred to survival. Thus, patient preference in treatment decision is essential (Fig. 1).

Digestive Surgery and Age

Surgery remains the most important part of the treatment in digestive cancer. Indeed, it is the only curative treatment and should be proposed when it is feasible. Moreover, in a palliative situation, surgery can avoid or treat intestinal obstruction and improve patient's quality of life. Older patients are often undertreated compared to younger patients (Colorectal Cancer Collaborative Group 2000).

- There is currently no geriatric screening tool which can identify if the old patient is treatable; each tool screens patients at high risk of complications (Duron et al. 2011).
- Necessity of a CGA, which can assess the patients' comorbidities, functional status, presence of cognitive dysfunction, and frailty, which are consistently associated with adverse treatment outcomes in relation to both toxicity and mortality (Sungurtekin et al. 2004).
- A geriatric assessment leads to modify treatment decision making in up to 20–50% of elderly patients (Lee et al. 2016).
- If CGA is not feasible due to lack of a geriatrician or lack of time, a rapid screening evaluation should be considered. The G8 screening tool (especially designed for a geriatric oncology population) has a good sensitivity (90%) but a poor specificity (23%) (Kristjansson et al. 2010; PACE participants et al. 2008).

Fig. 1 Principles of geriatric evaluation underlined by the SIOG (Nascimbeni et al. 2009)

Thus, surgery feasibility needs to be measured by a geriatric evaluation, to take into account underlying risk factors of perioperative morbidity and mortality and to anticipate potential complications.

Impact of Geriatric Evaluation in Digestive Cancer Surgery

If age remains the main risk factor of perioperative mortality after colorectal surgery, this operative risk has decreased these last 20 years (Nascimbeni et al. 2009). In major digestive surgery, the risk of postoperative mortality increases with age. This risk is multiplied by 2.21 (95% CI: 1.36–3.59; $p = 0.001$) in patients aged above 65 years old and especially in patients above 85 years old (Duron et al. 2011). Many studies have demonstrated major risk factors of poor surgical outcomes associated with age. Indeed, risk factors of poor surgical outcomes are better known and must be taken into account:

- Nutrition

  Nutrition in elderly digestive cancers is a major prognostic factor. The prevalence of malnutrition is estimated about 40% in the elderly hospitalized patients and increases the risk of poor surgical outcomes from 1.92 to 9.85 depending on the assessment nutrition tool. There is an increase of prolonged hospital stays, morbidity, and mortality for patients undergoing elective gastrointestinal surgery (Sungurtekin et al. 2004).
- Functional Status

  In a study including 270 patients ≥70 years (mean age 76.7 years), patients who impaired at least 2 domains of CGA had an odds ratio at 2.1 to develop postoperative complications (Lee et al. 2016). In these domains, disability is a crucial predictor of a poor postoperative outcome. Cancer patients defined as being functionally dependent according to the validated instrumental activity of daily living were found to have a two- to threefold increased risk of postoperative morbidity compared with those defined as independent (Kristjansson et al. 2010; PACE participants et al. 2008).
- Sarcopenia

  Sarcopenia is independently predictive of postoperative infections (OR = 4.6; 95% CI: 1.5–13.9) and geriatric rehabilitation stay (OR = 3.1; 95% CI: 1.04–9.4) and significantly associated with a prolonged length of hospital stay (15.7 ± 9.8 days vs. 11.8 ± 6.4 days for non-sarcopenic patients) in older CRC patients (Lieffers et al. 2012). A systematic review showed that sarcopenia and sarcopenic obesity impact outcomes of surgery in all digestive cancers (Mei et al. 2016).
- Physical Frailty

  Physical frailty defined by Fried criteria (weight loss, gait speed, grip strength, physical activity, and physical exhaustion) increases the risk of major complications following surgery of colorectal cancer [odds ratio (OR) 4.1 (1.4–11.6)] (Tan et al. 2012).
- Dementia

  In a large cohort of 207,693 patients aged above 60 who underwent major surgery, Hu et al. showed that patients with dementia had a significantly higher overall postoperative complication rate compared with controls (adjusted OR = 1.79; 95% CI: 1.72–1.86) (Hu et al. 2012).
- Comorbidities

  Certain comorbid conditions like 6-month weight loss ≥20%, smoking >20 cigarettes/day, an underweight condition, and cardiac arrhythmias showed a better predictive value on survival in colorectal cancer compared with other comorbidities in the Charlson index (Marventano et al. 2014; Janssen-Heijnen et al. 2007; Lemmens et al. 2005). However, an overall high Charlson index is predictive of perioperative complications.

Impact of Surgical Treatment on Elderly Patients

- Surgical treatment modalities as well as certain geriatric conditions may impact patient's perioperative outcomes:
- Laparoscopic surgery versus laparotomy

  A meta-analysis including 7 studies and 845 patients show that laparoscopy reduces intraoperative blood loss, time to first

ambulation visit, time to first oral intake, postoperative hospital stay, overall postoperative complication rate (odds ratio (OR) 0.39; 95% CI: 0.28–0.55; $P < 0.01$), surgical complications (OR 0.47; 95% CI: 0.32–0.69; $P < 0.01$), medical complications (OR 0.35; 95% CI: 0.22–0.56), and pulmonary infections (OR 0.49; 95% CI 0.26–0.93; $P = 0.03$) (Wang et al. 2016).

- Emergency treatment versus elective surgery

  Emergency surgery is associated with a rate of mortality of 16% in patients aged above >65 years old, and mortality increases up to 30% in patients aged above ≥80 years old (Modini et al. 2012).

Fast-Track Surgery and Prehabilitation in Digestive Surgery for Aged Patients

Since the 1990s, the multimodal rehabilitation (MMR) or fast-track (FT) surgery has shown multiple benefits on postoperative outcomes compared to usual care in older patients. The aim of this specific care is to combine patient education before surgery, stress reduction by the use of new anesthetics, analgesic and pharmacologic techniques, minimally invasive surgery, and a revision of fundamental postoperative care principles (use of tubes, drains, catheters, monitoring devices, early oral nutrition, mobilization, etc.) in order to define an active perioperative multimodal rehabilitation program (Wanden-Berghe 2016). A systematic review on fast-track care and nutritional rehabilitation, in CRC surgery in adults (16–94 years), shows that FT groups had an early bowel recovery ($p < 0.01$), less infections, less mortality, and shorter hospitalization stays compared to patients in usual care, thus showing the same benefits as in younger patients (Bagnall et al. 2014).

The nutrition management with immunonutrition (enteral nutrition with supplemental arginine) administered before and after surgery has shown a decrease in postoperative infections in colorectal surgery (Wanden-Berghe 2016).

If fast-track surgery improves surgical outcomes, recent articles show that prehabilitation surgery fails to show a benefit in elderly colorectal cancer patients (Montroni et al. 2018).

Chemotherapy and Age

Advance in age increases chemotherapy toxicity by decreasing physiologic reserves (decrease liver function, kidney function, and bone marrow function) or interaction with comorbidities and geriatric syndromes.

Extermann et al. and Hurria et al. showed that more than 50% of patients aged above 70 years old with first line of chemotherapy (especially for colorectal cancer) experienced at least one grade 3–4 toxicity. Most of the risk factors for chemotoxicity in this study were geriatric factors such as functional status, cognitive function, and nutrition. Another major risk factor is the chemotherapy intensity measured by MAX2 index (Extermann et al. 2012). Moreover, geriatric assessment reveals undiagnosed geriatric problems in more than 50% of elderly patients with cancer and thus can modify chemotherapy regimens in 21–53% of patients (Versteeg et al. 2014).

Colon Cancer

Treatment options for colorectal cancer in elderly patients are guided by clinical practice guidelines (Papamichael et al. 2015).

Surgery

See Fig. 2 and Table 1.

Local Cancer (Stages I and II)

The principles of surgical excision consist of a minimum of 5–10 cm of normal bowel that should be resected on either side of the primary colon tumor as well as lymph node dissection and mesocolon resection. Proximal and distal margins of resection must be adequate they imply at least a 1 cm margin. Celioscopic resection is advised and analysis of minimum of 12 lymph nodes is required. For very early stage, endoscopic resection in situ or intramucosal and submucosal is sufficient.

Stage II colon cancer is characterized by a low risk of recurrence, and chemotherapy improved 5-year survival rate from only 2% to 3%.

1. **Identify frail to fit patients by a comprehensive geriatric evaluation** (Van Cutsem et al. 2014).
2. **In frail patients,** a **prehabilitation program or fast-track management should be considered.**
3. **Anticipate bowel obstruction to reduce emergency to a minimum** and, in the case of obstructive disease, alternative procedures such as the construction of a diverting stoma or stenting, if cure is not the aim, must be considered.
4. **Anticipate and use with careful consideration the siting of the stoma.**
5. **Avoid the combination of an emergency procedure with a major resection or multimodality treatment.**
6. **Inform patients (especially high-risk patients) and their families** about the risks of possible functional impairment and oncological outcome before consenting to a treatment plan.
7. **Offer an alternative option for high-risk patients** ranging from no tumor-controlling treatment at all, to palliative treatment.

Fig. 2 The SIOG recommendations for personalized surgical management for elderly colorectal cancer patients (Cassidy et al. 2010)

Table 1 Principles of colon cancer treatment in the elderly

Stage of cancer	Treatment recommendations	Specificities for elderly patients
Stage I: T1–T2 N0 M0	**Radical surgery:** complete resection with at least a 5 cm margin, mesocolon resection, and lymph node dissection with an analysis of at least 12 lymph nodes	An increased risk of complications with age An increased risk of morbidity and mortality perioperative
Stage II: T3–T4 N0 M0	**Surgery +/− adjuvant chemotherapy**	**No evidence of benefits for using adjuvant chemotherapy** especially in the elderly Adjuvant chemotherapy is however often proposed for pMMR patients
Stage III: T1–T4 N1–N2 M0	**Surgery and adjuvant chemotherapy by intravenous 5-fluorouracil (LV5FU) or oral 5FU (capecitabine)**	Adjuvant chemotherapy decreased by 29% the risk of death at 5 years, even in elderly patients (Sargent et al. 2001) No evidence of benefits (disease-free survival, overall survival) compared with toxicity for use of **oxaliplatin or irinotecan and FU/LV** (Banerjee and Cunningham 2010)
Stage IV: metastasis	**Liver metastasis resection**	**Improve survival in elderly patients** (Papamichael et al. 2015)
	Palliative chemotherapy by 5FU combine with bevacizumab	**Adding bevacizumab** with 5FU improved PFS in patients >70 years old with HR = 0.53, 95% CI: 0.41–0.69, $p < 0.0001$ (Cassidy et al. 2010)
	Palliative treatments	**Hemostatic radiotherapy** **Left colic prosthesis** **Derivation colostomy**

However, adjuvant chemotherapy by FU/LV or capecitabine can be proposed in stage II CRC with high recurrence risk factors (T4, perforation, lymphovascular or perineural invasion, poorly differentiated histology), without any proof of potential benefits in an elderly population (Quasar Collaborative Group et al. 2007).

Locally Advanced Stage (Stage III)

Principles of treatment advise to combine surgery and adjuvant chemotherapy.

Indication of Liver Metastasis Resection

Around 20–34% of patients with CRC are diagnosed with synchronous liver metastasis. Liver resection still remains the only chance for long-term survival in patients with CRC liver metastasis. However, two studies found that these patients experienced more postoperative complications than younger ones, but the survival rate at 5 years was between 31.5% and 34.1%. So liver resection for CRC metastases in elderly patients can achieve a reasonable survival rate (Papamichael et al. 2015).

Adjuvant Chemotherapy

The benefit of adjuvant chemotherapy for stage III (node positive) CRC by intravenous 5-fluorouracil modulated with leucovorin (FU/LV) is well established, representing approximately a 30% reduction in the risk of recurrence and a 22–32% reduction in the risk of death even in elderly patients (Sargent et al. 2001). Chemotherapy tolerance is similar in a younger population. However adjuvant chemotherapy is proposed in 30–44% of patients aged above 75 years old, and this proportion decreases in patients aged above 85 years old (Kim 2015).

Capecitabine (an oral fluoropyrimidine) has proved to be as effective as FU/LV in adjuvant treatment in a subgroup analysis of patients aged above 70 years old, with no differences in toxicity by age, although it was more toxic than FU/LV (Twelves et al. 2005; Scheithauer et al. 2003). Patients aged above 80 years old experienced a higher incidence of grade 3 or 4 toxicity, especially diarrhea (31% vs. 13%) and hand-foot syndrome (Cassidy et al. 2002).

Adding oxaliplatin or irinotecan to FU/LV did not improve disease-free survival or overall survival (DFS, HR = 0.94; 95% CI: 0.78–1.13; OS, HR = 1.04; 95% CI: 0.85–1.27), it increases toxicities in patients aged above 75 years old with more neutropenia (OR = 17.3, 95% CI: 9.8–30.42) and nausea or vomiting (OR = 2.14, 95% CI: 1.73–2.65) (Banerjee and Cunningham 2010).

Palliative Chemotherapy

The goal of palliative chemotherapy in the elderly like in younger patients is to improve the overall survival and to limit progression compared to an observational care plan with acceptable toxicities. Studies show the same benefit of monochemotherapy based on FU/LV (Folprecht et al. 2004) compared to polychemotherapy (irinotecan (Folprecht et al. 2008) or oxaliplatin addition) (Goldberg et al. 2006) in patients over 70 years old on progression-free survival and overall survival, but older patients are more often undertreated (Doat et al. 2014). A prior impaired baseline geriatric evaluation (MMSE $\leq$27/30, and impaired ADL) is predictive of treatment failure in older patients, adverse outcomes, and poor survival (Seymour et al. 2011; Aparicio et al. 2016b). Fluoropyrimidine monotherapy appears to be the best option in first-line chemotherapy; an association should be discussed by a multidisciplinary team including geriatric physicians. (Fig. 3).

Targeted Therapy

Several targeted therapies have demonstrated activity in the treatment of metastatic CRC. Regarding antiangiogenic pathway inhibition, most of the data for elderly patients were obtained with bevacizumab. Cassidy et al. (2010) demonstrate the benefit of bevacizumab on free survival rate (6.4 months vs. 9.2 months, $p < 0.0001$) and overall survival (14.1 months vs. 17.4 months;

- Fit older patients can benefit from systemic cytotoxic combination therapy.
- Age alone should not be an exclusion criterion for the use of newer targeted agents in the treatment of patients with metastatic colorectal cancer.
- Those fit older patients selected for inclusion in clinical trials appear to derive a similar benefit to younger patients in terms of RR and PFS from the use of bevacizumab or cetuximab plus full-dose combination chemotherapy. However, the data are lacking as to whether this leads to significant patient-relevant gains such as improved survival with an acceptable quality of life.
- For those older patients for whom such therapy would be inappropriate, less intensive regimens, such as reduced-dose oxaliplatin plus 5-FU or lower dose capecitabine plus bevacizumab, may be use.

Fig. 3 Recommendations for use of chemotherapy in elderly patients SIOG (Nascimbeni et al. 2009)

$p = 0.005$) for adults and older adults subgroup (>70 years old) which leads to recommend this treatment in current practice guidelines (Van Cutsem et al. 2014). However this benefit decreases with age (Cunningham et al. 2013). This treatment was well tolerated with a similar quality of life for elderly patients after treatment, but they experienced more frequently severe thromboembolic events (1.5% vs. 4%) (Price et al. 2012; Kozloff et al. 2009).

EGFR receptor inhibition by monoclonal antibodies is a key point for a variety of processes involved in cancer cell growth, proliferation, angiogenesis, and invasion in patients with metastatic CRC lacking mutations in the RAS genes (wild-type RAS) (Scaltriti and Baselga 2006). Concerning EGF receptor inhibitors, there are very few available data in elderly patients. A Canadian study didn't show any difference between cetuximab compared to best supportive care on 572 pretreated patients with metastatic colorectal cancers (40% over 65 years old) on survival or toxicities (Asmis et al. 2011)

Rectal Cancer

The diagnosis of rectal cancer is made at an age median of 70 years and represents one third of colorectal cancers (Papamichael et al. 2015). Combination of treatment modalities is complex, and older patients are often undertreated as showed by the Netherlands Cancer Registry Study. Only 40% of fit patients with locally advanced rectal cancer received adjuvant chemoradiation (Nederlandse Kankerregistratie). However, the 5-year overall survival increased recently to reach 57% for elderly. A recent conference guideline recommends to improve elderly rectal cancer management by selecting patients with geriatric screening tools. Patients with G8 ≥15/17, Mini-Cog Score ≥4, time up and go test ≤20 s, and no fall history are considered as fit and can be treated like younger patients. However, patients with an abnormal tests need a thorough geriatric assessment to adapt care (Montroni et al. 2018).

Treatment Management Recommendations

The advances in surgical management have reduced mortality in elderly patients (>70 years old) from 7% to less than 3% in the last 10 years (Table 2). Poor prognostic factors are well known: geriatric status, American Society of Anesthesiology (ASA) score, emergency surgery, low rectal cancer, and advanced tumor stage (Alves et al. 2005; Barrier et al. 2003; Finlayson et al. 2012). Age was only linked with advanced stages and emergency procedures.

The main recommendations for elderly rectal cancer patient management aim to improve these risk factors:

Table 2 Management of rectal cancer for older patients

Stage of rectal cancer	Treatment recommendations	Specificities for elderly patients
T1 N0 M0 tumors	Proctectomy or trans-anal resection for lateral sided tumors <3 cm with good to intermediate histological differentiation or endoscopic resection as per colon cancer	Contact radiotherapy: in case of inoperability, endorectal radiotherapy for patients with T1 tumors providing excellent local control (95.5%), 74% survival rate for T1 tumors, and certain favorable T2 tumors (Papillon and Chassard 1992)
T2 N0 M0 tumors	Proctectomy +/− preoperative radiochemotherapy (oral or IV fluoropyrimidine and 45 to 50 gray over 5 weeks)	Increased postoperative morbidity and mortality with age (13% in patients over 80 years of age vs. 0.5% under 50) (Bhangu et al. 2014) Benefit of neoadjuvant treatment with a complete pathological response rate (pCR) up to 44% before surgery (Isbister 1997)
T3–T4 M0 tumors	**Superior rectum**: rectum and mesorectum surgical resection up to 5 cm under inferior pole of tumor Neoadjuvant chemotherapy recommended for T4 patients **Middle and inferior rectum**: neoadjuvant chemotherapy prior to complete mesorectum surgical resection	Patients ineligible for neoadjuvant radiochemotherapy: preoperative radiotherapy (25 Gy in 5 fractions) and surgery 1 week later. Complication risk raised at 30 days and at 6 months for older patients (Janssen-Heijnen et al. 2007) In some cases: standalone radiochemotherapy, surveillance, or local excisions for unfixed T2–T3 allow prolonged remission (Smith et al. 2015)
pT3–T4 N0	No adjuvant treatment	
pTx N1–2 M0	Adjuvant chemotherapy with 5FU	Less ascertained benefits than in colon cancer management
Stage IV: metastasis	Synchronous metastases resection or radiofrequency when possible Palliative radiotherapy, hemostatic radiotherapy +/− Palliative chemotherapy	

- Balance the benefit of treatment versus its adverse effects considering the life expectancy and the quality of life of the patient.
- Optimize patient reserves with multimodal prehabilitation especially for patients with neo-adjuvant chemoradiation and major surgery.
- Optimize surgery with a minimally invasive approach (laparoscopy and robotic surgery); avoid emergency surgery by anticipating complications.
- Consider chemoradiotherapy to improve local control in locally advanced cancer, but it increases toxicities and may prevent a curative surgery. Contact X-ray brachytherapy can be used alone for early rectal cancer (cT1 <3 cm) or as an adjunction for residual tumors (<3 cm) following external beam radiation therapy. The benefit of adjuvant chemotherapy alone is uncertain, and capecitabine is contraindicated in renal failure.
- Watch and wait could be efficient alternatives for frail patients.
- Remove liver metastasis only with curative intent.

Stage 0 to Stage I (T1–T2 N0 M0) Tumors

Surgery consists of proctetomy or transanal resection for lateral sided tumors measuring <3 cm, with good to intermediate histological differentiation or endoscopic resection as per colon cancer.

Endorectal radiotherapy is an alternative in case of inoperability for patients with T1 tumors providing excellent local control (95.5%) and

survival rate (74%) for T1 tumors and certain favorable T2 tumors (Papillon and Chassard 1992).

Stage II to Stage III (T2–T4 N0–1 M0) Tumors

The surgical treatment of rectal cancer implies a major surgery with anterior resection, complete mesorectal excision, sphincter conservation, and lymphadenectomy.

In locally advanced cancer, this procedure must be completed by pre-surgical treatments like radiotherapy (RT) and/or neoadjuvant chemotherapy to improve local cancer control. Classic protocol is oral or intravenous fluoropyrimidine and 45–50 grays over 5 weeks. However, this treatment is rarely feasible in elderly patients due to comorbidities and limited physiological reserves. Thus, elderly patients are less frequently treated with neoadjuvant radiotherapy or chemotherapy, and non-restorative procedures are more frequently used (Chang et al. 2007). Preoperative radiotherapy showed a benefit for local control compared to postoperative radiotherapy (Kunkler et al. 2014).

The complete pathological response rate (pCR) with neoadjuvant treatment and before surgery is 44% (Isbister 1997). Smith et al. published a study in 2015 evaluating the differences between radical surgery and observation after neoadjuvant treatment in cases of pCR. The study concluded that elderly patients, because of their higher surgical risk, obtained the greatest benefit from the "watch and wait" policy and showed an improved survival at 1 year after treatment (Smith et al. 2015). Another alternative is local resection, a treatment that has shown the same benefit in elderly populations than radical surgery for pT1 stage but an increased mortality in pT2 stage (Bhangu et al. 2014).

However this procedure could be an alternative for palliative management to decrease local symptoms for patients refusing stoma or with comorbidities (Garcia-Aguilar 2013).

The impact of cancer surgery on quality of life is very important in the elderly. Sphincter function, assessed clinically and if necessary after manometry, is an essential element to consider in preoperative assessment and the decision-making process. The delay of surgery following short-course radiotherapy has also been associated with a decrease in postoperative morbidity. But the frequency of postoperative complications and the alteration of quality of life due to poor sphincter function or due to stoma for elderly patients lead to find alternative management strategies.

Stage IV (T3–4 N2 M1): Palliative Treatments

At this stage, all treatments remain possible, but with the aim of limiting symptoms. The first objective is to avoid emergency surgery by trying to anticipate the risk of digestive obstruction and thus limiting the risk of postoperative complications. If the obstruction is located in the proximal rectum, colonic stents can be used. Colonic stents are not recommended for patients planned for chemotherapy without resection. Patients with mid/distal rectal tumors are not eligible for colonic stents and bypass surgery like Hartmann can prevent the digestive occlusion. Patients fit with tumor perforation should be explored urgently and should have peritoneal lavage and digestive or tumor resection. For unfit patients specialized palliative care should be enforced.

Another symptom to consider is rectal bleeding. For this symptom, several therapies are possible: surgical resection for fit patients, hemostatic radiotherapy, or local cauterization for unfit patients with persistent bleeding.

Chemotherapy or palliative radiotherapy may be considered to limit and slow down the local development of the tumor and to prevent especially painful complications (Montroni et al. 2018; Kunkler et al. 2014).

Surveillance

Surveillance consists of clinical inspection with digital rectal examination. The local extension is monitored by echo-endoscopic or pelvic MRI to

screen for local relapses. General extension must include research of pulmonary metastases because they are more frequent than in colon cancer.

Esophageal Cancer

Esophageal cancer is the eighth most common cancer and has the sixth worst prognosis because of its aggressiveness and poor survival rate. This cancer occurs with a median age of 68 years and is associated with a poor quality of life due to feeding difficulties. There are no recommendations for management of esophageal cancer in older patients.

The anatomopathology of this cancer in the elderly population is adenocarcinoma (50%) and squamous cell carcinoma (45%) (Skorus and Kenig 2017).

Curative treatment is based on esophagectomy which is a major thoracic surgery with a high rate of perioperative complications especially in older populations. If surgery is impossible due to an advanced cancer stage or physiological status of the patient, the alternative is chemotherapy +/− radiotherapy depending on cancer stage (Table 3).

Surgery Outcomes for Older Patients

Older patients have poor surgery outcomes. A 2013 systematic review analyzed the outcomes of 9531 and 2573 operations on young and elderly (>70 years old) patients, respectively (Markar et al. 2015). Esophagectomy in elderly patients was associated with increased in-hospital mortality, as well as increased pulmonary and cardiac

Table 3 Management of esophageal cancer in elderly patients (Bollschweiler et al. 2017)

Stage of esophageal cancer	Treatment recommendations	Specificities for elderly patients
Barrett's esophagus : high dysplasia or intramucosis carcinoma	<1 cm no surveillance 1–2.9 cm surveillance after 5 years 3–9.9 cm surveillance after 5 years	If limited life expectancy, no surveillance (Bollschweiler et al. 2017)
pT1a : mucosal infiltration	Endoscopic resection	For patients >70 years old: less perioperative complications and better 2 years survival than esophagectomy (Cummings et al. 2016)
pT1b (esophageal submucosa)-pT2 (muscularis propria)	Surgical resection and selective lymphadenectomy: transthoracic esophagectomy	If significant comorbidities: definitive chemoradiation (Bollschweiler et al. 2017)
Clinical T3: locally advanced cancer or esophagogastric junction	Squamous cell carcinoma or adenocarcinoma: preoperative chemoradiation: 5-FU, platin 40 Gy, or CROSS protocol	Benefit of neoadjuvant chemotherapy 5FU-cisplatin vs. surgery alone on overall survival after 70 years old with acceptable tolerance (Medical Research Council Oesophageal Cancer Working Group 2002) FLOT protocol had major adverse effects in >65 years patients (81.9% NCI-CTC grade 3–4) with no benefit on progression-free survival after 70 years old (Al-Batran et al. 2013)
	Or chemotherapy for adenocarcinoma: 5-FU, platin, or FLOT protocol (5-FU, leucovorin, oxaliplatin, docetaxel)	
	And transthoracic esophagectomy	
Inoperable cancer	Radiotherapy or chemoradiation	Intensity-modulated radiotherapy improves overall survival and cardiac mortality compared to 3-d radiation (Lin et al. 2016)
Metastatic cancer	Palliative chemotherapy: 5-fluorouracile, oxaliplatine, and also irinotecan or taxanes +/− Targeted therapy if HER2 positive: trastuzumab	
Supportive care	Self-expanding metal stent Intraluminal brachytherapy Radiotherapy Rigid plastic tube insertion	

complications. Preexisting comorbidities explain a large part of these increased complications. Indeed, lower pulmonary function and cardiovascular comorbidities are risk factors for higher mortality and morbidity after esophagectomy (Liu et al. 2015). Moreover Nakashima Y et al. showed that sarcopenia had a high prognostic impact after esophagectomy. Sarcopenia was present in near half of patients with esophageal cancer and was an independent risk factor for an anastomotic leak (HR = 2.3; 95% CI: 1.06–5.1, $p = 0.034$) and poor survival (HR = 2.3; 95% CI: 1.50–3.7, $p < 0.001$). The correlations between sarcopenia and surgical outcomes were not observed in the younger group (Nakashima et al. 2018). The age threshold of 80 years showed an even more significant association between in-hospital mortality and elderly age (pooled odds ratio = 3.19; 95% CI: 1.6–6.35; $P < 0.05$). The elderly group had poorer outcomes with a reduction of overall 5-year survival (pooled odds ratio = 0.73; 95% CI: 0.62–0.87; $P < 0.05$) and cancer-free 5-year survival (POR = 0.75; 95% CI: 0.64–0.89; $P < 0.05$) (Markar et al. 2015).

This meta-analysis included studies from 1970 until 2009. It is noteworthy that surgical techniques have evolved over this period with introduction of minimally invasive approaches that reduce postoperative overall complications especially for patients over 70 years of age (37.9% vs. 60.3%, $p = 0.016$) and pulmonary complications (20.7% vs. 39.7%, $p = 0.026$) compared with open esophagectomy (Li et al. 2015). Moreover, introduction of fast-track programs that optimize perioperative parameters reduces lengths of stay and 30-day mortality for patients over 75 years old compared with classic management (Oakley et al. 2016).

Chemotherapy

Neoadjuvant Chemotherapy

Preoperative chemotherapy by cisplatin 5-fluorouracil improves survival, but this gain of survival remains limited and only for patients with a major response (90% reduction of initial tumor). Patients with a minor response had comparable prognosis when compared to patients undergoing surgery only (Bollschweiler et al. 2017).

Palliative Chemotherapy

Almost half of people with esophageal or gastroesophageal junction cancer have metastatic diseases (bones, lungs, nodes) at the time of diagnosis. A recent meta-analysis showed that palliative chemotherapy/targeted therapy compared with best supportive care improved the median survival time by 1 month with more occurrences of severe toxicities. But there is no evidence that chemotherapy and/or targeted therapy decreases quality of life (Janmaat et al. 2017).

The REAL2 study showed the benefit of a first-line treatment with capecitabine, and oxaliplatin was the same as 5-fluorouracil and cisplatin with less toxicities. However, there is an increased risk of febrile neutropenia (Cunningham et al. 2013).

In case of positivity of HER 2, trastuzumab is indicated as a first-line choice, in combination with chemotherapy.

As a second-line choice, if the general condition of the patient allows it, two options are possible: taxanes or 5-fluorouracil and irinotecan.

Radiotherapy

Radiation is the standard therapeutic modality for inoperable esophageal cancer with a dual purpose: to improve local control and survival. For non-metastatic esophageal cancer, intensity-modulated radiotherapy had better outcomes in aged patients (>65 years) compared with three-dimensional radiotherapy on all-cause mortality (HR = 0.8, 95% CI: 0.72–0.95) and cardiac mortality (HR = 0.18; 95% CI: 0.06–0.54) (Lin et al. 2016).

Supportive Care

Most patients with esophageal and gastroesophageal carcinoma are diagnosed at an advanced stage or are ineligible for surgery and require palliative interventions. Palliative therapies for advanced esophageal cancer include surgery, radiation therapy, chemotherapy, endoscopic procedures, and combinations of these. A recent meta-analysis compared these technics.

Dai Y et al. conclude that self-expanding metal stent insertion is safe, effective, and quicker in palliating dysphagia compared to other modalities. However, high-dose intraluminal brachytherapy is a suitable alternative and might provide additional survival benefit with a better quality of life. Some anti-reflux stents and newly designed stents lead to longer survival and fewer complications compared to conventional stents. Combinations of brachytherapy with self-expanding metal stent insertion or radiotherapy are preferable due to reduced reinterventions. Rigid plastic tube insertion, dilation alone or in combination with other modalities, and chemotherapy alone are not recommended to palliate dysphagia due to a high incidence of delayed complications and recurrent dysphagia (Dai et al. 2014).

Nutritional management is the key to supportive care. This management includes oral supplementation if there is no dysphagia or enteral nutrition with a feeding tube or gastrostomy for patients unable to eat. The objective is the optimization of nutritional intake to limit infectious risks and improve prognosis after surgical or radiochemotherapy treatment (Yu et al. 2013).

Gastric Cancer

Gastric cancers have poor prognosis with a median survival of about 10 months and are often diagnosed at an advanced stage (Dai et al. 2014). The triple chemotherapy with epirubicin plus cisplatin and fluorouracil is standard for advanced esophagogastric cancer. The fluorouracil must be infused through an ambulatory infusion pump, which impairs the quality of life; cisplatin, which is nephrotoxic, requires intravenous hydration. In this randomized trial, capecitabine, an oral fluoropyrimidine, plus oxaliplatin, a platinum compound that does not require hydration, was as effective in prolonging overall survival as was fluorouracil plus cisplatin. The principles of gastric cancer management after 75 years old are the same as younger patients, but comorbidities assessed by CGA could impact therapeutic options (Table 4).

Localized Stage

Surgery

Surgery is the only curative treatment in gastric cancer. A population-based evaluation of outcomes in gastric cancer in the elderly showed that if elderly patients can support an oncologic surgery and chemotherapy, the overall survival is comparable between age groups (48% and 49.6% of survival rate at 5 years) (Schlesinger-Raab et al. 2016).

There is no gain in overall survival with extensive lymphadenectomy for gastric cancer in elderly patients. D "1.5" lymphadenectomy is most often realized (without splenectomy and left pancreatectomy).

Even though no study with a high level of evidence has focused on the impact of a rehabilitation protocol in early postoperative gastric cancer care, the limitation of operative shock is the top priority in frail older patients (Li et al. 2014). This should consist of limited pre- and postoperative fasting, limited hypothermia during surgery, effective pain management, and giving preference to minimally invasive celioscopic surgery (Hu et al. 2016).

Neoadjuvant Chemotherapy

There are no specific prospective studies evaluating neoadjuvant or perioperative chemotherapy in older patients; however, subgroup studies hint to their efficacy. Considering stages over IA (T1 N0 M0), 5FU perioperative chemotherapy (four to six cycles prior and posterior to surgery) associated with FOLFOX-type platinum salts is recommended each time patient's health condition allows it (Smyth et al. 2016a). There is no demonstrated benefit of preoperative radiochemotherapy.

Metastatic Stage

HER 2-Negative Tumors

First-line chemotherapy based on REAL2 (Cunningham et al. 2008) and FLO studies should be 5FU (fluorouracil and capecitabine) and oxaliplatin (Al-Batran et al. 2008). The REAL2

Table 4 Management of gastric cancer in elderly patients

Stage of gastric cancer	Treatment recommendations	Specificities for elderly patients
Localized stage		
	Curative surgery: gastrectomy and regional lymphadenectomy (D1 and D2) *D1 adenectomy: lesser curvature nodes and greater curvature nodes* *D2 adenectomy: celiac trunk nodes, hepatic artery nodes, gastric artery nodes*	D2 adenectomy: No gain in survival for aged patients (Passot et al. 2016)
Proximal cancer, corpus cancer, lignite	Complete gastrectomy and reconstruction on a Roux-en-Y loop	
Distal cancer	Partial gastrectomy with omega loop or Y loop	Y anastomosis limits *biliary reflux*
Stage > IA (T1 N0 M0)	Surgery + perioperative chemotherapy: FOLFOX (Smyth et al. 2016a)	
	If patient is unfit: adjuvant chemotherapy with LV5FU2 or abstention	
Metastasis stage		
HER2 negative tumor	1ère line: FOLFOX 4–6 cycles or capecitabine-oxaliplatine	REAL2 (Cunningham et al. 2008) and FLO (Al-Batran et al. 2008)
		If patient is unfit : 5FU alone or no chemotherapy
	2ème line: FOLFIRI or ramucirumab + paclitaxel (Smyth et al. 2016a)	No specific study or only subgroups of older patients with ramucirumab + paclitaxel
HER2 positive tumor	5FU, platin, trastuzumab (Smyth et al. 2016a)	
Palliative care	Palliative surgery for symptomatic tumors (dysphagia, bleeding, perforation) or palliative radiotherapy	

studies have shown that capecitabine with oxaliplatin may replace 5FU with cisplatin as a first-line choice. The FLO study showed longer progression-free survival with 5FU, leucovorin, and oxaliplatin association than 5FU, leucovorin, and cisplatin association in patients aged over 65 (6.0 months vs. 3.1 months). Moreover, oxaliplatin had a better tolerance profile with lessened nausea, vomiting, fatigue, renal toxicity, anemia and thrombosis. It should be noted that 5FU is administered in continuous drip at 2600 mg/m^2, not in bolus.

Second-line chemotherapy should be irinotecan, taxane, or ramucirumab or ramucirumab with paclitaxel (Smyth et al. 2016b) or FOLFIRI.

HER2-Positive Tumors

First-line chemotherapy should be based on a 5FU, cisplatin, and trastuzumab association. In case of contraindication to cisplatin, FOLFOX-trastuzumab or capecitabine-oxaliplatin-trastuzumab will replace it.

Second-line therapy is the same as for HER2-negative tumors.

Supportive Care

The main supportive care concern is nutritional support. Indeed 60% of patients with gastric cancers are undernourished (Hébuterne et al. 2014). Malnourishment increases postoperative complications and chemotherapy toxicity, diminishes response to chemotherapy, and alters quality of life. Consequent sarcopenia is a major prognosis factor of gastric cancers and must be screened for (Zhuang et al. 2016).

Nutritional management must be planned out prior to treatment with a before and after approach. Nutritional assistance must be set up if intakes are below 60% of nutritional needs, whether enteral (feeding jejunostomy) or parenteral so as to

cover nutritional needs (1.2–1.5 g of proteins/kg/day and 30–35 kcal/kg/day).

Immunonutrition is recommended for malnourished patients 7 days prior and after surgery. In case of gastrectomy, feeding must be fractioned into seven to eight meals per day.

Hemostatic radiotherapy is possible in case of intense bleeding.

Hepatocellular Carcinoma

The incidence of hepatocellular carcinoma (HCC) is increasing worldwide; it is currently the third cause of death by cancer in the world. Subjects are preferentially male and, in more than 80% of cases, affected by cirrhosis. Principal risk factors are hepatitis B and C, alcohol, and nonalcoholic steatohepatitis (NASH). There is an augmentation of the incidence of HCC in older subjects. Certain particularities are noteworthy, a greater prevalence in women, due to their long-life expectancy, lesser infections by hepatitis B virus, but more cirrhosis linked to hepatitis C or NASH. Many studies have shown that HCC is often mono- or pauci-focal, associated with lesser fibrosis, and more often encapsulated (favorable prognosis factor).

Treatments are based on Barcelona Clinic for Liver Cancer (BCLC) classification, taking into account comorbidities and patients' general health states. The place of CGA has not been evaluated in the management of HCC. Screening tools such as the G8 questionnaire or the VES13 could allow selection of older patients affected by HCC needing to benefit from a CGA. Only surgery (hepatic transplantation and surgical resections), per-cutaneous ablations such as radiofrequency are potentially curative. Intra-arterial chemoembolization, radioembolization for intermediate stages, and targeted therapy with sorafenib for advanced stages are palliative treatments.

Curative Treatments

Hepatectomy

Surgical liver resection is the curative treatment of early stage HCC (BCLC stage 0). It has been shown to be feasible for older patients since surgical techniques have evolved (Ishizawa et al. 2010). Many studies have shown there is no difference in global survival and progression-free survival in patients aged 70 years and older when compared to younger patients (Huang et al. 2009; Kaibori et al. 2016). Some studies have shown higher incidences of postoperative complications such as confusion and longer hospitalization in older patients (Kaibori et al. 2009; Nozawa et al. 2015). Two other studies have shown hepatectomy to be feasible in patients older than 80 years, with survival rates comparable to younger patients (Nozawa et al. 2015; Yamada et al. 2012). However, Nozawa et al. observed higher incidences of cardiovascular complications and confusion in this population.

Only 1 retrospective study has tried to identify geriatric risk factors linked to postoperative complications, in 70 patients aged over 70 years (Kaibori et al. 2016).

Orthotopic Liver Transplantation

Orthotopic liver transplantation (OLT) is a curative treatment for HCC, but access to OLT is still narrowed due to organ shortage. Lack of donor is frequent. Presence of comorbid conditions such as ischemic heart disease and diabetes, which are known to adversely affect post OLT course, limits transplantation access in older patients $\geq$70 years. An arbitrary threshold of >65–70 years is generally adopted worldwide.

Radiofrequency Ablation

Percutaneous ablative treatment (RFA) is a curative procedure for HCC tumors less than 3 cm. Studies on outcome in elderly patients after RFA showed conflicting results. Sato et al., in a large cohort of 54,145 patients with HCC, found that older age was significantly associated with mortality. Kao et al. showed that older patients had worse overall survival than their younger counterparts (Kao et al. 2012). Conversely, Shiina et al. reported that age was not associated with reduced survival after RFA (Shiina et al. 2012). Overall, RFA may represent an attractive alternative to SR in elderly patients with comorbidities.

Palliative Treatments

Chemoembolization

Transarterial chemoembolization (TACE) is the treatment of choice in intermediate stages of HCC. Studies have shown similar survival rates between young and elderly patients with HCC. Mirici-Cappa et al., in a large cohort study, found no difference in overall survival between the different age groups (Mirici-Cappa et al. 2010). Likewise, Cohen et al., in a prospective study of 102 patients, reported no difference in terms of survival or complication rate (Cohen et al. 2013). Only one large retrospective study, conducted by Yau et al. (2009), showed a significant difference, with a better median overall survival and disease-specific survival (15.2 months vs. 8.7 months, $p < 0.001$). However, there was no difference in terms of TACE-related mortality. This data suggests that TACE is effective with a good safety profile, in an elderly population.

Molecular Targeted Therapy (Sorafenib)

Sorafenib is now the standard care of patients with advanced HCC, but there are few studies regarding the use of sorafenib in elderly patients. There is only one prospective study comparing sorafenib in elderly >70 years versus younger patients ≤70 years (Di Costanzo et al. 2013).

They found surprisingly that elderly patients had a median time to progression and an overall survival rate that was longer than for younger patients, with less severe adverse effects although results were not statistically significant. Other retrospective studies found similar results. Jo et al showed that the median progression-free survival and the overall survival time were similar in older and younger patients even on very elderly (≥ 80 years) (Jo et al. 2014).

Data concerning tolerability and the safety profile of this molecule is lacking in elderly patients with HCC. Morimoto et al., in a retrospective study, reported that the discontinuation of sorafenib therapy due to SAE was more frequent among elderly patients ≥75 years than among younger patients (Morimoto et al. 2011). Likewise, Edeline et al. found similar frequency of dose reduction and occurrences of SAEs in the elderly group (>70 years) (Edeline et al. 2015). There was significantly less frequent definitive discontinuation of treatment due to toxicity in the younger group. However, they found higher incidence of bleeding in the elderly group, which was explained by concomitant platelets inhibitors.

Conclusion

Available data seems to indicate that age is not an independent factor of mortality or toxicity in patients with HCC. However, data is insufficient to conclude, and patients included in these studies are carefully selected. Identifying frail older patients, with appropriately validated tools (G8 scores and CGA), is necessary to offer elderly patients personalized treatment.

Pancreatic Cancer

Operable Stage

Surgery

Surgery is the only lasting cure, but unfortunately only 15–20% of patients are eligible for full resection (Table 5). This proportion diminishes with age; it is of only 8% after 85 years (Higuera et al. 2016). Pancreatic cancer surgery is taxing and requires patients to be selected beforehand. Many retrospective studies, one of which is French (Turrini et al. 2013), have shown there is no increase in morbidity or mortality in older patients compared to younger ones when they have been deemed operable (Frakes et al. 2015; Hayman et al. 2015).

For inoperable patients over 80 years of age, chemotherapy alone has shown survival rates similar to those from surgery (Kinoshita et al. 2015). Stereotaxic radiotherapy associated or not with gemcitabine has also shown results of good local control in a small retrospective study (Kim et al. 2013).

Table 5 Management of pancreatic cancer in elderly patients

Tumor stage	Recommended treatment	Geriatric specificities
Operable	Surgery Adjuvant chemotherapy with FOLFIRINOX (or gemcitabine or fluorouracil or gemcitabine + capécitabine)	High postoperative morbidity requiring rigorous patient selection Specialized center surgery Options: stereotaxic radiotherapy +/− gemcitabine if patient is inoperable or standalone chemotherapy
Borderline	No referential Chemotherapy with FOLFIRINOX or gemcitabine then surgery if operable	Relevance of neoadjuvant treatment to identify patient with rapidly progressive diseases ineligible to surgery Feasible but more studies needed
Locally advanced cancer	Supportive care + chemotherapy +/− Closure radiotherapy	Chemotherapy with gemcitabine Optional stereotaxic radiotherapy
Metastasis cancer	Supportive care + chemotherapy Age < 75 years, PS 0-1 FOLFIRINOX If PS = 2: gemcitabine + nab-paclitaxel If bilirubin >1.5 or comorbidities: gemcitabine If PS > 2: supportive care alone	FOLFIRINOX only for patients PS 0-1 with no comorbidity Nab-paclitaxel + gemcitabine or gemcitabine for patients PS 2 Palliative care if PS > 2 (Higuera et al. 2016)

Adjuvant Treatment

Adjuvant treatment is indicated for all operated patients at all stages and must start within 3 months of surgery. Despite a demonstrated survival gain, adjuvant treatment is only undertaken in 30–50% of older patients (Nagrial et al. 2014; Parmar et al. 2014). Age does not appear to be a prognosis factor (Frakes et al. 2015).

Single chemotherapy can be proposed to older subjects, either by gemcitabine (Oettle et al. 2013) or by fluorouracil, with comparable results. Gemcitabine has a better tolerance profile (Neoptolemos et al. 2010).

Locally Advanced Stages

Borderline

Borderline is defined by patients with local disease spread for whom surgery is still possible.

In these cases the use of neoadjuvant chemotherapy alone or chemoradiotherapy seems possible even in older patients in order to propose surgical resection despite the absence of a current referential and the necessity for more studies (Miura et al. 2015). This treatment also allows the selection of patients with rapid progression who will not benefit from curative surgical treatments.

Inoperable

This stage is defined by a vascular spread of the disease rendering surgery impossible. At diagnosis, 20–25% of patients have a locally advanced stage.

Referential-validated treatment is chemotherapy with gemcitabine (studies are ongoing to validate the same protocols as for metastatic stages) with the possibility of end-line radio-chemotherapy in selected patients (Huguet et al. 2014). This treatment is not often realized for older patients despite a demonstrated survival gain (Krzyzanowska et al. 2003).

Recently the development of stereotaxic radiation techniques for the pancreas has given interesting results with good tolerance and local control gains with a marked analgesic effect. This treatment is not yet recommended because of insufficient evidence but could be an option for older patients (Chuong et al. 2013).

Metastatic Stage

More than half of cases diagnosed at metastatic stages have a 5-year survival rate inferior to 2%.

In young patients referential poly-chemotherapy is FOLFIRINOX, validated by a prospective study showing 11.1 months of global

survival against 6.8 months for gemcitabine alone (Conroy et al. 2011). However, in this study, patients who were OMS >1 or aged >75 years were excluded. Retrospective studies have shown the feasibility and the efficiency of this treatment with adapted dosage in older patients PS 0 or 1 despite an increase in adverse effects (neutropenia and diarrhea) (Baldini et al. 2017; Guion-Dusserre et al. 2016).

Gemcitabine and nabpaclitaxel association has also shown better efficacy than gemcitabine alone (Von Hoff et al. 2013); this treatment could be proposed to patients over 75 years of age who are OMS 2.

For frail older patients, monotherapy with gemcitabine associated with supportive care is still the referent.

Supportive Care

Because of the anatomic relationships, patients regularly suffer from intense abdominal pain requiring morphine treatments. Invasive techniques such as celiac trunk alcoholization can be undertaken with good efficacy, allowing to diminish morphine prescriptions (Nagels et al. 2013).

Moreover, pancreatic tumors can cause biliary duct or duodenum obstructions requiring invasive prosthetic stent techniques. However palliative, these treatments result in quality of life improvement. These patients often suffer from cachexia and require adapted nutritional management.

Conclusions

It seems that age is not the main decision-taking factor in elderly patients suffering from digestive cancers. We would recommend a CGA or shorter screening tools to assess perioperative complications in order to improve decision-making. Prognostic of robust elderly patients seems to be similar to younger patients, but elderly population is still undertreated due to lack of evidence and imprecise geriatric evaluation.

Palliative chemotherapy, in older adults, only increases slightly survival with an increased toxicity, so that this option should be individualized. Decision should be made based on quality of life, compared with best supportive care.

Abstract

The decrease in muscle mass and strength represents one of the most relevant descriptor of physiological aging. Sarcopenia is the term coined to indicate the pathologic loss of skeletal muscle mass and strength/function during aging. The skeletal muscle decline has a multifactorial origin, involving lifestyle habits, disease triggers, and age-dependent biological changes. This phenomenon is part of the geriatric background and is today starting to disseminate in other specialties dealing with the complexity of frail older persons. In the oncology field, the interest in muscle wasting has mostly been focused on the clinical entity of cancer cachexia, a complex metabolic syndrome characterized by severe muscle loss, systemic inflammation, and malnutrition. The study of body composition in the oncological setting is crucial and may become one of the main characterizations of the oncogeriatric field, where clinical and research actions have to be designed taking into account the consequences of the aging process.

Introduction

Cancer is largely a late-life disease. In developed countries, the median age of cancer patients at diagnosis is over 65 (Global Burden of Disease Cancer Collaboration et al. 2016). Moreover, it is expected that more than 70% of all cancers will affect people aged 65 years and older by the year 2030 (Edwards et al. 2002).

Several mechanisms operating at multiple levels (molecular, cellular, systemic) have been invoked to explain the disproportionate incidence of cancer in old age (Balducci and Ershler 2005; Finkel et al. 2007; Campisi 2013). Indeed, aging and cancer seem to share a common pathogenic process consisting in the time-dependent accumulation of cellular damage (López-Otín et al. 2013; Hanahan and Weinberg 2011). This phenomenon results in two apparently opposite processes: an aberrant gain of cellular function (i.e., cancer) versus a progressive and generalized loss of fitness (i.e., aging) (López-Otín et al. 2013). Not surprisingly, the kinetics of tissue/organ degenerative processes and the incidence of cancer show similar trajectories, rising progressively at approximately the midpoint of adult life span (Rozhok and DeGregori 2016).

The decrease in muscle mass and strength represents one of the most relevant descriptor of physiological aging (Justice et al. 2016). In a fairly large percentage of individuals, an accentuated muscle loss takes place leading to adverse health outcomes (e.g., mobility disability, physical frailty, falls and fractures, mortality) (Pahor et al. 2009; Landi et al. 2015). Sarcopenia is the term coined to indicate the pathologic loss of skeletal muscle mass and strength/function during aging (1989). Sarcopenia has a multifactorial origin, involving lifestyle habits, disease triggers, and age-dependent biological changes (e.g., chronic inflammation, mitochondrial abnormalities, loss of neuromuscular junctions, reduced muscle regenerative capacity, hormonal alterations) (Fielding et al. 2011).

Muscle dysfunction also develops across several stages of cancer trajectory (Christensen et al. 2014). In the oncology field, interest in muscle wasting has mostly been confined to the clinical

entity of cancer cachexia, which is characterized by severe muscle loss (Fearon et al. 2011), systemic inflammation (Fearon et al. 2012), and malnutrition (Argilés 2005). Emerging evidence shows that decreased muscle mass is a prevalent condition in cancer patients regardless of disease stage and body mass (Prado et al. 2008; Martin et al. 2013; Shachar et al. 2016). The presence of sarcopenia in adults with cancer has been associated with increased chemotherapy toxicity, postoperative complications, and higher mortality rates (Kazemi-Bajestani et al. 2016), independent of disease stage (Tan et al. 2009; Villaseñor et al. 2012; van Vledder et al. 2012).

In addition, skeletal muscle health affects the risk of developing cancer, being muscle tissue a major regulator of metabolic and inflammatory pathways (Argilés et al. 2016; Whitham and Febbraio 2016). Finally, substantial evidence shows that muscle strength in healthy individuals is a strong independent predictor of cancer mortality risk (Ruiz et al. 2009).

Muscle Aging and Sarcopenia

The age-related loss of muscle mass and function (i.e., sarcopenia) is one of the most pervasive changes that accompany aging. As acknowledged by Rosenberg (1989), "...There may be no single feature of age-related decline that could more dramatically affect ambulation, mobility, calorie intake, and overall nutrient intake and status, independence, breathing...." Sarcopenia is indeed associated with a multitude of adverse health outcomes, among which falls, disability, institutionalization, and mortality are certainly the most worrisome (Rolland et al. 2008). After the age of 35 years, a healthy person loses muscle mass at a rate of 1–2% per year in conjunction with a 1.5% annual decline in strength, which accelerates to approximately 3% per year past the age of 60 (Hughes et al. 2002; Landi et al. 2016a). As a result, the muscle cross-sectional area of the thigh decreases by about 40% between 20 and 60 years of age. The magnitude of decline in fat-free mass is twice as greater in men than in women and is amplified in sedentary individuals relative to physically active peers (Hughes et al. 2002; Landi et al. 2016a). Besides losing muscle mass, an average adult can expect to gain approximately 0.45 kg (1 lb) of fat per year between the ages of 30 and 60 (Forbes 1999). This shift in body composition is often masked by relatively stable body weight and can result in a condition known as sarcopenic obesity, which further increases the risk of disability, morbidity, and mortality (Batsis et al. 2014; Rolland et al. 2009; Kalinkovich and Livshits 2016).

Although the decline in muscle mass and strength with age has been known for long time, only in recent years, sarcopenia has become a hot topic in gerontology. Several processes and mechanisms have been proposed to play a role in the multifaceted pathogenesis of sarcopenia, including lifestyle habits, systemic factors (e.g., inflammatory cytokines and hormones), local environment alterations (e.g., vascular dysfunction), changes in the neuromuscular system, and modifications of intramuscular specific processes (Marzetti et al. 2009). All these factors eventually lead to an imbalance between anabolic and catabolic processes, which results in muscle protein breakdown, loss of myocytes, insufficient satellite cell replenishment, and ultimately declines in muscle mass (in particular, type II fibers) and function (Marzetti et al. 2009). Overall, multiple factors have been indicated at the basis of the sarcopenic phenomenon, each of them following specific, independent, and mutually interacting mechanisms (Table 1) (Buford et al. 2010; Rier et al. 2016).

Lifestyle Factors

Among lifestyle factors, physical inactivity and inadequate nutrition represent the two most important contributors to poor muscle health in older adults (Martone et al. 2015). The relationship among them and sarcopenia is bidirectional. In fact, sedentariness combined with the ingestion of insufficient amounts of calories and specific nutrients (in particular, proteins) promotes the development of sarcopenia. Once sarcopenia starts to develop, the ability to move, shop for

Table 1 Etiological factors and mechanisms at the basis of sarcopenia in older persons. (Modified from Rier and colleagues (Rier et al. 2016))

Etiological factors	Mechanisms
Muscle disuse	Reduced physical activity Cognitive impairment Immobility Neuromuscular transmission impairment
Endocrine changes	Low testosterone concentrations Low growth factor concentrations Low IGF-1 concentrations Increased insulin resistance
Malnutrition	Inadequate food intake Malabsorption Increased catabolism and protein breakdown Decreased peripheral perfusion leading to muscle hypo-oxygenation
Low-grade chronic inflammation	Increased concentration of pro-inflammatory cytokines with direct and indirect negative effects on the skeletal muscle (e.g., TNF-α, IL-1, IL-6)

IGF-1 insulin-like growth factor-1, *TNF* tumor necrosis factor, *IL* interleukin

grocery, and prepare adequate meals may become impaired. The instauration of the consequent vicious circle may lead to severe malnutrition, weight loss, and further worsening of sarcopenia, finally ending into disability and, eventually, death (Evans 2010). Not surprisingly, while no pharmacological treatment is presently available to prevent age-dependent muscle wasting or to restore muscle mass and function, physical exercise and targeted nutritional supplementations represent the only interventions that may offer substantial therapeutic gain against sarcopenia and its negative correlates (Martone et al. 2015).

Endocrine Aging

Aging is marked by progressive, subtle derangements of nearly all biological systems, including endocrine ensembles (Chahal and Drake 2007). The nature and magnitude of age-related alterations in circulating hormones and target tissue responsiveness have taken center stage in sarcopenia research (Sakuma and Yamaguchi 2012a). Studies have indicated that several age-related endocrine defects such as decreases in anabolic hormones (e.g., testosterone, estrogen, growth hormone [GH], and insulin-like growth factor-1 [IGF-1]) (Sakuma and Yamaguchi 2012a), alterations in the renin-angiotensin system (Carter et al. 2005), and vitamin D deficiency (Cesari et al. 2011) may play a role in muscle wasting with aging.

Inflammation

The presence of a state of chronic low-grade inflammation is an established hallmark of the aging process (i.e., inflamm-aging) (Franceschi and Campisi 2014). The persistent elevation of several inflammatory mediators, in particular interleukin (IL)-6 and tumor necrosis factor-α (TNF-α), has been associated with sarcopenia (Jo et al. 2012). These mediators act in a complex and coordinated network involving multiple feedback mechanisms through which the function of individual factors may be modified, replaced, or modulated by others (Calvani et al. 2015). In this context, multivariate analytical strategies have recently been developed to capture the complex interrelation linking circulating inflammatory mediators to body compositional factors during aging (Calvani et al. 2016; Marzetti et al. 2014). Using such approaches, it was possible to characterize the hidden pattern of relationships among small muscle volume, low muscle strength, great intermuscular adipose tissue, and a cluster of inflammatory mediators (including myeloperoxidase, P-selectin, soluble intercellular adhesion molecule-1, and vascular cell adhesion molecule-1) in community-living young and older adults with varying levels of physical performance (Calvani et al. 2016).

For years, the induction of muscle protein breakdown has been considered to be the major pathway underlying the relationship between inflammation and sarcopenia (Combaret et al. 2009). However, a link among inflammation, mitochondrial dysfunction, and oxidative stress has more recently been proposed, possibly

providing a further mechanistic explanation for the association between inflammation and sarcopenia (Marzetti et al. 2013).

Neuromuscular Changes

A reduction in motor unit number secondary to motor neuron loss is considered to be a major drive of age-dependent muscle wasting. Relevant alterations associated with neuromuscular system dysfunction include muscle fiber loss, fiber type grouping due to repeating cycles of denervation-reinnervation, and increased neuromuscular degradation (Marzetti et al. 2009). The functional implications of such changes involve reductions in strength and coordination and increased fatigability (Hepple and Rice 2016). A destabilization of the neuromuscular junction has also been recently indicated as a possible contributor to the generation of the sarcopenic condition (Butikofer et al. 2011).

Oxidative Stress and Mitochondrial Dysfunction

According to the mitochondrial-free radical theory of aging (Miquel et al. 1980), the accumulation of somatic mutations in the mitochondrial DNA (mtDNA) would result in reduced energy production through oxidative phosphorylation (OXPHOS) and redirection of OXPHOS electrons into reactive oxygen species (ROS) generation. The combination of defective bioenergetics and oxidative stress eventually leads to mitochondrial permeability transition and cell dismissal via apoptosis (Wallace 2005). In postmitotic tissues, such as the heart, skeletal muscle, and nervous system, cell loss, in turn, would be primarily responsible for the appearance of age- and disease-associated phenotypes.

The loss of mitochondrial metabolic flexibility and integrity, due to alterations in mitochondriogenesis, dynamics, and removal, is presently believed to underlie many aspects of the aging process as well as several age-related disorders, including sarcopenia (Riera and Dillin 2015). The inability to adapt substrate oxidation to fuel availability impairs the metabolic homeostasis and the capacity to properly respond to metabolic demands. These events, coupled with inefficient mitochondrial biogenesis, are eventually followed by impaired degradation of dysfunctional mitochondria and accumulation of abnormal, ROS-producing organelles (Riera and Dillin 2015).

As a consequence of redox imbalance, mtDNA can undergo quantitative (e.g., large-size deletions and mtDNA content variations) and qualitative alterations (e.g., base modifications, abasic sites, single- and double-strand breaks, point mutations) that affect its structure and function. Recently, mtDNA content and the expression of mitochondrial transcription factor A (TFAM), a histone-like protein for mtDNA, as well as the modulation of TFAM binding to mtDNA have been found to be relevant targets of mitochondrial dysfunction and impaired mitochondriogenesis (Picca et al. 2014; Picca and Lezza 2015).

Derangements of the muscular mitochondrial quality control (MQC) axis have been associated with sarcopenia through either the inefficient removal of damaged mitochondria or the clonal expansion of dysfunctional organelles (Calvani et al. 2013a). MQC is based on a heterarchical network of interacting pathways and processes, including fission-fusion cycles and mitophagy, which tightly link mitochondrial viability/activity to skeletal myocyte functional needs. A relevant consequence of age-related MQC dysfunction is the activation of myonuclear apoptosis, a mechanism believed to represent a final common pathway through which muscle wasting proceeds (Marzetti et al. 2012).

The Operational Definition of Sarcopenia

One of the reasons for which Rosenberg proposed to name the age-related skeletal muscle reduction with the term "sarcopenia" was to promote a better recognition of this condition by the scientific community and research funding agencies (1989; Rosenberg 1997; Rosenberg and

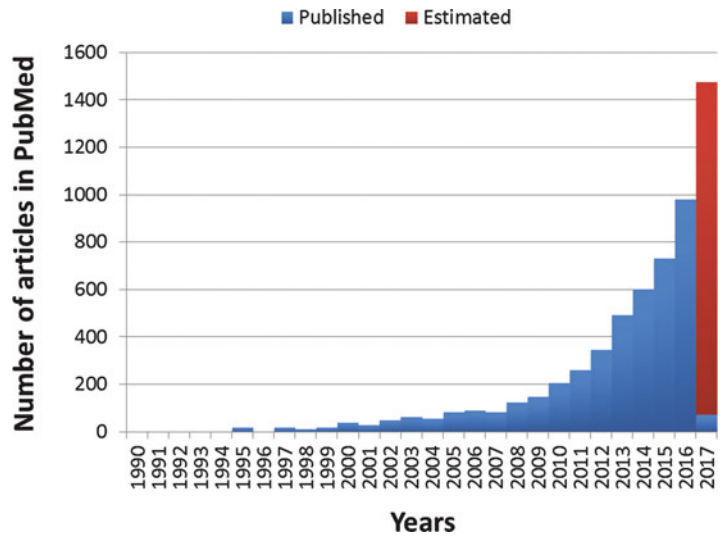

Fig. 1 Number of items retrieved from PubMed using the keyword "sarcopenia" according to year of publication. Updated on January 19, 2017

Roubenoff 1995). Indeed, there has been an exponential growth of interest around sarcopenia over the last two decades (Fig. 1).

From the first theoretical discussions about this universal phenomenon of aging (Herndon et al. 2002), it was necessary to develop operational criteria in order to feed the routine clinical and research practice. The first works in this direction proposed to center the sarcopenia definition on the only quantification of skeletal muscle mass. In particular, Baumgartner and colleagues (Baumgartner et al. 1998) defined sarcopenia as an appendicular lean mass being less than two standard deviations below the mean of a young reference group. Similarly, Janssen and colleagues (Janssen et al. 2004) proposed an index based on the quantification of muscle mass by bioelectrical impedance analysis (BIA) and provided cut points according to the likelihood of developing physical disability.

The fact that adipose tissue influences the muscle physiology via its endocrine properties (Prins 2002) suggested the need of a more holistic approach when defining the body composition profile of an individual. Newman and colleagues (Newman et al. 2003) showed that the quantity of muscle mass alone might not be sufficient to explain physical impairment in specific subgroups. In fact, the adoption of a fat-adjusted measure of appendicular lean mass was able to better explain the participants' physical performance compared with the previously proposed models in the Health, Aging and Body Composition study. Consistent results were also reported in other studies, where it was shown that the amount of fat tissue and intramuscular fat infiltrates might have an important role in the definition of the risk profile, even more relevant than the lean mass alone (Visser et al. 2005; Delmonico et al. 2007). In other words, the idea that the quality of muscle could be more important than its quantity for maintaining a healthy physical status started to go through.

The quality of muscle can be measured by quantifying the production of strength, force, and function. In this context, it is well established that muscle function is a powerful predictor of negative outcomes in the elderly and provides more information about the risk profile of an individual compared with body composition parameters (Cesari et al. 2009, 2015). Moreover, it surely is more relevant for clinicians working in the care of older persons. For this main reason, the different operational algorithms proposed over the years for capturing the condition of interest by several international groups of experts (Cruz-Jentoft et al. 2010a; Fielding et al. 2011; Morley et al. 2011; Muscaritoli et al. 2010) are characterized by a common denominator: all recognize sarcopenia as a bidimensional condition made of a quantitative (i.e., skeletal muscle mass) and a qualitative (i.e., skeletal muscle function)

component. Among the four main consensus definitions, that endorsed by the European Union Geriatric Medicine Society (Cruz-Jentoft et al. 2010a) is probably the one that received most acceptance and largest diffusion. According to this model, sarcopenia is defined by the simultaneous presence of low appendicular lean mass (assessed by dual energy X-ray absorptiometry [DXA]) plus muscle weakness (measured as poor handgrip strength) and/or impaired mobility (captured by slow gait speed). The publication of these consensus papers indicating possible ways for objectively framing a clinically relevant sarcopenia condition has given further boost to the production of scientific evidence in the field (Fig. 1).

Nevertheless, the creation of a bidimensional condition for sarcopenia generated some difficulties and controversies. Mixing variables capturing different aspects of the skeletal muscle could sometimes be perceived as confusing. The age-related decline of skeletal muscle follows a different (and less steep) trajectory than physical performance and muscle strength measures (Lauretani et al. 2003). This may (at least, partially) explain why physical function measures are stronger predictors of negative health-related outcomes than body composition parameters, perhaps because more sensitive to changes. This issue renders the bidimensional algorithms of sarcopenia unbalanced, in that their predictive value is usually driven by function rather than body composition.

Finally, in 2014, the Foundation for the National Institutes of Health (FNIH) Sarcopenia Project released a collection of papers that can today be regarded as the reference in the field. Differently from previous consensus papers based on arbitrary choices made by panels of international experts, the FNIH investigators conducted ad hoc statistical analyses in multiple cohort studies with the aim of objectively defining muscle weakness and low lean mass. It is noteworthy that the FNIH initiative followed a rigorous statistical approach based on Classification and Regression Tree (CaRT) models in order to select the best defining criteria from a wide spectrum of candidate variables. The analyses led to the identification of two sets of muscle weakness and low appendicular lean mass parameters, for which sex-specific cut-points were also generated (Table 2) (Studenski et al. 2014). Noticeably, the FNIH definitions conduct to a more conservative approach to sarcopenia compared with other algorithms (Dam et al. 2014), possibly suggesting a fairer balance between the two components.

Table 2 Variables and sex-specific cut points recommended by the FNIH initiative for defining muscle weakness and low appendicular lean mass

	Women	Men
Muscle weakness		
Handgrip strength (recommended)	<16 kg	<26 kg
BMI-adjusted handgrip strength (alternative)	<0.56	<1.0
Appendicular lean mass		
BMI-adjusted appendicular lean mass (recommended)	<0.512	<0.789
Appendicular lean mass (alternative)	<15.02 kg	<19.75 kg

BMI body mass index

When discussing about the controversies existing in the definition of sarcopenia, it cannot be forgotten the still unsolved issue related to the technique for body composition assessment. In fact, although the operational definitions largely rely on measures obtained by DXA or BIA, many methodologies exist for assessing body composition and the skeletal muscle. Each one of the multiple possibilities is characterized by pros and cons (Table 3), and each one defines a different sarcopenia profile (Pahor et al. 2009). In this heterogeneous scenario, efforts have been made to describe the different features of the available instruments. It is not excluded the possibility that different tools might be used with different purposes (e.g., screening vs. diagnosis) according to the setting (e.g., primary care vs. hospital care) where sarcopenia is assessed (Cesari et al. 2012; Beaudart et al. 2016).

Today, researchers and clinicians found themselves in front of a novel condition (i.e., sarcopenia) with some limitations to be clarified:

- Multiple methodologies to assess body composition in the absence of a recognized gold standard

Table 3 Characteristics of the most frequently used methods for the assessment of skeletal muscle. (Modified from Pahor and colleagues (Pahor et al. 2009))

Method	Strengths	Weaknesses
MRI	Best resolution Assessment of muscle quality (i.e., intramuscular fat infiltrates) Quantification of lean and fat mass	Highly expensive equipment Need of special training and expertise Time-consuming Space requirements Results specific of a body district
CT	Assessment of muscle quality (i.e., intramuscular fat infiltrates) Quantification of lean and fat mass	Highly expensive equipment Need of special training and expertise Time-consuming Exposure to radiations Space requirements Results specific of a body district
DXA	Quantification of lean and fat mass Commonly used in the clinical setting Relatively inexpensive exam No special training General and sectorial quantification of body composition components	No muscle quality assessment Space requirements Low-dose radiations Not differentiating water from bone-free lean tissue High costs for the machine
BIA	Relatively cheap device Inexpensive exam Minimal maintenance Portable	Variable body resistance No muscle quality assessment Low accuracy No specific body district
Anthropometry	Easy to assess Inexpensive	Very limited accuracy No muscle parameter assessment
Ultrasound	Low cost for the exam Qualitative assessment of (specific) muscles structure	Relatively high costs for the machine Need of trained personnel Evaluation of a very specific body district Operator-dependent

MRI magnetic resonance imaging, *CT* computerized tomography, *DXA* dual energy X-ray absorptiometry, *BIA* bioelectrical impedance analysis

- A bidimensional definition presenting one factor more relevant than the other in determining the risk profile
- Unclear clinical utility of sarcopenia, especially if framed as a mere screening condition for the identification of individuals at risk of disability (Cesari and Vellas 2012)

Translation of Sarcopenia in Oncology

Prevalence of Sarcopenia

The heterogeneity of operational definitions, methodological procedures, and defining cut-points makes it challenging, if not impossible, to clearly estimate the prevalence of sarcopenia in the general population. Since sarcopenia can be considered as a hallmark of poor health status, its prevalence tends to vary across clinical settings, from the lowest prevalence reported in the community/primary care up to the highest documented in nursing homes.

Consistently, the estimation of sarcopenia in oncology might be perceived as a pure epidemiological exercise lacking a robust clinical and biological rationale. In fact, the existing controversies about the objective assessment of sarcopenia are here further enhanced by the presence of an additional major confounder that is the oncological condition, differently affecting the skeletal muscle according to its site and severity. For completeness but with all the due precautions in the application of these data, it is worth to mention the systematic review conducted by Rier and colleagues (Rier et al.

2016) reporting a prevalence of sarcopenia (defined using computerized tomography) ranging from 5% to 89% in different populations of oncological patients.

Different Objectives

As mentioned, the construct of sarcopenia was originally developed for sustaining research on aging and developing interventions against physical function loss. For this reason, the first applications of sarcopenia have been conducted in community-dwelling older persons. In this context, the interest in measuring sarcopenia was to detect the biological substratum of a condition of risk exposing an older person (even if in apparently good health) to incident disability. Sarcopenia was then a sort of pre-disability condition for promoting healthy lifestyle and successful aging.

These objectives might not completely fit when the quantification of the skeletal muscle is conducted in a person affected by a potentially lethal disease such as cancer. In this setting, priorities may be different. Of course, the preservation of the functional status remains a cornerstone in the definition of the interventions, but the treatment of cancer has equal (if not superior) importance.

Often sarcopenia is incorrectly seen as a condition to screen the most vulnerable elders, a sort of risk assessment tool. Surely, sarcopenia is a strong predictor of negative health-related outcomes, independently of the setting where it is assessed. The prognostic value of low muscle mass is well established in oncology as well as in other specialties (Rier et al. 2016). However, easier, cheaper, and more clinical friendly instruments are available for this purpose in geriatrics as well as in other medical specialties. If the clinician (or public health authorities) does not see the special advantages for his/her practice from the assessment of a certain parameter, then it will never be implemented. It will be perceived as redundant if not useless, especially if time-consuming and/or possible generator of extra costs.

Sarcopenia should instead be considered as a biological marker capable of more actively feeding decisional algorithms in clinics. In particular, body composition may play a relevant role in defining the patient's risk profile for chemotherapy adverse reactions (Gérard et al. 2016). For example, the administration of lipophilic agents to individuals with different body composition profiles but equal body mass/surface may expose them to different levels of risk for adverse reactions. Unfortunately, to date, the use of sarcopenia (and body composition) in the oncology setting is still limited. Sarcopenia is commonly seen as a risk factor for negative outcomes, and body composition-adjusted protocols of chemotherapy are still lacking. Moreover, the paucity of efforts and funding in the area of cancer therapy toxicity (to which sarcopenia and body composition might greatly contribute) has already been evoked in specialized literature (Cleeland et al. 2012). Nevertheless, the conduction of specific research in this field is necessary (Prado 2013). Oncologists do not need additional tools for measuring the risk profile of their patients (Hamaker et al. 2012). At best, collaboration between oncologists and geriatricians might converge in the development of specific and shared screening instruments for frailty.

Different Tools

As mentioned, the definition of sarcopenia is usually based on algorithms measuring skeletal muscle mass via DXA or BIA. These instruments are not part of the oncological routine and might be perceived as burdening the already busy and time-limited schedule of cancer patients waiting for pharmacological and non-pharmacological treatments. In order to diffuse the evaluation of body composition in the oncological setting, it is therefore important to rely on measures that are already included in the diagnostic or therapeutic *iter* of the patient. Thus, some authors have started generating models of sarcopenia pragmatically taking advantage of body composition parameters routinely collected during the cancer staging. For example, Psutka and colleagues (Psutka et al.

2014) computed a skeletal muscle index from CT images obtained at the level of the third lumbar vertebra during abdomen scan. Such legitimate and scientifically valid approach has been growingly used over the last years for introducing discussions and interventions on body composition in oncology (Kazemi-Bajestani et al. 2016; Prado 2013). Certainly, the use of CT scans may deviate from the algorithms and recommendations designed for the community setting, limiting the possibility of comparisons of findings with other realities. However, it can be acceptable to proceed in parallel on the same condition of interest in two contexts because needs and resources are different. Moreover, everything may currently be justified by the lack of gold standard references on the topic.

Sarcopenia Versus Cachexia

One of the major ambiguities to solve when discussing about skeletal muscle wasting in cancer patients is the "sarcopenia and the cachexia" dilemma. Are we sure that when we measure sarcopenia in the oncology setting, we are not instead getting information on the apparently similar but biologically different condition of cachexia?

Cachexia is defined as a complex metabolic syndrome associated with underlying illnesses, generally heart failure, chronic obstructive pulmonary disease, and cancer. It is characterized by muscle wasting with or without loss of fat mass. The most relevant feature of cachexia is represented by weight loss (in adults) or growth failure (in children). It is a wasting disorder finding its biological roots in the commonly associated anorexia, inflammation, insulin resistance, and increased muscle protein breakdown (Evans et al. 2008; Sakuma and Yamaguchi 2012b).

If all these characteristics of cachexia are individually considered, it is possible to realize how close this condition is to the sarcopenia construct. In fact, the biological substratum of the two is largely overlapped. If cachexia and sarcopenia are considered as two conditions placed at different levels in the continuum of muscle decline, it is necessary to identify a clear and objective threshold that differentiates the two. It is possible that cachexia is simply a state of sarcopenia accelerated and accentuated by the massive catabolic stimulus caused by an index disease.

As occurred for sarcopenia, some confusion also stem from the lack of a clear and agreed definition of cachexia. Evans and colleagues (Evans et al. 2008) proposed to base the diagnosis of cachexia on the presence of weight loss accompanied by at least three out of five additional criteria (i.e., muscle weakness, fatigue, anorexia, low skeletal muscle index, and abnormal biochemistry) (Table 4). More recently, Fearon and colleagues (Fearon et al. 2011) described a different diagnostic model for cachexia in cancer. This latter operational definition is largely based on the quantification of weight loss and sarcopenia and differentiates three levels of severity (Table 5).

Table 4 Diagnostic criteria for cachexia in adults proposed by Evans and colleagues (Evans et al. 2008)

Main criterion	
Weight loss	At least 5% reduction of weight occurred within 12 months in the presence of underlying illness, or BMI <20 kg/m^2 if weight loss cannot be documented
Secondary criteria	
Decreased muscle strength	Poor handgrip strength
Fatigue	Physical and/or mental weariness resulting from exertion. Inability to continue exercise at the same intensity with consequent deterioration of performance
Anorexia	Limited food intake (i.e., total caloric intake less than 20 kcal/kg of body weight/day; less than 70% of usual food intake) or poor appetite
Low fat-free mass index	Lean tissue depletion (i.e., low mid-upper arm muscle circumference, low appendicular skeletal muscle index)
Abnormal biochemistry	Increased inflammatory status (CRP >5.0 mg/L; IL-6 $>$ 4.0 pg/mL)
Cachexia is defined by the presence of the main criterion plus at least three secondary criteria	

BMI body mass index, *CRP* C-reactive protein, *IL-6* interleukin 6

Table 5 Diagnostic model of cancer cachexia as proposed by Fearon and colleagues (Fearon et al. 2011)

Stage	Characteristics
Precachexia	Weight loss ≤5% Anorexia Metabolic change
Cachexia	Weight loss >5% over the past 6 months (in absence of simple starvation) BMI <20 kg/m^2 and any degree of weight loss >2% Appendicular skeletal muscle index consistent with sarcopenia and any degree of weight loss >2% Often reduced food intake Systemic inflammation
Refractory cachexia	Variable degree of cachexia Cancer disease both pro-catabolic and not responsive to anticancer treatment Low performance score Less than 3 months of expected survival

BMI body mass index

Looking at the criteria presented in both operational definitions, the overlap between sarcopenia and cachexia becomes evident. Moreover, it is noteworthy how many variables included in the construct of these forms of cachexia can be found in several definitions of the geriatric syndrome of frailty. For example, the symptoms/signs of weight loss, fatigue, and poor physical function are frequently indicated as key features of frailty clinical manifestations (Ferrucci et al. 2004).

Interventions against Skeletal Muscle Decline in Older Persons with Cancer

Methodological Considerations

Overlap between different clinical conditions is frequently observed in geriatric patients. With advancing age, the traditional concept of disease tends to lose its relevance in favor of the more pragmatic construct of function. In other words, the center of the medical action moves from the nosologic condition (traditionally framed within rigid and arguable burdens) toward a more holistic and comprehensive evaluation of the patient. The change in paradigm implies methodological differences to be accepted and implemented in the daily clinical and research routine. To put it simple, it means that sarcopenia in older persons cannot be understood and treated without perceiving it as the "tip of an iceberg." It represents one of the many conditions that might potentially represent the entry door to a multidimensional and multidisciplinary assessment of the individual. This can easily be appreciated by looking at the many etiological causes and mechanisms underlying the onset of sarcopenia (Table 1). As such, the boundaries between sarcopenia, cachexia, and frailty may become of lower relevance. It is instead more important the action following the detection of one of these conditions in which the skeletal muscle decline (and its detrimental consequences) plays a major role (Cesari et al. 2016b).

In a traditional model of care, the identification of a clinical condition is usually followed by a mono-dimensional, direct, and specific treatment. With geriatric conditions, the paradigm works differently. The intervention can here be designed and implemented only after a global and comprehensive evaluation of the individual, an approach that is not only focused on his/her biological and clinical profile but should include the environment where he/she lives (Studenski 2009; Marzetti et al. 2016; Cesari et al. 2016a). It is noteworthy that, consistently with this approach, it is not rare to see sarcopenia considered as a geriatric syndrome in the literature (Cruz-Jentoft et al. 2010b; Landi et al. 2016b). The prioritization of interventions according to the resulting risk profile and resources of the individual will then allow designing a person-tailored action plan, which includes pharmacological and non-pharmacological components.

In general, it is important to contextualize the sarcopenia phenomenon according to the framework of action. If sarcopenia or other risk conditions are simply used to aliment an adapted model of care, their operational definition should be based on the needs and resources of the intervention. Overlap and some degree of inaccuracy could be easily tolerated. Differently, if sarcopenia should serve as the biological substratum

for muscle-specific interventions (or actions affected by body composition), its standardized and rigorous assessment becomes crucial.

Physical Exercise

Physical exercise represents the most powerful intervention against the loss of muscle mass and physical impairment. In the phase III Lifestyle Interventions and Independence for Elders (LIFE) trial, Pahor and colleagues (Pahor et al. 2014) showed that the implementation of a physical activity protocol was able to reduce the incidence of mobility disability in sedentary and frail community-dwelling older persons. Consistent findings have also been reported by similar researches conducted in smaller groups of cancer patients showing the beneficial effects of exercise (Galvão et al. 2007; Adamsen et al. 2009; Galvao et al. 2010). Not surprisingly, physical exercise is today considered to be equivalent to medications, and special attention is devoted to the design and standardization of recommendations for its prescription (Eijsvogels and Thompson 2015).

Nutrition

Nutrition plays a major role in the maintenance of muscle mass and function. In particular, it has been shown that the dietary intake of protein represents the primary source for limiting the age-related loss of lean mass. Recent recommendations provided by international task forces are soliciting clinicians at increasing the minimum daily protein intake of their older patients, from 0.8 g/kg/day to 1.0–1.2 g/kg/day. For conditions characterized by enhanced catabolism (such as cancer cachexia), this threshold is raised up to 1.2–1.5 g/kg/day (Bauer et al. 2013; Deutz et al. 2014).

It is not only important the amount of protein introduced with the diet but also the pattern of their consumption. In fact, a physiological limit in the protein synthetic capacity of the organism has been reported, indicating that a spread feeding of proteins over the day should be preferred over a time-skewed pattern (Paddon-Jones and Rasmussen 2009). The amino acid composition of dietary protein also has a great impact of their muscle anabolic potency. Essential amino acids (in particular, leucine) represent the primary stimulus for protein synthesis and turnover (Calvani et al. 2013b).

Nicholson and Wilson (2003) proposed in 2003 the dynamic "Pachinko model" to describe the nutritional regulation of muscle physiology. Dietary constituents flow through the human system in a probabilistic way, influenced by non-modifiable factors described as fixed pins (e.g., age, gender, race, etc.) and others (e.g., epigenetic and/or transcriptional regulation of genes, hemodynamics) that can be modified by acting on "control knobs" (e.g., meal timing, physical exercise, gut microbiota manipulation). These latter represent the lever on which we can act for optimizing the effects of nutrition of muscle physiology (Calvani et al. 2013b) (Fig. 2).

Pharmacological Interventions

To date, no pharmacological intervention exists against sarcopenia. Multiple agents have been proposed and tested over the years for counteracting the skeletal muscle decline. Unfortunately, even the most promising agents (e.g., testosterone in hypo-androgenic men) (Snyder et al. 2016) and myostatin inhibitors (Woodhouse et al. 2016) have fell short of expectations, only showing partial improvements on secondary outcome measures.

One of the major issues affecting the development of medications targeting skeletal muscle decline is represented by its lack of proper recognition by regulatory agencies. In fact, if sarcopenia is not framed in agreement with the traditional standards of a nosologic condition, regulatory agencies are not in the position to adequately consider it. This is not a minor aspect because it substantially affects the interest of pharmaceutical companies at investing in the field.

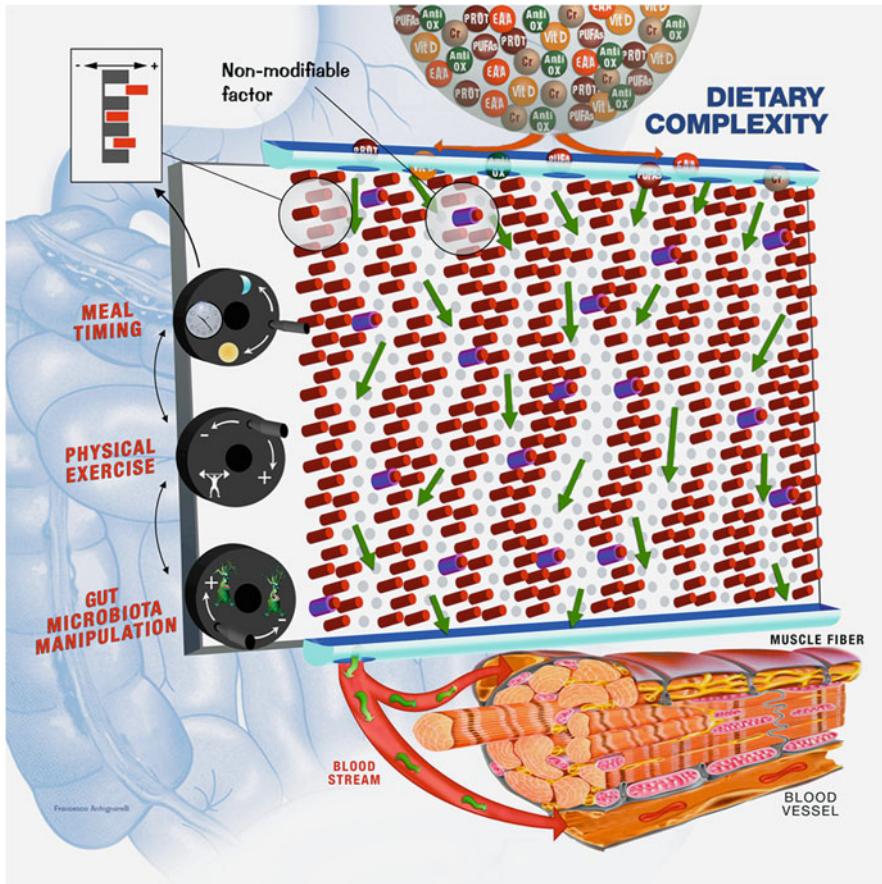

Fig. 2 The "Pachinko model" describing the nutritional regulation of muscle physiology. (Authorized reproduction from Calvani and colleagues (Calvani et al. 2013b))

In 2014, the Innovative Medicines Initiative (an agency of the European Commission mediating between the academic world and the European Federation of Pharmaceutical Industries and Associations) funded the "Sarcopenia and physical frailty in older people: multicomponent treatment strategies" (SPRINTT) project (Marzetti et al. 2015). This is a unique initiative aimed at having all the major stakeholders (e.g., researcher, clinicians, industry, patient representatives, regulatory agencies) involved in the development and validation of a nosologically framed condition of risk centered on the skeletal muscle. Hopefully, the study results will support the framing of a sarcopenic condition acceptable by regulatory agencies (in this case, the European Medicines Agency) and overcome some of the current barriers.

Adapted Model of Care

If the skeletal muscle decline is considered as one of the many risk factors exposing the older person at risk of negative outcomes, its proper identification and management can only occur in the context of adapted models of care. Under this scenario, the oncology and geriatric disciplines have started and intensified bidirectional exchanges over the last years in order to improve care services offered to the aging population of cancer patients (Hurria et al. 2017). The number

of oncogeriatric units is increasing worldwide. They represent the multidisciplinary setting where the specialist approach of the oncologist is supported by the geriatrician's expertise in the multidimensional evaluation of the complex frail elders (Cesari et al. 2013).

Conclusions

Since its origins dated about 25 years ago, sarcopenia has been object of increasing interest in the scientific community. This condition is part of the geriatric background and is today starting to disseminate in other specialties dealing with the complexity of frail older persons. Several controversies have characterized the theoretical framework, operationalization, and treatment of sarcopenia in the geriatric and scientific community settings. These same issues will likely affect the development of sarcopenia in the oncological context, where the study of this condition is challenged by different care priorities, clinical complexities, and biological mechanisms. Nevertheless, the study of skeletal muscle remains crucial for promoting care services aimed at enhancing the proper functioning of the individual, independently of the diseases he/she may present. Future research actions (supported by a pragmatic clinical approach) are necessary for better understanding the causes and contributors to the skeletal muscle decline in older persons with cancer and adapt to this population the growing (but already vast) knowledge that geriatric research has accumulated on the skeletal muscle system over the last couple of decades. The study of body composition in the oncological setting is crucial and may become one of the main characterizations of this interdisciplinary field, where clinical and research actions have to be designed taking into account the consequences of the aging process.

Contents

Abstract

The effects of aging on the nervous system are widespread and come from changes on molecules, cells, vasculature, and gross morphology. The changes in the brain include decrease in volume, gray matter thinning, abnormalities in proteostasis, apparition of white matter lesions, nerve cell death, dendritic retraction and expansion, synapse loss and remodeling, and glial cell (astrocytes and microglia) reactivity. There are also changes in the autonomous and peripheral nervous system, such as lower sensibility of adrenergic receptors and lower recovery of function after peripheral nerve damage. The mentioned changes can have an impact in the functionality of the person. In general, said impact of these

changes on a person's functionality is discrete, but combined with other environmental factors such as vascular disease, diabetes, or cancer, it can lead the individual to true impairment. Altogether, even without a disease, these changes put the older individual at higher risk of neurotoxic effects of chemotherapy, such as encephalopathy, neuropathy, and cognitive decline. The risk of developing neurotoxicity is dependent on numerous factors, including dose intensity, baseline neurological deficits, drug interactions, and drug mechanism of action. Early recognition of adverse neurologic effects and differentiation from central nervous system progression of cancer is critical for timely and appropriate adjustments in dosing or discontinuation of the drug, in order to protect the functionality and independence of the older patient with cancer.

Introduction

Aging can be defined as the process of gradual physiological deterioration that most living beings experience with time; it is usually seen as the result of accumulation of molecular and cellular damage. The changes that occur during an organism's lifespan that are categorized as aging are heterogeneous, heterochronic, and dynamic, which is why systematic study of this subject has been difficult and has just exploded in the last few decades (Lopez-Otin et al. 2013; Carmona and Michan 2016).

There is no clear evidence of which molecular, cellular, or physiological changes are the most important drivers of the aging process or how they influence one another, but it seems that the magnitude of an isolated mechanism is usually modest (Trindade et al. 2013). Dr. E. Lakatta once mentioned that "Aging appears not to be a process, but rather a manifestation of a time-dependent, stochastic, molecular disorder that ensues when our natural selection insurance policy expires." (Lakatta 2015)

Aging thus may be conceptualized as a progressive, time-dependent molecular disorder within the systems of an organism, accompanied by reduced complexity and increased entropy, leading to reduced efficiency and efficacy of molecular interactions that regulate cells, tissues, and organ structure and coordinate functions among organ systems, including the nervous system.

The issue of normal aging is a difficult one, given that most of the changes that occur with the passing of years are similar to those that happen in some of the diseases that are common in the elderly. The line that separates "physiological" aging from disease is a blurry and winding one, and in the nervous system, this distinction can be more difficult to make. Everyone will age, but not everyone will have a disease.

The effects of aging on the brain are widespread and come from changes on molecules, cells, vasculature, and gross morphology. Many brain functions reflect the effects of aging. For example, declines in motor abilities (Seidler et al. 2010), sensory function (Brodoehl et al. 2013), and cognitive skills have all been observed with natural aging.

Along with these functional declines, the cerebral levels of neurotransmitters, such as dopamine, acetylcholine, serotonin, and norepinephrine, and neurotrophic factors, such as brain-derived neurotrophic factor (BDNF) and nerve growth factor (NGF), are dramatically reduced in aging brains (Liu et al. 2017).

These changes will have an impact on the daily life of the elderly, but most of them will be overcome, and the healthy person will adapt to them. Still, even in the healthiest aged individual, there is more neuronal loss, vascular pathology, and changes at the cellular level compared with healthy younger adults (Schott 2017).

Changes in the Brain

It has been widely found that the volume of the brain declines with age at a rate of around 5% per decade after age 40, with the actual rate of decline increasing with age particularly over age 70. It seems that this reduction in volume comes from a decline in neuronal volume rather than number, and as a compensatory mechanism

for any cell death, dendritic sprouting may occur. It is important to mention that this loss of volume causes an expansion of the ventricular system which can be seen in imaging studies.

The changes in the brain have been mainly described in the prefrontal cortex and the hippocampus, and it seems that the least affected region is the occipital. These findings are backed up by the cognitive changes found with aging (Peters 2006).

Population-based autopsy studies of the brains of aged people without neurological diseases consistently report the presence of protein abnormalities (amyloid plaques, neurofibrillary tangles, and Lewy bodies), synaptic dystrophy, as well as the previously mentioned loss of brain volume in most of the brains (Elobeid et al. 2016). The theory behind the proteostasis abnormalities is that of a decline and overwhelming of the phagocytic and lysosome systems in nervous tissue. It is unknown what causes such lesions and whether they are the precursors to neurodegeneration and disease or simply the products of brain aging (Wyss-Coray 2016). An example of this is that in a population-based sample of nonagenarians and centenarians without dementia, almost half fulfilled the neuropathological criteria for Alzheimer's disease (AD) or had a mix of numerous pathologies. Yet, of the nonagenarians and centenarians who had been clinically diagnosed with dementia, 12% were free of pathological features, 23% could be considered to have AD, and 45% had mixed dementia (Kawas et al. 2015).

All of the major cell types in the brain undergo structural changes during aging. These changes include nerve cell death, dendritic retraction and expansion, synapse loss and remodeling, and glial cell (astrocytes and microglia) reactivity. Such structural changes may result from alterations in cytoskeletal proteins and the deposition of insoluble proteins such as tau and α-synuclein inside of cells and amyloid in the extracellular space (Mattson 2008).

There is considerable evidence for synaptic "remodeling" in the brain as we age. For example, there may be decreases in synaptic numbers in some brain regions, but these may be offset by increases in the size of the remaining synapses. In other brain regions, no loss of synapses can be discerned. Some of this remodeling has, as a consequence, the bilaterality of region activity on functional MRI found in older population. An example of this can be seen with cognitive testing. During normal aging, changes occur in the pattern of stimulation of neural networks, causing increased activation in some areas and decreased activation in others. Studies reveal that when an elderly person performs a cognitive task at the same level as that of a young adult, more areas of the former's frontal brain regions "light up," suggesting more brain activity is needed to maintain cognitive performance (Mattson 2008).

As aging happens, especially after the seventh decade of life, a nonlinear and brain-wide trend to gray matter thinning predominant in the parietal and frontal lobes is observed in normal subjects from the second to the eighth decade; this slight frontal atrophy is associated with a decrease in performance on executive and working memory tests (Lyons-Warren et al. 2004).

With the new MRI technologies, the cortical atrophy consecutive to an aging period as short as 1 year can be readily measured, and longitudinal studies have found that the annual atrophy rate varies across the cortex and is about 0.5% per year on average in a group of healthy subjects aged 60–91 years; the hippocampus (–0.84%) is the most affected area. In an AD sample, the annual atrophy rate was higher, with 1% per year change or more, with the widest affectation in the posterior cingulate/precuneus region and lateral temporal cortex (Fjell et al. 2009).

White matter (WM) is mostly composed of bundled myelinated or unmyelinated axons and myelin-producing glial cells, among other glial cell types. WM is essential for the transmission of electrical signals across different brain regions, and WM malfunction can therefore lead to serious neurobehavioral and cognitive impairments (Bennett and Madden 2014).

In normal aging, the changes identified in WM are atrophy, tract disruption, vessel impairments, increased inflammation, and loss of myelination. An estimated 28% of volume reduction happens in WM with aging. This begins around 40 years of

age, peaks at around 50, and decreases rapidly after 60 years and on (Liu et al. 2017).

Brain tissue depends vitally on a constant supply of oxygen and glucose by blood vessels. Aging induces a progressive thickening and stiffening of arteries that alter hemodynamics of cerebral vasculature and the efficiency of the transfer of energy metabolites to glial and neural cells. The vascular alterations can be manifested as WM lesions, also known as leukoaraiosis, which appear on T2-weighed MRI with aging. Depending on the anatomical location, some WM lesions may be responsible for distinct types of functional decline. For example, WM lesions in the frontal lobe are responsible for alterations in the speed of information processing, visual motor function, verbal fluency, and mental sequences (Bartres-Faz et al. 2001).

Animal studies have shown that there is increased splitting of the myelin sheath, myelin balloon formation and separation from the axon (Akiyama et al. 2002), reorganization of ion channels at the nodes of Ranvier, and decreased length of internodal length. These changes cause an increase in the axonal conduction threshold and thus a decrease in the stimulus response, reflecting overall neuronal excitability.

Degeneration of oligodendrocytes and their precursor cells increases with aging, leading to increased myelin breakdown, decreased remyelination, fluctuations in the constituents of myelin, and ultimate disruptions in WM integrity during normal aging (Liu et al. 2017).

Both astrocytes and microglial cells display a senescence-associated secretory phenotype, with the consequence of increased production of inflammatory factors and free radicals. However, this concept was recently challenged by the demonstration of downregulation of neurotoxic pathways and upregulation of neuroprotective pathways in aged microglia (Hickman et al. 2013).

Recent studies suggest that damaged mitochondria are removed and degraded by the autophagic pathway. Autophagic function may be compromised in the aging human brain. This may lead to the accumulation of dysfunctional or degenerating mitochondria, resulting in increased reactive oxygen species (ROS) generation and the release of redox-active iron (Yankner et al. 2008). Oxidative damage of DNA may be mediated by ROS derived from aging mitochondria. DNA damage is repaired efficiently in the young adult brain but persists in the aged brain. During normal aging, this may result in the silencing of genes involved in synaptic plasticity, mitochondrial function, and protein trafficking, potentially contributing to cognitive decline.

Damage to mitochondrial DNA can lead to failure of electron transport and reduced adenosine triphosphate (ATP) production. Moreover, the important calcium sequestering function of mitochondria may be compromised as the result of age-related DNA damage, which may increase neuronal vulnerability to excitotoxicity and apoptosis (Mattson 2008).

Together, the genetic, transcriptomic, and proteomic evidence suggest that changes in inflammation and intercellular communication represent chief aspects of normal brain aging and neurodegeneration. However, it is unclear whether inflammatory pathways simply drive aging and disease or whether aspects of the inflammatory response fulfill reparative and regenerative functions (Coppe et al. 2008).

Altogether, the mentioned changes can have an impact in the functionality of the person. In general, the said impact is discrete, but combined with other environmental factors such as vascular disease, diabetes, or cancer, it can lead the individual to true impairment.

Cognitive Changes

Cognitive aging is a lifelong process of change in cognitive capacity through time. The process is gradual and ongoing, and highly variable, within and between individuals. Cognition, and therefore cognitive aging, is not simply memory but all of its dimensions, including perceptual-motor function, language, executive function, complex attention, and social cognition (McArdle et al. 2009; Sachdev et al. 2014).

Cognitive function declines in parallel across the lifespan with decreasing brain volume,

dopamine receptors, and white matter integrity. At the same time, direct relationships between declining structural measures of the brain and cognitive function are not always observed, and when they are observed, they are of a modest magnitude. White matter hyperintensities appear to have more significance than total brain volume (Park and Reuter-Lorenz 2009).

There are genetic mechanisms associated with age-related cognitive impairment. Transcriptional profiling of the aging human frontal cortex in a group of 30 individuals ranging from 26 to 106 years of age showed that approximately 4% of the genes expressed in the brain are age regulated (Lu et al. 2004). Age-related changes in gene expression become apparent in middle age and are most notable after 70 years of age. Genes involved in synaptic functions that mediate memory and learning are significantly age downregulated, including glutamate receptor subunits and synaptic vesicle proteins (Yankner et al. 2008). Still, most of the information available on cognitive aging comes from neuropsychological testing.

The norms of cognitive function vary across educational levels and lifelong experiences. For these reasons, whenever a cognition examination is done, the most appropriate norm is the person tracked over time (Lin et al. 2017).

As with other changes associated with aging, cognitive abilities may show at least a small decline, but not all, and not all of the healthy individuals. It is important to mention that declining ability does not translate into impairment of daily activities, especially because these changes are subtle with healthy aging. The most consistent change is cognitive slowing. For example, on a writing task in which people were asked to substitute symbols for numbers as quickly as possible, 20-year-olds performed the task almost 75% faster on average than 75-year-olds. Age-related slowing is also evident on attentional tasks, such as trying to learn a telephone number or address if the information is given quickly or trying to understand the prescription of a new medication (Hartshorne and Germine 2015).

In older people, there can be a deficit in attention, particularly associated with multitasking. Processing information rapidly and dividing attention effectively are cognitive skills that peak in young adulthood and decline thereafter. Similarly, the ability to keep multiple pieces of information in mind at the same time is another skill that peaks around ages 18–20 and becomes more difficult at later ages (Caserta et al. 2009).

Quantitative reasoning and perceptual speed, which may be associated with loss of WM volume and integrity in areas such as the prefrontal cortex are usually associated with physiological aging (Caserta et al. 2009). However, verbal fluency and semantic memory do not decline with normal aging, perhaps because these skills are highly dependent on past experience such as education and occupation.

While memory declines for many people over time, the exact nature of the decline depends on the particular type of memory. Episodic memory performance declines from middle age onwards. This is particularly true for recall in normal aging and less so for recognition. The ability to recall new information peaks early and gradually becomes more challenging after age 40, particularly for visual material. Studies show that by age 70, the amount of information recalled 30 min after hearing a story once is about 75% of the amount remembered by an 18-year-old (Hartshorne and Germine 2015). Semantic memory increases gradually from middle age to the young elderly but then declines in the very elderly. Recognizing information by the help of cues is an ability usually well retained throughout the life (Buchman et al. 2014).

Some memory differences with age are due to declines in controlled, but not automatic, processes resulting in poor explicit memory but relatively good memory for gist or versions of stimuli that feel familiar. Consequently, aging memory relies heavily on gist, making it highly susceptible to distortions and misremembering (Park and Reuter-Lorenz 2009).

Normal age-related memory loss is distinguished from pathological memory loss both by the degree of impairment and the rate of cognitive decline. A structural correlate of pathological memory loss is volume loss in the medial temporal lobes, particularly the entorhinal cortex. This volume loss can appear at the earliest stages of

mild cognitive impairment, progressing to severe atrophy in AD, but generally is not observed in normal aged individuals. There is increasing evidence, therefore, that altered brain activation on functional imaging and the appearance of early pathological changes in medial temporal lobe structures may distinguish incipient dementia from normal aging (Hedden and Gabrieli 2004).

Visual perceptual abilities, principally the ability to understand spatial relationships, also decline with age, especially after age 80. Visual scanning ability also can diminish so that, for example, it becomes more difficult to see a misplaced object among other items. These changes can affect the ability to drive or work with the hands.

Executive functioning refers to higher level skills, such as the conceptualization of a problem, making appropriate decisions, and planning and carrying out effective actions. Older adults tend to be slower in conceptualizing problems and less ready to change strategies when circumstances shift. In one study involving decision making, one third of older adults did poorly compared to younger adult (Denburg et al. 2007).

Language and vocabulary are well retained throughout the lifespan. In fact, vocabulary continues to improve into middle age. Recall of general knowledge acquired at a young age and well-practiced skills also peak in middle age and are resistant to age-related decline. In general, these age-resistant cognitive skills have been strengthened by experience, including situations that require reasoning and judgment.

Age limitations interfere with performance when information acquired in an unfamiliar situation needs to be processed quickly or there are distractions that should be ignored, such as in a busy clinic or when receiving bad news. As a result, older adults on average consider fewer bits of information and use less effective decision-making strategies when they are in unfamiliar situations compared to younger adults. And this can have a really important impact while giving a cancer diagnosis or explaining a treatment and its effects and consequences (Tucker and Stern 2011; Hartshorne and Germine 2015).

The notion that cognitive ability and chronological age are not necessarily directly coupled within individuals has led to the concept of "mindspan" (similar to "lifespan" and "healthspan"), which defines the period of time during which intact cognitive ability is maintained. The goal of research on the neurobiology of cognitive aging is to discover the means by which mindspan can be maximized, maintaining the quality of life that is associated with intact cognitive ability (Fortenbaugh et al. 2015).

As stated before, cognitive aging isn't a disease, but it has similitudes to neurological degenerative diseases, for some it can even be a prepathological state. It seems that the healthy aging cognition has ways to adapt to the changes to function almost normally. Converging evidence from a range of studies using different approaches suggests that the additional age-associated neural activation, especially in prefrontal areas, appears to be functional and to enhance task performance. Many researchers and models have described these activation increases as "compensatory" and suggest that the brain reorganizes as a response to neural aging. The compensation is for the structural changes that occur in the brain in terms of both volumetric decrease and white matter integrity. Shrinkage and dysfunction may reach a critical point as pathology increases, and at that point, the reciprocity no longer exists. After that, the cognitive problems can have clinical manifestation (Park and Reuter-Lorenz 2009).

Changes in the Peripheral Nervous System

With respect to the peripheral nervous system (PNS), several clinical and experimental studies have described that normal aging is accompanied by reduction in maximal tetanic force, impairment of thermal, tactile, and vibration sensitivity, and autonomic dysfunction.

In noninjured peripheral nerves, normal aging is accompanied by impairment of cutaneous sensitivity. Thermal, tactile, and vibration thresholds are increased (Navarro et al. 1988). Hot pain thresholds are similar in young and elderly subjects in the hands, but in the feet, the older subjects

are significantly less sensitive to noxious heat (Navarro and Kennedy 1991). Two-point discrimination deteriorates with time, and vibratory sensibility thresholds also increase significantly with age, both in the hand and foot.

Interestingly, animal studies have demonstrated that aged individuals have a lower basal mechanical nociceptive threshold and exhibit more severe tactile allodynia after partial nerve injury compared to younger individuals (Kovacic et al. 2009).

Aging also affects functional and electrophysiological properties of the PNS, including a decline in nerve conduction velocity, muscle strength, sensory discrimination, autonomic responses, and endoneural blood flow (Verdú et al. 2000). On the other hand, conduction velocity of unmyelinated fibers is relatively unaffected in old individuals.

Age myelinated axons undergo atrophy and shape alterations. The myelin sheaths show ballooning, splitting, infolding, and remyelination. These changes may be partially explained by alterations in axonal transportation system which causes a reduction in the energy available for peripheral nerves (McQuarrie et al. 1989). In addition, a progressive reduction of nerve blood flow associated with an increase in nerve vascular resistance (due to a reduction in microvascular caliber) and a normal hyperemic response was observed in aged rats (Kihara et al. 1991).

Several clinical investigations have reported that both the rate and the degree of functional recovery of the peripheral nerves after injury are significantly reduced with aging (Verdú et al. 2000). The impaired functional reinnervation with aging may be also due to a reduction of the number of regenerating axons that succeed to reach their target, and due to a limited capability for terminal regenerative axon sprouting in target tissues. After nerve injury in the elderly, the collateral nerve sprouting, which is crucial for functional recovery, will be reduced in extent and of lower density (Kovacic et al. 2007).

This reduction in functional recovery is crucial to take into mind when giving neurotoxic chemotherapeutic agents to elderly people, because the effects can be more notorious and long lasting in comparison to younger patients. Post injury, the conduction in peripheral nerves tends to be slower, which can be the cause of dysesthesia and not only neuropathic pain.

With respect to peripheral organ function, the main motor dysfunctions reported in aged subjects are a progressive decline of muscle strength and of motor coordination (Greig et al. 1993; Potvin et al. 1980). There is an approximate loss of strength of 1.8–2.8% per year (Verdu et al. 2000). There is some evidence that this reduction can be slowed down or reduced by formal exercise prescription, but most of the evidence comes from younger elderly patients and noncancer population (Klepin et al. 2013).

Clinical and experimental investigations have also reported autonomic nerve dysfunctions with advancing age. In humans, the beat-to-beat heart rate variations in response to postural changes, Valsalva maneuver, and deep breathing are significantly diminished in old subjects compared with young adult subjects. Older people are more prone to hypothermia and heatstroke. Importantly, they are also sensitive to anticholinergic effects of drugs, which can cause rigidity, movement disorders, and even trigger delirium. These changes, if combined with pathologies, injuries, or toxicity from cancer treatments, can impact the quality of life, functionality, or even treatment completion.

Changes in the Autonomous Nervous System

The autonomic nervous system (ANS) is the part of the nervous system that is responsible for maintaining homeostasis. Its regulatory action occurs without involvement of one's conscious. In elderly people, autonomic functions are relatively well maintained at rest, but patients' ability to adapt to environmental or visceral changes are often notably impaired (Parashar et al. 2016). The most notorious clinical effect is seen in arterial tension and maximum heart rate.

The age-related changes in autonomic nervous system activity and regulatory functions are involved in both sustained hypertension and

transient hypotension in the elderly. Sustained increases in resting sympathetic activity, combined with changes in thickening of the arterial wall, contribute to hypertension. With age, there is an increase in systolic arterial tension, while diastolic arterial tension tends to lower, causing an increase in pulse pressure (Lakatta and Levy 2003).

Orthostatic hypotension and postprandial hypotension frequently occur in elderly people as a result of an impairment of the arterial baroreceptor reflex (Joseph et al. 2017). These changes in the baroreceptor reflex may put the older individual at increased risk of cerebral ischemia during hypotensive episodes, because the lower limit of autoregulation shifts to the high blood pressure range with age (Hotta and Uchida 2010).

Sympathetic tone is widely found to increase during aging in many parts of the body. There is an increase with age in plasma noradrenaline concentration and an increase in the burst discharge rate on muscle sympathetic nerve fibers. The age-related changes in sympathetic nerve activity appear to be higher in the heart and liver but lower in the kidneys (Wallin 2007; Seals and Esler 2000).

The sensitivity of alpha- and beta-adrenergic receptors in the heart and blood vessels is reduced. The normal increases in heart rate, cardiac output, and vasodilation after administration of beta-adrenergic receptor agonists are all diminished in elderly people (Lakatta 1993). This has been associated with the lower maximum heart rate and lower exercise capacity found in the elderly (Paneni et al. 2017).

The highly organized cooperative action of autonomic nerves and somatic nerves that control the bladder and urethra is necessary for both continence and micturition. Maximum urethral closing pressure decreases in the elderly. Apoptotic loss of striated muscle fibers in the external urethral sphincter gradually decreases the number of sphincter muscle cells in men and women with age (Strasser et al. 2000). The bladder capacity that generates the initial desire to void remarkably increases in the elderly, suggesting a decline of volume sensation of the bladder with age. This is believed to be because of a reduction in muscarinic receptors in the detrusor muscle (Suskind 2017).

Autonomic aging, combined with aging in the other systems and the high prevalence of polypharmacy, puts the older patient at higher risk of falls, gait impairment, arrhythmia, and treatment intolerance.

Chemotherapy and Cognition

Even though studies associating cognitive changes with chemotherapy have existed since the 1970s, it has been in approximately the last 10 years that pretreatment neuropsychological assessment has been part of some cancer studies. In this time, it has been proposed that superimposed to the age-related cognitive impairment, there are neurologic changes associated with cancer therapy. These changes have been referred to as "chemotherapy-related cognitive impairment (CRCI) or "chemo brain" (Wefel et al. 2015). The American Cancer Society defines CRCI as: increased forgetfulness, trouble concentrating and remembering details, difficulty with multitasking word finding, and taking longer to finish tasks, which are associated with chemotherapy administration (Craig et al. 2014).

CRCI has been reported in up to 12–75% of patients with cancer and is associated with cancer type, treatment, duration of follow-up, type of study design, and definition of cognitive impairment. Most of these published studies assessed the prevalence of CRCI in a heterogeneous group of patients, including both young and old patients (Loh et al. 2016). Severity of CRCI is typically mild to moderate in nature, such that impairments experienced would not typically qualify for a diagnosis of mild cognitive impairment (MCI) or dementia; however, even subtle impairments in cognitive functioning can greatly influence quality of life (Vega and Newhouse 2014).

The cognitive changes associated with chemotherapy are typically subtle (functioning is reduced but often remains in the normal range), and occur across various domains of cognition, including working memory, executive function, and processing speed, but not the retrieval

of remote memories (Ahles and Saykin 2007). Furthermore, although acute cognitive changes during chemotherapy are common, long-term posttreatment cognitive changes seem to persist in only a subgroup (17–34%) of cancer survivors (Ferguson and Ahles 2003).

There are several mechanisms proposed as the cause of chemotherapy-induced cognitive changes, but not a single one can fully explain the findings in tests, and it seems that they depend on the treatment regimens and the particular vulnerabilities of the individual. The most commonly proposed mechanisms are disruption in blood–brain barrier integrity, DNA damage and shortening of telomere length, cytokine dysregulation, estrogen and testosterone reduction, and genetic susceptibility. The interaction of two or more of the proposed mechanisms need to interact to produce a change big enough to translate into problems in cognitive ability (Ahles and Saykin 2007). Interestingly, these mechanisms are also involved in normal aging cognitive changes, which have led to the development of two broader theories about CRCI and cancer-related cognitive impairment, the phase shift theory and the accelerated aging theory.

The phase shift hypothesis postulates that cancer patients treated with chemotherapy will experience greater decline in cognitive function compared to noncancer/chemotherapy-treated persons, and that the trajectory of decline will parallel normal aging and will remain constant over time (Ahles 2012). Alternatively, the accelerated aging hypothesis proposes that treatment with chemotherapy may accelerate the normal aging process (Maccormick 2006). This model predicts that the slope of cognitive decline will be steeper for cancer patients treated with chemotherapy compared to noncancer or chemotherapy-treated patients. These are not mutually exclusive theories, such as that a subgroup of cancer survivors, perhaps the majority, may demonstrate the phase shift trajectory, whereas another vulnerable group may demonstrate an accelerated aging trajectory (Vega et al. 2017).

This framework has potential clinical value because it suggests that the trajectories of cognitive decline are dependent on premorbid cognitive and other system reserves. This idea is supported by a study in which women aged 60–70 years with low baseline cognitive reserve who underwent chemotherapy had lower performance on tests of processing speed compared with those not receiving chemotherapy, younger patients, and controls (Ahles et al. 2010).

Neuroimaging studies have revealed similar changes observed following chemotherapy treatment and in normal aging, including gray and white matter loss, altered white matter connectivity, altered resting state connectivity changes, and brain activation during tasks (Ahles and Saykin 2007; Mandelblatt et al. 2014). This data supports the idea that the biological processes that underlie normal aging, brain response to chemotherapy, cognitive decline, and neurodegeneration overlap, leading to the nonexclusivity of the CRCI theories previously mentioned.

Functional MRI studies have demonstrated the potential for compensatory activation after chemotherapy, which may maintain normal performance on neuropsychological testing, but reflect a change in resource utilization, similar to what is seen in normal aging (McDonald et al. 2012; Ferguson et al. 2007b; Kesler et al. 2011). Such findings suggest that the patient's neuropsychological testing may fall in the normal range despite being associated with additional resource utilization and experienced as more effortful by patients.

Even though most of the evidence for cognitive difficulties in cancer patients and survivors is attributed to chemotherapy, there is growing evidence to suggest that adjuvant endocrine therapy may impact cognitive function, either alone or in combination with chemotherapy (Vega et al. 2017). However, such effects observed may not occur equally with all endocrine therapies (Mandelblatt et al. 2014). This finding has been described primarily in breast cancer patients, but more and more evidence has appeared in patients with prostate cancer that are receiving androgen deprivation therapy (ADT).

Hormonal anticancer therapies can produce effects, such as depression and fatigue, that may indirectly affect cognitive functioning, and

may also directly affect cognitive functioning as studies suggest that lower testosterone and estrogen levels are associated with worse cognitive functioning in healthy older patients (Holland et al. 2011). Particularly in prostate cancer patients, both low testosterone levels and ADT increase the risk of cardiovascular disease, which is a known risk factor for dementia (Tsai et al. 2007).

Targeted therapies also have the potential to either directly affect brain function or indirectly effect cognition through peripheral extra-CNS mechanisms. For example, sunitinib, a tyrosine kinase (TK) inhibitor capable of crossing the blood–brain barrier (BBB) used to treat different types of cancers, has been shown to have deleterious effects on cognitive functioning, specifically to learning, memory, and executive functioning (Mulder et al. 2014). In a study evaluating TK inhibitors, more than 30% of patients developed some sort of cognitive decline (Abdel-Aziz et al. 2016).

There are unfortunately no universally accepted interventions for CRCI. The most promising ones have been the nonpharmacological interventions. Two pilot studies examining cognitive behavioral therapy in breast cancer patients demonstrated improvement on both objective and subjective (self-report) measures of cognitive function (Ferguson et al. 2007a, 2012). Computerized cognitive brain-training studies suggest improvement in executive functioning, and yoga may reduce subjective memory complaints. This kind of interventions is not cheap, is not widely available, and should be tailored to the individual patient (Kesler et al. 2013; Janelsins et al. 2016).

It is important to mention that currently there is no pharmacological treatment that is specific for CRCI. Some drugs used for cognitive impairment not related to cancer have been tried in the oncological environment, but the studies have yielded mixed results. A lot of research is still needed in order to find the best therapeutic approach to CRCI.

Older patients with a cancer history should be routinely asked about their cognitive functioning. If available, informants should be asked to confirm any reports of cognitive decline experienced by the patient. Clinicians should consider using a structured instrument that examines diverse aspects of functional abilities, psychiatric signs and symptoms, and cognitive functioning. Appropriate referrals to memory clinics, geriatricians, or oncogeriatric services should be done, since these integrative services could give better support to the patient with cancer and cognitive impairment.

Neurotoxicity of Anticancer Agents

There has been a rapid increase in the number of anticancer agents in the past decade, including chemotherapeutics, targeted therapies, immunotherapies, and hormonal therapies. There are a wide range of neurologic complications which can arise from these drugs, with side effects such as peripheral/central neuropathies, cognitive deficits, and encephalopathy. Elderly patients are particularly sensitive to these side effects, which can result in downstream effects such as increased fall risk (Ward et al. 2014) and decline in functional status. The risk of developing neurotoxicity is dependent on numerous factors, including dose intensity, baseline neurological deficits, drug interactions, and drug mechanism of action. Early recognition of adverse neurologic effects and differentiation from central nervous system (CNS) progression of cancer is critical for timely and appropriate adjustments in dosing or discontinuation of the drug. These neurotoxicities can be categorized into central, both central and peripheral, and autonomic effects, which are discussed below.

Central Neurotoxicities

Altered mental status (AMS), both acute and chronic, can be seen with certain cancer treatments. Ifosfamide, an alkylating agent used in both solid and hematologic malignancies, has an incidence of encephalopathy occurring in 5–30% of treated patients (Nicolao and Giometto 2003). Elderly patients have a higher

rate of developing encephalopathy, possibly due to lower serum albumin, hepatic or renal dysfunction, or drug interactions. The encephalopathy is reversible in the majority of cases; treatment involves discontinuing the agent, hydration, as well as administration of methylene blue (Brunello et al. 2007).

PRES, posterior reversible encephalopathy syndrome, is a syndrome characterized by the rapid onset of symptoms including encephalopathy, seizures, and other neurologic symptoms, with imaging demonstrating brain lesions with posterior and white matter-predominant distribution (Singer et al. 2015). Anticancer agents which have been associated with PRES include platinums, gemcitabine, methotrexate, and VEGF TK inhibitors (Pavlidou et al. 2016; Zahir et al. 2012; Deguchi et al. 2018; Rajasekhar and George 2007). Clinical and radiographic features of this syndrome are usually reversible with discontinuation of the causative agent.

Blinatumomab and CAR-T are newer biologic immunotherapies for hematologic malignancies that are associated with a cytokine release syndrome that causes acute encephalopathy. Blinatumomab specifically has a 13–22% risk of grade 3 or greater neurologic events. In one study, patients aged >65 with relapsed/refractory acute lymphoblastic leukemia (ALL) had similar hematologic responses to younger counterparts, however did have more neurologic events, although these typically resolved with treatment interruption (Kantarjian et al. 2016). Prophylaxis includes premedication with dexamethasone. CAR-T therapy has been associated with delirium, seizures, and altered mental status as neurologic manifestations of cytokine release syndrome. Treatment is supportive and involves discontinuation of therapy, although tocilizumab, an IL-6 receptor antibody, has been used to ameliorate symptoms in more severe cases (Frey 2017).

Progressive multifocal leukoencephalopathy (PML) is a rare neurologic disease characterized by progressive inflammation of the white matter of the brain. It is caused by infection with JC virus in immunocompromised patients. All anti-CD20 antibodies (rituximab, obinatuzumab, ofatumumab) carry a black box warning for PML after 22 patients developed PML in postmarketing data analysis in 2006. Other agents that have been associated with PML include alemtuzumab, bevacizumab, brentuximb, ibrutinib, and idelalisib (Raisch et al. 2016).

Peripheral Neurotoxicities

Chemotherapy-induced peripheral neuropathy (CIPN) is the most common neurologic side effect from anticancer agents, affecting 30–40% of patients treated with neurotoxic agents (Staff et al. 2017). Risk factors include age, genetic factors, and drug-related mechanisms such as dose intensity, duration of treatment, and route of administration. The most common agents associated with peripheral neuropathy are vinca alkaloids, epothilones, platinum agents, proteasome inhibitors, and taxanes. In elderly patients, peripheral neuropathy is a common cause of decreased quality of life and falls and needs to be addressed before it progresses to an irreversible stage (Richardson and Ashton-Miller 1996). Even after discontinuation or dose reduction, neuropathy may take months to resolve, and in some cases does not resolve completely. The site of peripheral nerve injury varies between these agents, but generally involve the dorsal root ganglion, nerve terminals, and microtubules (Staff et al. 2017).

There are unfortunately no proven preventative therapies for CIPN. Symptomatic treatment of CIPN includes serotonin and norepinephrine reuptake inhibitors (SNRIs) such as venlafaxine and duloxetine, tricyclic antidepressants, topical analgesics, gabapentin, and pregabalin. SNRIs such as venlafaxine have been successfully used for oxaliplatin and taxane-induced neurotoxicity – in a retrospective case control study of 206 patients, about 50% of patients reported a greater than 75% improvement in neuropathic pain (Kus et al. 2016).

Platinum agents, including cisplatin, oxaliplatin, and carboplatin, are among the most commonly used chemotherapies that are associated with neurotoxicity. Cisplatin most commonly is associated with peripheral neuropathy and

ototoxicity. The peripheral neuropathy is dose related, and is often permanent. It primarily affects the dorsal root ganglion, with toxic effects on the mitochondria (Siegal and Haim 1990). Carboplatin has less neurotoxicity compared to cisplatin, and is often substituted for cisplatin in elderly patients who have baseline neuropathy. Oxaliplatin can cause an acute cold-induced dysesthesia that persists approximately 2–4 days after infusion (Staff et al. 2017). Elderly patients, especially aged >70, may be more likely to develop peripheral neuropathy compared to younger counterparts (Raphael et al. 2017). Of note, peripheral neuropathy from platinum agents can worsen even months after discontinuing therapy.

Of the vinca alkaloids, vincristine is the most neurotoxic, with primarily a dose-related sensory neuropathy. The pathophysiology involves disruption of microtubules within axons which results in interference with axonal transport (Legha 1986). To limit the potential neurotoxic effects, the usual recommended dose is 1.4 mg/m^2 per dose, with an upper limit of 2 mg total per dose.

Epothilones, such as ixabepilone and eribulin, are non-taxane tubulin-polymerizing agents that are used in metastatic breast cancer, and are also associated with a sensory neuropathy. This is caused by disruption of microtubules in the spindle which results in damage to the ganglion soma cells as well as nerve axons.

Proteosome inhibitors are used in the treatment of multiple myeloma, and are associated with peripheral neuropathy in a stocking glove distribution mediated by a direct toxic effect on the dorsal root ganglion (Cavaletti et al. 2007). Up to 10% of patients can develop motor neuropathy which manifests as distal weakness in lower extremities. The incidence of neuropathy can be decreased by using once-weekly schedules and subcutaneous administration. Another option to minimize neurotoxicity is to use carfilzomib, a second-generation proteasome inhibitor with <1% incidence of grade 3–4 neuropathy (Vij et al. 2012). Ixazomib, an oral proteasome inhibitor, also has rates of low grade neuropathy of 30–40%, but <2% severe neuropathy (Kumar et al. 2015).

Taxanes are a frequently used class of chemotherapy in solid tumors, including breast, prostate, ovarian, and lung cancers. Drugs in this class include paclitaxel, docetaxel, cabazitaxel, and nab-paclitaxel. These antimicrotubule agents can lead to disruption of the mitotic spindle and interfere with axonal transport.

Toxicities of these drugs can be increased in the elderly due to a number of factors. As taxanes are mostly protein bound, the free fraction can be increased in hypoalbuminemic patients, leading to greater risk of toxicity (Wildiers and Paridaens 2004). Additionally, patients with preexisting diabetes are much more likely to develop neuropathy compared to patients without a history of diabetes mellitus. Paclitaxel has a higher risk of neuropathy compared to docetaxel, with incidence of any grade neuropathy about 60% versus 15%, and the neuropathy is primarily dose related, with neurotoxicity typically occurring after 1000 mg/m^2 for paclitaxel, and 400 mg/m^2 for docetaxel (Grisold et al. 2012). Cabazitaxel is a newer taxane used in the treatment of metastatic prostate cancer, and has a much lower incidence of neuropathy, with <1% of grade 3 or 4 toxicity, and may be a good option for elderly patients who are at risk for peripheral neuropathy (de Bono et al. 2010).

Traztuzumab emtansine (T-DM1), an antibody drug conjugate used in HER2 positive breast cancer, has a risk of grade 3 or greater peripheral neuropathy of 2.4% in the EMILIA trial (Dieras et al. 2017). However, the monoclonal antibodies pertuzumab and traztuzumab do not cross the blood–brain barrier due to large molecular weight, and are not associated with significant neurotoxicity on their own. Another antibody–drug conjugate used in lymphomas, brentuximab vedotin, can cause peripheral neuropathy in 30–50% of patients (Gopal et al. 2012).

Elderly patients are more likely to have comorbidities such as diabetes mellitus and hypercholesterolemia that predispose them to cerebrovascular events; thus, the administration of agents that increase the risk of vascular occlusive events must be done with caution. VEGF TKIs, such as sunitinib and sorafenib, are associated with a significant risk of hypertension and significantly

increase the risk of stroke, especially in older patients with renal dysfunction (Jang et al. 2016).

Nilotinib and ponatinib, BCR-ABL TKIs used for the treatment of CML, are associated with an increased risk of vascular occlusive events as well (Gomez-Galvan et al. 2017; Jain et al. 2015). This is thought to be mediated by promoting a prothrombotic state and possibly accelerating atherosclerosis.

Autonomic Toxicity

In addition to central and peripheral toxicities, a number of anticancer agents are associated with autonomic impairment. Autonomic side effects of vinca alkaloids like vincristine often precede other neurotoxicities, especially sensory neuropathy (Legha 1986). Common autonomic neuropathies include constipation, erectile dysfunction, and postural hypotension. These symptoms are often under-recognized as being secondary to treatment, but have a great impact on the lives of elderly patients. Institution of a bowel regimen is recommended for patients using vinca alkaloids to minimize gastrointestinal side effects. Postural hypotension can put elderly patients at risk for falls, and reconciliation of home medications such as antihypertensives should be done on a regular basis to avoid worsening hypotension.

Toxicity Associated with Immunotherapy

Immune checkpoint inhibitors have revolutionized the therapeutic landscape for a number of cancers, but can infrequently cause neurologic sequelae. These have been associated with a wide range of autoimmune-related neurologic toxicities which are rare, but do occur, including CNS demyelination, myositis, limbic encephalitis, optic neuritis, hypophysitis, peripheral neuropathy, Guillain-Barre like syndromes, and cranial nerve palsies. In a recent meta-analysis, the incidence of immune-related neurotoxicity with anti-PD-1 and anti-CTLA4 monoclonal antibodies is 3.8% and 6.1%, respectively, and up to 12% with both. However, many of the nAE included nonspecific symptoms such as headache, and the incidence of grade 3–4 neurologic toxicities was less than 1% overall. The average time of onset was between 6 and 13 weeks (Cuzzubbo et al. 2017). Hypophysitis is the most common, and can occur in up to 5% of patients (Spain et al. 2017). Hypophysitis is diagnosed by low levels of pituitary hormones, and MRI may show enhancement of the pituitary gland. The majority of these adverse effects occur early on in the treatment course, although can happen at any point during treatment. The neurologic toxicities can be effectively reversed with a prolonged taper of high-dose corticosteroids; however, this may be more problematic for an older population with comorbidities such as heart failure or renal dysfunction, as high dose corticosteroids are associated with fluid retention, myopathy, and GI bleeding. Pyridostigmine can be used in combination with low-dose steroids with successful reversal of myasthenia gravis induced by checkpoint inhibitors. IVIG and plasmapheresis can also be used for many of these neurologic sequelae as well, including myasthenia gravis and Guillain-Barre. While the pathogenesis is not well characterized, it is thought to be related to inflammation around endoneural micro vessels and subperineurial edema and inflammation (Manousakis et al. 2013).

Neurotoxicity of anticancer agents remains a major concern for patients and clinicians as it affects both quality of life and functional status. Although there are no reliable preventative strategies, it would be beneficial to identify patient-specific risk factors for these various neurotoxicities, and consider adjusting the regimen or dose intensity. Factors such as hypoalbuminemia, increased body fat percentage, and renal impairment may also increase risk of toxicities from anticancer therapies, and close monitoring of these clinical parameters while on therapy is essential. There are several genetic variants that have been associated with neurotoxic susceptibility to various therapies as well, and more research is needed to develop inexpensive genetic tests to help identify subsets of patients that may be at

greater risk. Finally, we recommend performing a careful geriatric assessment to identify baseline neurological deficits that may not be readily apparent from the initial evaluation to tailor treatment for patients.

Abstract

It is apparent that hematopoiesis, the formation and differentiation of the cellular components of blood, and bone marrow function are altered with aging, but the physiologic basis has yet to be fully elucidated. Specifically, the aging process is typically characterized by a reduction in functional reserve capacity. Thus, while basal function is normal, the ability to respond to increasing demand and infectious or inflammatory stress is compromised. In this chapter we provide a brief overview of normal, healthy bone marrow regulation and function and discuss changes observed with aging. These changes affect both intrinsic (e.g., pluripotent stem cells and committed hematopoietic precursors) and extrinsic (e.g., stroma and cytokines) factors of bone marrow function. The idiopathic acquisition of somatic mutations that occur in elderly individuals, termed clonal hematopoiesis of indeterminate potential, is also discussed. We conclude with a discussion of the functional changes in immune function, mediated by bone marrow B and T cells, that are observed in aging individuals.

Introduction

The aging process is characterized by alterations in the functions of many organ systems. Changes occur in the cardiovascular, endocrine, and immune systems and have been studied extensively. Changes in bone marrow function are also evident, but the physiologic basis for these alterations is less well understood. Clearly, the bone marrow plays an important role in normal homeostasis, producing cells responsible for maintenance of oxygen delivery, hemostasis, and host defense against infection. The bulk of evidence favors preservation of normal homeostatic bone marrow function with aging in healthy individuals, although functional deficits are apparent under conditions of hematopoietic stress. Which of these observed cellular alterations are normal physiologic responses and which are consequences of coexistent disease processes remain under debate. In order to place published experimental data in perspective, an understanding of the regulation of normal hematopoiesis is essential.

Normal Bone Marrow Function

The production of mature peripheral blood cells from primitive precursors within the marrow results from a complex interaction between primitive hematopoietic stem cells, the stromal microenvironment, and a set of soluble regulatory cytokines produced locally. The orderly development of the hematopoietic system requires that a strict balance be maintained between self-renewal, cell differentiation, and cell death. Continued production of terminally differentiated peripheral blood cells occurs, while a balance is maintained between amplification of immature precursors and maturation with transit into the peripheral blood compartment. Most immature precursors go unrecognized by traditional light-microscopic examination. The earliest morphologically recognizable myeloid, erythroid, and megakaryocytic precursors are actually relatively mature progeny of a cell found at low numbers within the marrow. This self-renewing cell is referred to as the primitive hematopoietic stem cell (Fig. 1).

The concept of a primitive hematopoietic stem cell was introduced by Till and McCulloch (1961) in the early 1960s. They analyzed the number and nature of cells giving rise to trilineal spleen colonies in an irradiated mouse model and noted that each colony was derived from a single clonogenic precursor. Furthermore, these precursors were capable of continuously repopulating (Becker et al. 1963; Wu et al. 1968). The cell type giving rise to the spleen colonies was termed a colony-forming unit-spleen (CFU-S). This same cell was later shown to also be capable of giving rise to peripheral blood and thymic lymphocytes (Abramson et al. 1977; Visser and Van Bekkum

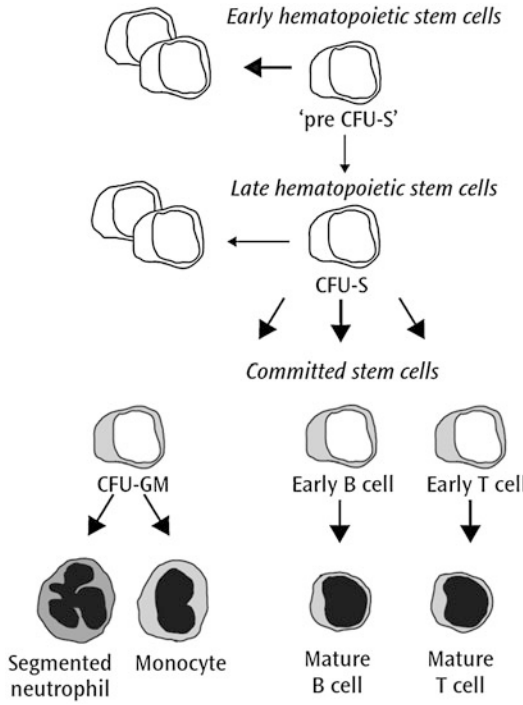

Fig. 1 Early hematopoietic stem cells have a high proliferative potential, with more limited differentiation kinetics. Their progeny, the late stem cells, undergo preferential differentiation to form stem cells committed to the various hematopoietic lineages. These undergo terminal maturation to form the recognizable peripheral blood and lymph node elements. Each stage of stem cell differentiation is antigenically characterized by a constellation of surface antigens which can be readily measured by flow cytometry. *CFU-S*, colony-forming unit-spleen; *CFU-GM*, colony-forming unit-granulocyte/macrophage

1990) and, thus, became the prime candidate for the then-elusive pluripotent stem cell. Since this initial description, a series of cell types has been characterized, and both early and late stages of stem cell differentiation are identified. It is now known that pluripotent stem cells are short-lived (Harrison et al. 1988; Micklem et al. 1987) and represent only a small fraction of cells within the bone marrow and fetal liver. They can be defined by their maximum differentiating and repopulating ability as measured by competitive repopulation assays (Harrison 1980; Harrison et al. 1993). Such assays measure the long-term functional ability of stem cells (Fig. 2). Using this methodology, competitor and donor hematopoietic populations are derived from mice that carry allelic variants of genes specifying quantifiable cellular markers. One population, termed the competitor, is an aliquot of fresh bone marrow cells that serves as an internal standard for repopulating potential. In each experiment, different donor populations containing unknown stem cell contents are measured relative to the repopulating ability of the internal standard competitor pool. Thus, various donor cell populations and bone marrow fractions can be compared (Jordan et al. 1995).

Hematopoietic stem cells have been subfractionated based on size, density, and the expression of cell surface molecules (Visser and Van Bekkum 1990; Lu et al. 1987; Terstappen and Lund-Johansen 1994). There is a general consensus that most human stem cells are contained within the cell population expressing surface CD34 (where "CD" refers to the international nomenclature for antigens, the so-called clusters of differentiation). CD34-positive (CD34+) stem cells represent a spectrum of stages of differentiation and lineage commitment, with variable functional properties, in vitro laboratory properties, and surface antigen expression (Table 1). The majority of CD34+ bone marrow cells are "late stem cells," already committed to either the hematopoietic or stromal cell lineages (Civin et al. 1984; Simmons and Torok-Storb 1991). The most immature progenitors within the CD34+ population are further fractionated by the differential expression of CD38, CD45RA, CD71, CDw90 (Thy-1), and HLADR (Baum et al. 1992; Brandt et al. 1990a; Huang and Terstappen 1994; Lansdorp et al. 1990; Terstappen et al. 1991; Verfaillie et al. 1990). A newly identified population of stem cells in both mice and humans has been characterized as CD34− but capable of multi-lineage repopulation in experimental models. The precise relationship between these CD34− stem cells and traditional CD34+ stem cells is not well understood (Bonnet 2001).

The establishment of hematopoiesis during embryonic development, as well as the continued maturation and differentiation of bone marrow precursors in vivo, requires an interaction with both cellular and soluble factors. Observed changes in stem cell numbers coincide with

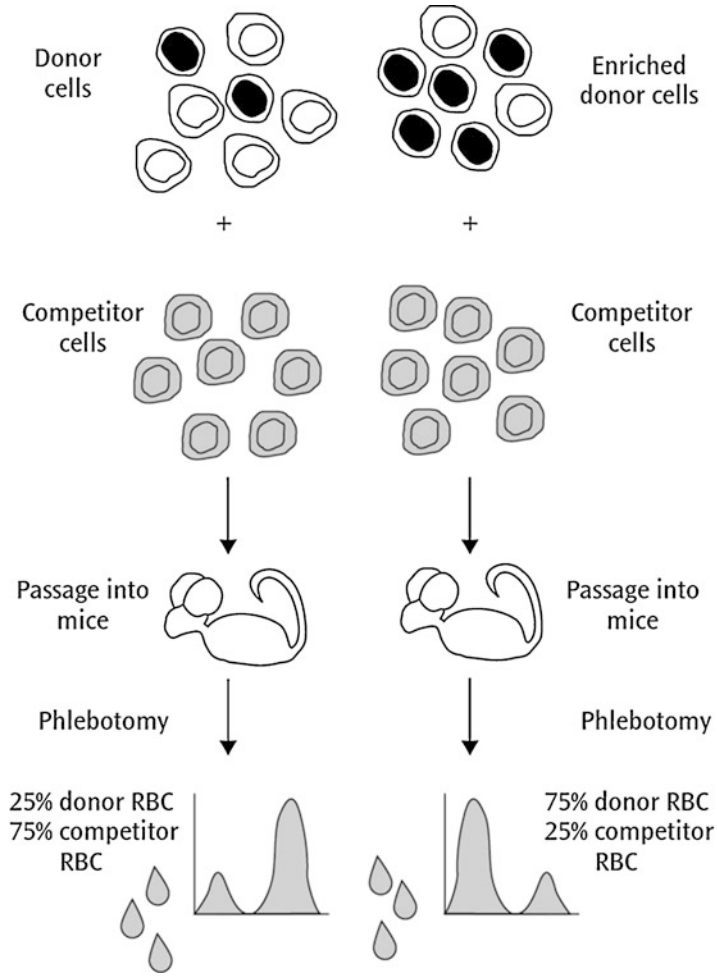

Fig. 2 Primitive hematopoietic stem cells are defined by their maximal differentiating and repopulating abilities, as measured by a technique called competitive repopulation. Donor and competitor cells are chosen from mouse strains to express different surface allelic markers. The mature progeny are assayed for the proportion of cells expressing each marker, and this value is used to estimate the stem cell number (relative to a standard dose of competitor cells) and evaluate for stem cell enrichment efficiency. In this example, the enriched donor sample is three times as efficient as the original sample and, therefore, reflects an increased proportion of functional stem cells. *RBC* red blood cells

alterations in the stromal cell content of the yolk sac, liver, spleen, and bone marrow when these sites become active in hematopoiesis (Klein et al. 1983; Van den Heuvel et al. 1987). In the liver, spleen, and bone marrow, increased numbers of fibroblastoid colony-forming units (CFU-f) precede the onset of hematopoiesis (Van Den Heuvel et al. 1991). When re-cultured in vitro, CFU-f are capable of maintaining hematopoiesis in both human and mouse long-term marrow cultures (Cappellini et al. 1984; Van Den Heuvel et al. 1988). This suggests a close interaction between stem cell proliferation/maintenance and stromal cell support. CFU-f are primarily fibroblastoid stromal cell types and are assayed by plating bone marrow in soft agar in vitro. However, normal hematopoietic stroma in vivo is heterogeneous and, in addition to CFU-f, is composed of macrophages, endothelial cells, and fibroblast (reticular) cells, with many of the fibroblasts converting to adipocytes over time (Allen 1981; Laver et al. 1986; Tavassoli and Friedenstein 1983; Wang and Wolf 1990; Westen and Bainton 1979; Xu et al. 1983). The mechanism for stem cell dependence on stromal cell layers is most likely an interaction of stem cell membrane proteins with adhesion molecules present on the surface of stromal cells (Fig. 3). Such adhesion is postulated to activate the stromal cell components, with resultant production of cytokines (Anderson et al. 1990; Huang et al. 1990; Ploemacher et al. 1986; Williams et al. 1990; Wolf 1978; Wolf et al. 1995; Zsebo et al. 1990).

The most primitive pluripotent stem cells do not appear to respond to any one cytokine given

Table 1 Definition of hematopoietic stem cells

Properties	Early stem cells (pre-CFU-S)	Late stem cells (CFU-S)	Lineage-committed stem cells
Functional	Self-renewal; long-term radioprotection of the host	Production of myeloid, erythroid, and lymphoid elements	Radioprotection of the host
Laboratory	CFU-S formation in secondary transplantation into lethally irradiated mice (long-term repopulation)	Secondary spleen colony assays (CFU-S) Long-term liquid Dexter	Methylcellulose colony formation for multipotential lineage growth
Antigenic	Mouse: Sca-1 (stem cell antigen) positive, Thy-1.1 weakly positive, Lin (lineage markers) negative, KDR receptor (vascular endothelial growth factor receptor II) positive Human: CD34 positive, Rh123 (rhodamine dye) weakly positive, CD38 negative, CD71 (transferrin receptor) negative, HLA-DR negative, c-Kit receptor positive, CD45RO positive, CD45RA weakly positive, CDw90 (Thy-1) weakly positive		Human: CD34 positive, RH123 (rhodamine dye) strongly positive May express variable CD33 (myeloid), CD10/CD19 (B lymphoid), CD38, and HLA-DR

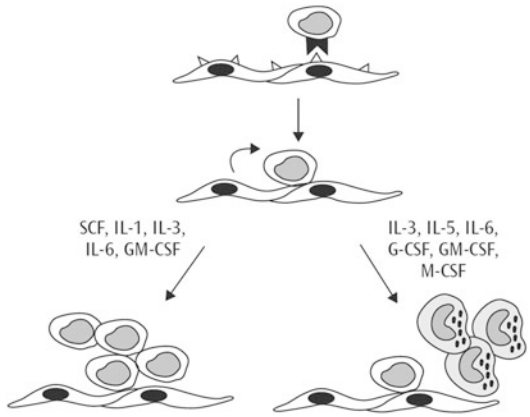

Fig. 3 Binding of hematopoietic stem cells to stroma via surface adhesion molecules results in the release of multiple cytokines by the activated stromal cells. The relative levels of these cytokines and the efficiency with which they can bind to receptors on the stem cell allows for a balance between stem cell replication and differentiation. *SCF*, stem cell factor (c-Kit ligand, Steel factor); *IL*, interleukin; *GM-CSF*, granulocyte/macrophage colony-stimulating factor; *G-CSF*, granulocyte CSF; *M-CSF*, macrophage CSF

alone. Colony growth in soft agar can be seen when these cells are incubated with interleukin-3 (IL-3) in combination with a variety of other growth factors (Heimfeld et al. 1991). Committed myelomonocytic precursors and lymphoid progenitors have been demonstrated to respond to the early-acting growth factors, stem cell factor (SCF, also known as c-Kit ligand and Steel factor), Flt-3/FIt-2 ligand thrombopoietin (TPO), and IL-1, as well as IL-6, granulocyte colony-stimulating factor (G-CSF), granulocyte/l-macrophage CSF (GM-CSF), macrophage CSF (M-CSF), IL-7, IL-5, IL-11, IL-12, and leukemia inhibitory factor (LIF) (Ogawa and Matsunaga 1999). Commitment to the erythroid lineage requires both early-acting growth factors and erythropoietin (EPO). Megakaryocytic differentiation is less well understood but requires many of the same early-acting growth factors. TPO induces differentiation in vitro (Bartley et al. 1994; Kaushansky et al. 1994), and ex vivo megakaryocytic expansion is now possible (Maurer et al. 2000).

The Effect of Aging on Bone Marrow Function

A multitude of alterations in hematopoiesis have been ascribed to the aging process, when studied in mice (Table 2). No major changes in basal hematopoiesis, however, are noted with aging (Coggle and Proukakis 1970; Everitt and Webb

Table 2 The physiologic basis of aging in the hematopoietic system of mice

Observed aging phenomenon	Probable physiologic mechanism
Myeloid abnormalities	
Increased proliferative capacity of late stem cells (CFU-S)	Unknown
Increased differentiative capacity of late stem cells (CFU-S), with production of more committed stem cells	Altered stromal cell regulation and increased demand for mature cells
Decreased resynthesis of cytokine substances in bone marrow	Altered stromal cell regulation, with increased fibroblast content of bone marrow
Decreased ability of early stem cells to repopulate the bone marrow of lethally irradiated mice	Decreased marrow graft content of activated stromal cell components capable of cytokine secretion and initiation of hematopoietic reconstitution
Decreased in vitro CFU-GM colony formation	Decreased sensitivity of CFU-GM to exogenous IL-3, G-CSF, and GM-CSF
Reduction in hematopoietic reserve	Blunted proliferative response to stress, most likely secondary to abnormal cytokine regulation
Reduced cycling of committed stem cells (CFU-GM)	Increased demand for mature cells and increased complement of CFU-GM
Increased spontaneous chromosomal abnormalities	Decreased DNA repair mechanisms; altered telomerase activity
T-lymphoid abnormalities	
Blunted T-cell proliferative response to mitogens	Increased content of mature T cells in bone marrow, with shortened duration of response to cell activation accompanied by a decrease in bone marrow-derived thymocyte progenitors; decreased local cytokine production by macrophages and stromal cells
Increased T-cell content of bone marrow	Compensatory increase in infiltrating effector T cells secondary to blunted T-cell proliferative response
B-lymphoid abnormalities	
Increased autoantibody production	Cytokine dysregulation, most notably increased IL-6; restricted VH gene usage
Decreased production of normal immunoglobulin-producing cells	Cytokine dysregulation, most notably IL-7 and IL-4; abnormal T-cell regulation; decreased B-progenitor content of bone marrow
Restricted V_H gene usage	Decreased B-cell precursors and increased peripheral selection; progression decline in *RAG-1* gene activity

IL, interleukin; *G-CSF*, granulocyte colony-stimulating factor; *GM-CSF*, granulocyte/macrophage CSF; *RAG-1*, recombination-activating gene 1

1958). The aging process is typically characterized by a reduction in functional reserve capacity. Thus, while basal function is normal, the ability to respond to increasing demand and infectious or inflammatory stress is compromised. This compromise may involve all lineages within the bone marrow and is the most frequently cited mechanism for the anemia of aging. Older mice and humans recover hemoglobin values more slowly after phlebotomy than do their younger counterparts (Boggs and Patrene 1985), and a less than optimum increase in hemoglobin level is noted during transitions to high altitude (Udupa and Lipschitz 1984).

The fragility of the aging hematopoietic system is further highlighted by studies of mice approaching their maximal life expectancy (Williams et al. 1986). The median lifespan of the experimental mouse line C57BL/6 is 24 months, and the maximum reported life expectancy is 48 months. Mice at 48 months of age have been used in experiments in which they are housed either individually or in groups of five or more animals. Under experimental conditions where

crowding occurs, a significant alteration in bone marrow function results, and the majority of animals become anemic. Examination of their bone marrow shows decreases in the number of countable stem cells and morphologically recognizable mature progeny. Therefore, when viewed globally, these experiments support the clinical impression that minor stresses that may not affect hematopoiesis in younger individuals can cause significant abnormalities in aged animals. Since no abnormalities in basal hematopoiesis can be detected, it is probable that these clinically apparent effects are secondary to blunting or suppression of cell proliferation and function during inflammatory or other physiologic stresses. This is most probably a consequence of cytokine mediation.

There is general consensus that aging causes decrements in the proliferative potential of some cell types (Goldstein 1990; Hayflick 1976; Norwood et al. 1990). There may be blunting of the proliferative response of normal marrow hematopoietic cells, resulting in inadequate amplification of myelopoiesis. This could potentially lead to neutropenia (Finkelstein et al. 1983; Weinstein et al. 1983) or could be manifested as a slow recovery from myelotoxic chemotherapy (Begg and Carbone 1983). Age-related deficits in compensatory myelopoiesis have also been ascribed to changes in the number of bone marrow progenitors, alterations in the responsiveness of these progenitors to regulatory cytokines (Lipschitz et al. 1984), decreased production of cytokines (Gillis et al. 1981; Nagel et al. 1988; Buchanan and Rothstein 1989), or defects in the bone marrow microenvironment (Lee et al. 1989).

The majority of studies to delineate the effects of aging on hematopoietic cell proliferation have been performed in rodents, predominantly mice or senescence-accelerated strains of mice. Contradictory studies exist, and alterations in the function of the hematopoietic system during the aging process are not universally accepted. It is likely that some of the confusion results from differences in experimental procedures, differences between strains of laboratory mice, or inherent differences between rodent models and normal human physiology. For example, bone marrow cellularity in rodents increases with increasing age, while cellularity in humans decreases. Such basic differences in physiology may significantly impact the extrapolation of results from experimental animal studies. However, despite some limitations, many lessons can be learned from in vitro evaluations. In the following sections, the specific effects of aging on each stage of normal stem cell differentiation will be discussed. As will become obvious, a multitude of laboratory abnormalities are found. Most of these are minor alterations or are poorly reproducible. No consistent patterns have been found, and the effect of aging on stem cell function remains a debated topic.

Pluripotent Stem Cells (Pre-CFU-S and CFU-S)

It appears that pluripotent stem cells have a finite replicative capacity (Lipschitz and Udupa 1986). Nonetheless, it is evident that stem cells can function far longer than the lifespan of the host, such that the physiologic consequences of this finding are unclear. In serial transplantation studies in W/W-anemic recipient mice, stem cells from healthy C57BL/6(B6) donors generated normal hematopoiesis for at least 100 months, which is 3–4 times the lifespan of normal mice (Zaucha et al. 2001). In human allogeneic bone marrow recipients, hematopoiesis is sustained for at least 20–30 years after transplantation. Evidence exists, however, that stem cells are heterogeneous in self-renewal capacity; young CFU-S (pre-CFU-S) show a high self-renewal capacity and give rise to older CFU-S with diminishing self-renewal and increasing differentiation potential (Fig. 3) (Schofield and Lajtha 1973; Schofield et al. 1980). During the aging process in mice, hematopoietic stem cells appear to accumulate (Sudo et al. 2000). These repopulating cells retain their self-renewal potential but develop a more restricted myeloid differentiation preference and less lymphoid differentiation potential. This anomaly has been postulated to result from repeated hematopoietic stem cell self-renewal and symmetric division, which may gradually

produce intrinsically defective stem cells. In addition to defects in lymphoid lineage commitment, functional efficiency in homing and engraftment is also affected (Morrison et al. 1996).

Basal hematopoiesis shows no significant change, yet a significantly reduced reserve capacity is evident during stress or intercurrent illness. In order to understand why elderly people appear to possess less hematopoietic reserve than their youthful counterparts, early stem cell function has been evaluated in aging mice. Several studies have attempted to quantitate the number of pluripotent stem cells in the bone marrow (Schofield et al. 1986; Sharp et al. 1989). In the majority of cases, no differences could be detected in the absolute number of late stem cells (CFU-S) or committed multi-lineage stem cells (CFU-mix) when comparing bone marrows obtained from young or old mice. Marginal differences in proliferative potential, however, have been found (Sharp et al. 1989). There is a suggestion that cells originating from older bone marrows proliferate to a greater extent and produce more committed stem cells than those from younger donors. This leads to a three- to fourfold increase in the relative and absolute numbers of the most primitive stem cell subsets. It has been proposed that these precursor cells proliferate in the older animal to compensate for their age-specific functional abnormalities (Globerson 1999). This finding appears to be somewhat confusing, and its relevance to physiologic stem cell functioning during aging is uncertain. A direct relationship between increased stem cell pool and murine strain-specific lifespan has been suggested. The basic mechanism for this observation clearly involves many factors extrinsic to the stem cell itself and appears to be a result of stromal cell dysregulation.

It is generally accepted that the function of marrow stem cells, when these cells are transplanted into other animals or studied in culture, does not change significantly with age, although alterations in accessory cells occur (Schofield et al. 1986). Resynthesis of cytokines appears to be slower in older mice, suggesting abnormalities in cytokine regulation or stromal cell function. However, while stromal cell dysfunction and abnormalities of stem cell proliferation can be demonstrated in vitro, these abnormalities do not appear capable of resulting in a significant decrement in stem cell function in vivo. As an exception to these findings, a single study (Sletvold and Laerum 1988) identified a decrease in absolute CFU-S number using a novel chronobiological approach. The authors suggested that both circadian and seasonal variations in stem cell number exist. Using a calculation of mean CFU-S number, as identified by day-8 spleen colony assays, older mice appeared to have a slight decrement in absolute stem cell number. They also demonstrated less variability by season and time of day than younger littermates. The magnitude of this change, however, was quite small. It is probable that normal physiologic variations in stem cell number contributed to the difficulty in interpreting these data.

Applying these findings to elderly human patients is problematic. Whether or not small changes in in vitro stem cell number lead to in vivo abnormalities is unclear. In order to answer this question, functional studies are needed. Using serial transplantation into lethally irradiated mice, stem cells show a gradual loss of self-replicative ability (Schofield et al. 1980). While early evidence suggested that CFU-S from young donors were better able to repopulate the marrow of irradiated mice than stem cells obtained from older donors, this difference was probably related to stromal cell content and induced cytokine secretion. There is evidence suggesting that many of the early published serial transplant studies had significant methodologic artifacts (Harrison et al. 1978; Ross et al. 1982). Furthermore, as noted above, any defect in stem cell number or function is marginal. Therefore, in summary, it appears that the CFU-S have sufficient reserve capacity to produce adequate numbers of hematopoietic cells for periods that far exceed the maximum life expectancy of the host (Harrison 1973). Furthermore, although functional defects are evident, most observed abnormalities of stem cell function are likely secondary to alterations in stromal cells or stem cell/stromal cell interactions.

Committed Hematopoietic Precursors

Studies have examined the effect of aging on the number of both committed hematopoietic stem cells [CFU-granulocyte/macrophage (CFU-GM), CFU-erythroid (CFU-E), burst-forming units-erythroid (BFU-E), etc.] and differentiated bone marrow cells (Williams et al. 1986). In mice, the results are similar for late and early stem cells. Most studies show no age-related reduction in the number of erythroid (BFU-E and CFU-E) or granulocyte/macrophage (CFU-GM) progenitor cells. Furthermore, there appears to be no age-related differences in the proportion of CD34+ marrow cells or of more mature CD34+ subsets, defined as CD34+/CD33+ cells (Chatta et al. 1993). Maximum colony formation by primitive CD34+ cells stimulated with combinations of cytokines, including G-CSF, GM-CSF, and IL-3, is also similar in young and old subjects. However, an inverse correlation between the number of CD34+ stem cells isolated from peripheral blood and age has been documented (Egusa et al. 1998). It is possible that this results from a similar functional homing defect as described for early stem cells, although this hypothesis has not yet been tested directly. Also, similar to early stem cells, the kinetics of the proliferative response may be altered, although no consistent pattern of abnormalities is found. Alterations appear to be growth factor-specific and thus do not represent a generalized stem cell defect. For example, dose-response studies have identified a decrement in the sensitivity of cells obtained from elderly subjects to G-CSF, but not to IL-3 or GM-CSF. Similarly, the ability of early erythroid-committed progenitors (CFU-E) to respond to EPO and IL-3 is unchanged (Hirota et al. 1988). When using a similar strategy to evaluate the mature progeny of committed stem cells (Sletvold et al. 1988), no significant decrement in mature peripheral blood neutrophils, erythroid cells, or platelets can be identified.

Progenitor Cell Cycle Kinetics

Another explanation for changes in marrow reserve during aging is an abnormality in the ability of stem cells to maintain proliferation, either temporally or in response to a stimulus. Several subtle abnormalities in both early and committed stem cell proliferation have already been discussed. Interestingly, it has been shown that the bone marrows of aged mice accumulate stem cells and that these mice contain stem cells that are abnormal in cycle (Globerson 1999). They replicate on addition of cytokines, but maintenance of the cycling rate of CFU-GM, as measured using the thymidine suicide technique (Lord and Schofield 1985), is lower in elderly than in young adult mice (Iscove et al. 1970; Tejero et al. 1984). Data suggest that the reduced cycling of CFU-GM in older mice may be due to a constant demand for mature cells and an increased complement of CFU-GM modulated by stromal regulation (Tejero et al. 1989).

Stem Cell Integrity

The proliferative lifespan of the stem cells that sustain hematopoiesis throughout life is not clearly delineated. It has been proposed that the sequential loss of telomeric DNA from the ends of human chromosomes during cell division eventually reaches a critical point that triggers cellular senescence (Vaziri et al. 1994). This occurs because of the absolute requirement for DNA synthesis to begin at the binding site for the DNA replicative enzyme DNA polymerase (a process called priming) and the fact that this enzyme causes unidirectional DNA synthesis only. This unidirectional process results in incomplete replication of the terminal ends of the linear chromosomes distal to the DNA polymerase binding site (Olovnikov 1973; Watson 1972). In order to compensate for this replicative defect, eukaryotes have evolved a specialized rescue mechanism involving both chromosomal nucleoprotein modifications and a novel enzyme known as telomerase (Fig. 4). Eukaryotic chromosomes end in specialized nucleoprotein structures called telomeres, which in humans contain tandem repeats of the nucleotide TTAGGG. Telomeres are critical for chromosome stability and function, and the loss of telomeres signals cell cycle arrest and

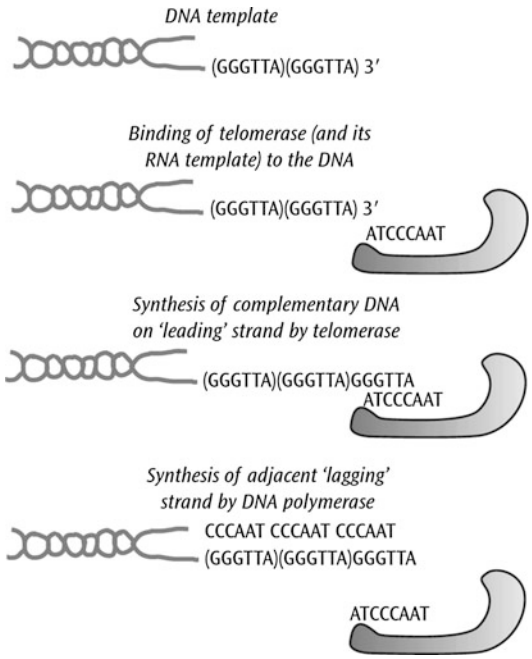

Fig. 4 Linear chromosomal DNA cannot be fully replicated by DNA polymerase. Therefore, special DNA sequences, called telomeres, have evolved at the ends of human chromosomes. A special enzyme called telomerase contains an integral RNA template. It is capable of adding nucleotides to the replicating (leading) end of the chromosome in an attempt to extend its 3′ end, allowing replication to be completed. DNA polymerase fills in the adjacent (lagging) strand but uses telomeric DNA as a site of initiation of synthesis (primer). If telomerase is not present, the chromosomal ends become progressively shortened until chromosomal replication can no longer proceed

chromosomal loss in yeast (Lundblad and Szostak 1989). Shortening of telomeres during mammalian aging in vivo has been observed in dermal and epidermal cells, peripheral blood leukocytes, and colonic epithelium, but not in sperm DNA (Allsopp et al. 1992; Hastie et al. 1990; Vaziri et al. 1993). There is evidence suggesting that early (pre-CFU-S) human stem cells (CD34+/CD38dim/-) from bone marrows of adult donors have shorter telomeres than similar cells obtained from fetal liver or umbilical cord blood (Vaziri et al. 1994). This finding suggests that the proliferative potential of hematopoietic stem cells may indeed be limited. To support this contention, telomeric shortening has been studied in stem cells after they have been induced to undergo excessive replication cycles. Shortened telomeres are well described in peripheral blood leukocytes following allogeneic bone marrow transplantation, in some bone marrow failure syndromes, and following some cytotoxic chemotherapy regimens (Robertson et al. 2000). The telomeric shortening after bone marrow transplant corresponds to approximately 15 years of aging, yet acquired bone marrow failure has not been described. Thus, telomeric shortening as a cause of suboptimal marrow responsiveness to proliferative stimuli or altered hematopoiesis appears unlikely.

Stem cell utilization, as measured by X-chromosome inactivation, also appears to be independent of telomere length. It has been known for some time that clonality assays in healthy elderly women can be unreliable owing to an acquired progressive skewing of X-chromosome inactivation (El Kassar et al. 1998). It was postulated that this could be the result of a decreased stem cell pool, and telomeric senescence was implicated as the primary cause. However, it has become clear that factors other than telomeric senescence (random stem cell loss or X-allelic exclusion) are important in altering hematopoiesis with aging. Evidence in laboratory-bred safari cats (Abkowitz et al. 1998) suggests that this skewing is a result of inherited genetic factors that cause a selective advantage to certain cells carrying one or the other X chromosome. Thus, hemizygous selection appears to be the cause of the age-dependent skewed hematopoiesis that characterizes the bone marrows of elderly individuals.

The process of aging is also associated with a general loss in the biologic competence of both single cells and the individual as a whole. At the cellular level, this loss is seen as a decrease in the ability of proliferating cells to replicate and of postmitotic cells to function effectively. When cytogenetic analysis was performed on the dividing bone marrow of rats (Sen et al. 1989), the incidence of chromosomal abnormalities (predominantly hypodiploidy) increased gradually with aging. Other abnormalities, such as polyploidy or changes in mitotic index, were not significant. The overall DNA content remains constant owing to the small number of

hypodiploid cells present (6.57% in males and 5.99% in females). When other tissues outside of the bone marrow are examined for similar abnormalities, an increase in univalency and nondisjunction are found in the ovaries of females (de Boer and van der Hoeven 1980). No significant alterations in sperm chromosome number or structure could be identified in even the very oldest males, although the division frequency did decline sharply at the extremes of aging (Sen et al. 1989).

Evidence for possible abnormalities of DNA repair and chromosomal dysregulation during aging was found in studies in which cytogenetic alterations were examined following exposure to mutagens (Singh et al. 1986). Older animals developed a higher frequency of micronuclei, reduced metaphase indices, and lower sister chromatid exchange per cell when compared with younger counterparts. Treatment with mutagens will significantly increase micronuclei and sister chromatid exchange in most strains of mice at all ages. The important point to note, however, is that the magnitude of this change increases significantly in older animals. When strain-dependent genetic predispositions are taken into account, sensitivity to mutagens and a decreased ability to repair abnormalities appear to characterize the aging animal.

The Effect of Aging on Stem Cell Clonality

The discovery of age-associated clonal hematopoiesis arose from studies exploring the phenomenon of X-inactivation skewing in elderly individuals (*discussed above*). Age-associated skewing of X-chromosome inactivation, which is particularly common within the myeloid compartment of stem cells, was hypothesized to be a result of somatic mutation acquisition, subsequently conferring a growth advantage and a clonal hematopoietic state. In fact, Busque et al. demonstrated that somatic *TET2* mutations were highly enriched in the peripheral blood of elderly women with X-inactivation skewing and that the variant allele frequencies of the mutations were highly concordant with the degree of skewing (Busque et al. 2012). There were no differences in the hematologic parameters between individuals with and without *TET2* mutations. This presence of stem cell clonality in the absence of an overt hematologic phenotype has been confirmed in multiple additional studies.

Clonal hematopoiesis, or clonal hematopoiesis of indeterminate potential (CHIP), is currently defined by the presence of somatic mutations, with variant allele frequencies between 2% and 20%, in genes commonly associated with myeloid neoplasms (e.g., *DNMT3A, TET2,* and *ASXL1*) but without overt signs of hematologic malignancy (Steensma et al. 2015). Three concurrent studies first described the phenomenon of age-associated clonal hematopoiesis in large cohorts (Genovese et al. 2014; Jaiswal et al. 2014; Xie et al. 2014). The studies demonstrated that clonal hematopoiesis is an age-dependent genetic event that occurs in up to 10% of individuals over the age of 70 years and in virtually no individuals under the age of 40 years. The presence of CHIP is an unfavorable risk factor that has been associated with a significantly increased risk for hematologic malignancy (HR 12.9), reduced overall survival (HR for death 1.4), and increased risk of coronary heart disease (HR 2.0) when compared to individuals without CHIP (Genovese et al. 2014; Jaiswal et al. 2014).

Studies using alternative parameters to define CHIP have reported even higher frequencies in elderly individuals. Using error-corrected sequencing to detect variants at frequencies as low as 0.03%, Young et al. demonstrated that 95% of healthy individuals (50–60 years old) harbored CHIP mutations (Young et al. 2016). Interestingly, the mutations were frequently (76.9%) present in multiple hematopoietic compartments (i.e., lymphoid and myeloid) and stable over time (27.5% of individuals had the same mutation 10 years apart). The clinical significance of very low-frequency variants or the hematopoietic compartment of the variants has yet to be elucidated. Using whole-genome sequencing and barcodes of mosaic somatic mutations (down to 1% allele frequencies), Zink et al. reported that over 50% of individuals over the age of 85 years

demonstrated clonal hematopoiesis, whereas less than 0.5% of individuals less than 35 years old were classified as having clonal hematopoiesis (Zink et al. 2017). This was also the first study to report that a germline mutation (*TERT,* telomerase reverse transcriptase, rs34002450) predisposes individuals to clonal hematopoiesis (OR 1.37).

Clonal hematopoiesis has been demonstrated to confer significant risks in the setting of cancer. First, there is an approximately 5% absolute risk for hematologic cancer development for individuals with CHIP (Genovese et al. 2014; Jaiswal et al. 2014). Second, individuals with CHIP who are treated with chemotherapy for non-hematologic malignancies have a significantly higher incidence of lethal secondary cancers, known as therapy-related myeloid neoplasms (median survival 6–11 months), than individuals without CHIP (Gillis et al. 2016; Takahashi et al. 2017). Likewise, individuals with CHIP who receive autologous stem cell transplants for lymphoma are at a significantly increased risk of developing therapy-related myeloid neoplasms (Gibson et al. 2017a). Case series also suggest that CHIP can be transferred to recipients through allogenic stem cell transplantation (Gibson et al. 2017b). Interestingly, the prevalence of CHIP is higher in individuals with solid cancers (approximately 25%–30%) than in non-cancer cohorts; however, as in healthy individuals, the prevalence in cancer patients is also significantly associated with increased age, with an approximate 6% increased odds of CHIP for every 10 years of age (Gillis et al. 2016; Coombs et al. 2017).

Clonal hematopoiesis also increases the risk of cardiovascular disease by promoting the development of atherosclerosis, ultimately resulting in coronary heart disease. Using mouse models prone to atherosclerosis (*Ldlr*$^{-/-}$), Fuster et al. demonstrated that partial bone marrow reconstitution with *Tet2*-deficient cells (to model clonal hematopoiesis) was sufficient for clonal expansion and resulted in a significant increase in atherosclerotic plaque size (Fuster et al. 2017). *Tet2*-deficient macrophages increased the expression of pro-inflammatory cytokines, including interleukin (IL)-6 and 1β, which likely exacerbated atherosclerosis. This effect could be reversed with IL-1β blockade (Fuster et al. 2017). These findings were confirmed in a large case-control study, which demonstrated that individuals with CHIP have an increased risk of coronary heart disease and early-onset myocardial infarction (1.9-fold and 4.0-fold, respectively) (Jaiswal et al. 2017). These increased risks were attributed to increased coronary artery calcification (a marker of coronary atherosclerosis burden) and cytokine release, and the mechanism was validated in mouse models of CHIP.

In summary, it is established that clonal hematopoiesis occurs increasingly with age; however, the etiology is unknown at this time. There are genes that most commonly harbor clonal hematopoiesis mutations (e.g., *DNMT3A, TET2, ASXL1*, and *PPM1D*); however, the translational significance of each gene has yet to be elucidated. One study reported an association of *TET2*, but not *DNMT3A*, mutations with age (Buscarlet et al. 2017). While there is no clear cutoff defining clinically significant variant allele frequencies for CHIP mutations, it is known that the risks of cancer and coronary heart disease are significantly increased (49-fold and 2.2-fold, respectively) in individuals with higher variant allele frequencies ($\geq$ 10%) (Jaiswal et al. 2014, 2017). Data suggests that progression from CHIP to coronary heart disease may be precipitated through inflammatory processes, but the mechanism for clonal expansion from CHIP to overt hematologic malignancy is unknown at this time.

The Effect of Aging on Bone Marrow Stroma

Age-related variations in hematopoiesis are well documented, but, as noted previously, it is sometimes difficult to distinguish between the influence of extrinsic (marrow microenvironment) and intrinsic (genetic or stem cell) factors. Bone marrow stroma is an important source of extrinsic signals necessary for the maintenance of both in vitro and in vivo hematopoiesis. Direct-contact signaling between stem cells and stromal cells via adhesion receptors and secretion of cytokines has been documented (Williams et al. 1990; Wolf

et al. 1995). Serial transplantation studies in aging mice have suggested that defective secretion of cytokines and decreases in the ability of bone marrow stroma to maintain stem cell replication are the major factors responsible for the decreased cell proliferation that characterizes aging. This deficiency has been further evaluated in other experimental models (Boggs et al. 1991), where a variety of latent deficiencies of the hematopoietic microenvironment have been documented. No change in the capacity of stromal cells to bind stem cells has been identified. However, when colony formation in culture is studied during aging (Sidorenko et al. 1990), an increase in the bone marrow content of stromal precursor cells forming fibroblast colonies (CFU-F) is noted. This increase in bone marrow stroma is not associated with changes in bone marrow stem cell content, although a relationship between stromal cell number and bone marrow cellularity is apparent. The changes in stromal cell content, cell number, and cellular organization (Schofield et al. 1986; Sidorenko 1985; Sidorenko et al. 1986) point to an age-related reorganization of the bone marrow microenvironment.

How stromal cell reorganization influences stem cell physiology is not well understood. This most likely reflects a general paucity of experiments designed to evaluate the contribution of stroma to cell proliferation and function. The few functional studies in the literature are generally not well controlled. A single report suggests decreased neutrophil function when granulocytes are grown in long-term cultures of stroma from older as opposed to younger donors (Udupa and Lipschitz 1987). In this study, neutrophil function following stimulation by mitogen 4-phorbol-12-myristate-13-acetate (PMA) was decreased in cultures initiated from the bone marrow stroma of older mice. However, neither cytokine production nor variability in culture conditions was evaluated.

The Effect of Aging on Cytokine Production and Release

Although the steady-state blood cell levels are normal, many older persons appear to have an impaired ability to accelerate hematopoiesis in response to physiologic stress. This impairment, in large part, appears to be due to a disordered cytokine regulatory network. Abnormalities in both constitutive expression and induced expression have been described (Baraldi-Junkins et al. 2000). The majority of evidence documents alterations in both cytokine secretion and cellular responses to cytokines in vitro, and few of these proteins have been measured directly in vivo (Table 3). No published studies have identified decreases in the serum levels of cytokines necessary for myeloid proliferation or differentiation (Li et al. 1988). However, an age-related decline in secretion of human IL-3 and GM-CSF by phytohemagglutinin (PHA)-stimulated peripheral blood mononuclear cells has been demonstrated in elderly persons and centenarians when compared with young adults (Bagnara et al. 2000). Furthermore, a paradoxical increase in serum SCF was noted, illustrating the complexity of this system and suggesting the presence of an as-yet uncharacterized compensatory mechanism to maintain the stem cell pool.

Of the cytokines studied in some detail in the literature, the most consistent results have been with measurements of IL-2, IL-6, and IL-7 (Fong and Makinodan 1989; Holbrook et al. 1989). Levels of IL-2 show a consistent decrease, likely contributing to abnormalities of T-cell function. Likewise, several studies (Stephan et al. 1998; Updyke et al. 1993) have evaluated the contribution of decreased production of IL-7 on altered B-lymphoid differentiation during aging. IL-7 is produced by bone marrow stromal cells and is required for pre-B-cell development (Namen et al. 1988). Whether alterations in cytokine secretion or production in vitro will translate into meaningful in vivo phenomena remains to be seen. Decreases in IL-2 and IL-7 production correlate with clinical data showing decreased immune function in elderly individuals.

Perhaps the most important cytokine for gerontologists is IL-6 (Ershler 1993). IL-6 is a multifunctional protein (Fig. 5) produced by a wide variety of cells under varied conditions. It is the critical factor in the acute-phase inflammatory response and appears to be involved in such diverse activities as induction of B-cell proliferation and maturation, regulation of protease

Table 3 A variety of cytokine abnormalities (in vivo and in vitro) that have been associated with aging

	Mouse	Human
In vivo abnormalities	Decreased serum IL-3 Decreased serum IL-2 Increased serum IL-6	Increased serum IL-6 Increased serum SCF
In vitro abnormalities Abnormalities in cytokine production and/or secretion	Decreased production of IL-1, IL-6, and TNF by LPS-stimulated peritoneal macrophages Decreased production of IL-7 by long-term bone marrow cultures	Decreased production of IL-2 by anti-CD3-stimulated T cells Decreased production of IL-3 and GM-CSF by PHA-stimulated PBMC Decreased production of IL-4 and IFN-γ by conA-stimulated mononuclear cells Increased production of IL-6 by PHA-stimulated lymphocytes
Abnormalities in cellular responses to cytokines	Decreased responsiveness of B precursors to IL-7 Decreased responsiveness of bone marrow stromal cells to PDGF and IGF-I	Decreased responsiveness of marrow progenitors to G-CSF

IL, interleukin; *SCF*, stem cell factor (c-Kit ligand, Steel factor); *TNF*, tumor necrosis factor; *LPS*, lipopolysaccharide; *GM-CSF*, granulocyte/macrophage colony-stimulating factor; *PHA*, phytohemagglutinin; *PBMC*, peripheral blood mononuclear cells; *IFN-γ*, interferon gamma; *conA*, concanavalin A; *G-CSF*, granulocyte colony-stimulating factor; *PDGF*, platelet-derived growth factor; *IGF-I*, insulin-like growth factor I

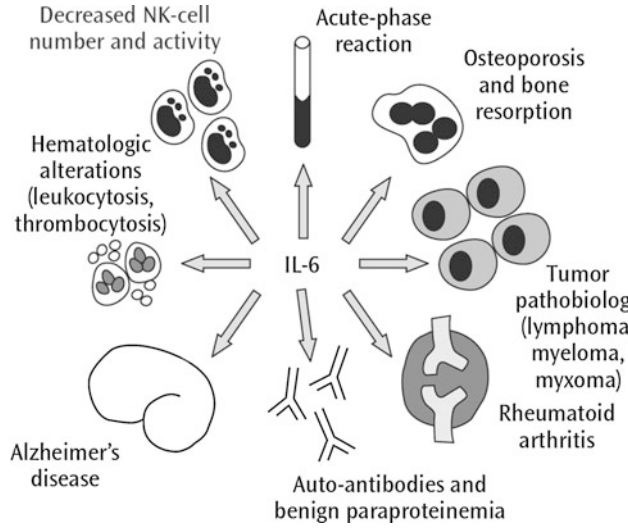

Fig. 5 Interleukin-6 (IL-6) exerts a number of important effects on many organ systems. Increases in IL-6 during normal aging are thought to contribute to the pathogenesis of several neoplastic and non-neoplastic (predominantly inflammatory) disorders

inhibitors such as α1-antichymotrypsin and α2-macroglobulin, and stimulation of bone resorption in vitro. Dysregulation of IL-6 expression has been implicated in the pathogenesis of a variety of neoplastic and non-neoplastic disorders, including multiple myeloma (Kawano et al. 1988; Klein et al. 1989), non-Hodgkin lymphoma (NHL) (Merz et al. 1991; Nachbaur et al. 1991), rheumatoid arthritis (Ganter et al. 1989; Garman et al. 1987), Castleman's disease (Brandt et al. 1990b; Yoshizaki et al. 1989), and cardiac myxoma (Jourdan et al. 1990).

The regulation of IL-6 gene expression is complex, with low to absent levels found in the serum of normal individuals. With aging, however, there is a gradual increase in the level of measurable IL-6, even in the absence of documented inflammatory stimuli (Daynes et al. 1993; Foster et al.

1992; Tang et al. 1991). It has been postulated that changes in IL-6 regulation may constitute one of the fundamental aging processes and could conceivably contribute to a broad spectrum of age-associated diseases (Ershler 1993). Because of the known effects on B-cell proliferation, dysregulation of IL-6 gene expression may well be related to the appearance of autoantibodies and perhaps the benign paraproteinemias that occur in aging mice (Radl 1990; Radl et al. 1975). Furthermore, since α1-antichymotrypsin and α2-macroglobulin may adversely alter the breakdown of amyloid precursor proteins, IL-6-induced increases in these protease inhibitors may contribute to the pathogenesis of Alzheimer's disease (Abraham et al. 1990; Bauer et al. 1991; Vandenabeele and Fiers 1991).

When administration of recombinant human IL-6 was tested in vivo in rhesus monkeys, a number of alterations in hematologic and immune parameters were observed (Sun et al. 1993). IL-6-treated animals lost an average of 10.9% of their body weight over a 28-day period of IL-6 administration. In addition to weight loss, there was a decrease in hemoglobin and hematocrit without evidence of peripheral hemolysis or obvious bone marrow suppression. A transient leukocytosis and a sustained thrombocytosis were also noted. Decreases in natural killer (NK)-cell activity and number were identified. Such changes are transient when normal young adult monkeys are studied but are sustained in elderly animals. A similar dichotomy is noted when examining serum protein. In normal adult monkeys, total protein levels rise after administration of IL-6, secondary to increases in acute-phase reactants and the appearance of a hypergammaglobulinemia. However, unlike the young adult animals, older subjects show a fall in serum total protein, which remains depressed for up to 1 week after the administration of IL-6 is discontinued. Thus, IL-6 clearly has a multitude of diverse effects on metabolism and homeostasis, and these effects may be variable during aging.

Perhaps the most extensively studied effect of IL-6 on aging is that related to osteoporosis. Osteoblasts are among the many cell types that secrete IL-6, and IL-6 stimulates bone resorption in vitro (Ishimi et al. 1990). Increasing levels of IL-6 with aging may contribute to postmenopausal osteoporosis (Roodman 1992). Decreasing estrogen levels result in a decrease in IL-6 gene expression (Girasole et al. 1992) with increased bone resorption and osteoclast activation. The system is complex, however. In addition to IL-6, at least two other cytokines are implicated in the generation of osteoporosis. Both insulin-like growth factor I (IGF-I) and platelet-derived growth factor (PDGF) have been identified as mitogens for marrow stromal cells (Tanaka and Liang 1995; Tanaka et al. 1994). They enhance cell growth and bone turnover through their actions on bone formation and bone resorption and appear to be less potent in older individuals. This lack of stimulation may result in decreased progenitor cell proliferation and subsequently a diminished expansion of new osteoblasts.

The Effect of Aging on Immune Function

Bone Marrow T Cells

The reported decline in immune responses during aging has been largely attributed to reduced functioning of the T-cell compartment (Fig. 6) (Pawelec et al. 1999). The majority of studies designed to investigate the biologic basis for the T-lymphocyte changes utilize mouse models. Sharp et al. have shown an increase in the proportion of T lymphocytes in bone marrow with age (Sharp et al. 1990). When these cells were sorted by flow cytometry and studied for proliferative response to mitogen (concanavalin A), T lymphocytes from bone marrow of older mice showed a significantly lower response than those obtained from younger donors. When adjusting the cultures for the presence of equal numbers of T lymphocytes, older bone marrows appeared to initially manifest a higher level of proliferation. However, the response was maintained for a shorter duration, suggesting a functional deficit. Thus, there are greater numbers of effector T lymphocytes in the bone marrow of older animals, but they show a proliferative response of shorter duration.

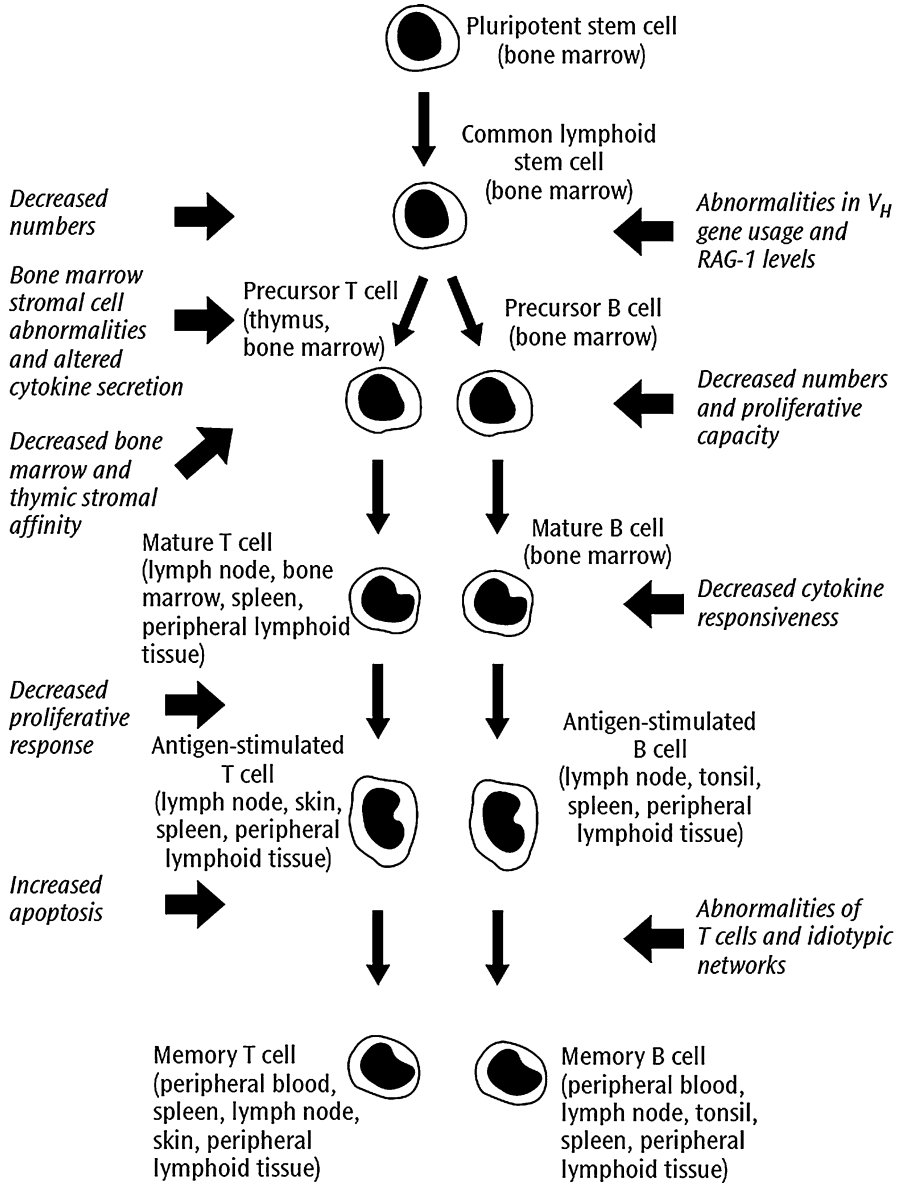

Fig. 6 A multitude of abnormalities in both T- and B-cell differentiation and proliferation have been ascribed to the aging process. These defects occur at all stages of T- and B-lymphocyte development

Concomitant with the increase in mature T cells, Globerson et al. have identified a decrease in the number of bone marrow-derived thymocyte progenitor cells with aging (Globerson et al. 1992). It was suggested that this decrease may be a normal function of aging that accompanies involution of the thymus. The proportion of mature T cells (CD4+/CD8+ ratios) derived from bone marrow of both young and older individuals appears similar. Since these mature T cells are long-lived and can continue to proliferate in response to immunogenic stimuli, the observed decrease in thymocyte progenitors may have little functional impact.

Thymic involution, however, imparts additional functional abnormalities to T-lymphocyte proliferation and function during aging. Sustained cell production by the thymus depends on the

continued migration of bone marrow thymocyte precursors to the thymus. As previously demonstrated (McCormick and Haar 1991), the ability of bone marrow-derived prothymocytes from aged individuals to migrate in response to thymic supernatants is grossly defective. Preincubation of these same bone marrow cells with neonatal thymic epithelium dramatically improves the ability of the aged bone marrow stem cells to migrate in vitro. Growth hormone and IGF-I stimulate thymopoiesis, and their levels decrease with age (Montecino-Rodriguez et al. 1998). It is apparent that thymic factors, hormone levels, and bone marrow cytokines are necessary for the function and differentiation of prothymocytes in the bone marrow, and alterations in either their levels or the cellular response influence T-cell production during aging.

When bone marrow-derived T lymphocytes are studied by flow cytometry (Hozumi et al. 1993), the majority are CD3+ cells possessing a cytotoxic/suppressor phenotype (CD8+), although both CD8+ and CD4+ cells do increase numerically with aging. These T lymphocytes are thymic-derived and are not biased for any usage of specific T-cell receptor (TCR) β chains. Their proportions differ from T-cell subsets within the spleen and peripheral blood, suggesting that this population of T lymphocytes preferentially proliferates in the bone marrow microenvironment. Their proliferation appears to be dependent on the surrounding bone marrow non-T-cell population (Hozumi et al. 1993). Direct contact between bone marrow T cells and non-T cells leads to inhibition of T-lymphocyte proliferation after addition of exogenous mitogen. Whether or not this inhibition prevents cytotoxic T cells from recognizing homologous bone marrow hematopoietic elements and proliferating (autoimmunity) is unknown at this time but certainly appears feasible. Globerson identified an additional mechanism responsible for abnormal T-cell differentiation and function in aging mice (Globerson 1994). Bone marrow cells from young and old mice were co-cultured with lymphoid-depleted fetal thymic explants. Although the proportion of total T cells developing from older bone marrow donors was significantly lower than that of younger bone marrow donors, there was no difference in the ratio of T-cell subsets or reactivity to mitogen. Unlike previous studies, which implicated only thymic-derived defects, this study suggested an intrinsic lesion in the bone marrow-derived T-cell precursors. Whether this reflects abnormal differentiation or an increase in programmed cell death has not yet been established. It was noted that the frequency of thymocyte progenitors in older bone marrow donors is reduced by approximately 40% during aging. If the older cells were cultured in the presence of fetal thymic explants for 24 h longer than those of younger donors, T-cell development was normalized. This suggests the possibility that bone marrow-derived T cells of older donors have a decreased affinity for thymic stroma. Thus, there are multiple defects that accumulate in the bone marrow T-cell compartment with aging. Decreased affinity for stroma, in addition to decreases in migratory activity and cell replication during aging, can be of major impact.

Bone Marrow B Cells

B-lymphocyte development is modulated by a complex network of positively and negatively acting cytokines, as well as by cell-to-cell interactions. T-lymphocyte function appears to exert a major role in B-cell development. Few abnormalities of aging have been directly attributed to defects in B-cell development or function within the bone marrow (Fig. 6). An age-related decrease in the number of pre-B lymphocytes in the bone marrow has been confirmed (Schulze and Goidl 1991). These cells were identified by cell surface phenotyping as CD19+/CD10+ dual-positive cells. The decrease in early B-cell precursors is accompanied by a decreased capacity to generate surface immunoglobulin-positive mature B cells. Neither the presence of inhibitory factors nor increases in suppressor T cells could be identified as the cause of these effects.

Development of B-cell precursors into mature immunoglobulin-bearing B cells depends on soluble factors such as IL-4 and IL-7, as well as cellular interactions provided by stromal cells

and T cells (Kincade 1987). During the aging process in mice, stromal cell function appears to become altered. Release of IL-7 by stromal cells requires cell-to-cell contact with B-cell precursors. Evidence suggests that the secretion of IL-7 by aged stromal cells is delayed when compared with stromal cells from young donors (Stephan et al. 1998). Since marrow stromal cells are the only local source of IL-7, this delayed secretion may have a profound effect on the generation of new B lymphocytes in the marrow. Furthermore, there may also be a decreased overall response to cytokine-induced proliferation. Jonsson and Phillips identified a two- to fivefold lower response to IL-7 in mice over 20 weeks of age when compared with younger animals (Jonsson and Phillips 1993). This decrease appeared to be secondary to a reduced frequency of IL-7-responsive pro-/pre-B cells in the bone marrow of the older mice, and could not be overcome by the addition of large amounts of IL-7. Despite these intrinsic defects, most of the age-related changes in B lymphocytes appear to be reflective of aging T lymphocytes. There is a constant decrease in the amount and affinity of antibody produced by aged animals (Price and Makinodan 1972), accompanied by age-associated increases in autoantibody production (Viale et al. 1994). The decline in antigen responsiveness associated with aging has been characterized in both qualitative and quantitative terms (Schulze and Goidl 1991; Price and Makinodan 1972). The magnitude of responses to both thymic-independent and thymic-dependent antigens are depressed. Furthermore, in the aged, the expressed antibody repertoire is principally composed of low-affinity antibodies with a decrease in, or absence of, medium- and high-affinity antibodies. Along with this lack of maturation in antigen affinity, there occurs a concomitant change in the expressed repertoire of antibodies to a given antigen. Auto-anti-idiotypic antibodies produced during the normal immune response of the aged animal are markedly enhanced when compared with those seen in the immune responses of younger adults. This abnormality is accompanied by a rise in titers of autoantibodies and a gradual increase in total serum immunoglobulin concentration.

Some of the molecular genetic abnormalities responsible for these alterations have also been described. Aging mice have been found to have higher frequencies of peripheral mature B cells utilizing restricted variable gene (VH) families. This suggests that older animals express less diversified antibody repertoires as a consequence of reduced B-cell precursors and increased peripheral selection (Viale et al. 1994). This restricted gene usage may contribute to the increase in autoimmunoreactivity noted during aging. Although CD5+ B cells have been associated with immunereactive populations, no significant differences in the frequency of CD5+ B cells have been observed during aging.

A mechanism postulated for the decrease in VH gene usage is the progressive decline in expression of recombination-activating gene 1 (*RAG-1*). This gene is expressed in early pre-B lymphocytes, where it is involved in the process of recombination and rearrangement of immunoglobulin gene segments to produce mature immunoglobulin. *RAG-1* messenger RNA is expressed by B-cell precursors and in mouse bone marrow increases during the first 2 months of life to reach a maximum level at 2 months of age (Ben-Yehuda et al. 1994a). This level is maintained until adulthood, where levels progressively decrease. A decrease in *RAG-1* gene expression is directly correlated with a loss of antigen diversity within the immunoglobulin gene family (Ben-Yehuda et al. 1994b). This may explain why, with increasing age, the antibody response becomes progressively more dominated by IgM and low-affinity antibody, with decreased immunoglobulin class switching and decreased somatic mutation. This abnormality also affects T-cell function, as shown by studies in nude mice (Ben-Yehuda et al. 1994a). Transfer of young T cells is capable of restoring full antigen diversity and *RAG-1* gene expression to bone marrow cells.

Thus, both extrinsic and intrinsic changes in bone marrow B cells occur with aging. The number of B-cell progenitors is decreased. Changes in regulatory mechanisms, predominantly stromal cell and T-cell function, are the major factors responsible for the major decline in the B-cell immune response with age (Ghia et al. 2000).

The interactions of B-cell production and differentiation and thymic involution remain to be elucidated.

Conclusions

While many defects in hematopoiesis have been ascribed to the aging process, their specificity remains controversial. The difficulty in assessing functional abnormalities is in part related to the coexistence of other disease processes in the aging population. However, more importantly, it is the complex interactions between normal stem cells and their progenitors, the bone marrow stroma, and the immune system (both T and B lymphocytes), as well as the multitude of cytokines produced, which contribute to a vast interactive network. While multiple studies in mice and other rodents have attempted to dissect this complex process, human studies must confirm these findings. The importance of these studies cannot be underestimated, since an understanding of the physiology of hematopoiesis is paramount to the construction of less toxic and more effective therapies for the aging patient population.

by many physiologic changes which can impact the pharmacology, pharmacokinetics, and pharmacodynamics of medications. Moreover, older patients tend to accumulate medications over time, leading to polypharmacy (PP). Polypharmacy is a "disease" that has many risk factors and causes which can potentially lead to poor outcomes. Deprescribing, or the process of systematically reducing or discontinuing drugs, has been deemed an effective "cure" for PP. Older patients with cancer are particularly susceptible to adverse outcomes from PP and potentially inappropriate medications (PIMs). This chapter describes the impact of aging and cancer on geriatric pharmacotherapy as well as the incidence and definitions of PP and PIMs in the context of geriatric oncology. Finally, processes and models of deprescribing that can be applied to older patients with cancer are discussed.

Deprescribing · Polypharmacy · Geriatrics · Geriatric oncology

Introduction

Advanced age is the number one risk factor for the development of cancer (McIntyre 2016). As a result, older adults (≥65 years old) represent the majority of patients with cancer globally. By 2030, around 70% of all cancer diagnoses will be made in adults 65 years and older (NCCN 2015). Older patients are often less fit and, in general, tolerate medical therapies poorly. Advanced age is accompanied by many physiologic changes which can impact the pharmacology, pharmacokinetics (PK), and pharmacodynamics (PD) of medications. Moreover, older patients tend to accumulate medications over time, leading to polypharmacy (PP). Drugs for chronic disease management, symptomatic management, and prevention of treatment induced toxicities are often used alongside anticancer therapies. The complex interplay between PP, physiologic changes of aging, and competing comorbidities all add to the risk of chemotherapy toxicities, poorer quality of life, and less than ideal patient outcomes.

Polypharmacy is a geriatric syndrome that has been defined many ways. The most commonly used definition of PP is the use of five or more medications on a regular basis (Maggiore et al. 2010). This definition is easily incorporated into daily practice but may not capture the true impact of PP on patient care and outcomes. Other terms commonly used to define PP include potentially inappropriate medications (PIMs), medication overuse, medication related problems, and medication underuse. Polypharmacy, especially in the setting of comorbidity, can lead to adverse drug effects, drug-drug interactions, drug-nutrient interactions, nonadherence (i.e., early discontinuation of chemotherapy), and increased health care utilization (Maggiore et al. 2010). The use of medication screening tools to assess PP in older patients with cancer has recently been summarized in detail (Whitman et al. 2016a). The 2015 Beers Criteria, Screening Tool to Alert Doctors to Right Treatment/Screening Tool of Older Persons' Prescriptions (START/STOPP), and the Medication Appropriateness Index (MAI) have each been endorsed by the American Geriatrics Society and discussed within the National Comprehensive Cancer Network's (NCCN) Clinical Practice Guidelines for Older Adult Oncology. There is a lack of consensus on the best method to define and evaluate PP and PIMs in older patients with cancer.

Currently, health care providers are challenged with managing patients' chronic disease states in the setting of cancer. Patients with diabetes, hypertension, chronic obstructive pulmonary disease (COPD), arthritis, gastroesophageal reflux disease (GERD), and other complex disease states are provided medication therapies that are guideline-driven and often managed by specific providers. Drugs given for chronic diseases often interact unpredictably with chemotherapy and can result in increased toxicity. Moreover, considerations for reducing PP and pill burden in older patients with cancer and in patients with a limited life expectancy are often overlooked. An effective geriatric model that can be applied to older patients with cancer has been developed. The

authors describe a framework of evaluating each medication by considering the time-to-benefit, patients' life-expectancy, goals of therapy, and purpose of therapy (curative versus palliative) (Holmes et al. 2006). Furthermore, deprescribing has been touted as an effective way to minimize PP, especially for older patients with cancer; deprescribing will be discussed and explored later in this chapter.

This chapter will review basic tenants of pharmacology, PK, and PD that are specific to geriatric patients. Additionally, the definitions, incidence, assessment, and management of PP and PIMs in older cancer patients will be extensively reviewed. Finally, the role of deprescribing will be discussed in the context of geriatric oncology.

General Pharmacotherapy Considerations in Geriatric Oncology

Both chronological age and functional age have been used to define elderly patients. Regardless of this definition, as individuals age they have expected physiological changes that can impact drug therapy. These progressive impairments and reduced functional reserve impact multiple systems and organs such as the gastrointestinal (GI) tract, kidneys, liver, cardiovascular, musculoskeletal, and central nervous system (CNS). Older patients with cancer, in particular, may have accelerated changes in these parameters due to a number of reasons (e.g., chemotherapy exposure, antimicrobial use, PP, frailty) (Shi et al. 2008). Moreover, older patients with cancer with comorbid conditions have exaggerated changes in PK and PD. These age-related changes can significantly impact the way our bodies handle medications (i.e., PK) and the way medications impact our bodies (i.e., PD). All of these changes affect choice, frequency, and dosing during drug administration. Common PK considerations in medication therapy include drug absorption, distribution, metabolism, and elimination (i.e., ADME). Each of these factors can impact or be impacted by chemotherapy, supportive medications, and preventative drug use. Additionally, PP and PIM use add an additional layer of complexity due to unclear interactions with physiologic changes from aging and drug adverse effects; the risks of adverse drug effects increase exponentially with the number of medications. Specifically, the risk of an older adult experiencing an adverse drug effect is 35% and 82% when exposed to $\geq$5 and $\geq$ 7 medications, respectively (Cashman et al. 2010; Sokol et al. 2007). Many adverse effects can be mistaken as symptoms from an existing malignancy or perceived as cancer progression (Riechelmann et al. 2009). Physiologic changes, PP, and PIM use all need to be considered when evaluating older patients with cancer.

Absorption

Changes associated with absorption are primarily driven by alterations in the GI tract. Gastric pH tends to increase with aging due to natural changes (i.e., reduced secretion of digestive enzymes and gastric acid) or due to chronic use of acid suppressive therapies (e.g., proton pump inhibitors [PPI], antacids); chronic PPI use is common in older cancer patients who may have GI symptoms associated with their underlying malignancy. Moreover, numerous medications used in the setting of cancer require an acidic pH for optimal absorption. For example, oral chemotherapy agents such as dabrafenib, dasatanib, erlotinib, gefitinib, and vismodegib all require acidic environments for absorption and it is recommended to avoid chronic acid suppressive therapy; this is particularly significant because poor absorption can lead to suboptimal drug levels and poor outcomes (Segal et al. 2014). Likewise, other supportive medications used in oncology requiring an acidic pH include some azole antifungals (i.e., itraconazole) and ferrous sulfate. Intestinal atrophy can be a contributor to decreased gastric acid secretion but also may lead to a general decrease in bowel surface area resulting in less drug absorption (Shi et al. 2008).

Other factors contributing to a decrease in GI absorption include reduced splanchnic blood flow, decreased GI motility (impaired peristalsis and colonic transit), and slightly delayed gastric emptying (Shi et al. 2008). Changes in motility

along many sites of the GI tract can be troubling in older adults, especially in the setting of added PP and adverse effects. For example, older cancer patients taking opioids for cancer-related pain can expect additional decreases in GI motility resulting in constipation. This, in turn, can lead to greater time for drug accumulation in the stomach and small intestines possibly resulting in higher drug levels and an amplification of PD drug effects.

In general, passive diffusion of smaller drug therapy molecules remains unchanged in the elderly, but there may be a decrease in active transport resulting in a decrease in bioavailability. Absorption of the nutrients calcium, vitamin B-12, iron, and glucose may be reduced with aging (Mangoni and Jackson 2004). In general, drug transport effects seem to be minimal and of no particular clinical significance (McLean and Le Couteur 2004).

Finally, considerations relating to drug absorption that are particularly relevant to older adults with cancer include transdermal and subcutaneous drug administration, swallowing difficulties, poor nutrition, and the impact of feeding tubes on drug variability (Wooten 2012). Age-related skin changes, reduced muscle mass (sarcopenia), and general frailty can all impact transdermal and subcutaneous absorption. Older cancer patients are offered therapies such as transdermal opioids (e.g., fentanyl patches), hormone therapies, anticoagulation, and other topical therapies. Poor muscle tone and cachexia can prevent use of these therapies because of erratic or insufficient drug absorption. There is also the potential for both local and systemic reactions due to changes in absorption (Shi et al. 2008). Swallowing difficulties is also a barrier for drug therapy adherence and attainment of appropriate drug levels; this can lead to poor outcomes, especially for anticancer therapies. Poor nutrition may lead to decreases in drug transport cofactors that assist in active transport across GI mucosa; the significance of these changes remains unclear. Feeding tubes can be a barrier to drug absorption due to inappropriate drug-tube binding (e.g., phenytoin). Likewise, patients that administer medications via gastrostomy tubes or jejunostomy tubes may have issues with losing dignity and embarrassment, especially if drug administration occurs frequently throughout the day without much privacy.

Distribution

Drug distribution is determined by factors such as drug clearance, dose, plasma protein binding, red blood cell viability, and changes in the body's adiposity, total body water, and muscle tone. Body fat generally increases by about 20 to 40% and total body water and lean body mass decrease by 10% with advancing age (Shi et al. 2008). As a result of this change in fat-water distribution, drugs that are more lipophilic (e.g., diazepam) may have a larger volume of distribution into tissues resulting in a longer drug half-life; lipophilic drugs with actions in the CNS in elderly patients may be particularly troublesome. In contrast, hydrophilic drugs such as digoxin and atenolol have smaller volumes of distribution; thus, these drugs concentrate in the plasma requiring lower doses in elderly patients. Of note, patients with cancer can have altered drug distribution due to edema from their cancer therapies or from their malignancy (e.g., third spacing). Older cancer patients typically have less bone marrow fat and bone marrow reserve (Hurria and Lichtman 2008). This is often due to myelosuppressive cancers (e.g., acute myeloid leukemia), chemotherapy, and/or radiation. As a result, older patients are at an increased risk of myelosuppression and its accompanied complications.

Changes in plasma protein binding associated with aging are generally insignificant. Though coupled with drug interactions and changes in plasma protein due to comorbidities (particularly cancer and malnutrition), physiological changes become relevant (doxorubicin, etoposide, and taxanes are highly plasma protein bound). Albumin is the most common site of plasma protein binding for medications. Albumin concentrations typically decrease by about 10% or stay the same with aging while alpha-1-acid glycoprotein tends to increase with age; alpha-1-acid glycoprotein changes are likely due to increased inflammation associated with aging. Decreased albumin can

increase unbound drug and increase toxicity, especially for drugs with a low therapeutic index (Shi et al. 2008). Anemia and poor nutrition in elderly cancer patients can effects quantity and quality of red blood cells. This is important in the chemotherapy context because agents such as anthracyclines and taxanes are transported by red blood cells; therefore, effects from chemotherapy could be unpredictable (i.e., increased toxicity and/or decrease efficacy) (Hurria and Lichtman 2008).

Metabolism

A change in the ability of older adults to hepatically metabolize medications is the second most clinically meaningful of the PK effects, after renal elimination. Older adults tend to have a decrease in hepatic mass and blood flow of about 20–30% and 20–50%, respectively. These changes lead to reduced "first-pass" metabolism (Mangoni and Jackson 2004). Metabolism of drugs in the liver is primarily dependent on metabolizing enzymes and hepatic perfusion. Protein binding also plays a role in drug metabolism; more unbound drug (due to reduced plasma protein binding) increases the amount of drug clearance through the liver. The majority of drugs metabolized in the liver undergo phase I metabolism through the cytochrome (CYP)-P450 system (i.e., oxidation, hydrolysis). A smaller but still significant percentage of medications undergo phase II metabolism. In phase II metabolism, polar molecules are added to drugs (i.e., glucoronidation) in order to increase molecular weight, hydrophilicity, and, ultimately, clearance through the kidneys (Wooten 2012).

Phase I metabolism is more likely to be impaired in the elderly with as much as a 30% reduction in metabolizing enzymes; this is due to possible decreased enzyme synthesis as well as reduced liver volume and blood flow (McLean and Le Couteur 2004). Drugs that undergo phase I metabolism can have several negative consequences in older patients with cancer. Firstly, anticancer agents can have reduced clearance and an extended half-life, leading to increased toxicities. For example, paclitaxel is metabolized by CYP3A4, the major phase I drug metabolism enzyme. If there are less enzymes as a result of aging or less metabolic activity due to drug-drug interactions or pharmacogenomic changes, paclitaxel-induced toxicities, such as neuropathies, can be exaggerated. Secondly, anticancer agents that require activation by phase I enzymes ("pro-drugs") can be impacted. Tamoxifen requires activation by CYP2D6 to an active metabolite, endoxifen. Reduction in this conversion to an active metabolite may reduce efficacy. Though in vitro testing has not provided reasonable evidence that CYP2D6 activity is reduced with aging, this still may be clinically meaningful (McClean and Le Couteur 2004). There are inadequate data regarding anticancer dose adjustments in the setting of hepatic impairment and age-related changes.

Efflux transporters that are vital to drug clearance should also be considered. P-glycoprotein (P-gp) is an essential efflux transporter that is expressed in intestinal tissue, hepatocytes, and in the blood-brain barrier. These transporters act as gate-keepers to prevent inappropriate xenobiotics from entering vital organs and tissue spaces. It is unclear whether there are significant age-related changes in P-gp concentration. Drug interactions and pharmacogenomic changes in P-gp can still impact drug therapy, particularly in older patients (McClean and Le Couteur 2004).

Elimination

Aging also has a significant impact on kidney function. Older patients have a decrease in renal mass, blood flow, and the size and number of functioning nephrons. Also, older patients are sensitive to drug therapies, such as beta blockers and vasodilators, which can reduce blood flow to the kidneys. Renal mass decreases by 25–30% with aging. No clearly defined cut-point has been established to describe specific time points in renal mass decline; each individual patient's renal function is somewhat variable. In contrast, renal blood flow consistently declines about 1% or 0.75 to 1 ml/min per year after the age of 40 (Hurria and Lichtman 2008; McLean and Le

Couteur 2004; Shi et al. 2008). Age-related changes are important, but confounders like hypertension, vascular disease, diabetes mellitus, and nephrotoxic drug therapies most likely play a more important role (McClean and Le Couteur 2004). Prediction of renal function in elderly patients may also be difficult due to changes in muscle mass and falsely elevated creatinine levels; therefore, serum creatinine should not be used as the sole marker for renal function in elderly patients (Lichtman and Boparai 2008). Various PK equations have been developed to predict renal function in the general population; age-related changes confound the applicability of these equations. Examples of common tools include Cockcroft/Gault, Jelliffe, Wright, and the modification of diet in renal disease (MDRD) (Charhon et al. 2012).

Impairments in renal function can impart difficulties in anticancer drug administration. Many chemotherapy and targeted agents require adjustment with renal impairment (i.e., cisplatin, carboplatin, capecitabine, melphalan, and methotrexate). There are some established guidelines for specific drugs, but the majority of recommendations are not evidence-based and drug labeling lacks clear guidance. Again, PP and comorbidities can add to drug toxicities when considered alongside older adults' progressive decline in renal function.

General Pharmacodynamic Principles

Pharmacodynamics is defined as the science of how drugs affect the body (Wooten 2012). Medications exert their effects through drug receptors resulting in a therapeutic response. Older patients with cancer are susceptible to adverse effects due to PD changes associated with aging. As with PK, the presence of multiple comorbidities, frailty, drug-drug interactions, and PP can potentiate pharmacologic responses in negative ways. Older patients become more sensitive to particular medication classes such as cardiovascular and CNS acting agents. As the body ages, there may be fluctuations in drug affinities at particular receptor sites, changes in postreceptor signals, and disruption of physiologic equilibrium (i.e., baroreceptor reflex). Likewise, the number of receptor sites may change (Shi et al. 2008). Both drug efficacy and toxicities are impacted by PD changes.

Specific adverse effects are notable and worth mentioning in older adults. Administration of anticholinergic or antimuscarinic agents (e.g., diphenhydramine, amitriptyline, doxepin, oxybutynin) to older patients can result in dizziness, orthostatic hypotension, dry mouth, falls, urinary retention, tachycardia, agitation, and delirium. The negative consequences of these classes of medications can predispose older patients with cancer to poor tolerance to anticancer therapies. Cardiovascular medications, particularly antihypertensives, can also increase older adults' risk of adverse drug effects such a fatigue, dizziness, orthostatic hypotension, and falls. Beta-blockers are reported to be less effective in terms of heart rate and blood pressure control due to changes in receptor selectivity (Rossello et al. 2015). Though, older patients on beta-blocker therapy still commonly report bothersome side effects, such as fatigue. Medications that act through the CNS are commonly used as supportive therapies in older cancer patients (i.e., benzodiazepines for anticipatory nausea and vomiting; prochlorperazine for nausea; diphenoxylate and atropine for diarrhea). Older adults can be extremely sensitive to these therapies and caution is warranted. It is important to monitor for falls, excessive sedation, and other geriatric syndromes for patients taking CNS medications (Mangoni and Jackson 2004).

Pharmacologic effects in older adults can be unpredictable; therefore, starting with lower doses and titrating as appropriate is always good practice. Significant morbidity can result from inappropriate drug therapy in older adults. Likewise, studies have shown that long term use of anticholinergic medications, particularly in older adults, may result in increased brain atrophy, dysfunction, and general clinical decline (Risacher et al. 2016). Moreover, in the context of older cancer patients, response to anticancer therapies may be exaggerated as well. Tools looking to predict chemotherapy toxicity utilize patient specific variables that overlap with PK and PD principles (e.g., anemia). Finally, information on PK, PD,

Table 1 Summary of pharmacokinetic changes in older cancer patients

Parameter	Change
Absorption	Increased gastric pH Intestinal atrophy Reduced bowel surface area Reduced splanchnic blood flow Decreased GI motility Slightly delayed gastric emptying Decreased active drug transport Reduced absorption of vital nutrients (calcium, vitamin B12) Reduced subcutaneous tissue and muscle mass Swallowing difficulties Poor nutrition (reduced active transport cofactors) Presence of feeding tubes
Distribution	Increased body fat Decreased total body water Decreased lean body mass Increased general edema (cancer or drug related) Reduced bone marrow fat and reserve Decreased albumin Increased alpha-1-acid glycoprotein Anemia (reduced quantity of red blood cells)
Metabolism	Reduced hepatic mass Decreased hepatic blood flow Decreased "first-pass" metabolism Reduced phase I metabolizing enzymes (CYP450) Variability in efflux transporter expression (P-glycoprotein) Pharmacogenomic effects (single nucleotide polymorphisms)
Elimination	Reduced kidney mass Reduced renal blood flow Decreased size and function of nephrons Decreased creatinine clearance

PP, and potential chemotherapy toxicities should be used in conjunction with a comprehensive geriatric assessment (CGA) for older cancer patients (Decoster et al. 2015) (Table 1).

Polypharmacy in Older Cancer Patients

In comparison to the general geriatric population, there is currently a paucity of data describing PP and PIMs in older cancer patients. With an increase in complex pharmacotherapy and the advances in targeted therapies and immunotherapies in oncology, the concepts of PP are becoming ever more important. While the definitions of PP will be described extensively below, it is important for readers to view PP as a "disease" (Garfinkel et al. 2015). As with other disease states, PP has risk factors, causes, and requires appropriate assessment and treatment. Likewise, PP can result in impaired "normal" functioning and is distinguished by signs and symptoms (e.g., drug-drug interactions, falls). This section describes PP and PIMs in the context of geriatric oncology and serves to guide clinicians when evaluating their patients holistically, especially in alignment with a CGA (Image 1).

Definitions and Incidence of Polypharmacy

In a recent review, Bushardt et al. (2008) provide 24 definitions of polypharmacy that are currently described in the literature. This variability in definitions sheds light on the lack of consistency in the general population. The incidence of PP in general community-dwelling older patients ranges from 13% to 92% (Maggiore et al. 2010). Based on studies in older cancer patients, PP incidence is about 60% (range, 29–96%); Table 2 summarizes the literature on PP and PIM incidence in older cancer patients. Currently, there is no concrete, agreed upon definition for PP in older cancer patients. Specifically, LeBlanc et al. (2015) have emphasized the need for standardized measures and definitions of PP for this population. Maggiore et al. (2010) also highlighted the importance of developing a geriatric oncology-centric definition. The studies described here help to fill this gap of uncertainty and guide clinicians in practice. Table 3 provides a compilation of specific definitions for PP that have been published in the geriatric oncology literature.

As discussed above, the most commonly referenced definition of PP in older cancer patients is the regular use of five or more medications (Park et al. 2016). This number includes prescription, over-the-counter (OTC) products, dietary

Image 1 Illustrative representation of polypharmacy. Ms. K takes a total of 13 different medications and 20 "pills" daily. She spends on average 7 h each week sorting and taking her medications

supplements, and complementary and alternative medicines (CAM). Using a specific medication cut-point to define PP has many advantages and disadvantages. Firstly, the use of a specific number is easily incorporated into clinical practice. Also, it has been shown that medication number itself is a good indicator for nonadherence versus patient age alone (Corcoran 1997). The risk of drug-drug interactions and adverse drug effects increase exponentially with the number of medications (Sokol et al. 2007). Several studies looking at PP and their relationship to specific outcomes found associations between the use of five or more medications and the presence of frailty, comorbid conditions, and impaired physical functioning (Turner et al. 2014). Moreover, in a study evaluating PP in cancer patients over the age of 65, the authors found that in patients taking four or more medications, their understanding of drug indication, dose, and frequency of use was impaired (Si et al. 2012).

A landmark study looking at PP cut-points in older cancer patients helps to establish a PP definition, particularly for clinicians wanting to use PP as a referral trigger. This study was designed to assess whether PP could predict clinically important adverse events. The authors found that taking 3.5 or 5.5 medications correlated with increased patient exhaustion and falls, respectively. Moreover, taking 6.5 medications or more predisposed patients to frailty, impaired physical functioning, and reduced performance status. The authors note that they did not look at specific medication classes and their associated risk (i.e., anticholinergic burden) or the presence of comorbid diseases (Turner et al. 2015). Nevertheless, this study does provide reasonable evidence to use a cut-point of five or more medications in this population.

In contrast, a disadvantage to using medication quantity for the sole marker of PP has been alluded to in the previously described study. Medication appropriateness, or the use of unnecessary medications, may be an even better predictor of negative patient outcomes. For example, if an older patient with metastatic colon cancer is taking diphenhydramine for insomnia, many would consider this PP due to its inappropriateness, even if this was their only medication. Diphenhydramine increases the risk of falls, sedation, and other anticholinergic effects. Therefore, medication quantity does not always predict poor outcomes. Considering appropriateness encourages the clinician to evaluate the risk versus benefits, particularly when safer alternatives may exist. Likewise, a quantitative definition disregards the potential for harm in an extremely vulnerable population (Sharma et al. 2016). A recent study found a statistically significant association with PIM use (as defined by the Beers Criteria) and the presence

Table 2 Summary of polypharmacy and potentially inappropriate medication incidence

Study	Date	Definitions	PP %	PIMs %	Pertinent results/outcomes	Other
Sokol et al.	2007	NR	NR	NR	Average number of medications = 9.1	NR
Riechelmann et al.	2009	PIMs as unnecessary or duplicate	NR	22	Assessment by palliative care team reduced PIMs by 2%	NR
Flood et al.	2009	NR	NR	21	32% of patients took 9 or more medications	NR
Puts et al.	2009	PP ≥5 meds Drug related problems or PIMS – *Vigilance Sante criteria*	56.3	47.6	PP and age ≥ 76 were associated with having one or more potential drug problem; half of the problems were found to be of moderate severity	As needed medications were not included
Prithviraj et al.	2012	PP ≥ 5 meds PIMS based on Beers Criteria (present or not present)	80	41	Average number of medications = 7.3; PP linked to IADL disability; score ≥ 3 on VES-13; having ≥5 comorbidities; and to be prescribed a Beers list medication – being underweight was also associated with PP	Patients with a new cancer diagnosis
Jorgensen et al.	2012	PP – no (0–1), minor (Barnett and Jabraj 2017; Bergen et al. 2016; Bjerre et al. 2015), or major (≥5)	34.7	NR	More PP up to 18 months prior to cancer diagnosis compared to controls – Analgesics, acid suppressive therapies, and antibiotics	NR
Yeoh et al.	2013	Drug-related problems (DRPs) or PIMs	NR	91.5	3 drug related problems per patient; 92% of the DRPs were resolved by the MTM pharmacist; increase in general understanding of treatment goals occurred post-MTM	NR
Turner et al.	2014	PP ≥ 5 meds	57	NR	Association between PP and frailty (pre-frail and frail); PP associated with Charlson Comorbidity Index and impaired physical functioning	Mean number of drugs 5.7
Saarelainen et al.	2014	PP ≥ 5 PIM – Use of a Beers Criteria med	NR	26.5	PIM user more likely to be female, age 75–79, use ≥5 meds, be frail, high distress score ≥ 5, and falls in previous 6 months; 52.5% of frail patients were using ≥1 PIM (association between PIM use and frailty); 82.4% PIMs using taking ≥5 meds	Mean number of meds 5.7; mean PIMs 0.31

PP polypharmacy; *PIMs* potentially inappropriate medications; *NR* not reported; *START/STOPP* Screening Tool to Alert Doctors to Right Treatment/Screening Tool of Older Persons' Prescriptions; *IADL* instrumental activities of daily living; *VES-13* vulnerable elders survey; *MTM* medication therapy management; *HEDIS DAE* Healthcare Effectiveness Data and Information Set Drugs to Avoid in the Elderly; *EPP* excessive polypharmacy; *Rx* prescription; *OTC* over-the-counter; *PH* prolonged hospitalizations; *CCB* calcium channel blockers

of frailty. The most common PIMs in this study included benzodiazepines, tricyclic antidepressants, alpha blockers, and pro-kinetic agents (Saarelainen et al. 2014).

Factors Influencing Polypharmacy in Older Cancer Patients

The "disease" of PP has many risk factors. Older patients with cancer often have many concomitant comorbid conditions. More than 80% of older cancer patients have at least one chronic disease at the time of their diagnosis (Corcoran 1997). Of the patients who take preventative medications, half report having adverse effects attributable to these drugs (Lees and Chan 2011). One study in older palliative cancer patients found that, on average, patients took seven preventative medications (Lindsay et al. 2014). Along the same lines, older patients often see a plethora of physicians for their other, noncancer conditions. Specialists often prescribe based off of clinical practice guidelines that have a one-disease, one-drug focus. Over 50% of older cancer patients receive prescriptions by more than one provider and 31% use more than one pharmacy (Sokol et al. 2007). Prescriptions obtained from several pharmacies can lead to incomplete medication lists, duplication of therapies, and increased costs. Particularly relevant to older cancer patients is the lack of primary care provider coordination (Balducci et al. 2013).

Table 3 Common definitions of polypharmacy

Definitions of polypharmacy in geriatric oncology[a]
Simultaneous use of two drugs or more
Long-term concomitant intake of two or more medications
Use of four or more medications
Use of five or more medications
Use of ten or more medications (excessive polypharmacy or hyperpolypharmacy)
Use of a large number of medications
Taking more drugs than clinically warranted
Use of several drugs concurrently for the treatment of one or more coexisting diseases
Unnecessary or inappropriate medications
Medication underuse (the indicated drug is not used)
Medication duplication (similar medications are used)
Medications without a clear indication
Presence of drug-drug interactions

[a]These definitions should not be restricted to prescribed medications. Over-the-counter (OTC), herbal medicines, and supplements should be included

Primary care providers can serve as a medication "hub" where the patients' whole clinical picture is evaluated. The lack of a primary care provider may potentiate PP, miscommunication between patients and providers, and patients' poor understanding of their drug therapies.

Transitions of care are large contributors to PP in this population. In a study evaluating prescription knowledge among older cancer patients, only 5% after hospital discharge could accurately identify drug names, indications, doses, and frequency. Also, up to 40% of patients were discharged on a medication no longer clinically indicated (e.g., PPI while no longer on steroids). Moreover, during subsequent office visits, almost a third of patients failed to report at least one medication and two-thirds of patients did not review for any regimen changes associated with their new prescriptions (Si et al. 2012).

Patients with cancer are exposed to anticancer agents and supportive care medications that often interact with preventative therapies. Also, 30–50% of older cancer patients use at least one CAM therapy, which also adds to PP and potential medication-related problems (LeBlanc et al. 2015; Nightingale et al. 2015a; Prithviraj et al. 2012). Prescribing cascades are common in elderly cancer patients. This occurs when medication adverse effects go unrecognized and are subsequently treated with additional drug therapies. Figure 1 reviews a common prescribing cascade in older cancer patients. The oncologist should adopt the motto, *assume every symptom is a drug adverse effect until proven otherwise*, into every day practice. Obtaining the root cause of adverse effects and new symptoms can be difficult due to their nonspecific nature. Providers can mistake adverse drug effects as cancer-related symptoms and, even more importantly, patients may perceive new symptoms as cancer progression (Riechelmann et al. 2009).

In a study of newly diagnosed older cancer patients, 62% experienced a drug-related problem (Turner et al. 2014). Similarly, a study in elderly Danish cancer patients found that there was a significant increase in PP up to 18 months prior to a cancer diagnosis. Notably, PP was due to an increase in opioid therapies, acid-suppressive agents, and antibiotics within 6 months prior to diagnosis. The authors stratified PP in no PP (0–1 medications), minor PP (2–4 medications), and major PP ($\geq$5 medications). Minor PP occurred in 34% of patient cases versus 29.9% of controls. Likewise, major PP occurred in 24.3% of patient cases versus 17.4% of controls. A diagnosis of lung cancer had a strong association with PP (40.9% for cases versus 24.9% for controls). The phenomenon of PP preceding a cancer diagnosis is likely due to treatment of nonspecific cancer-related symptoms (Jorgensen et al. 2012). Therefore, the presence of PP, in addition to the standard cancer work up, could be utilized as an additional tool in patient assessment.

A number of other factors influencing PP include patient nonadherence, drug costs, hoarding medications, and medication "catch-up." Nonadherence can result in poor therapeutic response (e.g., elevated blood pressure); as a result, drug doses may be inappropriately increased. Supra-therapeutic doses can result in untoward adverse effects (e.g., orthostatic hypotension and falls in the case of antihypertensives). Other factors affecting medication adherence include patients' health literacy, hearing acuity, vision, memory, and poor medication scheduling (Corcoran 1997). Cost may be a factor leading

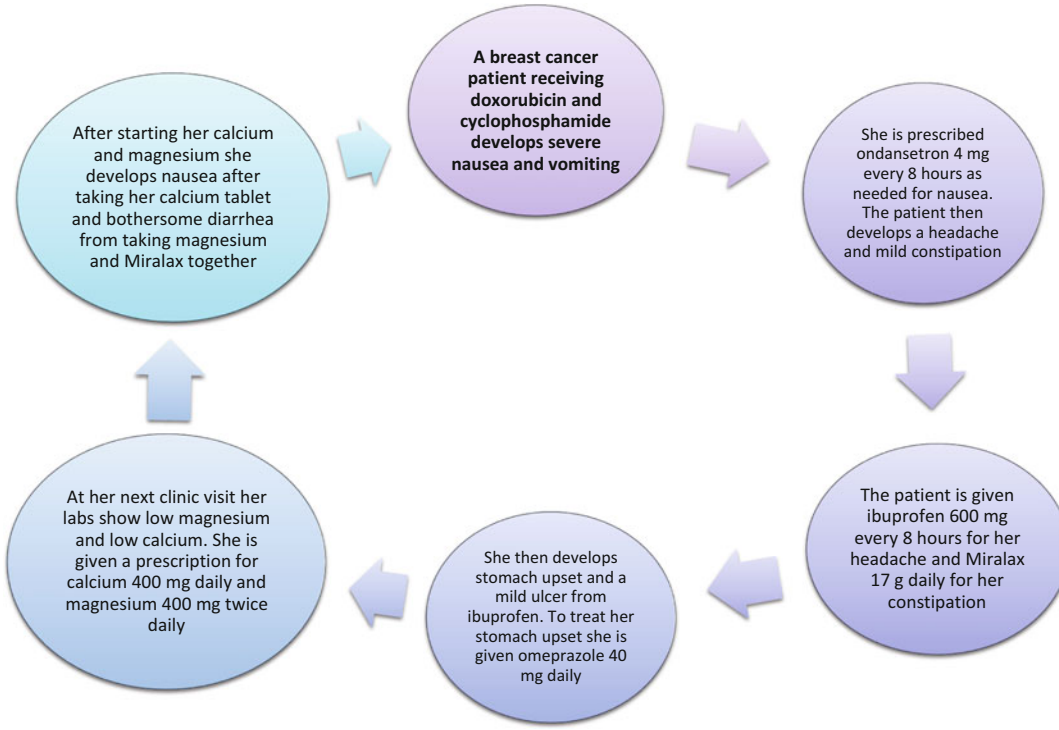

Fig. 1 Geriatric prescribing cascade

patients to either not take their medications as prescribed or "hoard" medications and subsequently take excessive doses or combinations at times when symptoms become prevalent (i.e., dose "catch-up" phenomenon) (Corcoran 1997). For example, patients taking long acting opioids can deviate from their suggested schedule and, during times of pain crises, patients may take extra doses of long-acting and short-acting opioids; this can lead to constipation, falls, sedation, and even respiratory depression (Marvin et al. 2017).

Medical culture and direct-to-consumer advertising has created the notion of "a pill for every ill" (Corcoran 1997). This is particularly important for older cancer patients who have comorbid conditions, are vulnerable to adverse effects, are frail, and have a high symptom burden from their underlying malignancy and cancer therapies. Patients often expect a new prescription during each encounter, but providers should attempt to rule out other causes prior to starting new therapies (e.g., prescribing cascades, other iatrogenic causes, temporary side effects of treatment) (Straand and Sandvik 2001). In addition to common geriatric slogans (e.g., "start low and go slow"), the philosophy of "*primum non norcere*" could be interpreted as "do not rush to treat when no treatment is needed." This philosophy should be adopted within the older cancer population. Finally, clinicians' unawareness of their lack of knowledge regarding PP and medication use represents the highest level of risk for their patients (Garfinkel et al. 2015).

Evaluating Polypharmacy and Potentially Inappropriate Medication Use

An accurate medication list is the first step in identifying PP and PIMs. While no one study has determined the ideal individual to complete a comprehensive medication review in this population, studies support the involvement of a clinical pharmacist in the multidisciplinary

team (Balducci et al. 2013; Delien et al. 2016; Grodzicki-Korc et al. 2014). A medication history should include a "brown bag" assessment where patients bring all of their prescription, OTC, and CAM therapies for physical review (Corcoran 1997). The clinic environment is ideal for this type of review. Clinicians should obtain information on the number of prescribers, number of pharmacies utilized, and barriers to drug adherence. A medication review should occur prior to initiation or modification of anticancer therapies, during times of transitions of care, or in the case of new comorbid conditions. There are a number of existing geriatric screening tools to help identify PP and PIMs. A geriatric oncology specific tool has yet to be developed (Whitman et al. 2016a). When screening for PP and PIM use, the overall goal should be to identify medications that are causing side effects, impairing the patient's quality of life, or not improving outcomes. Once identified, the clinician should work alongside the patient and their caregivers to determine the best way to reduce inappropriate medication use. Polypharmacy assessment and management should not be a "one-size fits all" approach and using a combination of screening tools may be required.

Medications Screening Tools for the Older Cancer Patient

A review by Whitman et al. (2016a) describes several implicit and explicit screening tools and how they could be applied to older patients with cancer. Table 4 provides an expanded list of the existing geriatric screening tools (Bulloch and Olin 2014; Whitman et al. 2016a). The NCCN guideline for Older Adult Oncology supports the use of the Beers Criteria, START/STOPP, and the MAI concurrently. Use of certain tools or models, such as the MAI, require a more comprehensive understanding of the patient's current clinical picture, their treatment goals, and the prescribed indication for each therapy (McNeil et al. 2016; Turner et al. 2016). For example, the MAI takes into account aspects such as medication indication, effectiveness, drug-disease interactions, and cost of therapies. A study evaluating PIMs in palliative cancer patients considered several situations as inappropriate: statin therapy without a cardiovascular event in the preceding 12 months; gastric protectants without a history of a GI bleed, peptic ulcer, gastritis, or chronic NSAID use; antihypertensives if blood pressure was less than 90/60 mmHg or symptoms of hypotension; antidiabetic medications used with a fasting blood glucose less than 50 mg/dL or signs of hypoglycemia; or use of a medication without a clear medical indication (Fede et al. 2011). Another implicit medication screening model is the "Good Palliative- Geriatric Practice" (GP-GP) algorithm (Garfinkel and Mangin 2010).

Table 4 Geriatric medication screening methods

Fit for the Aged (FORTA)

[a]Tools that have been applied to older cancer patients

This algorithm has not been specifically applied to older cancer patients, but many of the concepts are relevant; this model will be discussed further in the deprescribing section of this chapter. Drawbacks of implicit tools include more time commitment and less intra-rater reliability (Whitman et al. 2016a).

The goal of each medication assessment should be to ensure that every medication therapy fits the individualized needs and circumstances of the patient (Balducci et al. 2013). Balducci et al. (2013) and Maggiore et al. (2010) describe concise lists of questions to assess PP and PIMs in older cancer patients:

1. Is there a proper indication for each medication?
2. Is the medication achieving the desired effect (e.g., for a pain medication, is the pain controlled?)
3. Does the patient present with nonspecific symptoms (e.g., fatigue, impaired cognition) that may be ascribed to some of the medications?
4. Are the medications prescribed at an appropriate dose?
5. Is there potential for clinically important drug-drug interactions?
6. May some of the drugs interfere with the antineoplastic treatment?
7. What is the risk of drug-tumor interactions?
8. Does the patient adhere to the treatment plan?
9. Are there conditions that needed treatment and at present are left untreated?

A. Perform a careful review of the patient's list of medications, including indications and dosages
B. Directly inquire about over-the-counter and herbal/complementary agents
C. Evaluate in advance the potential interactions between the chemotherapy regimen and other medications to minimize drug interactions and subsequent toxicity; discuss with pharmacy staff where appropriate
D. Consider use of electronic drug databases that may help identify at-risk drugs, drug classes, dosages, and schedules, bearing in mind the limitations of such tools, especially if pharmacy-based support is not readily available or accessible
E. Maintain an open and active line of communication with the patient's other medical providers regarding changes or additions to medication lists
F. Continue to perform routine medication reconciliation at every clinical visit in conjunction with pharmacy and/or nursing staff where appropriate

This nine-question framework and recommendations for PP assessment should be used alongside explicit screening tools to identify the greatest incidence of PP, PIMs, and other medication-related problems. Other useful implicit tools include the Assessing Care of Vulnerable Elders-3 (ACOVE-3), Assessment of Underutilization (AOU), Screening Medications in the Older Drug User (SMOG), Assess, Review, Minimize, Optimize, Reassess (ARMOR) tool, Tool to Improve Medications in the Elderly Via Review (TIMER), and the Systematic Tool to Reduce Inappropriate Prescribing (STRIP) (Bulloch and Olin 2014). Currently, existing evidence supports use of the Beers Criteria, START/STOPP, and the MAI sequentially (Whitman et al. 2016b). Finally, an important question to ask when evaluating for PP and PIMs is "why is the patient on a PIM in the first place? Is it because they have previously failed a safer alternative or because no alternative medication exists?" (Prithviraj et al. 2012).

Consequences of Polypharmacy in Older Cancer Patients

Polypharmacy and PIM use can lead to a number of untoward adverse effects and other negative

Table 5 Polypharmacy and associated outcomes

Potential risks associated with polypharmacy in geriatric oncology	
Impaired physical functioning	Postoperative complications
Grade III-IV chemotherapy toxicities	Cognitive impairment
Frailty	Delirium
Falls	Pill burden
Reduced adherence to oral chemotherapy	Patient financial toxicity
Reduce adherence to essential drugs	Increased global health care costs
Drug-drug interactions	Compromising anticancer therapies (failure of treatment)
Drug-disease interactions	Poor lower extremity function
Increased rate of outpatient visits	Increased mortality
Weight loss	Hip fractures
Impaired balance	Increased length of hospital stay
Increase nursing home admissions	Early discontinuation of anticancer therapies

outcomes. These poor outcomes are the consequence of the "disease" of PP. Table 5 sums up the potential risks associated with PP in the older cancer population. A recent study evaluated the association between PP and PIM use among older adult oncology patients undergoing chemotherapy and their risk of chemotherapy toxicities. The authors found no significant association between the number of medications and chemotherapy toxicities but did see a higher incidence of hospitalizations and early cessation of chemotherapy (Maggiore et al. 2011). Though, a similar study failed to find an association between PP, chemotherapy toxicity, and hospitalization rate (Maggiore et al. 2014). In a population of elderly head and neck cancer patients, PP and PIMs occurred in 29.3% and 24% of patients, respectively, and were associated with clinically meaningful outcomes. Specifically, use of benzodiazepines and calcium channel blockers increased the risk of prolonged hospitalizations and increased the rate of hospital readmission within 2 years (Park et al. 2016).

Health care utilization may increase as a result of PP and PIM use. Patient office visits due to adverse drug events occur in about 60% of patients between the ages of 65 and 74 (Sokol et al. 2007). Likewise, inappropriate medication use in this population has led to an increased rate of nursing home admissions, increased hospital length of stay, more frequent emergency department visits, and an increased rate of visits to outpatient oncology clinics (Lees and Chan 2011). A considerable financial burden is imposed on the patient as well as the health care system as a whole. The term "financial toxicity" has been used to describe real and perceived distress to older cancer patients undergoing active treatments (Lees and Chan 2011; Souza et al. 2014).

A study examining comorbidities in older cancer patients found that the majority of patients experienced anguish due to a side effect of treatment or were inconvenienced in their daily lives to due drug-therapy monitoring. Over 80% of patients in this study took at least one of the following drug classes: antihypertensives, lipid lowering agents, antiplatelets, or bisphosphonates. The most commonly reported adverse events were dizziness on standing (i.e., postural hypotension secondary to low blood pressure), muscle aches, easy bruising, and indigestion or reflux. Patients reported dissatisfaction with drug therapy monitoring (e.g., monthly cholesterol checks, weekly INR monitoring, and daily blood pressure measurements) that resulted in a poor quality of life (Cashman et al. 2010).

Other significant outcomes of interest include falls, frailty, impaired physical functioning, and cognitive impairment (Mossello et al. 2015). Polypharmacy often results in an increased serotonergic and anticholinergic burden. As a result, patients are more likely to have impaired balance and falls. Falls result in significant health care costs and are a leading cause of fatal and nonfatal injuries in older adults (Bergen et al. 2016). As described previously, PP (defined as taking $\geq$5 medications) resulted in a four times higher likelihood of being frail, having impaired physical functioning, and experiencing exhaustion (Turner et al. 2014).

Finally, PP may also be a risk factor for poor adherence to essential therapies. Excessive pill burden and complex dosing may limit patients' willingness to stick to their prescribed regimen,

especially for oral chemotherapy. Oral chemotherapy is effective *only* if patients adhere to their therapy. Rates of oral chemotherapy adherence range from 17% to 98% for patients with breast cancer and hematologic malignancies to 97% for patients with ovarian cancer. Likewise, adherence to other anticancer therapies can be impacted by PP and PIMs in instances when adverse effects cause patients to miss clinic appointments (e.g., falls, hip fractures) or when patients have intolerable side effects from preventative medications (e.g., prescribing cascades) that result in early discontinuation of anticancer therapies. Finally, patients with baseline cognitive impairments are more likely to develop delirium from anticancer therapies and other supportive care medications (McIntyre 2016).

Deprescribing in Older Cancer Patients

Deprescribing has been deemed an effective "cure" or "antidote" for the "disease" of PP (Cassels 2017; Frank and Weir 2014). Deprescribing has been defined several ways but most commonly as the process of reducing or discontinuing drugs, aimed at minimizing PP and improving patient outcomes (Todd et al. 2016b). Importantly, deprescribing should consider existing or potential harms of medications, especially in the context of individual patient values and goals (Scott et al. 2015). The "good prescribing continuum" should consider initiation of drug therapy, monitoring, adjustment, and appropriate medication discontinuation. Clinicians are encouraged to assign drug therapies a "best before" date when initiating drug therapies; this practice serves as a reminder to continuously re-evaluate the necessity and appropriateness of pharmacotherapy (Scott et al. 2015).

Deprescribing studies specific to older adults with cancer are lacking. The majority of studies looking at medication cessation are in patients with limited life expectancy, palliative cancer patients, or in the general geriatric population. One deprescribing-focused study specific to older patients with cancer was conducted in a large academic cancer center. This study evaluated a clinical pharmacist-driven deprescribing model that used several implicit and explicit medication screening tools simultaneously to identify PIMs (Whitman et al. 2016b). Nevertheless, the majority of existing deprescribing frameworks and models can be applied to older cancer patients. The philosophy of deprescribing can be psychologically daunting for both patients and providers. There is often a mismatch of expectations between patients, general care providers, and specialists; therefore, it is essential to review barriers and individual perspectives in regards to deprescribing (Reeve et al. 2013).

Deprescribing Models

Currently, there are three well-validated models that serve to guide clinicians in the deprescribing process. An additional model exists that is specific to the older cancer population that also deserves review. Effective use of these models requires a broad understanding of a patient's full clinical picture. Likewise, simultaneous use of explicit medication screening tools is supported by the literature. Other medication management and deprescribing frameworks exist but are specific to palliative care and patients with terminal illnesses in the end stages of their disease (Lees and Chan 2011; Lindsay et al. 2014; Riechelmann et al. 2009). Moreover, the Choosing Wisely Initiative is an organization aimed at practicing evidence-based medicine, minimizing duplicative therapies, and maximizing the use of truly necessary test procedures, and medications (Sharma et al. 2016). The efforts from this organization are in alignment with the practices of deprescribing and PP reduction. One recommendation by the Choosing Wisely Initiative (2013) advises against prescribing lipid-lowering medications in patients with limited life expectancy. Policy-driven efforts, such as the Choosing Wisely Initiative, are good adjuncts to practice-based deprescribing models.

The first deprescribing model of interest was developed by Holmes et al. (2006). Four factors should be considered when evaluating drug

therapy continuation: the remaining life expectancy of the patient, time until benefit of drug therapies, individual goals of care, and the target of the treatment (e.g., preventative versus palliative). Prognostication of a patient's remaining life expectancy can inform decisions about both prescribing and deprescribing. Patients with a limited life expectancy or advanced illnesses, such as dementia, may have a limited opportunity to obtain benefits from certain medications and medication classes (e.g., statins, bisphosphonates, antihyperglycemics) (Steinman and Hanlon 2010; Stevenson et al. 2004). Likewise, in a study evaluating deprescribing in the last 48 h of life, it was shown that preventative medications were more likely to be discontinued by geriatricians who expected a patient's death. This adds to the evidence that better prognostication can lead to easier decisions about deprescribing. In the same study, it was determined that patients dying from an oncologic disease were also more likely to have medications discontinued compared to patients with general frailty or dementia (Van Den Noortgate et al. 2016). Goals of care assessment should include medication-related goals and overall goals of their disease state. Older patients with cancer are often faced with the choice of using life prolonging medications (i.e., antibiotics) that may impact their quality of life versus medications that only provide comfort. Prioritizing goals such as extension of longevity, reduction in symptoms, minimizing drug therapy costs, and reducing pill burden is an important part of the deprescribing assessment (Steinman and Hanlon 2010). Additional evidence supports the addition of time to harm or number needed to harm (NNH) for a particular medication to this model; this concept is the essence of looking at overall risk versus benefit of individual therapies (Todd et al. 2016b).

The second model uses a five-step process that guides deprescribing. The authors emphasize that deprescribing should not be about denying effective treatment and that the process of deprescribing should be positive and patient-centered. They note the uncertainties and discomfort expressed by many clinicians, especially in regards to stopping chronic medications. They re-iterate the notion that PP is a "disease" and that clinicians should aim to alter the natural history of the "disease" by diagnosing the problem (i.e., PP) and making a therapeutic decision (i.e., withdrawal drug therapies). The authors emphasize that deprescribing conversations may be best accomplished in concordance with a palliative care team (Todd et al. 2016b). The five step process is listed below:

1. Ascertain all drugs the patient is currently taking and the reasons for each one
2. Consider overall risk of drug-induced harm in individual patients in determining the required intensity of deprescribing intervention
3. Assess each drug for its eligibility to be discontinued
4. Prioritize drugs for discontinuation
5. Implement and monitor drug discontinuation regimen

The third model is the Good Palliative-Geriatric Practice (GP-GP) algorithm. Application of this algorithm in clinical practice has provided key evidence that reduction in PP by deprescribing resulted in improved outcomes. This model uses a series of statements to frame discussion with patients and guardians (Garfinkel and Mangin 2010). The algorithm use a "Yes," "No," or "Not sure" framework that guides the clinician. Factors taken into account include evidence-based consensus for drug therapy based on indication, dosing, and possible side effects; the validity and relevancy of the indication based on patient specific factors; known adverse effects that possibly outweigh the benefits of therapy; adverse effects attributable to drug therapy; alternative therapies; and dosing frequency. Based on answers to selected questions, the provider can continue with the same dosing rate, reduce the dose, stop drug therapy, or shift to another drug. In a study applying this algorithm to 64 older adults, it was found that out of 311 medications identified as inappropriate,

286 (92%) were subsequently discontinued. No significant adverse drug events were reported after stopping medications and 84% of patient reported an improvement in general health. Likewise, several patients who stopped unnecessary drug therapies reported improvements in cognitive function, as determined by a Mini-Mental State Examination. An average of 4.2 drugs were stopped per patient and only 2% of medications were restarted.

Finally, a study evaluating deprescribing in a geriatric oncology clinic provides evidence supporting the feasibility of this practice in the older cancer population. A total of 17 older cancer patients (≥65 years old) underwent a comprehensive medication assessment by a clinical pharmacist. Potentially inappropriate medications were identified by applying the 2012 Beers Criteria, STOPP criteria, and the MAI sequentially. The authors utilized medication-condition matching, adverse effects, drug-drug interactions, patient goals, and life expectancy as factors in PIM discontinuation. Patients were taking an average of 11.4 medications and, overall, a total of 73 PIMs were identified. A total of 55 PIMs or three medications per patient were deprescribed by the clinical pharmacist and geriatric oncologist. Upon patient follow-up, the authors noted improvements in several patient reported outcome measures: reduction in fatigue after stopping statins, a decrease in episodes of dizziness and orthostasis after tapering antihypertensives, and subjective reports of improved quality of life. A limitation of this study was that it did not use standard outcome measures. Nevertheless, this is the first study to display real time deprescribing in the older cancer population (Whitman et al. 2016b).

Prioritizing Deprescribing Interventions

One of the most difficult decisions for clinicians is deciding when discussions regarding deprescribing should occur. A study evaluating deprescribing in palliative care patients, caregivers, and health care providers found that patient and caregiver perspectives about medication continuation changed based on the stage of their disease. Prognosis, or patient understanding of their remaining life expectancy, served as a tipping point or "transition" where less importance was placed on certain medications (i.e., preventative versus symptom-focused) (Todd et al. 2016b). This concept has also been named the "brink," or optimal time to discontinue specific medications (Garfinkel and Mangin 2010). Having discussions about deprescribing before the patient has reached this point may result in poor outcomes (Todd et al. 2016b). It has also been shown that focusing on improvement in quality of life and reducing symptom burden is more effective than focusing on pill burden and cost (Steinman and Hanlon 2010). Other studies report that the volume of drug therapy (i.e., pill burden) is in fact an issue, especially in the setting of dysphagia (Todd et al. 2016b).

A number of "red flags" can be considered to help the clinician prioritize which therapies to deprescribe. The most common are the lack of a clear indication or duplicate indications. Matching each medication to a respective condition is an easy way to determine inappropriate medication use. Likewise, this "match" should not be solely based on guideline appropriateness but should also consider how continuing a particular medication will help the patient obtain their goals (Steinman and Hanlon 2010). Another good marker is if the patient or caregiver questions the ongoing indication or benefit of the drug (Farrell et al. 2015b). A study evaluating patient and caregiver attitudes toward deprescribing found that 92% of individuals would be hypothetically willing to have a medication stopped, especially if it were ineffective or they had a general dislike of medications (Reeve et al. 2016).

Medications causing obvious adverse effects should be considered for deprescribing (Steinman and Hanlon 2010). Likewise, patients with end-stage diseases, terminal illnesses, dementia, or extreme frailty should have a PP review with the goal of minimizing drug therapies (Graham 2015; Scott et al. 2015). One review of deprescribing in older patients notes that the presence of frailty should always be a catalyst for deprescribing (Frank and Weir 2014).

Additionally, the presence of "prescribing inertia" or a "repeat prescription syndrome" in which there is automatic renewal of every medication without a clear understanding of appropriate use or indication should be considered a trigger for deprescribing (Straand and Sandvik 2001). Finally, it has been emphasized that deprescribing discussions are appropriate during any patient interaction, especially when new medications are initiated (Frank and Weir 2014).

The revised patients' attitude towards deprescribing questionnaire (rPATD) is an effective tool used to obtain beliefs and attitudes about deprescribing from older adults and caregivers. Having this information prior to broaching the topic of deprescribing could be helpful in prioritizing patients who are willing to have these conversations; this could help alleviate providers' concerns regarding clinic consultation time. The questionnaire could also be used to target patients who may require education regarding medication management and rationales for appropriate drug discontinuation (Reeve et al. 2016).

Barriers to Deprescribing

There are a number of barriers to deprescribing. One of the most pressing barriers is the lack of clear evidence of the deprescribing process and the dearth of randomized trials evaluating patient outcomes. Tables 6 and 7 list common barriers experienced by providers and patients. Both providers and patients can be psychologically impacted by decisions to stop or change medication therapies. Patients are often told that they will be required to take a medication "for the rest of their lives." When life changing events occur, such as a diagnosis of a metastatic cancer, the notion of discontinuing a drug therapy may come as a surprise to patients. Mismatched expectations about indefinite medication use occur commonly in situations of terminal illness diagnoses but can also occur when general practitioners and specialists have differing opinions and recommendations. This fragmented care and inconsistent advice among multiple providers can lead to patient mistrust of health care (Stevenson et al. 2004). Similarly, deprescribing discussions may result in a patient's confrontation with their mortality, especially when they were told they would take a particular medication until they died. Moreover, patients may feel a sense of futility of previous efforts in maintaining their health (i.e., regular glucose checks daily, strict vegetarian diet) (Maddison et al. 2011). Feelings of abandonment by the medical community and a loss of self-worth may occur when patients are

Table 6 Common barriers for providers

Provider barriers to deprescribing in geriatric oncology
Difficulty determining life expectancy
Difficultly discussing with patients how reduced life expectancy can impact treatment goals
Suboptimal communication between family physicians and specialists resulting in polypharmacy
Providers reluctant to stop medications initiated by another prescriber
Lack of ownership of deprescribing efforts (i.e., family physicians believe specialists should take the lead)
Hesitation to compromise patient hope by stopping chronic medications
Lack of confidence to deprescribe medications safely (i.e., safe taper)
Lack of comprehensive evidence of benefits or harm of deprescribing in this population
Underappreciation of the scale of polypharmacy-related harm
Concern for legal ramifications of not following clinical practice guidelines

Table 7 Common barriers for patients

Patient barriers to deprescribing in geriatric oncology
Patients feeling "abandoned" or not worthy of treatment
Difficulties in understanding the concept of medication discontinuation
General reluctance of patients and families to change medications
Underappreciation of the scale of polypharmacy-related harm
The belief that taking a medicine to prevent or treat a disease is always needed ("pill for every ill")
Fear of poor response by their providers
Belief that adverse drug events are due to natural aging processes
Fear of drug withdrawal

told their preventative medications are no longer needed.

Another significant barrier is limited consultation time that leads to obtaining incomplete information from patients and, thus, reduced opportunity for deprescribing. Patient and family meetings about life expectancy, number needed to treat (NNT), and time-to-benefit of therapies are difficult for providers to undertake, especially with limited clinic hours (Hilmer et al. 2012). The mentality of "don't-rock-the-boat" is common and convenient for providers, especially if their patient is currently displaying clinical stability (Cullinan et al. 2017). Likewise, patients interested in reducing their medication load may fear these conversations as well. They may have a general fear of poor provider response, concern for being denied other helpful therapies in the future, and distress regarding "wasting time" talking about medications (Cassels 2017).

Patients and providers may not want to stop specific therapies due to concerns of worsening their underlying condition or feelings of physical dependence. There are also concerns about medication withdrawal, especially when providers feel uncomfortable designing tapering regimens. Many providers have fears about stopping preventative medications and find it more difficult than stopping medications for acute conditions (Todd et al. 2016a). Patients may intentionally and unintentionally withhold information about adverse drug events that could help guide deprescribing. This may be due to beliefs that side effects are occurring as a result of natural aging or due to poor communication with care providers. Demands and influences of family members regarding continuing medications is another barrier.

It is also important to consider steps to overcome barriers to deprescribing. Determining who has the explicit responsibility to manage patients' medications and make decisions about deprescribing needs to occur (Barnett and Jabraj 2017; Cullinan et al. 2017). It is also vital to include deprescribing recommendations in chronic disease state guidelines and to encourage providers to discuss more detailed medication expectations during initiation of therapy (i.e., situations when therapies can be stopped in the future) (Rossello et al. 2015). Finally, a culture shift needs to occur where adopting the "less-is-more" mind state surpasses the notion of "taking any medication is better than doing nothing at all" (Frank and Weir 2014). Patients and caregivers should also be encouraged to ask the following questions (Scott et al. 2015):

1. What are the treatment options (including nondrug therapies) for my condition?
2. What are the possible benefits and harms of each treatment (drug)?
3. What might be reasonable grounds for discontinuing use of a drug?

Outcomes Associated with Deprescribing

There is limited information regarding outcomes as a result of deprescribing in the older cancer population. The best evidence comes from a 2010 Garfinkel study as previously discussed. This study found improvements in quality of life, improvements in cognition, and a reduction in mortality. A study evaluating over 10,000 patients undergoing a PP assessment and reduction in PIM found no significant change in mortality but a statistically significant decrease in 90-day readmissions and hospital length of stay. In a summary of drug withdrawal trials, it was found that antihypertensives, psychotropic drugs, and benzodiazepines were appropriately discontinued and about 20–100% of patients presented with no harm (Johansson et al. 2016). Also, a study evaluating inpatient medication reviews by pharmacists or physicians found that reduction in PIM through deprescribing resulted in a 36% reduction in emergency department visits from 30 days to 1 year, reduced hospital length of stay, and global improvement in health. In contrast, a study in older frail people living in residential aged care facilities found no beneficial effects of deprescribing for reducing falls, fractures, hospital admissions, cognitive, physical, and bowel function, quality of life, or sleep (Potter et al. 2016). Eliminating unnecessary drugs through deprescribing may result in improved adherence to other essential

therapies (Scott et al. 2015). A study evaluating discontinuation of statins in patients with a limited life expectancy of 1 month to 1 year found a statistically significant improvement in patient quality of life without an increased risk of mortality (Kutner et al. 2015). This is the first randomized controlled trial evaluating deprescribing a preventative medication; this study is particularly relevant to the older cancer patient, who often presents in the later stages of the disease.

In contrast, negative outcome associated with stopping medications includes return of symptoms, drug withdrawal effects, or unexpected rebound symptoms (e.g., acid hypersecretion about cessation of a PPI or an inflammatory insult after stopping a statin). Likewise, worsening of patients' preexisting diseases can occur (i.e., return of high blood pressure). Therefore, tapering necessary medications and monitoring patients closely should be practiced (Van Nordennen et al. 2014).

The safest and most effective method to stop medications is unknown. Some evidence supports the simultaneous cessation of as many medications as possible, the "all-at-once" approach. Other studies support discontinuing one medication at time in order to determine cause-and-effect of any adverse outcomes (Garfinkel and Mangin 2010). Regardless of method, medications such as benzodiazepines, antihypertensives, opioids, and other psychotropic medications should be slowly tapered. Many resources currently exist to help guide clinicians in appropriately tapering medications (Cassels 2017).

The Future of Deprescribing in Geriatric Oncology

Additional well-designed studies may be necessary to provide sufficient evidence that deprescribing is an effective modality in this population. The study examining statin discontinuation in patients with limited life expectancy is a landmark study supporting deprescribing. It does, however, provoke the issue of what level of evidence will be sufficient enough for providers to make safe, meaningful deprescribing decisions (Holmes and Todd 2015). Whether or not randomized studies evaluating deprescribing will alleviate anxiety and fears for both patients and providers is yet to be seen.

Of particular interest is the use of clinician decision support tools and online platforms for PP assessment and deprescribing. A Canadian-based research group has developed and tested the MedStopper/database tool. This tool is a list of drug-indication pairs that, when entered into the online tool, rank medications from potentially most stoppable to least stoppable. Potentially inappropriate medications are identified through explicit screening tools such as the Beers Criteria and STOPP. Guidance is provided on tapering therapies and possible withdrawal symptoms. Medication classes, such as statins, are accompanied by risk calculators and information on NNT and NNH (Cassels 2017). In addition to this online tool, the Canadian Deprescribing Network has developed evidence-based deprescribing guidelines for PPIs, benzodiazepine receptor agonists, antipsychotic drugs, and antihyperglycemic agents (Bjerre et al. 2015; Farrell et al. 2015a, 2016; Pottie et al. 2016). These tools are concise algorithms that can be applied to a number of patient populations, including older cancer patients.

Conclusion

Older patients with cancer are at an increased risk for PP, PIM use, frailty, and many other poor outcomes. Polypharmacy should be seen as a "disease" that can interact unpredictably with other chronic disease states, anticancer therapies, and age-related physiologic changes. Pharmacokinetics and PD of drug therapies are important considerations and should be taken into account in the context of anticancer treatments as well as general pharmacotherapy. PP is common in the older cancer population, occurring in about 60% of patients. Deprescribing has been described as an effective "antidote" to PP; though, it has several barriers and there are limited studies in the older cancer population. A culture shift regarding overuse and inappropriate use of medications may be necessary to help drive policy changes related to

PP and deprescribing. Nevertheless, reducing inappropriate medication use has been considered, by several authors, as a leading global issue of the highest priority (Garfinkel and Mangin 2010).

Drug Interactions in Aging and Cancer 21

Ronald J. Maggiore

Contents

Abstract

Potential drug interactions (PDIs) can lead to adverse drug events (ADEs), which can be a source of potential morbidity, disability, and mortality among older adults. Older adults with cancer may be more susceptible to the negative impact of PDIs due to increased medications warranted as part of their cancer treatment (including symptom management and supportive care for the treatment plan). Polypharmacy is a geriatric syndrome that has led to increased complications among older adults with and without cancer and increases the risk of both PDIs and ADEs. Although several PDIs can be of unclear clinical significance when encountered, they may be more of an issue with competing medications used for comorbidities that face older adults with cancer. Moreover, this risk may be further augmented when the cancer treatment regimen is orally administered. The consequences of these types of PDIs may have more significant "downstream" effects on treatment adherence and persistence. However, as more anticancer drugs become available and adopted into clinical practice (particularly oral agents), additional studies will need to address PDIs within the dynamic landscape of cancer therapeutics and their impact on older adults with cancer who are at increased risk of toxicities.

Introduction

Medication-related issues pose potential risks for older adults in general. First, aging in of itself leads to physiologic changes that impact the pharmacokinetics and pharmacodynamics of many drugs, including anticancer agents (Gerard et al. 2016; Korc-Grodzicki et al. 2014). Second, commensurate with increasing age, there is an increase in number of comorbidities leading to a potentially legitimate need for increased number of medications (Turner et al. 2016a). In those older adults impacted by cancer in addition to these other health issues, the cancer treatment drugs and those used to support the treatment regimen ("supportive care" medications) and/or cancer-related symptoms increase the number of agents an older adult is taking concurrently at any given time (Turner et al. 2016a; Sharma et al. 2016). These observations have led to why polypharmacy can pose a potentially more significant problem for older adults with cancer, who are disproportionately affected by functional impairments and other geriatric syndromes compared to those older adults without cancer (Maggiore et al. 2010; Mohile et al. 2011).

PDIs Among Older Adults with Cancer: Insights from Polypharmacy

Exploring polypharmacy-related issues in advance lays the groundwork for addressing the complex issue of potential drug-drug interactions (PDIs) in older adults with cancer. Defining polypharmacy has been challenging since there is no universally accepted definition for it nor how best to operationalize it and its associated outcomes within a clinical research context (Beuscart et al. 2016; Maggiore et al. 2010; Sharma et al. 2016). However, several experts would agree that the number of medications, whether prescription or over-the-counter, should not be the sole aspect of polypharmacy examined or measured (Hajjar et al. 2007; Sharma et al. 2016). Appropriateness of medication use as defined by a lack of a given drug's indication, therapeutic duplicity with another agent, or agents belonging to drug classes generally is deemed unsafe for older adults in general or those with particular medical conditions. However, some older adults with particular health conditions such as certain cardiac issues may derive benefit from specific drugs or drug classes; therefore, a given patient's not being on a specific agent due to oversight may also be a manifestation of medication inappropriateness. These prescribing quality issues surrounding potentially inappropriate medication (PIM) use have led to the development of more novel criteria to measure these aspects of polypharmacy (American Geriatrics Society 2015 Beers Criteria Update Expert Panel 2015; O'Mahony et al. 2015; Schmader and Hanlon 2013). Prior studies have demonstrated that the presence of polypharmacy among older adults or patients with cancer, regardless of setting or definition, can increase the risk of adverse drug events (ADEs) and significant morbidity as a result (Budnitz et al. 2011; Hajjar et al. 2003; Hanlon et al. 2006; Maher et al. 2014). Therefore, evaluating polypharmacy in broad terms yet specifically within a geriatric oncology context is quintessential for appraising PDIs and ADEs in this population. Key findings from several geriatric oncology polypharmacy studies have been highlighted below (Table 1).

Risk for PDIs: How Many Medications Are Too Many?

We know that the risk for PDIs increases proportionally to the number of meds concurrently taken in both geriatrics and geriatric oncology studies (Hajjar et al. 2003; Hanlon et al. 2006; Nightingale et al. 2015). As a result, the degree of "pill burden" may be the most consistently reported risk factor for PDIs. There is no absolute cutoff for "too many" medications since some older adults with certain comorbid conditions may require increasing numbers of appropriately

Geri onc geriatric oncology, *HCAM* herbal/complementary/alternative medications, *HEDIS DAE* Healthcare effectiveness data and information set drugs to avoid in the elderly, *IADL* instrumental activities of daily living, *OTC* over-the-counter, *PIM* potentially inappropriate medication, *RF* risk factor, *Rx* prescription, *SD* standard deviation, *VES-13* Vulnerable elders survey-13

prescribed medications to manage these conditions optimally; furthermore, the optimal threshold may be contingent upon the outcome being studied (Turner et al. 2016b). Based on a focused literature review, older adults with advanced cancer typically are taking anywhere from three to nine concurrently prescribed meds (LeBlanc et al. 2015). Several experts have used a cutoff of five or more concurrent medications (prescription vs. non-prescription notwithstanding) as exceeding this threshold appears to significantly raise the risk of PDI and risk for toxicity.

On the other hand, PIM use can range from 17% to 51% among older adults with cancer depending on the definitions utilized (Flood et al. 2009; Maggiore et al. 2014; Nightingale et al. 2015; Prithviraj et al. 2012). Increased medication use is associated with an increasing number of comorbidities in the geriatric oncology population (Nightingale et al. 2015) and, in some cancer types such as AML, may be associated with worse survival (Elliot et al. 2014). Moreover, "pill burden," which also must also take into account medication financing, dosing, side effect, and administration challenges facing the patient and his or her caregiver(s), can also serve as a major risk factor for poorer adherence to oral anticancer regimens and thus potentially worse cancer outcomes (Efficace et al. 2012; Millic et al. 2016; Ruddy et al. 2009).

PDIs: Methods for Identification

The prevalence of PDIs is also largely dependent on the definitions and methods utilized beyond just inherent issues with accuracy and reliability with patient self-report, medical record reviews, and the accounting for multiple prescribing providers and/or dispensing pharmacies. Regardless of how a given patient's medication list is obtained, significant methodological and data interpretation issues stem from the type of software or compendium that is utilized to review and analyze for PDIs and their respective severity. A review by Riechelmann and De Giglio (2009) reported that up to one-third (13–61% overall prevalence) of outpatients with cancer are affected by PDI across eight studies (years 2005–2009). Only 19% of these PDIs were categorized as high severity, with only about half of these being supported by Level 1–3 evidence. That being said, very few of the identified PDIs involved chemotherapy agents directly. Although some experts advocate for more routine involvement for electronic "built-in" alerts for PDIs in oncology practice (Riechelmann and Girardi 2016), there remains much variability among electronic drug information databases. Among different prescribing decision support tools, the evidence base each utilizes to assign a PDI's level of risk and its clinical relevance for a given patient scenario can be very heterogeneous, with some of these resources missing more common PDIs identified by a pharmacist (Clauson et al. 2007; Hoody et al. 2011; Saverno et al. 2011). Therefore, it may be prudent for oncologists to review "clinically significant" PDIs initially identified such electronic resources or tools with oncology pharmacist input where available prior to prescribing a new anticancer agent or regimen.

PDIs: Illustrative Examples

Several studies have evaluated the prevalence or incidence of PDIs (27–75%) among adults with cancer across settings, with a trend toward a higher prevalence in those studies focusing on older adults with cancer (Table 2). In addition to differences in the drug software or resources utilized, the study population varied significantly across studies that could explain some of the differences in results, especially with inherent differences in cancer types and cancer treatments encountered. Several unifying themes emerge when examining these studies as a whole. First, most studies included patients receiving or about to receive cancer treatment, the majority of which involved intravenous chemotherapy agents. Among the studies that evaluated the types of PDIs involving chemotherapy agents versus other medications, those involving chemotherapy agents tended to represent a minority of the PDIs identified (<25%). More frequent and/or more clinically significant PDIs may be encountered

Table 2 Select PDI studies in oncology and geriatric oncology

Study	Type of study	N	Age	Number of meds per patient	PDI software or resource used	PDI prevalence/ incidence	PDI level of evidence	PDI severity	PDI types
Outpatient									
Girre et al. (2011)	Prospective (1 year, single site)	105	Median = 79 (range, 70–97)	Mean=4.7 (range, 0–14); 47% taking ≥5 meds	French drug thesaurus	33% of patients; 45 PDIs (only in patients ≥2 meds: $N = 97$)	Not reported	24% of PDIs moderate-severe level	Not delineated

when oral anticancer agents are evaluated exclusively.

Overall, the PDIs encountered by an electronic drug database could be of unclear clinical significance: how concerned should the provider be? Of the few PDIs involving anticancer and supportive care drugs identified in the studies in Table 1, interactions involving warfarin, CYP3A4-mediated agents, and concurrent use of medications that might prolong the QT interval are commonly encountered (Table 3). Finally, it is important to point out the potentially deleterious impact of acid-suppressing drugs such as proton pump inhibitors (PPIs) on the potential efficacy of oral tyrosine kinase inhibitors (TKIs) used to treat several types of cancer. For those who cannot discontinue the acid suppressant, this interaction may be circumvented with the concurrent ingestion of cola beverages with the TKI, for example (Gay et al. 2016; van Leeuwen et al. 2016).

PDIs and Outcomes: What Do We Know?

The outcome most directly attributable to PDIs is adverse drug events (ADEs), which can lead to morbidity, hospitalization, and potential death even among patients with cancer although the

Table 3 Select common PDIs encountered in oncology/geriatric oncology studies

Drug/drug class A	Drug/drug class B	Mechanism	Potential toxicity
Warfarin	Capecitabine 5-fluorouracil Tamoxifen Other drugs	Several interactions including CYP2C9	Increased serum concentrations of warfarin = increased risk of bleeding
Some SSRIs (e.g., fluoxetine) other CYP2D6 inhibitors	Tamoxifen	CYP2D6 interactions	Decreased serum concentrations of tamoxifen
NSAIDs Furosemide Sulfa drugs	Methotrexate	Decreased metabolism and/or excretion of methotrexate	Increased serum concentrations of methotrexate
Itraconazole, fluconazole, other CYP3A4 inhibitors	Vincristine Other anticancer agents that are CYP3A4 substrates	CYP3A4 interactions	Increased serum concentrations of the anticancer agent
NSAIDs	Antiplatelet agents Anticoagulants Corticosteroids SSRIs	Overlapping toxicity profiles	Increased risk of bleeding
Fentanyl	Fluconazole (CYP3A4 inhibitor)/ ondansetron	CYP3A4 interactions/ concurrent use of drugs that prolong the QT interval	Increased (inhibitor) or decreased (inducer) serum concentrations fentanyl/ increased risk of QT prolongation
Acid suppressants (e.g., PPIs)	Certain oral TKIs, such as: Axitinib Crizotinib Dabrafenib Dasatinib Erlotinib Gefitinib Nilotinib Pazopanib	May decrease absorption of the TKI	Decreased serum concentrations of the TKI

NSAID nonsteroidal anti-inflammatory drug, *PPI* proton pump inhibitor, *SSRI* selective serotonin reuptake inhibitor, *TKI* tyrosine kinase inhibitor

incidence may be lower than that compared to those with non-cancer chronic illnesses (Buajordet et al. 2001; Budnitz et al. 2011). The likelihood of a medication or PDI precipitating an ADE is often measured by validated algorithms (Michel and Knodel 1986). A study by Del Giglio et al. (2009) evaluated the likelihood of ADEs as the cause of admissions to an oncology ward over the course of a year. Of 458 admissions evaluated, 13% were deemed to be medication-related, with 11% of these being ADE-related due to chemotherapy (i.e., neutropenic fever mostly in patients with hematologic cancers) and 2% involving other drugs (PDIs with warfarin, NSAIDs, ACE inhibitors). Popa et al. (2014) found an association between a number of higher-evidence PDIs with an increased risk for non-hematologic chemotherapy toxicity but not hematologic toxicity. We do know that pharmacist-led interventions can decrease polypharmacy (including PIM use) and thus mitigate the prevalence of PDIs in older patients with cancer and can lead to better outcomes such as oral anticancer therapy adherence and persistence (Flood et al. 2009; Wong et al. 2016). Some online resources have been developed to aid oncology providers in evaluating PDIs with the use of some of the oral anticancer agents (http://oncologypro.esmo.org/Guidelines-Practice/Drug-Drug-Interactions-with-Kinase-Inhibitors/Types-of-Drug-Drug-Interactions).

PDIs in Geriatric Oncology: Future Directions

As noted above, several limitations impact our interpretation of the current data on PDIs (and polypharmacy) in geriatric oncology. Many studies have heretofore been retrospective, with heterogeneous methodologies and operational definitions and with very few being outcome-based. We generally know that oral anticancer therapies pose the greatest risk for clinically significant PDIs than intravenous agents. Since the conduct of many of these studies, newer oral anticancer agents have since been approved and introduced into clinical oncology practice, including agents that carry labeled QT prolongation risks (e.g., vandetanib, crizotinib, osimertinib) or those that can significantly increase the risk for severe bleeding events (e.g., ibrutinib, ponatinib).

With the advent of novel oral anticoagulants (e.g., apixaban, rivaroxaban) or use of low-molecular-weight heparins in patients with cancer instead of warfarin and less use of phenytoin as a preferred initial anticonvulsant in this population (e.g., as compared to levetiracetam), some of the more common PDIs previously studied may not be as clinically important or germane in the current era of cancer therapy. Since January 2010, at least 35 either brand-new oral anticancer agents or those with a new disease indication were approved by the US Food and Drug Administration (http://www.fda.gov/Drugs/InformationOnDrugs/ApprovedDrugs/ucm279174.htm). Furthermore, some oral anticancer agents are rapidly supplanting older (and usually intravenous) cytotoxic therapy options, particularly for patients with chronic lymphocytic leukemia (i.e., ibrutinib, idelalisib) and prostate cancer (e.g., enzalutamide, abiraterone). It is important to highlight that even these drugs are metabolized extensively by the hepatic cytochrome P-450 system and thus can be heavily influenced by concurrent use of CYP3A4 inducers/inhibitors (Benoist et al. 2016; De Zwart et al. 2016; Lambert Kuhn et al. 2016).

Therefore, it will be important to reexamine in a prospective fashion how these newer oral anticancer therapies impact older adults or those with other comorbidities that may be more vulnerable to medication-related issues: polypharmacy (including PIM use), PDIs, and "pill burden." Potential outcomes of interest would warrant more rigorous evaluation of their impact on older adults with cancer: ADEs (including chemotherapy toxicity), financial toxicity, functional outcomes, and morbidity such as unplanned emergency room visits and hospitalizations. Certainly, the development of more innovative interventions will be key to address these issues and successfully mitigate such risks. Given the increasing complexity of both geriatric and cancer care in general, a multidisciplinary approach will likely need to be incorporated in future studies and in clinical practice.

Erika E. Ramsdale, Jason Zittel, and Diana Sarfati

Contents

Abstract

Comorbidity, the presence of coexisting diseases, is common in older adults with cancer. However, measurement of comorbidity is challenging due to its manifold presentation; numerous measures have been developed and validated, but there is no "gold standard" for comorbidity measurement in patients with cancer. However, a few tools have been developed specifically for quantification of comorbidity in older adults and/or patients with cancer. Comorbidity has complex interactions with cancer risk, prognosis, cancer treatment decisions, and tolerability of cancer treatment. For older adults in particular, comorbidity can imply "competing risks" for mortality and therefore a projected lack of benefit for

anticancer therapies; on the other hand, comorbidity is not always associated with worse outcomes from these therapies. Comprehensive geriatric assessment (CGA) along with assessment of patients' goals and overall life expectancy can assist with decision-making in older adults with cancer and comorbidity.

Comorbidity · Cancer

Introduction

Cancer is a disease of aging. By 2030, it is estimated that 70% of incident cancers will be diagnosed in persons ≥65 years (Smith et al. 2009). As the population ages, and as cancer detection and treatments improve, rapidly increasing numbers of older adults will be either cancer survivors or living with cancer as a chronic condition. Many other chronic diseases also increase in incidence with increasing age, including cardiovascular disease, kidney disease, lung disease, metabolic syndromes, and degenerative musculoskeletal diseases. The interplay between age, cancer, and other chronic diseases is extraordinarily complex and affects the care of the older patient with cancer in a number of ways. Older patients, and especially those with significant chronic conditions, are typically excluded from cancer clinical trials, thus limiting the evidence base available to their providers (Lewis et al. 2003); moreover, clinical guidelines for cancer treatment do not often consider the potential interactions between chronic diseases and cancer or cancer treatments (Boyd et al. 2005). Co-management of cancer and other chronic diseases may be very challenging in the setting of increasing fragmentation of healthcare, particularly for the older patient, who may have more difficulty coordinating and attending multiple specialist appointments. A cancer diagnosis often dominates discussions of clinical decision-making, but many older adults (especially those with indolent malignancies) are more likely to die of other causes, leading to overtreatment of cancer. On the other hand, older adults with chronic diseases may be denied treatment for cancer based on concern for toxicity, and undertreatment is also possible. This chapter further explores the relationship between cancer and comorbidity in older patients.

The objectives of this chapter are:

1. To define comorbidity, discuss its prevalence in older patients with cancer, and review the available measures of comorbidity in patients with cancer
2. To review what is known about the association between comorbidity and cancer risk, cancer detection, and survival
3. To present a general approach to decision-making in older adults with cancer and comorbidity
4. To examine the effect of comorbidity on cancer treatment choice and tolerance
5. To discuss the potential impact of cancer treatment on comorbidities, in particular geriatric syndromes

Definition of Comorbidity

Comorbidity is the presence of any additional coexisting ailment in a patient with a particular index disease, such as cancer (Feinstein 1970). Typically, these coexisting ailments are chronic diseases or health conditions which have long-term consequences for health and quality of life; comorbidities can influence the approach to management of the index disease. Comorbidity is associated with adverse outcomes in older adults with cancer, including decreased survival (Sogaard et al. 2013; Piccirillo et al. 2004; Lee et al. 2011), reduced quality of life, increased hospitalizations and healthcare costs, and increased toxicity from anticancer therapies (Lee et al. 2011). Some comorbidities can increase the risk of developing cancer (Extermann 2007; Giovannucci et al. 2010; Vigneri 2009).

Comorbidities are typically classified into specific disease categories, often grouped by organ system; examples include diabetes, coronary artery disease, or chronic renal insufficiency. However, another type of comorbidity prevalent in older adults, particularly frail older adults, is the

"geriatric syndrome." Geriatric syndromes are multifactorial conditions not limited to a particular organ system and include cognitive impairment, delirium, fatigue, incontinence, malnutrition, pressure ulcers, gait disorders, falls, sleep disorders, and sensory deficits. Some of these syndromes may be the result of a specific disease, but they may also result from low physiologic reserve, or "the loss of compensatory ability through the accumulated effects of multiple impairments," thus relating them to frailty, itself a complex geriatric syndrome (Tinetti et al. 1995; Fried et al. 2001). Some geriatric syndromes, unlike chronic diseases, may be intermittent. Like chronic diseases, however, they can impact a patient's functionality, vulnerability to adverse outcomes, and survival (Naeim and Reuben 2001).

Prevalence of Comorbidity

The prevalence of comorbidity in patients with cancer varies widely, depending upon how it is defined and measured (see below); in one review of the literature, prevalence estimates ranged from 0.4% to 90% (Lee et al. 2011). Comorbidity prevalence can also vary by cancer primary site: patients with lung and colorectal cancers have a higher prevalence and burden of comorbidity compared to patients with breast or prostate cancers, whose prevalence is similar to that of non-cancer cohorts (Cho et al. 2013; Edwards et al. 2014). This difference may be at least partially attributable to risk factors (such as smoking or dietary intake) which contribute both to cancer and to other chronic conditions. Among patients with cancer, those from racial/ethnic minority groups (Putt et al. 2009; Tammemagi et al. 2005) and those with a low socioeconomic status (SES) have a higher prevalence of comorbidity (Tammemagi et al. 2005; Louwman et al. 2010; Cook et al. 2013). Patients with low SES have a higher incidence of certain cancers that have a tendency to co-occur with chronic conditions (such as lung cancer).

Geriatric syndromes may be more prevalent in patients with cancer: in a study of Medicare beneficiaries (n = 12,480), 18% (n = 2349) reported a history of cancer; of those with cancer, 60.3% had at least one geriatric syndrome, compared with 53.2% of non-cancer patients ($p < 0.001$) (Mohile et al. 2011).

Measures of Comorbidity for Older Patients with Cancer

Given the breadth of the concept of comorbidity, it is challenging to determine how best to quantify comorbidity as well as how to incorporate this measure into treatment decision-making for older adults with cancer. One recent review assessed 21 distinct published measures of comorbidity in adults with cancer using six qualitative criteria: experience with cancer patients, content/face validity, concurrent validity, predictive validity, reliability, and feasibility (Sarfati 2012). The authors concluded that no gold standard approach exists to measure comorbidity in the context of cancer. However, 8 of the 21 indices analyzed (Charlson Comorbidity Index [CCI] (Charlson et al. 1987), Satariano Index (Satariano and Ragland 1994), Elixhauser (Elixhauser et al. 1998) and Tammemagi (Tammemagi et al. 2005) approaches, Fleming's Comprehensive Prognostic Index (Fleming et al. 1999), National Cancer Institute [NCI] Combined Comorbidity Index (Klabunde et al. 2007), Alcohol-Tobacco-Related Comorbidities Index (Reid et al. 2002), and Washington University Head and Neck Comorbidity Index (Piccirillo et al. 2002)) scored at least moderately well on all criteria. Of these, three (CCI, Elixhauser approach, and NCI Combined Comorbidity Index) were developed for use in all cancer subtypes; the remainder are cancer site specific. Several measures, such as the Cumulative Illness Rating Scale (CIRS) (Linn et al. 1968), Index of Coexistent Disease (ICED) (Greenfield et al. 1993), and Adult Comorbidity Evaluation-27 (ACE-27) (Piccirillo et al. 2004), scored highly on all criteria except for feasibility due to the amount and detail of data capture required. Some included measures which were developed for other specific purposes, lacking generalizability to the cancer population. One of the authors

has subsequently developed cancer-specific measures of comorbidity, using administrative hospitalization and pharmaceutical data (Sarfati et al. 2014a, b).

Another review narrowed focus to four validated comorbidity measures incorporated into clinical trials of older adults with cancer: the CCI, CIRS, ICED, and the Kaplan-Feinstein Index (Kaplan and Feinstein 1974). All were found to be relatively easy to use, did not require much time to be completed (<10 min), and had a generally good inter-rater and test-retest reliability (Extermann 2000). More recently, the Cancer and Aging Research Group (CARG, http://www.mycarg.org) in collaboration with the National Cancer Institute (NCI) and the National Institute on Aging (NIA) held a discussion focusing on comorbidity measurement in the older adult, generating a summary of comorbidity measurement scales (Williams et al. 2016a). The authors concluded that ultimately, it is not as important as exactly how comorbidity is measured, but rather that comorbidity is being considered in older adults with cancer. However, a standardized measure of comorbidity would facilitate research and cross-trial comparisons.

For older adults with cancer, there are no specific screening or measurement tools for geriatric syndromes. Often, the presence of these syndromes is uncovered during the course of a comprehensive geriatric assessment (CGA), a multidisciplinary assessment of an older adult's health and functioning. Comorbidity is one domain included within the assessment, incorporating one or more of the tools discussed above as well as, typically, attention to geriatric syndromes. The CGA is resource-intensive to perform, and who to assess with this method remains unclear (Mohile et al. 2015). The use of CGA in the care of older adults with cancer is discussed later in the chapter.

In summary, there is no standard tool for the quantification of comorbidity burden in older adults with cancer. Some measures have been studied head to head in specific populations of patients with cancer (Sarfati 2012). A majority of the studies included the CCI given its usefulness in non-site-specific cancer. Ultimately, the appropriate tool depends on the population, setting, and the specific clinical or research question. No one tool is optimal for all situations, but measurement of comorbidity is critical in older adults with cancer given its impact on prognosis, treatment tolerability, and survival outcomes. Table 1 summarizes the comorbidity measures available.

Comorbidity and Cancer Risk

Cancer is a disease of aging; advanced age is one of the biggest risk factors for development of cancer. At 50 years of age, the risk for developing cancer is approximately 1/1000, but by age 80, the risk has increased to about 1% per year (Extermann 2007). The interaction between comorbidity and cancer risk is complex. Increasing prevalence of comorbidities with age may contribute to the increased risk of cancer. In addition, many of the risk factors associated with developing cancer (lifestyle, diet, obesity, smoking, and alcohol abuse) are also risk factors for the development of many common chronic conditions. Certain chronic conditions themselves are also independent risk factors for cancer, perhaps due to shared pathophysiologic mechanisms; for example, the inflammatory pathways activated in diseases such as diabetes, obesity, and autoimmune disorders are known to promote tumorigenesis and tumor progression (Extermann 2007; Giovannucci et al. 2010; Vigneri et al. 2009). Less commonly, some medications used to treat chronic conditions have been associated with increased cancer risk (Extermann 2007).

Diabetes is increasing in prevalence, due both to lifestyle risk factors and advancing age of the population. More than 25% of adults ≥65 years have diabetes (Centers for Disease Control and Prevention 2017). Diabetic patients have an increased risk of breast, pancreatic, liver, colorectal, and endometrial cancers. Compared to non-diabetics, diabetics have a relative risk (RR) >2 for cancers of the liver, pancreas, and endometrium; RR of 1.2–1.5 is seen for cancers of the colon and rectum (Vigneri et al. 2009). The mechanisms which link diabetes and cancer risk may include hyperinsulinemia (endogenous due to

Table 1 Comorbidity measures

Index	Items	Data source	Population	Reason/purpose	Inclusion of older adults in development	Studies using index in cancer patients
Summative						
Satariano (Satariano and Ragland 1994)	7 selected conditions	Clinical notes data, administrative data	1,011 breast cancer patients	Assess effect of comorbidity on 3-year survival	46% ≥65 years; 26% age 75–84	Breast (Satariano and Ragland 1994; Newschaffer et al. 1997), head and neck (Reid et al. 2002)
National Institute on Aging/National Cancer Institute Collaborative Study (Yancik et al. 1996)	6 selected conditions	Clinical notes data	7,631 patients with cancer	Investigate comorbidity burden	3 cohorts of equal numbers: age 55–64, age 65–74, and age ≥ 75 years	Various cancers (Yancik et al. 1996)
Elixhauser (Elixhauser et al. 1998)	30 dichotomous conditions	Administrative data	1,779,167 adult acute care hospital patients	Measure comorbidity and effect on length of stay, total charges, and in-hospital mortality	Included all age ≥ 18 years; mean age of cohort 57 years	Cervical (Brewer et al. 2011), colorectal (Lieffers et al. 2011), head and neck (Lee et al. 2016)
Alcohol-Tobacco-Related Comorbidities Index (Reid et al. 2002)	11 conditions associated with alcohol or tobacco	Administrative data	9,386 head and neck cancer patients	Assess comorbidity and association with survival	All age ≥ 65: 61.9% 65–74 years, 31.6% 75–84 years, 6.5% ≥85 years	Head and neck (Reid et al. 2002; Castro et al. 2007)
Tammemagi (Tammemagi et al. 2005, 2003)	259 comorbidities in 56 comorbidity categories (lung) 268 comorbidities in 16 comorbidity categories (breast)	Administrative data	1,155 lung and 906 breast cancer patients	Assess comorbidity and association with 1-year mortality	Lung: age ranges not reported Breast: 54% >60 years, 9% >80 years	Breast (Tammemagi et al. 2005), lung (Tammemagi et al. 2003)
Multipurpose Australian Comorbidity Scoring System (Holman et al. 2005)	102 conditions	Administrative data	1,069,770 hospital patients	Develop generalized measure of comorbidity, effect on 1-year mortality, 30-day readmission, and LOS	Age data not reported	Development cohort included 615 breast cancer patients (Holman et al. 2005)
Systems based						
Cumulative Illness Rating Scale (Linn et al. 1968)	13 or 14 organ system categories, each rated 0–4	Clinical notes data	Unclear	Measure of physical impairment	Modified CIRS-G (Miller et al. 1992) was developed from	Various cancers (used CIRS-G) (Extermann et al. 1998), colorectal

Table 1 (continued)

Index	Items	Data source	Population	Reason/purpose	Inclusion of older adults in development	Studies using index in cancer patients
Index (Klabunde et al. 2007, 2000)	empirically derived weights		breast cancer patients	2-year non-cancer mortality		2000), colorectal (Hines et al. 2009; Baldwin et al. 2006), head and neck (Sanabria et al. 2008), prostate (Klabunde et al. 2000)
Elixhauser Index (van Walraven et al. 2009)	30 conditions weighted by empirically derived weights	Administrative data	228,565 adult acute care hospital patients	Combine Elixhauser conditions into index discriminative for death in hospital	Mean age 59 years	Colorectal (Baldwin et al. 2006), head and neck (Chang et al. 2016)
Cancer-specific						
Washington University Head and Neck Comorbidity Index (Piccirillo et al. 2002)	7 conditions, each rated 0–4	Clinical notes data, Administrative data	1,094 head and neck cancer patients	Assess comorbidity ability to predict survival	39% >65 years	Head and neck (Piccirillo et al. 2002; Castro et al. 2007; Sanabria et al. 2008)
Simplified Comorbidity Index (Colinet et al. 2005)	7 conditions weighted between 1 and 7	Clinical notes data	735 patients with lung cancer	Assess comorbidity and ability to predict survival	Median age 62.5 years	Lung (Colinet et al. 2005; Jacot et al. 2008)
Hematopoietic Cell Transplantation-Comorbidity Index (Sorror et al. 2005)	17 conditions, each rated 0–3	Clinical notes data	1,055 patients undergoing hematopoietic cell transplantation (HCT)	Develop a comorbidity score for HCT that predicts non-relapse mortality and survival	Median age 45 years; included patients up to 73 years	HCT (Sorror et al. 2005)
C3 Index (Sarfati et al. 2014a)	Cancer site-specific: 50 weighted conditions; non-site-specific: 42 weighted conditions	Administrative data	14,096 patients in New Zealand cancer registry	Develop cancer-specific index and assess ability to predict survival	25% age 65–74 years; 30% ≥75 years	Colorectal, breast, gynecologic, upper GI, urologic (Sarfati et al. 2014a)

Pharmacy-based comorbidity index (PBCI) (Sarfati et al. 2014b)	19 weighted conditions	Pharmacy-based data	14,096 patients in New Zealand cancer registry	Develop cancer-specific index and assess ability to predict survival	25% age 65–74 years; 30% ≥75 years	Colorectal, breast, gynecologic, upper GI, urologic (Sarfati et al. 2014b)
Case-mix approaches						
Diagnostic Cost Group (Ash et al. 1989)	800 diagnostic classifications by ICD-9 into 78 diagnostic subgroups aggregated into 9 diagnostic cost groups	Administrative data	38,705 Medicare beneficiaries	Predict resource use in HMOs	All patients ≥65 years	Colorectal (Baldwin et al. 2006)
Adjusted Clinical Groups (Weiner et al. 1991)	5000 ICD-9 diagnosis codes assigned to 34 ambulatory diagnostic groups	Administrative data	16,000 HMO enrollees and Maryland Medicaid beneficiaries	Predict resource use in HMOs	Unclear, included all ages from birth	Colorectal (Baldwin et al. 2006)
Overall health						
American Society of Anesthesiologists (Reid et al. 2001)	Score from 1 (healthy) to 6 (brain dead) based on severity of systemic disease	Clinical notes data may be obtained from administrative	388 head and neck cancer surgical patients	Originally to assess acute operative risk but evaluated as measure of comorbidity and prognostic ability for mortality in head and neck cancer	All patients ≥65 years: 66.5% 65–74 years, 28.6% 75–84 years, 4.9% ≥85 years	Breast (Lash et al. 2003), colorectal (Dobbins et al. 2015), head and neck (Reid et al. 2001), prostate (Froehner et al. 2003, 2014)
Older Americans Resources and Services (OARS) Questionnaire Physical Health subscale (Fillenbaum and Smyer 1981)	14 specific comorbid conditions rated on 3-point scale	Patient questionnaire	997 community-dwelling older adults (age ≥ 65 years)	Measure degree that comorbidity interferes with patients activities	All patients ≥65 years	Used as part of geriatric assessment for breast, colorectal, lung, and lymphoma patients (Hurria et al. 2005)

Adapted from Sarfati 2012, with permission

insulin resistance or exogenous), hyperglycemia, or chronic inflammation, but these mechanisms are not completely understood (Giovannucci et al. 2010). The effect of hyperinsulinemia on insulin-like growth factor-1 (IGF-1) and insulin receptors has been postulated to have an impact on cellular signaling pathways including proliferation, protection from apoptotic stimuli, invasion, and metastasis. Moreover, the chronic pro-inflammatory state caused by metabolic abnormalities seen in diabetes reduces intracellular antioxidant capacity, predisposing susceptible cells to malignant transformation (Vigneri et al. 2009).

Obesity, a risk factor for many comorbidities, including diabetes, is also a risk factor for multiple cancer types, including postmenopausal breast cancer and cancers of the endometrium, esophagus, colon and rectum, prostate, pancreas, and kidneys, as well as leukemia and multiple myeloma. It is estimated that 20% of all cancers are related to excess weight, with a substantial proportion (25–50%) of these cases associated with obesity in postmenopausal women (Reeves et al. 2007). Specifically, the risk of developing breast cancer is increased in obese versus nonobese postmenopausal women, whereas obese young premenopausal women appear to be at decreased risk (Extermann 2007). In addition, women who gain significant weight during adulthood are at increased risk of breast cancer (Magnusson et al. 1998). The mechanisms by which obesity influences cancer risk are not fully understood. However, proposed mechanisms include increased levels of leptin as a growth factor for cancer, as well as involvement of interleukin-6 (IL-6) and IGF-1 which both increase with increasing weight (Extermann 2007; Vigneri et al. 2009). However, risk seems to decrease to baseline levels with weight loss (Parker and Folsom 2003).

However, aging itself is associated with an increase in inflammatory cytokines (including IL-6) and a state of chronic inflammation, and the term "inflammaging" was coined to describe this phenomenon (Franceschi and Campisi 2014). It has long been recognized that inflammation and cancer are related, and inflammation is increasingly recognized as a contributor to the development of most or all age-related chronic conditions, including arthritis, cardiovascular disease, and metabolic syndromes. Therefore, the association between certain chronic conditions and the risk of cancer may reflect these underlying shared etiologic pathways. More research is needed to elucidate the interactions between increasing age, comorbidities, and cancer risk, including determination of whether "inflammaging" can be prevented or mitigated and whether this affects risk and outcomes of cancer and chronic illness.

Comorbidity and Prognosis

Cancer Screening and Early Diagnosis

The early detection of cancer improves outcomes including mortality and quality of life. However, in older adults decisions regarding screening are not always straightforward. Guidelines have been created by multiple groups to help with early detection of certain cancers, but most lack evidence supporting use in older or frail adults or those with significant comorbidities that pose competing risks for morbidity and mortality.

Several large studies of screening for breast, colorectal, and prostate cancers have not shown an interaction between comorbidity burden (typically assessed using the CCI) and likelihood of screening (Terret et al. 2009). However, other studies have shown that the presence of comorbidity can increase or decrease receipt of cancer screening, via separate mechanisms. Certain conditions such as diabetes, cognitive decline, psychiatric disorders, and hip fracture have been associated with a trend toward lower use of screening for breast, cervical, and colorectal cancers (Heflin et al. 2002; McBean and Yu 2007; Kiefe et al. 1998). It is postulated that these comorbidities may dominate the use of clinical resources (the "competing demands" hypothesis), leaving little time to address screening, and/or clinicians may believe that cancer screening is unlikely to offer benefit in the setting of these

comorbidities. Functional loss due to chronic conditions influences providers to recommend against screening in an older adult (Blustein and Weiss 1998). Conversely, the presence of comorbidities has been associated with an increase in receipt of cancer screening in some studies (the "surveillance effect"), thought to be due to more frequent contact with healthcare providers (Heflin et al. 2002). In some cases, the effects of a particular comorbidity are mixed: end-stage renal disease (ESRD), for example, is associated with increased screening for colorectal cancer (likely secondary to the association between ESRD and anemia) and decreased screening for prostate cancer (perhaps attributable to anuria and resultant lack of urinary symptoms) (Taneja et al. 2007).

Cancer screening guidelines do not take comorbidity into account but increasingly incorporate language regarding life expectancy (Table 2). Severe or chronic comorbidities can significantly impact life expectancy and thus can indirectly impact calculation of risk/benefit of cancer screening. Estimates of life expectancy can be performed using population data (Walter and Covinsky 2001), or by using validated indices such as the Lee-Schonberg index (Lee et al. 2006; Schonberg et al. 2009), which incorporate questions about comorbidity (e.g., diagnoses of diabetes, chronic lung disease, and congestive heart failure) and estimate 4- and 10-year likelihood of mortality. Both of these methods for calculation of life expectancy are available at http://eprognosis.ucsf.edu. Decision-making modules for breast and colorectal cancer screening, also available at this website, calculate number needed to harm, number needed to screen to prevent one death, and ratio of patients who would die in 10 years regardless of screening decision based upon entered age, BMI, functional measures, and selected comorbidities.

Comorbidities may also influence stage of cancer at diagnosis, although the relationship is again complex. A review evaluating the impact of comorbidity on cancer diagnosis and survival highlighted multiple studies indicating an association between comorbidity (generally measured by the CCI) and an earlier stage at diagnosis for cancers of the lung, breast cancer, and colon/rectum, again perhaps due to the surveillance effect (Sogaard et al. 2013). One study, however, suggested a more complicated relationship between comorbidity and stage of breast cancer at diagnosis: women with cardiovascular disease, osteoarthritis, and genitourinary disease had a 7–24% lower risk of being diagnosed with advanced breast cancer, while women with diabetes, renal disease and other endocrine disorders, psychiatric disease, osteoporosis, hematologic disease, obesity, and AIDS had an 11–20% higher risk of being diagnosed with advanced disease (Fleming et al. 2005). A study of 149,045 Medicare beneficiaries $\geq$67 years indicated likelihood of advanced-stage breast cancer was highest in patients with "unstable" comorbidities (defined as comorbidities that are life-threatening and/or difficult to control such as severe heart failure and end-stage liver disease) compared to those with "stable" or no comorbidities, even when controlling for mammographic screening use and time-to-diagnosis after mammography (Yasmeen et al. 2012). A study of 14,096 patients with breast, colon, rectal, liver, stomach, ovarian, uterine, bladder, or kidney cancer showed an association between comorbidity burden (measured by the C3 Index (Sarfati et al. 2014a)) and odds of being diagnosed with distant metastases as well as the odds of remaining unstaged after diagnosis (Gurney et al. 2015). Dementia had the strongest individual impact on advanced or unknown stage at diagnosis.

Clearly, the interactions between comorbidity, cancer screening, and stage of the cancer at diagnosis in older adults are complicated. Comorbidities appear to independently influence patients and providers decisions about cancer screening, though how they influence the decision varies based on severity and type of comorbidity as well as the patient's and provider's preferences, estimation of life expectancy, and assessment of risk/benefit of screening. Both the surveillance effect and the competing demands hypothesis are likely to play roles in these relationships.

Table 2 Selected screening guidelines

	Last update	Recommendation (average-risk patients 65 and older)	Consid. of life expectancy?	Age cutoff
Breast cancer				
USPSTF (Siu and U.S. Preventive Services Task Force 2016)	2016	Age 65–74: Screen with mammography every 2 years	No	75
		Age 75 and older: No recommendation for screening (evidence of benefit is lacking)		
ACS (Oeffinger et al. 2015)	2015	Age 65 and older: Mammograms every 2 years or can continue yearly screening for 55 and older; screening should continue as long as a woman is in good health and is expected to live 10 more years or longer	Yes	No
NCCN	2017	Age 65 and older: Recommend annual screening with mammogram; no upper age limit, consider severe comorbid conditions limiting life expectancy (e.g., less than 10 years), and no further intervention would occur based on screening findings	Yes	No
ACOG (American College of O-G 2011)	2011	Age 65–74: Screening with mammography and clinical breast exam annually	Yes	No
		Age 75 or older: Woman should in consultation with their physicians, decide whether to continue mammographic screening		
ACR (Lee et al. 2010)	2010	Age 65–74: Screening with mammography annually	Yes	No
		Age 75 and older: Screening with mammography should stop when life expectancy is less than 5–7 years on the basis of age or comorbid conditions		

Cervical cancer				
USPSTF (Moyer and U.S. Preventive Services Task Force 2012a)	2012	Age 66 or older: If adequate prior screening and are not high risk, then recommend against further screening	No	Yes
ACS (Saslow et al. 2012), NCCN, ACOG	2012	Women ages 66+ who have had ≥3 consecutive negative Pap tests or ≥ 2 consecutive negative HPV and Pap tests within the last 10 years, with the most recent test occurring in the last 5 years, should stop cervical cancer screening	No	Yes
Colorectal cancer				
USPSTF (U.S. Preventive Services Task Force et al. 2016)	2016	Age 65–75: Screen with high-sensitivity fecal occult blood testing, sigmoidoscopy, or colonoscopy	Yes	86
		Age 76–85: Individual decision, taking into account the patient's overall health and prior screening history		
ACS (Levin et al. 2008)	2008	Age 65 and older: Screen; no upper age limit provided	No	No
NCCN	2017	Age 65–75: Screen with colonoscopy, stool-based testing, flexible sigmoidoscopy, or CT colonography	Yes	86
		Age 76–85: Individualized based on discussion of risks and benefits based on comorbidity status and estimated life expectancy		
MSTF (Rex et al. 2017)	2017	Age 65–75: Screen with first-tier test which includes colonoscopy and fecal immunochemical test (FIT) (second-tier tests include CT colonography, FIT-fecal DNA test every 3 years, and flexible sigmoidoscopy)	Yes	No
		Age 76 and older: Consider discontinuation of screening when persons up to date with screening, who have prior negative screening (particularly colonoscopy), reach age 75 or when life expectancy is less than 10 years Persons without prior screening should be considered for screening up to age 85, depending on age and comorbidities		

(*continued*)

Table 2 (continued)

	Last update	Recommendation (average-risk patients 65 and older)	Consid. of life expectancy?	Age cutoff
Lung cancer				
USPSTF (Moyer and U.S. Preventive Services Task Force 2014)	2014	Age 65–80: If 30-pack-year smoking hx and currently smoking or quit <15 years ago, screen annually for lung cancer with low-dose CT. Discontinue screening when the patient has not smoked for 15 years or develops a health problem that substantially limits life expectancy or the willingness to have curative lung surgery	Yes	81
ACS (Wender et al. 2013)	2013	Age 65–74: Screen with low-dose CT if in good health, have at least a 30-pack-year smoking history, and are currently smoking or quit <15 years ago	Yes	75
NCCN	2017	Age 65–74: If ≥30 pack-year smoking history and smoking cessation <15 years ago, screen them annually until they are no longer a candidate for definitive treatment	Yes	75
Prostate cancer				
USPSTF (Moyer and U.S. Preventive Services Task Force 2012b; Draft Recommendation Statement 2017)	2012	All ages: Recommend again prostate-specific antigen (PSA)-based screening	N/A	N/A
	2017 (draft)	Age 65–69: Recommend that clinicians inform men about the potential benefits and harms of PSA-based screening for prostate cancer. Recommend individualized decision-making about screening after discussion	Yes	70
		Age 70 and older: Recommend against PSA-based screening		

ACS (Wolf et al. 2010)	2010	Age 65 or older: Men who have at least a 10-year life expectancy should have an opportunity to make an informed decision with their healthcare provider about whether to be screened for prostate cancer after receiving information about the potential benefits, risks, and uncertainties associated with prostate cancer screening; prostate cancer screening should not occur without an informed decision-making process	Yes	No
NCCN	2017	Age 65–75: Panel supports continued use of PSA for early detection of prostate cancer in informed, healthy men	Yes	No
		Age 76 or older: Testing above the age of 75 should be done with caution and only in very healthy men with little or no comorbidity. Very few men in this age group benefit from PSA testing		
AUA (Carter et al. 2013)	2013 Reviewed 2015	Age 65–69: Strongly recommend shared decision-making for men age 55–69 years that are considering PSA screening and proceeding based on a man's values and preferences Does not recommend routine PSA screening in any man with less than a 10- to 15-year life expectancy	Yes	70
		Age 70 or older: Does not recommend routine PSA screening in men age 70+ years or any man with less than a 10- to 15-year life expectancy

Comorbidity and Survival Outcomes

Comorbidity has been associated with poorer overall survival in patients with cancer (Sogaard et al. 2013). Comorbidity may impact survival in several ways, including delays in cancer diagnosis (see above discussion), selection of less aggressive treatment regimens (Lee et al. 2011), potentiation of treatment-related toxicities (Asmis et al. 2008; Hurria et al. 2011a), association with increased cancer recurrence,(Piccirillo et al. 2004; Meyerhardt et al. 2003) or as a competing cause of death (Lee et al. 2011). The relationship between comorbidity, cancer, and survival is not straightforward, but some general trends can be surmised from the available literature. Most observational studies in patients with cancer show a 1.1–5.8-fold higher 5-year mortality for patients with comorbidity (inconsistently but most often measured using the CCI) (Sogaard et al. 2013). The more lethal the cancer type, the less impact comorbidities had on overall survival: the relative impact of comorbidity on survival is much higher in patients with breast cancer than those with lung cancer, for example (Read et al. 2004; Janssen-Heijnen et al. 2007). Increasing severity of comorbidity is correlated with decreasing overall survival: in a study of 62,591 Danish women with early-stage breast cancer, the adjusted hazard ratios (HR) for overall (all-cause) survival were 1.45 for patients with low comorbidity (95% confidence interval [CI] 1.4–1.51), 1.52 (1.45–1.6) for patients with moderate comorbidity, and 2.21 (2.08–2.35) for patients with high comorbidity as measured by the CCI (Land et al. 2012a). A US study including 32,074 patients (most $\geq$65 years) with melanoma and colorectal, breast, and prostate cancers reported that comorbidity was associated with later stage at diagnosis and poorer survival but that the poorer overall survival was attributable to the comorbid (non-cancer) causes (Gonzalez et al. 2001). Other large studies have shown similar findings (Edwards et al. 2014; Piccirillo and Costas 2004).

It is less clear that comorbidity impacts cancer-specific survival. A study of 6325 Danish patients $\geq$70 years confirmed that comorbidity was associated with an increased overall mortality for all cancer subtypes examined but was associated with increased cancer-specific mortality only for lung cancer (Land et al. 2012b). An inverse association between comorbidity burden and cancer-specific survival has been shown in a few studies of patients with colorectal (Sarfati et al. 2009; van de Poll-Franse et al. 2012) and breast (Land et al. 2012a) cancer; however, other studies have not upheld this association (Braithwaite et al. 2012; Janssen-Heijnen et al. 2005). The validity of cause-of-death data has been questioned, as it is possible that a considerable number of deaths are incorrectly assigned as due to cancer, when in fact they were due to non-cancer comorbidity (Sarfati et al. 2010). Other potentially confounding factors, including age, functional status, and differing measures for comorbidity used across studies, make it very difficult to tease out correlations.

There is some evidence that comorbidities impact progression-free survival of cancer in addition to overall survival. Diabetes, in particular, has been shown to increase the recurrence risk of colorectal cancer (Meyerhardt et al. 2003); the association of hyperinsulinemia with cancer risk has been discussed previously in this chapter. However, in retrospective cohort studies, metformin (commonly used to treat diabetes) has been associated with reduced recurrence risk in cancers of the breast, liver, ovaries, uterus, colorectum, and pancreas (Morales and Morris 2015). In a prospective cohort study of 17,712 patients with cancer treated at a single site, the adjusted odds ratios (OR) for recurrence compared to patients with no comorbidity were 1.18 (95% CI, 1.07–1.3), 1.37 (1.22–1.53), and 1.54 (1.31–1.8) for patients with mild, moderate, and severe comorbidity, respectively (Piccirillo et al. 2004).

Comorbidity and Cancer Treatment

Approach to Decision-Making in Older Adults with Cancer and Comorbidities

The impact of comorbidity contributes to the considerable complexity involved in treatment decisions for older patients with cancer. Older patients

and patients with significant comorbidity are underrepresented in randomized clinical trials for cancer treatments (Lewis et al. 2003; Scher and Hurria 2012; Chao et al. 2010), limiting the applicability of results to these patients (Fortin et al. 2006). Oncologists cannot simply rely upon clinical "gestalt" and the assessment of physical fitness, as measures of comorbidity have been shown to be poorly correlated with measures of functional status in older adults with cancer (Extermann et al. 1998). On the other hand, some studies have shown a synergistic, rather than additive, effect of comorbidity and physical frailty on mortality outcomes (Chen et al. 2014). Comorbidity is associated with both polypharmacy and potentially inappropriate medications in older adults with cancer (Nightingale et al. 2015), increasing the risk of drug-drug interactions and adverse drug events (ADEs) (Riechelmann et al. 2005, 2007). The comorbidities themselves may introduce drug-disease interactions with chemotherapy or increase toxicity of therapy through other mechanisms. Oncologists, older patients, and caregivers face a daunting task in the selection of treatment approach.

Perhaps the first appropriate step (predicated on the congruence of treatment with the patient's wishes) is to obtain as much information as is feasible about the interlocking domains contributing to the health and functioning of an older patient with cancer, including an evaluation and measure of comorbidity burden. The comprehensive geriatric assessment (CGA) is an interdisciplinary evaluation of an older person across multiple domains (physical fitness, social and emotional functioning, cognition, comorbidities, medication use, and nutrition), using a set of validated instruments (Extermann and Hurria 2007). It is recommended for all older adults with cancer by the American Society of Clinical Oncology (ASCO) (Mohile et al. 2018), International Society of Geriatric Oncolohy (SIOG) (Extermann et al. 2005) and National Comprehensive Cancer Network (NCCN) (Hurria et al. 2012) guidelines. The CGA has been shown to predict adverse outcomes including mortality (Ramjaun et al. 2013; Maione et al. 2005; Klepin et al. 2013) and treatment toxicity (Hurria et al. 2011a; Ramjaun et al. 2013; Extermann et al. 2012) in older adults with cancer. Its major limitation is the time and clinical resources required to perform it, but the use of screening tools (Augschoell et al. 2014; Bellera et al. 2012) and/or abbreviated CGA (Overcash et al. 2005; Shahrokni et al. 2017) may mitigate this limitation. CGA has been shown to be feasible to perform in clinical trials (Hurria et al. 2011b).

The next step in decision-making is to determine the patient's overall life expectancy. This may be estimated from population data (Walter and Covinsky 2001), validated indices (Lee et al. 2006; Schonberg et al. 2017) (available at https://eprognosis.ucsf.edu), or CGA-based prediction tools (Brunello et al. 2016; Kanesvaran et al. 2011). Patients with very limited life expectancy from non-cancer causes ("competing risks") may not have sufficient time to benefit from antineoplastic therapy, even if they could potentially tolerate it. This determination may be especially crucial for curative-intent therapies such as adjuvant chemotherapy; patients with severe comorbidities or other competing risk for mortality may not live long enough for the projected benefit (reduced risk of recurrence) to outweigh the immediate risk of toxicity (Ramsdale et al. 2013). Indeed, estimation and comparison of the risk of death from cancer versus death from non-cancer causes is an important step in determination of appropriate treatment strategy for older adults.

Cancer-specific prognosis and prediction tools have emerged to help guide treatment decisions, particularly for adjuvant therapy. Adjuvant! Online is an online risk assessment tool to predict benefit of adjuvant therapy in patients with early-stage breast cancer. It includes an estimate of comorbidity burden, but the categories are not well-defined, and the model output is very sensitive to variation in comorbidity; provider interpretation of comorbidity burden can therefore significantly skew the risk/benefit ratio of adjuvant treatment (Ozanne et al. 2009). Moreover, this tool was developed in a cohort of women $\leq$69 years of age and does not accurately predict outcomes in older patients (de Glas et al. 2014).

The PREDICT tool for benefit of adjuvant therapy in early-stage breast cancer, on the other hand, predicts 5-year overall survival in older adults with breast cancer and slightly overestimates 10-year overall survival, except in the patients >85 years (de Glas et al. 2016). However, PREDICT does not incorporate comorbidity burden in its assessment (Wishart et al. 2010). Multiple other cancer site-specific prediction tools exist for recurrence or survival (Rabin et al. 2013); most include age but not comorbidity.

Once the decision to pursue treatment is made, based upon patient preference and life expectancy estimates, subsequent refinement of the treatment plan should incorporate consideration of patient comorbidities. Comorbidities can introduce significant drug-disease and/or drug-drug interactions into the treatment plan, and some treatment options should be avoided for patients with certain comorbidities (e.g., doxorubicin for patients with severe cardiac disease, cisplatin for patients with renal insufficiency). General associations of toxicity of antineoplastic therapy (surgery, chemotherapy, and radiotherapy) in patients with comorbidities will be explored, but a full discussion of drug-disease interactions with chemotherapy is beyond the scope of this chapter; this information is widely available in cancer and chemotherapeutics textbooks. The impact of cancer treatment on geriatric syndromes will be discussed later in the chapter.

Comorbidities and Cancer Treatment Choice

Vignette studies indicate that clinicians are less likely to offer cancer treatment to older patients and patients with comorbidity (Keating et al. 2008; Krzyzanowska et al. 2009; van der Poel et al. 2015; Ring 2010). One review examined the impact of comorbidity on treatment recommendations by multidisciplinary teams (i.e., in tumor boards or cancer team meetings), where decisions are increasingly made for patients with cancer. It noted that comorbidity was not often considered in these decisions, but when they were, they were associated with failure to reach a treatment recommendation as well as guideline-discordant treatment. Furthermore, multidisciplinary team decisions were less likely to be implemented for patients with comorbidity (Stairmand et al. 2015). A review of chemotherapy use in patients with solid tumors (Lee et al. 2011) reported that comorbidity is associated with decreased chemotherapy receipt in 11 of 16 examined studies (with reported ORs ranging from 0.25 to 0.99), with no association reported in 4 studies. Two of four studies examining referral patterns showed that patients with comorbidity were less likely to even be referred to an oncologist. Most of these studies did not report survival outcomes, so it is unclear how decreased treatment affected survival. Moreover, it is unclear whether decreased use of chemotherapy resulted from physician decision to offer treatment, patient preferences, or other factors.

The benefit/risk ratio of cancer treatment is often most compelling in patients with curable malignancies. Patients with comorbidities are less likely to be offered and to receive curative-intent treatment for their cancer. Curative-intent treatments for solid tumor subtypes typically involve surgery and may additionally involve chemotherapy and radiotherapy; curative-intent therapies for hematologic malignancies typically involve chemotherapy and may require autologous or allogeneic stem cell transplant. Some illustrative examples of the impact of comorbidity on treatment selection and receipt are reviewed below; the available data are limited by variability in the definitions of comorbidity and the tools used to measure it. In general, comorbidity affects curative-intent treatment decisions independent of age but to a lesser extent than age itself.

Breast. In an analysis of the SEER-Medicare dataset, patients with early breast cancer and severe ("unstable") comorbidities are less likely to receive breast-conserving surgery (BCS) plus radiotherapy (RT) versus BCS alone or mastectomy, and this finding is independent of age; interestingly, patients with less severe ("stable") comorbidities were more likely to receive BCS + RT than those women with no

comorbidities (Yasmeen et al. 2013). The findings of CALGB 9343 (Hughes et al. 2013), indicating that adjuvant RT may be omitted in patients ≥70 years with early favorable-risk tumors, have not significantly changed overall practice patterns for these patients, and comorbidity continues to be associated with decreased receipt of adjuvant RT. (Chu et al. 2017) However, though age is associated with decreased receipt of adjuvant systemic therapy (chemotherapy and hormonal therapy) (Bouchardy et al. 2003), comorbidities do not seem to affect these decisions in most studies (Lash et al. 2003; Houterman et al. 2004).

Colorectal. Studies of curative-intent surgery for patients with colorectal cancer either show no association (Lemmens et al. 2005; Janssen-Heijnen et al. 2005) or an inverse association (Zhang et al. 2007) between increasing comorbidity and receipt of surgery. For rectal cancer, receipt of adjuvant RT is lower among patients with comorbidity (Janssen-Heijnen et al. 2005). Numerous studies confirm that receipt of adjuvant chemotherapy is lower for patients with comorbidity, independent of age (Etzioni et al. 2008; Khrizman et al. 2013). In SEER-Medicare data, the OR for receipt of chemotherapy is 0.38 for patients with the most comorbidity (CCI ≥2), compared to no comorbidity (CCI 0) (Schrag et al. 2001).

Lung. The presence of comorbidity is associated with lower resection rates in patients aged 60–79 with localized non-small cell lung cancer (NSCLC) (Janssen-Heijnen et al. 2005). However, age appears to be much more predictive of treatment receipt than comorbidity: in a study of >20,000 veterans ≥65 years, comorbidity was only weakly negatively associated with treatment receipt, and a fit patient aged 75–84 with no comorbidities was significantly less likely to receive surgery than a patient aged 65–74 with severe comorbidity (Wang et al. 2012). For limited small cell lung cancer, patients ≥70 with comorbidities are more likely to receive chemotherapy alone versus definitive chemoradiation, independent of age (Janssen-Heijnen et al. 2005).

Other solid tumors. In patients >75 years with localized prostate cancer, patients with comorbidities were less likely to receive radical prostatectomy and more likely to receive RT or hormonal therapies (Hall et al. 2005). In patients >70 years with ovarian cancer, increasing severity of comorbidity was associated with less use of surgery and standard chemotherapy (Jorgensen et al. 2012).

Hematologic malignancies. In studies of older adults with aggressive non-Hodgkin lymphoma (NHL), comorbidity was either not associated with receipt of curative-intent therapy (Lin et al. 2012) or inversely associated (although with less effect than increasing age) (Janssen-Heijnen et al. 2005). For patients with leukemia or being considered for hematopoietic stem cell transplant, a comorbidity index has been developed and validated (Hematopoietic Cell Transplantation-Comorbidity Index, HCT-CI) (ElSawy et al. 2015), with strong prognostic significance. It has been used to select intensity of leukemia treatment for older adults (Djunic et al. 2012) and is suggested to evaluate eligibility for transplant in addition to age (Sorror et al. 2014).

Comorbidities and Cancer Treatment Toxicity

A description of treatment tolerance and toxicity is difficult to distill from discussion of individual interactions between treatment and specific chronic conditions; for example, patients with renal insufficiency are likely to be at high risk from nephrotoxic chemotherapy, but are not necessarily at higher risk of toxicity from other therapies. However, a number of studies have examined the relationship between general measures of comorbidity and cancer treatment tolerance. In the abovementioned review of comorbidity and chemotherapy use in patients with solid tumors (Lee et al. 2011), five of seven studies examining chemotherapy toxicity demonstrated increased rates of grade 3–4 toxicity in patients with comorbidities; in three other studies, there were no differences in hospitalization rates or complications at 1 year between patients with and without comorbidities. Multiple other studies have indicated that comorbidity is associated with

increased toxicity from chemotherapy (Hall et al. 2005; Gronberg et al. 2010) or RT (Hamstra et al. 2013) or increased surgical complications (Dehal et al. 2013; van Gestel et al. 2013; Tomaszewski et al. 2014). However, other studies have found no increase in chemotherapy toxicity (Jehn et al. 2014; Gross et al. 2007; LoConte et al. 2010; Vickers et al. 2012) or adverse surgical (Peters et al. 2011; Lemmens et al. 2007) or RT (Peters et al. 2011; Cardia et al. 2011) outcomes. Moreover, patients with comorbidity benefit from treatment for their cancer in many of these studies, with further confirmation of benefit in propensity-matched cohorts (Gross et al. 2007; Bradley et al. 2014). Patients with more lethal cancers and comorbidities may gain more benefit than risk from aggressive antineoplastic therapy, even if elderly; on the other hand, patients may be over-treated if they have less aggressive malignancies, such as low-risk prostate cancer, and are more likely to die from non-cancer causes (Bradley et al. 2014).

For older patients with cancer, tools have been developed and validated to predict chemotherapy toxicity (Hurria et al. 2011a; Extermann et al. 2012). In the development cohort for the Chemotherapy Risk Assessment Scale for High-Age Patients (CRASH) score, 518 patients $\geq$70 years with hematologic and solid tumor malignancies were assessed at baseline with CGA, including comorbidity assessment with the CIRS-G, and then followed up to 6 months to measure incidence of grade 3–4 toxicity during chemotherapy (Extermann et al. 2012). CIRS-G was not associated with chemotherapy toxicity in this cohort and is not included in the final scoring tool. In the development of the Cancer and Aging Research Group (CARG) tool (Hurria et al. 2011a), 500 patients $\geq$65 years with solid tumor malignancies were assessed at baseline, including comorbidity evaluation with the OARS Physical Health survey; this was not associated with grade 3–5 toxicity from chemotherapy, but several items related to comorbidity are included in the final model: anemia, renal insufficiency, and poor hearing were all associated with increased toxicity in this cohort.

Impact of Cancer Treatment on Comorbidities

The impact of cancer treatment on comorbidities is obviously highly dependent on the individual comorbidities as well as the particular treatment regimen chosen. It is important to remember that for chemotherapy regimens in particular, the treatment encompasses not only the chemotherapeutic agents but a number of supportive care medications, increasing the risk of drug-drug and drug-disease interactions. Please refer to ▶ Chap. 20, "Pharmacology of Aging and Cancer" for additional discussion of these risks. For older adults, the impact of cancer treatment on the development or trajectory of geriatric syndromes (including dementia/cognitive impairment, frailty/functional impairment, and incontinence) is of particular interest.

Cognitive impairment. Postoperative delirium is common after cancer surgery; incidence in studies ranges from 11% to 50% (Zhu et al. 2017; Raats et al. 2015; Gallagher et al. 2014; Takeuchi et al. 2012). Although approximately 30–40% of cases are preventable, high-risk patients are often not identified and managed preoperatively, and delirium is often not recognized early, if at all (Korc-Grodzicki et al. 2015). Delirium has long-term consequences for the older patient, including persistent cognitive impairment and even progression to dementia, as well as significantly increased mortality (Inouye et al. 2014).

The subjective phenomenon of "chemo brain" has long been recognized by patients young and old, but the extent of objective impairment varies across studies (Ahles et al. 2012); patient-reported measures in patients with breast cancer who received adjuvant chemotherapy demonstrate significant impairment persisting to at least 6 months post-chemotherapy (Janelsins et al. 2016), and studies of childhood survivors of cancer indicate that cognitive issues can persist years after completion of treatment (Williams et al. 2016b). Hormone therapy, in particular androgen deprivation therapy (ADT) for prostate cancer, has also been associated with cognitive decline, particularly for visuomotor tasks (McGinty et al. 2014), and evidence suggests the risk of impairment increases

with increasing length of treatment (Gonzalez et al. 2015). However, not all studies have confirmed an association between ADT and cognitive decline (Alibhai et al. 2010).

It has long been recognized that RT to the brain, particularly whole-brain RT (WBRT), can cause significant cognitive impairment. Although modern RT techniques prevent most cases of acute brain injury and early-delayed impairment (1–6 months posttreatment), up to 90% of patients develop cognitive impairment >6 months post-treatment ("late-delayed brain injury") (Greene-Schloesser et al. 2012). This impairment, which includes progression to overt dementia, has significant interactions with and effects on quality of life (QoL) and functional status (Greene-Schloesser and Robbins 2012).

Functional impairment and frailty. Data on the effects of cancer treatment on functional status and emergence of frailty are very limited. Obviously, older patients may become functionally impaired after cancer surgery due to immobility, pain, delirium, or a combination of factors; increased age, pre-existing severe comorbidities, and frailty/sarcopenia increase the risk of postoperative functional decline and disability (Billmeier et al. 2013; Shen et al. 2017). The effects of chemotherapy on functional status and development of frailty are less clear; the implementation of longitudinal CGA measures over time throughout the treatment course in multiple ongoing studies will hopefully address this question. The use of ADT in older men with prostate cancer has been associated with falls and frailty (Bylow et al. 2011; Winters-Stone et al. 2017), presumably due to the decline in testosterone and subsequent changes in body composition such as muscle loss and gain of fat. These functional impairments can persist even after discontinuation of ADT (Moe et al. 2016).

Incontinence. Urinary incontinence impairs QoL and social functioning in older adults. Both prostatectomy and prostate irradiation cause high rates of urinary incontinence (Wallis et al. 2017). Urinary incontinence a year post-surgery is most prevalent in men who were obese and inactive (59%) compared to nonobese and physically active (16%) (Wolin et al. 2010). Incontinence can also result from treatment of rectal, gynecologic, or bladder cancers, particularly after pelvic surgery or irradiation, metastatic cancer to the spine causing spinal cord compression, or use of neurotoxic chemotherapies such as taxanes (Denlinger and Engstrom 2011; Shah-Khan and Shah 2008).

Conclusion

The interrelationships between age, comorbidity, cancer, and cancer treatment are complex and heterogeneous and not easily distilled for use in algorithmic approaches to the treatment of the older patient. However, this chapter has attempted to review what is known about these relationships and provide a general approach to the older patient with cancer and comorbidity. Patient preferences play a strong role in treatment decisions, and life expectancy should be estimated for every patient to assist in calculation of the risk/benefit ratio of treatment options, particularly for curative-intent therapies. Online tools such as the CARG and CRASH scores for chemotherapy toxicity can help further refine estimation of risk. In addition to considering the impact of treatment on the trajectory of chronic diseases in older patients, providers should also consider the potential impact on a subset of comorbid conditions particularly associated with aging: the geriatric syndromes, including frailty, cognitive impairment, and incontinence.

Many gaps in knowledge still exist regarding the impact of comorbidity in older adults with cancer. Measures of comorbidity vary widely across studies, and the best method for measuring it is unclear (Sarfati 2012). Many studies do not incorporate measures of comorbidity at all, leading to calls for standardized inclusion of estimation of comorbidity burden in clinical trials (Williams et al. 2016a). Common eligibility criteria in clinical trials limit enrollment of older adults with comorbidities, severely limiting the evidence base available for clinical decision-making. Inclusion of a more representative population in clinical trials, via relaxed eligibility criteria, and use of "practical" clinical trial design are two approaches to provide more generalizable

data (Kim et al. 2016). Ultimately, bridging these knowledge gaps is crucial to providing high-quality care for older patients with cancer.

Biomarkers of Aging (With a Clinical Potential in Oncology)

23

Joleen M. Hubbard

Contents

Abstract

Frailty is a result of underlying physiologic processes associated with aging that lead to poor functional reserve. With increasing degrees of frailty, the ability to recover from major stresses on the body such as cancer treatment becomes more difficult. Varying degrees of frailty can be subtle, which explains the difficulty of distinguishing which older adults will have excess toxicity from cancer therapy and ones will tolerate it well. Thus, a biomarker of aging would be a very useful tool to predict toxicity and functional decline with cancer treatment and guide treatment decisions for older patients.

Based on the large body of work in the field of aging research, several processes have emerged as hallmarks of the aging process. There is a decline of the lymphocyte component of the total leukocyte count. Systemic inflammation increases and likely contributes to age-related diseases. Telomere length decreases with cellular replication over time. Finally, repeated exposure to environmental stress results in cellular senescence. Researchers are now exploring biomarkers of these processes and their potential application in geriatric oncology. While they may not be pure aging biomarkers, they may be characterized as biomarkers of frailty that have the

potential to identify patients at increased risk for adverse events, functional decline, and poorer survival related to cancer treatment. This chapter will discuss the characteristics of an aging biomarker, the various markers that have been investigated, and the evidence for the use of these biomarkers in older adults with cancer.

Biological marker · Frailty · Inflammatory markers · Telomere length · Immunosenescence

Introduction

Frailty exists on a continuum from pre-frail to frail, eventually leading to disability. As a person progresses on this continuum, their functional reserve decreases, placing the patient at increased risk for poor outcomes after major physiologic stresses on the body such as injury, surgery, and cancer therapy. While older age is a risk factor for frailty, the development of frailty is not dependent on chronologic age. Frailty is a result of underlying physiologic processes leading to poor functional reserve, and measurement of these processes can give more of a sense of a person's biologic age.

Understanding a patient's biologic age is a large need in the field of oncology. Varying degrees of functional reserve among older cancer patients result in great heterogeneity in the ability of older adults to tolerate cancer treatment. Some older patients tolerate treatment well and derive as much benefit from treatment as younger patients, while others have increased rates of toxicity resulting in treatment reductions and/or cessation of treatment. This variation in treatment tolerance is likely a reflection of varying degrees of frailty among older patients, which is a known risk factor for poor tolerance of cancer treatment. A number of studies have shown that pre-frail and frail patients, identified by a geriatric assessment, are at increased risk of toxicity to cancer therapy (Extermann et al. 2012; Hurria et al. 2011; Cohen et al. 2016).

Currently, pre-frail and frail patients are identified by administering a geriatric assessment tool. There is international consensus emphasizing the importance of geriatric assessment in older adults, although there is a lack of consensus on which scale to use (Wildiers et al. 2014). Geriatric assessment tools have a moderate ability to predict toxicity; however, the lack of financial resources and expertise has limited the routine use of these tools in routine clinical practice in the United States. As the cancer incidence rises with the rapidly aging population, this will become an increasing problem.

Although useful for identifying frail patients, geriatric assessments do not give us a measure of the underlying physiologic mechanisms that contribute to frailty. There is a known phenotype associated with both aging and frailty, which includes cellular and systemic inflammation, shortened and/or dysfunctional telomeres, and a decrease in muscle mass. These factors are likely interconnected as part of an "inflammaging" process and may be candidates for easily measuring a patient's degree of frailty and, therefore, biologic age.

The Ideal Aging Biomarker

The American Federation for Aging provided guidelines on four characteristics of an ideal aging biomarker (Simm et al. 2008; Baker and Sprott 1988; Johnson 2006). The biomarker of aging should be associated with the following abilities:

1. Predict the rate of aging.
2. Monitor the process of aging, not the biology of a disease.
3. Be tested repeatedly without harming the individual.
4. Be able to be tested in both human and animal models.

The difficulty with identifying biomarkers of frailty in the oncology population is that there is a large interplay between the potential biomarkers, disease, and treatment. Patients may be frail

related to the disease itself. For instance, patients with widely metastatic disease have a high degree of systemic inflammation leading to anorexia, cachexia, and poor physical performance. In chemosensitive disease, treatment of these patients with systemic therapy can result in improvement of these processes. In addition, the treatment of the disease may contribute to frailty (Demaria et al. 2017; Bailur et al. 2017).

Since many processes related to aging and frailty contribute to diseases associated with aging, it is unlikely that we will find a pure biomarker of aging that is not affected by the underlying disease. However, these markers may be very useful as predictive markers of toxicity and/or functional decline from cancer therapy. These biomarkers could be used to predict adverse outcomes prior to initiating therapy and may be a useful guide during the treatment of the disease.

The Ideal Frailty Biomarker for Oncology

Given the interplay of biomarkers of frailty between the patient, the disease, and the treatment, it will be important to assess these markers over time to determine their ability to predict which patients are at risk. Biomarkers of frailty need to be tested in prospective clinical trials to determine the following:

1. Feasibility of rapid, repeated measurement before, during, and after treatment.
2. Correlation with toxicity (development of adverse events).
3. Correlation with adjustments in doses, withholding doses, or discontinuation of treatment.
4. Correlation with physical performance and functional decline.

Identifying frailty among cancer patients is extremely important for multiple reasons. First, it is important to recognize upfront which patients are at increased risk for toxicity and decreased functional decline with cancer treatment. This information helps guide the clinician and patient to make informed choices regarding the type and aggressiveness of cancer treatment that patient should pursue. Second, while on cancer treatment, it is important to recognize if frailty is developing and/or worsening, so that adjustments in doses and interventions such as physical therapy and nutritional support can be offered to prevent the transition into disability. Third, investigating the underlying biology is the identification of targets for the development of therapeutic and/or pharmacologic interventions.

Classes of Biomarkers of Aging

Cellular Markers of Inflammation

Increased age is associated with decreased cell-mediated immunity termed immunosenescence. In the peripheral blood, this manifests as an increase in myeloid cells and a decrease in lymphoid cells (Sieburg et al. 2006). In the general geriatric population, lymphopenia is considered to be a marker of frailty. In the general geriatric population, higher neutrophil and lower lymphocyte counts are associated with lower physical activity and poor muscular strength (Fernandez-Garrido et al. 2014).

Numerous studies have evaluated lymphopenia as a marker for outcomes in oncology patients. Lymphopenia is independently associated with both progression-free and overall survival in a variety of cancers (Ray-Coquard et al. 2009). Low lymphocyte counts may also be a predictor for hematologic toxicity. When measured prior to treatment, lymphopenia has been shown to be associated with higher levels of chemotherapy-induced neutropenia and febrile neutropenia (Blay et al. 1996; Ray-Coquard et al. 2003).

The exact mechanism is unknown, but there is a suggestion that early lymphoid precursors are the most sensitive to induction of differentiation in response to DNA damage (Wang et al. 2012). Regardless of the cause, lymphopenia is considered a marker of immunosenescence (Falandry et al. 2013; Pawelec and Solana 1997). Multiple studies have evaluated the

lymphocyte count in relation to other leukocytes and platelets as a marker of aging and/or frailty as well as a prognostic factor. The neutrophil-lymphocyte ratio (NLR), the lymphocyte-monocyte ratio (LMR), and the platelet-lymphocyte ratio (PLR) all have robust data showing an association with oncologic outcomes. Because these ratios can be derived from a complete blood count test routinely measured prior to treatment, they may be a readily accessible, easily measured biomarker.

Neutrophil-Lymphocyte Ratio (NLR)

A recent meta-analysis of 100 studies including 40,559 patients with solid tumors reported by Templeton et al. (2014a) evaluated the effect of the neutrophil-lymphocyte ratio (NLR) on cancer-specific and overall survival outcomes. The hazard ratio for overall survival among all tumor types and stages showed poorer outcomes for patients with a high NLR (cutoff 4.0) in terms of cancer-specific survival (HR 1.61, 95% CI = 1.36–1.91; $P < 0.001$), progression-free survival (HR 1.63, 95% CI = 1.39–1.91; $P < 0.001$), and overall survival (HR 1.81, 95% CI = 1.67–1.97; $P < 0.001$). These effects were consistent regardless of the disease subtype, site of disease, and stage of disease.

More recently, the relationship between frailty and ratios of leukocyte counts was evaluated in older adults with cancer (Nishijima et al. 2017). Using the Carolina Frailty Index (CFI), 133 patients who had a geriatric assessment were characterized as robust (54%), pre-frail (22%), and frail (24%). The CFI was positively correlated with the NLR ($r = 0.22$, $p = 0.025$). On multivariate analysis, those with an elevated NLR were more likely to be frail or pre-frail (OR 3.8, 95% CI = 1.1–12.8). Higher NLR was also significantly associated with instrumental activity of daily living (IADL) scores ($p = 0.040$) and a prolonged timed up and go (TUG) test ($p = 0.016$).

The relationship between the NLR both frailty and survival outcomes in these studies warrants further investigation to determine how best to utilize this information to guide cancer treatment for older adults.

Lymphocyte-Monocyte Ratio (LMR)

The aforementioned study reported by Nishijima et al. (2017) also evaluated the relationship between the LMR and frailty. The LMR was positively correlated with the IADL score ($r = 0.197$, $p = 0.046$). Patients with prolonged TUG tests also had a lower LMR ($p = 0.013$).

The LMR has also been shown to correlate with oncologic survival outcomes in multiple different malignancies. A meta-analysis involving 4260 patients with head and neck cancer demonstrated a significant associated with elevated LMR and improved DFS (HR 0.70; 95% CI 0.62–0.80) as well as improved OS (HR 0.5; 95% CI 0.44–0.57) (Tham et al. 2018). Another meta-analysis of 1795 patients with various stages of pancreatic cancer also demonstrated improved disease control DFS/RFS/TTP (HR =0.38, 95% CI: 0.15–0.95, $P = 0.04$) and OS (HR = 0.56, 95% CI: 0.38–0.83, $P = 0.004$) for those with an elevated LMR. These results were independent of ethnicity, surgical treatment, and cancer stage (Li et al. 2017).

The largest meta-analysis evaluating the relationship between LMR and non-hematologic solid tumors was reported by Nishijima et al. (2015). This analysis included 11,197 patients from 29 studies. Patients that had a LMR <3.0 had poorer cancer-specific survival (HR, 1.73; 95% CI: 1.55–1.93; $P < 0.001$), disease-free survival (HR, 1.56; 95% CI: 1.31–1.86; $P < 0.001$), and overall survival (HR, 1.56; 95% CI: 1.27–1.91; $P < 0.001$). The LMR was prognostic for survival for multiple tumor types and stages of disease.

Platelet-Lymphocyte Ratio (PLR)

Templeton et al. (2014b) also performed a large meta-analysis investigating the prognostic role of the PLR in 12,574 patients with solid tumor malignancies. Among the 12 studies with a dichotomous definition for elevated PLR (median cutoff 185), the hazard ratio for PLR on overall survival was stronger for patients with metastatic disease (HR 2.0; 95% CI: 1.6–2.7) than patients with nonmetastatic disease (HR 1.5; 95% CI: 1.0–2.2). Within the eight studies that categorized PLR into three groups (<150/150–300/>300),

the association with poorer overall survival was significant for metastatic disease (HR 1.6; 95% CI: 1.1–2.4) but nonsignificant for early-stage disease (HR 1.0; 95% CI: 0.8–1.3). The negative prognostic association for PLR was significant for colorectal, hepatocellular, gastroesophageal, ovarian, and pancreatic carcinomas in the dichotomous group and for colorectal cancers among the studies that categorized PLR into three groups. Based on these results, PLR may also provide prognostic information for older adults with cancer, especially for those with metastatic disease.

Circulating Markers of Systemic Inflammation

Levels of circulating pro-inflammatory mediators such as IL-6 and TNF-alpha D-dimer, and plasminogen activator inhibitor (PAI)-1, increase with age (Ershler et al. 1993; Fagiolo et al. 1993; Sindermann et al. 1993). These markers are thought to accelerate the aging process and exacerbate multiple age-related diseases (Bruunsgaard et al. 2001; Franceschi et al. 2007; Vasto et al. 2007). There is a co-stimulatory affect between markers of inflammation and pro-thrombotic factors. Cytokines such as TNF-α and IL-6 stimulate production of pro-thrombotic factors such as PAI-1 and fibrinogen (Kanapuru and Ershler 2009). In turn, D-dimer, a marker of the clotting process, has been shown to induce synthesis and release cytokines IL-1B, IL-6, and PAI-1 (Robson et al. 1994). Likewise, when vascular cell adhesion molecule (VCAM) is exposed to inflammatory markers TNF-α and IL-1B, it is cleaved to soluble (s)-VCAM, which is elevated in patients with age-related diseases (Carter and Wicks 2001).

Several studies have shown that inflammatory mediators correlate with measures of physical function and are elevated to a greater degree in frail patients than in age-matched, non-frail controls (Cesari et al. 2004; Ferrucci et al. 2002a; Hubbard et al. 2009; Leng et al. 2007; Pieper et al. 2000; Walston et al. 2002; Yao et al. 2011; Collerton et al. 2012). A study of 110 patients >75 years demonstrated that a combination of inflammatory markers (TNF-α, IL-6, CRP) and low albumin correlated with lower physical function scores, independent of age, sex, body mass index (BMI), smoking status, number of comorbidities, and number of medications (Hubbard et al. 2009).

In the general geriatric population, elevated chronic inflammatory and pro-coagulant markers predict functional decline (Cohen et al. 2003; De Martinis et al. 2006; de Saint-Hubert et al. 2011; Ferrucci et al. 1999, 2002b; Huffman et al. 2011; Puts et al. 2005; Reuben et al. 2002). An analysis of disabled women ≥65 years showed higher IL-6 levels at baseline were associated with higher levels of functional decline including decreased mobility, activities of daily living deficits, increased walking limitations, and decreased walking speed, compared to women with low IL-6 levels (Ferrucci et al. 2002a). These markers also correlate with functional decline after hospitalization and postoperative complications from oncologic surgery (de Saint-Hubert et al. 2011; Ronning et al. 2010).

Markers of chronic inflammation and coagulation are also associated with all-cause mortality risk in the elderly. In a population of community-dwelling adults (mean age 78), soluble (s)-VCAM was independently correlated with poorer functional status at baseline (HR 1.2, $p = 0.002$) (Huffman et al. 2011). After adjusting for functional status, demographic factors, and comorbidities, higher plasma s-VCAM, D-dimer, and IL-6 concentrations were independently related to mortality within 4 years. Inflammatory mediators can have greater predictive ability among patients without baseline functional impairments, suggesting they may identify pre-frail patients that may not otherwise have been identified without extensive geriatric assessment testing (Pieper et al. 2000; Cohen et al. 2003; Reuben et al. 2002).

Circulating Inflammatory Markers in Oncologic Studies

Markers of systemic inflammation correlate with physical function, functional decline, and mortality in the general geriatric population. These circulating inflammatory markers are felt to reflect

underlying biologic aging and frailty. Multiple studies have evaluated these biomarkers' association with frailty, toxicity, and survival outcomes for cancer patients.

Systemic inflammatory markers have been shown to correlate with frailty in cancer patients. Browers et al. (2015) measured systemic markers of inflammation felt to be related to aging and frailty including telomere length, interleukin-6 (IL-6), regulated upon activation normal T cell expressed and secreted (RANTES), monocyte chemotactic protein 1 (MCP-1), and insulin-like growth factor 1 (IGF-1) among young ($n = 42$) and older ($n = 162$) patients with nonmetastatic breast cancer. The biomarker levels were then correlated with patients' Leuven Oncogeriatric Frailty Score (LOFS). The investigators found that IL-6 levels correlated with frailty among older patients. IL-6, telomere length, IGF-1, and MCP-1 correlated with age.

Multiple studies have shown elevated inflammatory markers are associated with a poorer prognosis among oncology patients. For example, higher circulating IL-6 levels have been shown to correlate with poorer survival in patients with hormone-refractory metastatic breast cancer (Bachelot et al. 2003). Likewise, elevated C-reactive protein (CRP) is associated with worse survival in multiple urologic cancers, including renal, bladder, and prostate cancers as well as colorectal and gastroesophageal cancers (Saito and Kihara 2011; Roxburgh and McMillan 2010).

Investigators have shown that systemic inflammation plays a major role in the decline of cancer patients, especially in terms of nutrition and physical function. The systemic inflammation-based Glasgow Prognostic Score (GPS), based on levels of CRP and hypoalbuminemia, was derived as a surrogate of systemic inflammatory status. Data from 8333 patients from 28 studies in patients with operable cancer demonstrate the GPS was a predictor of survival independent of stage, pathological features, and comorbidity (HR range 1.5–5.1) (McMillan 2013). Similar prognostic ability of the GPS was seen in 11 studies involving 1504 patients with metastatic cancer. In a study of 56 patients with advanced-stage colorectal cancer, the GPS not only predicted survival, but it also predicted toxicity to chemotherapy (Sharma et al. 2008). A higher GPS score correlated with higher grade 2/3 diarrhea and higher incidence of grade 2/3 toxicity compared to those with lower scores ($p = 0.023$ and 0.015, respectively).

One argument against using inflammatory mediators has been that they may reflect other underlying processes such as the response to surgical intervention and the underlying cancer itself. If used in the adjuvant setting, circulating acute phase reactants from the surgery itself should be resolved 6–8 weeks postoperatively (Baigrie et al. 1992; Wirtz et al. 2000). In addition, multiple studies have associated inflammatory markers with poorer prognosis and toxicity, independent of tumor stage (Bachelot et al. 2003; Laird et al. 2013).

Although chronic inflammatory mediators have not been established as true aging biomarkers, the fact that they correlate with measures of physical status, functional decline, and mortality in the older adult population suggests they may reflect underlying biologic processes that could predict a patient's risk of toxicity from cancer treatment and, therefore, their ability to tolerate it. The levels of inflammatory mediators can be measured with ELISA assays on plasma samples collected during blood draws routinely done for cancer management. Therefore, the measurement of these levels could become an efficient way of providing the oncologist insight into potential tolerance of cancer therapy as well as prognosis and provide guidance as to the most appropriate regimens and doses for the older cancer patient.

Telomere Shortening

Telomeres are DNA protein complexes capping the end of chromosomes that provide chromosomal stability and prevent DNA degradation and recombination. Telomeres shorten with each cell division, eventually leading to cellular senescence and apoptosis (de Lange 2002). Cawthon et al. (2003) reported a pivotal study of 143 patients >60 years of age which showed that shorter telomere length correlated with both

age and higher mortality. Subsequent studies have not shown a consistent correlation with telomere length and mortality, but several have shown positive association with telomere length and better health in older age (Atzmon et al. 2010; Bekaert et al. 2005; Njajou et al. 2009; Pallis 2013). Various lifestyle factors, including obesity, smoking, and marital status, also affect telomere length (Mishra et al. 2012).

Because there appears to be associations with telomere length and health status, investigators have studied telomere length as a potential biomarker among cancer patients. Willeit et al. (2010) evaluated telomere length of 787 individuals. Shorter telomere length was associated with developing cancer over the course of 10 years (HR 1.60; 95% CI: 1.30–1.98; $P < 0.001$). The shortest telomere length also correlated with higher cancer mortality (HR 2.13; 95% CI: 1.58–2.86; $P < 0.001$). There have been reports of shortened telomere length and poorer prognosis in a number of different cancers including colorectal, breast, lung, and sarcoma (Pallis et al. 2014). However, not all studies consistently show a correlation between telomere length and cancer incidence and/or mortality (Pooley et al. 2010; Prescott et al. 2012).

It does not appear that telomere length is associated with frailty as measured by geriatric assessment. A study reported by Falci et al. (2013) evaluated telomerase activity and telomere length of cancer patients $\geq$70 years of age ($n = 52$) compared with 39 age-matched controls that underwent a geriatric assessment. Telomere length was significantly shorter in cancer patients, but only correlated with age in non-cancer patients. They did not find that telomere length was associated with geriatric assessment scores. Several other studies have not found a correlation between measures of frailty and telomere length in the general population (Lorenzi et al. 2018; Saum et al. 2014).

Telomere length does not appear to be associated with frailty, which would potentially predict an increased risk for toxicity. There are a few studies on telomere length and toxicity. One study in colorectal cancer did find an association of telomere length with hematologic toxicity and mucositis in patients receiving 5-fluorouracil (Garg et al. 2012). Among breast cancer patients receiving paclitaxel, those with a higher percentage of critically shortened telomeres had higher toxicity, but there was no correlation with toxicity and average telomere length (Quintela-Fandino et al. 2017).

While telomere length plays a role in the aging process, the conflicting results in studies related to cancer incidence and mortality make the role of this biomarker in geriatric oncology unclear. In addition, there is not universal agreement on the method of measuring of telomere length, which can be complex (shortest telomere length by fluorescent in situ hybridization, quantitative real-time polymerase chain reaction [qPCR], measuring cleaved fragments). Further studies are needed to determine if telomere length can consistently predict outcomes for cancer patients.

Cellular Senescence Markers

Senescent cells accumulate with age as a reaction to lifelong cellular stress (Ressler et al. 2006; Liu et al. 2009). Although senescent cells are not mitotically active, they acquire a senescence-associated secretory phenotype (SASP), with increased production of proteins involved in chronic inflammation and coagulation, very similar to the markers associated with poorer physical function and mortality in the elderly (Campisi 2005; Coppe et al. 2008). p16INK4a is considered a marker of cellular senescence and is felt to be a potential biomarker for aging.

The p16INK4a gene is a cell cycle regulator that inhibits downstream activation of cyclin-dependent kinases 4/6 leading to permanent cell cycle arrest, otherwise known as cellular senescence (Romagosa et al. 2011). p16INK4a is activated during cellular stress responses and considered a tumor suppressor gene. Circulating levels of p16INK4a can be measured in T lymphocytes by qPCR.

p16INK4a age levels increase with age and age-related diseases (Lawrence et al. 2018; Tsygankov et al. 2009). Higher levels of p16INK4a expression in T lymphocytes are seen

with lifestyle factors such as inactivity and tobacco use (Song et al. 2010). p16INK4a levels appear to be associated with frailty in the general geriatric population. In a small study of older women ($n = 11$) in a resistance training program, higher levels of p16INK4a-positive cells in adipose tissue were associated with poorer grip strength, 400-meter walk time, gait speed, and their perception of mobility (Justice et al. 2017). Waaijer et al. (2017) found a stronger association of p16INK4a levels with functional measures than with age.

Transgenic mouse models allow researchers to track and eliminate senescent cells. After exposure to a cellular senescence-inducing agent such as chemotherapy, Demaria et al. (2017) showed senescent cells in mice contribute to local and systemic inflammation leading to worsening side effects, and clearing these cells reduces those effects. They also found that humans with increased senescent marker expression in T cells prior to receiving chemotherapy had a greater degree of chemotherapy-induced fatigue. These results suggest that markers of senescence may be able to predict greater toxicity to cancer treatment.

Importantly, chemotherapy may also affect p16INK4a expression in patients exposed to chemotherapy. In a study of breast cancer patients undergoing adjuvant anthracycline-based chemotherapy, chemotherapy exposures were associated with an increase in p16INK4a expression that would be found with 10.4 years of aging (Sanoff et al. 2014). Therefore, this biomarker may also predict accelerated aging in cancer survivors.

Discussion

It is likely that all of the aforementioned potential markers of aging and/or frailty are interrelated. For instance, telomere shortening and the resultant dysfunction lead to cellular senescence (Wang et al. 2012). Cellular senescence is felt to be an underlying process contributing to the increase in inflammation associated with functional decline and mortality in the elderly (Franceschi et al. 2007; De Martinis et al. 2006; Freund et al. 2010). Inflammation can lead to impaired lymphopoiesis (Wang et al. 2012). Systemic inflammation is also associated with sarcopenia, which can result in a more sedentary lifestyle that is also associated with shortened telomeres (Mishra et al. 2012).

Regardless of the underlying process that set off the interrelated processes associated with biologic aging, further study is needed to determine which markers are the most easily measured, low burden to patient and the financial system, and the most reliable at identifying frail patients vulnerable to the toxicities from cancer treatment. This research will also provide valuable information on the underlying biologic mechanisms contributing to increased toxicity and poorer survival outcomes. Ultimately, identifying the underlying mechanisms of frailty leaves the potential for pharmacologic interventions that may improve the tolerability of cancer treatment for frail patients.

Geriatric Screening in Cancer Patients 24

Lore Decoster and Cindy Kenis

Contents

Abstract

Cancer is primarily a disease of older persons. This older population with cancer is heterogeneous with respect to overall health status due to differences in the aging process. The performance of a multidimensional geriatric assessment is recommended in older patients with cancer to inventory health problems and tailor geriatric interventions and treatment decisions accordingly. This strategy however requires

resources and may not be necessary in all older patients with cancer. Therefore the use of geriatric screening tools is proposed in order to identify those patients who would benefit from further evaluation by geriatric assessment and subsequent multidisciplinary approach. Several screening tools have been studied in geriatric oncology with different performance for various parameters such as sensitivity and specificity for detecting an impaired geriatric assessment and prognostic and predictive value for various outcome measures, depending on the setting. In clinical practice, the preferred screening tool may depend on the clinical situation. If the result is abnormal, a screening tool should always be followed by a geriatric assessment and subsequent multidisciplinary approach.

Introduction

Treatment decisions for older patients with cancer are complex. Because of variations in the aging process, the overall health status of this older population with cancer is very heterogeneous with differences in comorbidities, functional status, geriatric syndromes, and socioeconomic aspects resulting in decreased physical reserve. In addition, cancer and its treatment may further decrease this physical reserve. Chronological age is a poor descriptor of this process, and the gold standard for its evaluation is a geriatric assessment (GA) (Puts et al. 2012; Wildiers et al. 2014). A GA is a multidimensional, interdisciplinary diagnostic process to determine an older person's psychosocial, functional, cognitive, and nutritional health status in order to develop a coordinated and integrated plan for treatment and follow-up. The performance of GA in older patients with cancer has shown to identify previously unknown health problems, predict treatment-related toxicity and oncological outcomes including overall survival, and influence cancer treatment decisions. In addition GA can be followed by GA-based recommendations and interventions in order to possibly improve outcome parameters. Implementing the performance of a GA in all older patients with cancer is however resource-intensive, which ultimately limits its widespread use, and not necessary in all patients. Therefore the use of geriatric screening tools has been proposed to identify patients in need of GA and multidisciplinary approach (Decoster et al. 2015; Hamaker et al. 2012).

Definition of a Screening Tool

A screening tool in older patients with cancer is a brief assessment, conducted to help the clinician to identify those patients in need of further evaluation by GA and subsequent GA-based recommendations and interventions and follow-up. A GA assesses multiple geriatric domains such as social support, functional status (FS), falls, cognition, mood, nutrition, comorbidities, and polypharmacy. A screening tool typically assesses only a few domains from the GA or each of the domains superficially.

Screening tools might also have prognostic/predictive value for important outcome measures such as treatment-related toxicity, functional decline, and overall survival (OS).

Screening tools should be simple and take a few minutes, while GA takes much longer. High sensitivity and negative predictive value (NPV) are the most important characteristics for screening tools in order to identify all patients at risk for adverse outcomes. In addition, a high specificity is of interest in order to limit the number of fit patients who unnecessarily undergo GA.

Screening Tools in Older Patients with Cancer

The International Society of Geriatric Oncology (SIOG) provided a consensus statement to recommend the use of screening tools for older patients with cancer who should be further assessed by GA (Decoster et al. 2015).

A variety of screening tools have been investigated in older patients with cancer with the G8 and Vulnerable Elders Survey-13 (VES-13) as the most widely studied. Screening tools are available at www.siog.org.

Most screening tools were compared to geriatric assessment (GA) for sensitivity and specificity, although the geriatric domains and tools used in the GA as well as the cutoff for abnormal GA varied between different trials making comparison difficult. In addition many screening tools were also compared to different outcome measures including FS, treatment-related toxicity, and OS. There are a variety of benefits and challenges with each screening tool, which must be weighed against one another.

G8

The G8 is an eight-item screening tool, specifically developed for older patients with cancer (Bellera et al. 2012). The G8 covers a number of domains from the GA including functional capacity, health, nutritional status, and cognitive impairment as well as self-rated health. The maximum total score for the G8 is 17, and a score of 14 or lower is considered abnormal. The G8 can be administered by any health-care professional and takes about 5 min to complete.

The G8 is one of the most sensitive screening tools (sensitivity ranging from 65% to 92%); however, it has only modest specificity (range 3–75%) (Decoster et al. 2015). The G8 has also been validated in a population of older patients with hematological malignancies where a cutoff of $\leq$14 resulted in a sensitivity of 89% and a specificity of 100% (Velghe et al. 2014).

Attempts to improve the G8 have been made. An IADL-modified G8 with replacement of the G8 neuropsychological item by the four-item IADL score leads to a more specific test than the original G8 (specificity of 67% vs. 65%, $p < 0.05$), while sensitivity was maintained (77% vs. 76%, $p = 0.53$) (Petit-Monéger et al. 2016). In a second study, a modified G8 was developed including six independent predictors for abnormal G8: weight loss, cognition/mood, performance status, health status, polypharmacy ($\geq$6 medications per day), and history of heart failure/coronary heart disease. This modified G8 demonstrated a sensitivity of 89% and a specificity of 79% at the optimized cutoff of $\geq$6/35, and its performance was homogeneous across tumor subtypes (Martinez-Tapia et al. 2016). Both modified G8 tools should be further evaluated within the older population with cancer.

G8 was also compared to different outcome measures. The tool showed high sensitivity and NPV for functional decline within 3 months of cancer treatment decision but low specificity (Kenis et al. 2014). In various cancers, G8 was predictive for chemotherapy-related toxicity, but this was not observed in hematological malignancies (Dubruille et al. 2013; Stokoe et al. 2012). Finally G8 was prognostic for OS in two studies in various cancer types but not in hematological malignancies (Dubruille et al. 2013; Kenis et al. 2014; Liuu et al. 2012).

Vulnerable Elders Survey (VES)-13

The VES-13 is a 13-item self-administered tool developed for identifying older people in the community at an increased risk of functional decline or death over 2 years (Saliba et al. 2001). The VES-13 includes functional capacity, self-reported health, and age. The maximum total score is 10 with a score of $\geq$3 considered abnormal, and it takes approximately 5 min to complete. Patients 85 or older score three points based on their age and are therefore at the cutoff value only because of age. In older persons in the community, abnormal VES-13 was associated with functional decline, OS, and health outcomes (Min et al. 2009; Saliba et al. 2001).

Although self-completion may be an asset because the patient can perform the screening before his/her appointment, this may also be a disadvantage. Patients may over- or underestimate their own health status, and self-completion may sometimes be troublesome because of a low level of education, cognitive impairment, or language barrier. In a study in older patients with breast cancer, more than one third was unable to

complete VES-13 autonomously (Monfardini et al. 2010).

In older patients with cancer, sensitivity of VES-13 ranged from 39% to 88% and specificity from 62% to 100% (Decoster et al. 2015). When compared with subparts of GA, VES-13 showed a high sensitivity for FS but not for comorbidity.

In two studies comparing G8 with VES-13, the G8 was significantly more sensitive (Pottel et al. 2012; Soubeyran et al. 2014).

In various cancers, VES-13 was predictive for the occurrence of severe chemotherapy-related toxicity (Stokoe et al. 2012), and in a study in gastrointestinal cancers treated with chemotherapy, VES-13 was significantly correlated with OS (Kitamura et al. 2013).

Flemish Version of the Triage Risk Screening Tool (fTRST)

The triage risk screening tool (TRST) was developed to identify older patients at risk for failed discharge home from the emergency department (Meldon et al. 2003). The fTRST is a modified version of the TRST developed for older persons on non-geriatric hospital departments. The tool is composed of five yes/no questions, and a score of $\geq$2 is considered as at risk. The fTRST is a very short tool, which takes only 2 min to complete.

In older patients with cancer, the fTRST demonstrated a sensitivity of 64–67% with a specificity of 80–100% when using the validated cutoff of $\geq$2. When lowering the cutoff to $\geq$1, the sensitivity was increased to 91% but at the cost of lower specificity (42–50%) (Decoster et al. 2015).

In two direct comparisons with the G8, the fTRST was equally sensitive (Kenis et al. 2009, 2014).

fTRST was predictive for functional decline and prognostic for OS for both cutoff scores (Kenis et al. 2014).

Groningen Frailty Indicator (GFI)

The GFI is a 15-item questionnaire addressing various domains. It was developed in people aged 65 years and over including hospital inpatients, nursing home residents, and community-dwelling elderly (Steverink et al. 2001). A score of $\geq$4 indicates a risk for physical, social, and/or psychological impairment. In community-dwelling elderly, an abnormal GFI correlated more strongly with a decline in self-management abilities than chronological age (Schuurmans et al. 2004).

In older patients with cancer, the sensitivity to detect abnormal GA ranged from 39% to 66% and specificity from 86% to 87% (Decoster et al. 2015). In direct comparisons, both the G8 and the VES-13 were more sensitive than the GFI (Baitar et al. 2013; Kellen et al. 2010; Kenis et al. 2009).

In two studies in patients treated with chemotherapy, the GFI correlated with OS (Aaldriks et al. 2011, 2013).

Study of Osteoporotic Fractures (SOF) Index

The SOF index is a three-item tool designed to measure pre-frailty and frailty. Patients presenting one of the items were considered to be in a pre-frailty status, and patients with more than one item were considered frail.

In older men and women without cancer, a score of two or more was associated with higher risk of recurrent falls, disability, fractures, and death (Ensrud et al. 2008, 2009).

In various cancer patients, the SOF index demonstrated a sensitivity of 89% and a specificity of 81% when compared to GA (Decoster et al. 2015).

Karnofsky Performance Status (KPS) and Eastern Cooperative Oncology Group Performance Status (ECOG-PS)

KPS and ECOG-PS are tools frequently used by oncologists to classify the performance status of their patients (Karnofsky and Burchenal 1949; Oken et al. 1982).

When compared to the GA, the KPS resulted in a sensitivity and a specificity of, respectively, 29% and 44% for a cutoff value of $<$80 and 78% and 91% for a cutoff value of $\leq$80 (Decoster et al. 2015).

The ECOG-PS on the other hand resulted in a sensitivity of 94% and a specificity of 55% at a cutoff of 1 (Decoster et al. 2015).

Fried Frailty Criteria of Physical Frailty Phenotype

The Fried frailty criteria include five items: weight loss, handgrip strength, gait speed, exhaustion, and physical performance. A score of ≥ 3 indicates "frailty."

In the general population, the physical frailty phenotype predicts the risk of falls, disability, fracture, and death (Ensrud et al. 2008, 2009).

When compared to the GA, the Fried frailty criteria resulted in sensitivity and specificity ranging, respectively, from 37% to 87% and from 49% to 86% (Decoster et al. 2015). In subgroup analysis, wide variations in specificity were observed in different tumor types: for example, 60% in early breast cancer versus 19% in early gastrointestinal cancer (Kellen et al. 2010).

Barber Questionnaire

The Barber questionnaire was developed to identify older persons at risk for dependency in the community (Barber et al. 1980). It consists of nine yes/no questions, and patients with a score of ≥ 1 are considered candidates for further evaluation through GA.

In various cancers, the Barber questionnaire presented a sensitivity of 74% and a specificity of 30% to detect an abnormal GA (Decoster et al. 2015). In a breast cancer population, the sensitivity was lower at 59%, but the specificity was higher at 79% (Molina-Garrido and Guillen-Ponce 2011).

Identification of Seniors at Risk (ISAR)

The ISAR is a six-item, self-administered tool developed for the emergency department (McCusker et al. 1998). A score of two or more categorizes patients as at risk for adverse outcome.

For older patients presenting at the emergency department, ISAR correlates with baseline functional impairment and with functional decline at 6 months (McCusker et al. 1998).

In older patients with cancer, sensitivity and specificity were 70% and 10%, respectively, to detect abnormal GA (Decoster et al. 2015).

Oncogeriatric Screen (OGS)

The OGS is a screening tool developed for oncology patients aged 75 years or over (Valéro et al. 2011). It consists of ten yes/no questions exploring five items (autonomy, malnutrition, depression, cognition, and comorbidity). Patients are considered in need of further evaluation through GA if at least one response for an item is positive. The OGS is a tool to be filled in by the treating physician.

In a study in various cancers, patients presented with one to three risks out of the five items were considered "vulnerable," and patients with four or five risks were considered "frail" using the Balducci classification ("fit," "vulnerable," and "frail") (Balducci and Extermann 2000). In this trial the OGS demonstrated a sensitivity of 88% and a specificity of 44% (Valéro et al. 2011).

Abbreviated Comprehensive Geriatric Assessment (aCGA)

The aCGA is a screening tool developed in older patients with cancer and consists of the 15 items of the full GA that correlated the most with the findings of the GA (Overcash et al. 2005, 2006). It takes approximately 5 min to complete the aCGA.

The aCGA has a sensitivity of 51% and a specificity of 97% when compared to the full GA (Decoster et al. 2015). The sensitivity was high for functional impairment (97% for activities of daily living (ADL) and 92% for instrumental activities of daily living (IADL)) but low for cognitive impairment (23%) (Kellen et al. 2010).

Gerhematolim

Gerhematolim is a screening tool developed for older patients with hematological malignancies (Fargeas et al. 2009a). It is composed of 27 questions and biological data.

In a study in hematological malignancies, it resulted in a sensitivity of 95% and a specificity of 87% compared with GA (Fargeas et al. 2009b).

Senior Adult Oncology Program 2 (SAOP2)

The SAOP2 screening tool was developed for older patients with cancer to determine when a multidisciplinary approach was indicated (Extermann et al. 2009).

In a small group of patients with various cancers, the tool demonstrated a very high sensitivity of 100% but a low specificity of 40%. Of note, specificity in this trial was defined as impairment in the same domain as the screening question.

Functional Tests as Screening Tool

Different functional tests have also been investigated as screening tools to identify patients at risk of adverse outcome who might benefit from GA.

The first is the physical performance test (PPT), which was designed in older outpatients (Reuben and Siu 1990). It is an objective measure of physical function based on seven timed items. Each item was scored on a five-point Likert scale (0–4) with the best score being 28. Patients were classified in three classes: no health impairment (PPR $>$ 20), moderate impairment (10 $<$ PPT $<$ 21), and severe impairment (PPT $<$ 11). The PPT takes approximately 5 min. When compared to the KPS, the PPT seemed to be a more accurate measure of impairment in older cancer patients with 83% of patients with a KPS between 60% and 80% demonstrating no health impairment according to the PPT (Terret et al. 2003).

The handgrip test measures the maximal strength of the dominant hand using a hydraulic hand dynamometer. In the general older population, handgrip strength is predictive for functional decline (Garcia-Pena et al. 2013). The result of this test in older patients with cancer was significantly higher in fit patients and lower in frail patients according to both the impression of the oncologist and the VES-13 (Servent et al. 2012). In older patients with cancer, the handgrip test was significantly associated with OS (Kanesvaran et al. 2011).

The timed up and go (TUG) is a test of balance and requires a person to stand up, walk 3 m, turn, walk back, and sit down. The time to complete the test is correlated with functional mobility in hospitalized older persons (Podsiadlo and Richardson 1991). In a cohort of older patients undergoing surgery for solid tumors, the TUG was as predictive as the GA in identifying patients at high risk of complications (Huisman et al. 2014).

Use of Screening Tools in Daily Practice

In a busy oncology practice, SIOG recommended to incorporate a geriatric screening tool in the routine assessment of all older patients with cancer in order to identify patients in need of further evaluation by GA (Decoster et al. 2015). No particular screening tool was recommended but rather left to the discretion of the professional health-care provider to choose the tool that fits best with their practice model and patient population. The choice of the tool may therefore depend on different factors such as ease of use, local experience and preferences, available time, personnel to perform the test, and accuracy of the test in the setting. However it was clearly stated that screening tools should not replace GA and an abnormal result on the screening tool should always be followed by GA in order to set up a multidisciplinary care plan for tailored geriatric interventions and follow-up.

Discussion

The management of older patients with cancer is a major public health challenge due to the heterogeneity of this population with regard to social

status, functional capacities, mental status, nutrition, comorbidities, and polypharmacy. Chronological age and clinical judgment are not effective to identify fit from unfit patients.

The gold standard to obtain a complete image of the global health of the older patient remains the performance of GA, which may lead to GA-based recommendations and interventions and treatment adaptations (Wildiers et al. 2014). However although the performance of such a lengthy GA should be considered as time well spent, it is not necessary in all older patients with cancer.

For this reason a two-step approach has been proposed by the recommendation guideline of SIOG in which patients are first screened by means of a geriatric screening tool and, if the result is abnormal, are evaluated by GA (Decoster et al. 2015). It is important to realize that although we have a large amount of screening performance data, screening tools should never replace GA because such an assessment will give more information on the global health status of the patient, will correctly identify the problems present, and allow tailored interventions.

The use of screening tools in geriatric oncology does have some limitations such as the following: (1) the minimum age (65 or 70) at which to start applying these tools is unclear with both age cutoffs used in clinical studies, (2) screening tools do not identify the precise geriatric problem in contrary to GA and as a consequence cannot trigger tailored recommendations and interventions and follow-up, and (3) for centers that do not have access to geriatric expertise, an abnormal result on the screening tool should be followed by a referral to a geriatric team outside the center and may thus cause delays in treatment decision-making and planning, but on the other hand, a normal result on the screening tool may reassure the treating physician that the patient will likely not have an abnormal GA.

Many different screening tools have been studied in older patients with cancer, and some of them were specifically developed for the older population with cancer (G8, OGS, aCGA, SAOP2, Gerhematolim). The two most studied screening tools in older patients with cancer are G8 and VES-13, of which the G8 data are the most robust (extensively studied, high sensitivity with acceptable specificity, and prognostic/predictive for important outcome measures). However, the performance of different screening tools may depend on the setting, and the preferred screening tool may depend on the clinical situation. For that reason, SIOG did not recommend or discourage a specific screening tool (Decoster et al. 2015). The choice of screening tools is thus left to the treating geriatric oncology team based on the local expertise and situation; however preference should go to tools, which are extensively studied and demonstrated high sensitivity.

Comprehensive Geriatric Assessment (CGA) for Cancer Patients

25

Koshy Alexander and Beatriz Korc-Grodzicki

Contents

Abstract

Chronologic age alone is a poor descriptor of heterogeneity in the aging process and is an inadequate indicator to determine responses among older patients to cancer treatment. Geriatric conditions such as functional and cognitive impairments are frequently unrecognized or inadequately addressed in older adults. Identifying geriatric conditions by performing a geriatric assessment can help clinicians manage these conditions and prevent or delay their complications. A comprehensive geriatric assessment (CGA) includes evaluation of an older individual's functional status, comorbid medical conditions, cognition, nutritional status, psychological state, and social support, as well as a review of the patient's medications. Multiple studies have shown the benefits of utilization of CGA in older cancer patients.

Administering a CGA may not be practical in all clinical settings. Screening tools may be considered initially keeping in mind that they do not replace CGA. If abnormal, screening should be followed by CGA and guided multidisciplinary interventions. This chapter will describe the CGA domains, the most commonly used assessment tools, as well as the benefits of performing such assessments in the older cancer patients.

Keywords
Geriatric assessment · Physiologic age

Introduction

Geriatric conditions such as functional and cognitive impairments are frequently unrecognized or inadequately addressed in older adults. Identifying geriatric conditions by performing a proper assessment can help clinicians manage these conditions and prevent or delay their complications. Comprehensive geriatric assessment (CGA) involves the evaluation of the physical, psychosocial, and environmental factors that impact the well-being of older individuals (Devons 2002). CGA is a multidimensional, interdisciplinary diagnostic process to determine the medical, psychological, and functional capabilities of a frail elderly person in order to develop a coordinated and integrated plan for treatment and long-term follow-up (Ellis et al. 2011).

Chronologic age alone is a poor descriptor of heterogeneity in the aging process and is an inadequate indicator to determine responses among older patients to cancer treatment. There is wide variation in the ability of patients of the same age to tolerate cancer therapy. A systematic and evidence-based way of describing this heterogeneity is needed to guide oncology treatment decisions. Rather than chronologic age, patients' physiologic age or fitness level based on a "fit to frail" spectrum is more meaningful. Frailty is an important geriatric syndrome that is characterized by multisystem dysregulation, leading to decreased physiological reserve and increased vulnerability for adverse health outcomes (Li et al. 2011). Frail older adults have multiple chronic conditions and difficulties maintaining independence. They may be more vulnerable to therapy toxicities and may not have substantial lasting benefits from therapy. CGA may be used as a tool to determine reversible deficits and devise treatment strategies to mitigate such deficits. The CGA represents the future of geriatric oncology to reduce toxicities and treatment-related hospitalization of the elderly (Della Pepa et al. 2017).

Which patients would benefit from CGA is an area of controversy. Many oncologic studies have used age $\geq$70 years as the age for implementing geriatric assessment, but other age cutoffs have been proposed (Wildiers et al. 2014). The International Society of Geriatric Oncology (SIOG) in 2005 created a task force to review the evidence on the use of CGA in older cancer patients. SIOG recommends that a CGA, with or without screening and with follow-up, should be used in older cancer patients (age $\geq$65) in order to detect unaddressed problems and improve their functional status and possibly their survival (Extermann et al. 2005). Administering a CGA can be time consuming and may not be practical in all clinical settings. Hence screening tools can be considered initially. Screening tools (detailed in ► Chap. 24, "Geriatric Screening in Cancer Patients") should not replace CGA but could be used in a busy practice in order to identify those patients in need of full CGA. If abnormal, screening should be followed by CGA and guided multidisciplinary interventions (Decoster et al. 2015). The National Comprehensive Cancer Network (NCCN) guidelines for senior adult oncology addresses specific issues related to the management of cancer in older adults including the role of CGA in proper selection of patients for cancer treatment (Hurria et al. 2012). In 2015, an expert panel using the Delphi technique met consensus that "all patients aged 75 years or older and those who are younger with age-related health concerns" should undergo CGA and that all domains (function, physical performance, comorbidity/polypharmacy, cognition, nutrition, psychological status, and social support) should be included (Mohile et al. 2015).

Domains

CGA in older cancer patients includes evaluation of functional status, comorbid medical conditions, cognition, nutritional status, psychological state, and social support as well as a review of the patient's medications (Extermann and Hurria 2007). When providers and investigators evaluate only some, but not all of the above domains, it is called Geriatric Assessment (GA), as opposed to evaluation of the full spectrum which constitutes a CGA. There are no specific tools that are set as the "gold standard" for the assessment of each domain. The choice of tools is usually provider and resources driven (Table 1).

Cognition

One in three seniors dies with a form of dementia in the United States today. Of the estimated 5.5 million Americans living with Alzheimer's dementia in 2017, an estimated 5.3 million are age 65 and older (Alzheimer's Association 2017). The incidence of dementia doubles every 5 years after the age of 65 years (Corrada et al. 2010). Since over 50% of new cancers are diagnosed in those over the age of 65, the overlap of cognitive dysfunction and cancer is a real problem. Preexisting dementia affects the diagnosis and treatment of cancer. Patients with a precancer diagnosis of dementia are less likely to receive invasive diagnostic testing as well as standard or curative intent treatments (Gupta and Lamont 2004; Gorin et al. 2005).

Impaired cognition can result in significant difficulties in understanding treatments and procedures, which is important in the process of obtaining informed consent, remembering and following treatment instructions, delaying diagnosis of complications, and decreasing adherence to prescribed primary and supportive treatments. At the same time, both cancer and cancer therapies can negatively affect cognition, and older adults with preexisting cognitive impairment may be more susceptible to cognitive decline with therapy than younger patients (Magnuson et al. 2016). Hence, it is imperative to evaluate and continue to monitor cognitive function in older cancer patients through the treatment trajectory.

Tools for the Assessment of Cognition

The *MiniCog*® (Shephard and Kosslyn 2005) is a fast and simple screening test that requires minimal training to administer. It combines an uncued 3-item recall test with a clock-drawing test (CDT) and assesses executive function and memory. Scoring is not affected by education levels or language abilities.

The *Folstein Mini-Mental State Examination (MMSE)* (Folstein et al. 1975) is a widely used 30-point screening tool that assesses multiple cognitive domains. Education levels, language, and culture can be barriers.

The *Montreal Cognitive Assessment (MoCA)* (Nasreddine et al. 2005) was designed as a rapid screening instrument for mild cognitive dysfunction. It takes a little longer to administer, 10–12 min, but is more sensitive in detecting mild changes. It is also a 30-point tool that assesses multiple cognitive domains including attention and concentration, executive function, conceptual thinking, etc.

The *Blessed Orientation-Memory-Concentration (BOMC) Test* and a 6-item Orientation-Concentration-Memory test based on it are available (Katzman et al. 1983). A positive correlation has been shown between scores on the 6-item test and neuropathology (plaque counts obtained from the cerebral cortex of 38 subjects at autopsy). This test is easily administered by a nonphysician and can discriminate among mild, moderate, and severe cognitive deficits. This test is used in the Cancer and Aging Research Group toxicity tool (Hurria et al. 2011).

Cognitive screening tests may not be sensitive enough to detect subtle disorders. Hence more detailed neuropsychological tests administered by trained neuropsychologists may be considered when necessary.

Function

Performance Status

Functional disability is common in older cancer patients and its prevalence increases with age

Table 1 Domains and frequently used assessment tools

Domain	Tool	Type of tool	Scoring, comments
Cognition	MiniCog (Shephard and Kosslyn 2005)	Performance based	Not influenced by education level or language abilities
	Mini-Mental State Examination (Folstein et al. 1975)	Performance based	Score may be influenced by educational level, age, language, and motor, visual, or hearing impairments
	Montreal Cognitive Assessment (Nasreddine et al. 2005)	Performance based	Greater sensitivity to detect mild levels of cognitive impairment
	The Blessed Orientation-Memory-Concentration Test (Katzman et al. 1983)	Performance based	A 6-item shorter version based on this tool is also validated. Each score is multiplied by a constant, yielding a weighted score
Function and performance	Performance status scales: Karnofsky Performance Status (Schag et al. 1984)	Self-report	Scored 100 (normal without complaints) to 0 (dead), at 10 point decrements
	Eastern Cooperative Oncology Group (Oken et al. 1982)	Self-report	Scored 0 (fully active without restrictions) to 5 (dead)
	Activities of Daily Living (Katz 1983)	Self-report	Skills needed to live independently in the home
	Instrumental Activities of Daily Living (Lawton and Brody 1969)	Self-report	Tasks needed to live independently in the community
	Timed Up and Go (Podsiadlo and Richardson 1991)	Performance based	Quick, requires no special equipment or training
	Gait Speed (Studenski et al. 2011)	Performance based	Speed is of walk at a "comfortable pace"
	Grip Strength (Mathiowetz et al. 1985)	Performance based	Requires a hand-held dynamometer
	Tinetti Gait and Balance Scale (Tinetti 1986)	Performance based	Balance-sitting, standing, turning in diff circumstances. Gait-stance, initiation, stepping, trunk sway
Comorbidity	Charlson Comorbidity Index (Charlson et al. 1987)	Calculated	Mortality predictor
	Cumulative Illness Rating Scale – Geriatrics (Salvi et al. 2008)	Calculated	Diseases of physiological systems are assigned points (1–5) based on their severity to get a total score
Nutrition	Body Mass Index	Calculated	Based on height and weight
	Mini Nutritional Assessment (Oster et al. 1999)	Self-report	Identifies those "at risk" of malnutrition
Psychosocial status and quality of life	Medical Outcomes Study- Social Support Survey (Sherbourne and Stewart 1991)	Self-report	Measures emotional, tangible, affectionate support, and positive social interaction
	UCLA Loneliness Scale (Russell 1996)	Self-report	Options for each question ranges from "Often" to "Never"
	Geriatric Depression Scale (Yesavage et al. 1982)	Self-report	Distinguishes mild and severe depression from normal
	Patient Health Questionnaire-9 (Kroenke et al. 2001)	Self-report	Scores each of the 9 DSM-IV criteria as "0" (not at all) to "3" (nearly every day)
	Distress Thermometer (Roth et al. 1998)	Self-report	Single item tool. Scored 0 (none) to 10 (extreme)

(*continued*)

Table 1 (continued)

Domain	Tool	Type of tool	Scoring, comments
Medication appropriateness and polypharmacy	Brown Bag Review	Medication review	Reduces costs and improves patient welfare
	Use of inappropriate medications in the elderly; e.g., Beer's criteria (Fick et al. 2015) Screening Tool of Older People's Prescriptions and the Screening Tool to Alert to Right Treatment (O'Mahony et al. 2015)	Medication review	Identifies inappropriate medications and prescribing omissions
	Number of medications	Medication review	Identifies polypharmacy
	Fit fOR The Aged score (Wehling et al. 2016)	Medication review	Classifies medications into A (indispensable) through D (avoid)

(Serraino et al. 2001). Performance status scores such as the Eastern Cooperative Oncology Group (ECOG) (Oken et al. 1982) and Karnofsky Performance Status (KPS) (Schag et al. 1984) are scores often used in oncology to estimate a patient's functional status. However, they tend to under-represent the degree of functional impairment in older patients (Repetto et al. 2002).

A better understanding of the older patient's functional status can be obtained by assessing the patient's ability to perform his/her activities of daily living (ADL) independently. The basic ADLs are self-care skills needed in order to live independently in the home, which include bathing, dressing, grooming, toileting, transferring, feeding, and continence (Katz 1983). In patients with dementia, caregiver rated ADL tools are also available (Bucks et al. 1996; Hindmarch et al. 1998). The instrumental activities of daily living (IADLs) refer to tasks that are needed to live independently in the community and include shopping, transportation, using the telephone, managing finances, medication management, cooking, cleaning, and laundry (Lawton and Brody 1969).

In a study on older lung cancer patients receiving chemotherapy, independence in performing IADLs and higher quality of life scores were associated with better prognosis (Maione et al. 2005). Impaired functional status is associated with a higher risk of toxicity from chemotherapy. The Chemotherapy Risk Assessment Scale for High-Age Patients (CRASH) score (Extermann et al. 2012) and the scoring system developed by the Cancer and Aging Research Group (CARG) (Hurria et al. 2011) detailed in ▶ Chap. 38, "Early-Stage Breast Cancer in Older Adults" include assessment of patient's function.

Falls

A fall is as "an unexpected event in which the participant comes to rest on the ground, floor, or lower level" (Lamb et al. 2005). Approximately 30% of people over 65 years of age living in the community fall each year (Campbell et al. 1990). The rate of fall-related injuries increases with age (Peel et al. 2002). Older people fall more often for a variety of reasons including problems with balance, poor vision, and dementia. Falls tend to have a multifactorial etiology including intrinsic (person-related) and extrinsic (environment-related) factors. Hence the assessment (Smith et al. 2017) and interventions (Gillespie et al. 2012) to prevent them should be multidisciplinary (physical therapy, occupational therapy, home safety, medication evaluation, evaluation for cataracts, etc.) with the goal to minimize the risks without compromising functional independence. The Tinetti Gait and Balance Scale is a rapid,

reproducible assessment tool for the evaluation of fall risks, gait, and balance (Tinetti 1986). The test is scored on the patient's ability to perform specific tasks and takes 10–15 min to complete.

Physical Function

Physical function can also be assessed by other objective and sensitive measures of performance, including gait speed, grip strength, balance, and lower extremity strength. Decreases in these measures are associated with worse clinical outcomes (Cesari et al. 2009). A commonly used test for functional mobility is the *Timed Up and Go (TUG)*, which is brief and simple to implement in clinical settings. It measures the time it takes for a patient to stand up from an armchair, walk 10 ft. to a marker on the floor, turn, walk back to the chair and sit down (Podsiadlo and Richardson 1991). It can predict the patient's ability to go outside alone safely. Those with compromised performance in the TUG commonly have difficulties in ADLs. *Gait Speed* is an important indicator in older persons, as it has been shown to be an independent predictor of mortality across numerous population-based studies (Studenski et al. 2011). Average gait speeds for community-dwelling older adults range from 0.60 to 1.45 m/s with a desired gait speed often cited as 1.2 m/s, the speed required to cross most intersections (Hornyak et al. 2012). Patients are instructed to "walk at a comfortable pace" when measuring the speed. Grip strength measured by a hand-held dynamometer is important to assess cancer patients and is relatively quick and easy to do. *Grip strength* correlates with sarcopenia and has been shown to be associated with adverse outcomes in patients with cancer (Kilgour et al. 2013; Chen et al. 2011).

Comorbidity

Comorbidity in cancer patients represents the sum of the medical conditions, other than the cancer, the individual suffers from. As an individual ages, the life expectancy decreases (Walter and Covinsky 2001) and the number of comorbid medical conditions increases (Yancik 1997). Consequently, an older patient may have multiple competing risks for death. In the elderly, the combination of a high burden of competing risks and high rates of treatment-related complications conspires to reduce the net benefit of numerous interventions (Welch et al. 1996). Hence the impact of these comorbid medical conditions should be taken into consideration when charting out treatment plans and estimating the risks and benefits of treatments. Frequent comorbidities in the elderly such as cardiovascular disease, hypertension, diabetes, or dementia influence the management of cancer. Comorbidities may increase the risk of complications, modify cancer behavior, or mask symptoms. On the other hand, cancer treatment may decompensate or worsen previously stable comorbid conditions.

Measurement of Comorbidity

Comorbidity burden is often measured using standardized indices such as the Charlson Comorbidity Index (CCI) (Charlson et al. 1987) and the Cumulative Illness Rating Scale – Geriatrics (CIRS-G) (Salvi et al. 2008). The CCI is the most extensively studied comorbidity index for predicting mortality. It is based on the 1-year mortality of patients admitted to a medical hospital service. It is a simple instrument validated in older cancer patients with well-defined rating criteria. The CCI however, may under-detect non-lethal endpoints. The Cumulative Illness Rating Scale (CIRS) addresses all relevant body systems without using specific diagnoses. Its geriatric version, the CIRS-G, was designed for use in elderly populations. While it details several geriatric concerns, the scale may over-detect minor problems and it is quite complicated to rate. Other valid comorbidity indices such as the Index of Coexisting Disease (ICED) and the Kaplan Index have been less utilized in the Geriatric Oncology literature (de Groot et al. 2003).

Nutrition

Nutritional status should be assessed as part of CGA, as malnutrition and weight have significant roles in older cancer patients. With the growing

global obesity epidemic, there is consistent evidence that higher amounts of body fat are associated with increased risks of a number of cancers (Lauby-Secretan et al. 2016). On the other hand, weight loss in patients with cancer is an independent adverse prognostic factor and is associated with a lower performance status (Dewys et al. 1980). Malnutrition is prevalent up to 83% in older patients with cancer scheduled to receive chemotherapy and weight loss has been observed in 40–91.6% of patients during the course of chemotherapy, depending on cancer location (Cailleta et al. 2016). Malnutrition is associated with treatment complications and increasing mortality in patients receiving chemotherapy, radiation therapy, or surgery (van der Schaaf et al. 2014; Gourin et al. 2014; Fiorelli et al. 2014; Langius et al. 2013; Ehrsson et al. 2012; Buskermolen et al. 2012). Assessment tools include Body Mass Index (BMI), unintentional weight loss, as well as longer, validated tool such as the Mini Nutritional Assessment (MNA) (Oster et al. 1999). The MNA correlates highly with clinical assessment and objective indicators of nutritional status.

Psychosocial Status

Social Isolation

Social isolation, the lack of social ties, is an independent predictor of mortality in the older population in general (Seeman et al. 1993). In a study on breast cancer survivors, patients with inadequate social support experienced greater distress (Kornblith et al. 2003). Social isolation and low levels of social support have been associated with an increased incidence of cancer as well as higher mortality risk in patients with cancer (Ikeda et al. 2013; Kroenke et al. 2006). Increased social isolation is a risk factor for poor tolerance of adverse effects of cancer treatment (Penedo et al. 2012). The *Medical Outcomes Study (MOS) Social Support Survey* provides a multidimensional tool to evaluate emotional/informational, tangible, and affectionate support as well as positive social interactions. Adequacy of the MOS Social Support Survey correlates with improved functioning and wellbeing, whereas low scores indicate the need for support services to improve health outcomes (Sherbourne and Stewart 1991). The *UCLA Loneliness Scale* measures the adequacy of an individual's interpersonal relationships and loneliness (Russell 1996).

Depression

In older cancer patients, the prevalence of clinically significant depression ranges from 3% to 25%. Though the psychological impact of cancer on the elderly is less adverse or similar compared with younger patients, organic mental disorders are more prevalent in the older group (Kua 2005). Patients with cancer and depression are less likely to receive definitive treatment, and hence, experience worse survival compared to those without depression (Goodwin et al. 2004). The *Geriatric Depression Scale* (in its variants with 2, 4, 15, or 30 items) is a widely used tool to assess depressive symptoms. It is a multiquestion, self-rating instrument, validated in the aged, and capable of distinguishing the mildly and severely depressed from normal (Yesavage et al. 1982). In various studies utilizing CGA in patients with solid tumors, it identified depression in 10–65% of patients (Caillet et al. 2014). The *PHQ-9 questionnaire* scores each of the nine DSM-IV criteria for depressive disorders as "0" (not at all) to "3" (nearly every day) making a criteria-based diagnosis. It is additionally, a reliable and valid measure of depression severity. These characteristics plus its brevity make the PHQ-9 a useful clinical and research tool (Kroenke et al. 2001).

Distress

Receiving a diagnosis of breast cancer, contemplating the uncertainty of the future, and anticipating the daunting process of choosing and undergoing treatments can induce significant distress. The *Distress Thermometer (DT)* is a single item tool that asks patients to rate their distress in the past week on a scale of 0 ("no distress") to 10 ("extreme distress") (Roth et al. 1998). It is used in psycho-oncology and validated for patients and cancer patients' families (Nelson et al. 2010). It offers an efficient means

of identifying cancer patients with psychological distress.

Medications and Polypharmacy

Pharmacotherapy in older patients is a complex issue. Regular, comprehensive medication reviews are necessary to address potentially inappropriate medications (PIM) and to identify potential drug-drug and drug-disease interactions. The review should include prescription and over-the-counter medications as well as all alternative/homeopathic supplements. Pharmacist-led comprehensive medication assessments in geriatric oncology patients have demonstrated a high prevalence of polypharmacy (5–9 medications), excessive polypharmacy (10 or more medications), and PIM use (Nightingale et al. 2015).

Polypharmacy is common among the elderly, and although it can be therapeutic in nature, it is linked to adverse events (Hammond and Wilson 2013). The medical comorbidity burden in older patients increases the number of drugs prescribed increasing the potential for side effects from individual drugs as well as those resulting from drug-drug interactions. There is substantial overlap between use of prescription medications and herbals/supplements. A study showed that among prescription drug users, 16% also took an herbal/supplement for nonspecific reasons such as "health." This raises the concern further for unintended interactions (Kaufman et al. 2002). In cancer patients, the drug burden includes not only those used in the treatment of the cancer but also those used for supportive care and the management of symptoms related to therapy-induced toxicity (Lichtman and Boparai 2008).

Older adults are prone to medication errors and discrepancies due to complex regimens, formulary changes, particularly at changes in care settings such as discharge from the hospital. Patients with medication discrepancies also have higher rehospitalization rates (Coleman et al. 2005). Increased pill burden and regimen complexity can also result in nonadherence.

Tools such as *Beers criteria* (Fick et al. 2015) and *Screening Tool of Older People's Prescriptions (STOPP)* and the *Screening Tool to Alert to Right Treatment (START)* (O'Mahony et al. 2015) can help identify PIMs and potential prescribing omissions (PPO). PIM and PPO exposure are associated with increased rates of hospital visits (Moriarty et al. 2014). Efficient software systems can be incorporated into the electronic prescription algorithm to easily identify PIMs and PPOs.

The *Medication Appropriateness Index Criteria* measures the appropriateness of prescribing.

It uses 10 criteria for *each* medication to determine whether it is appropriate, marginally appropriate, or inappropriate (Samsa et al. 1994).

Fit fOR The Aged (FORTA) is the first positive/negative listing approach labeling medications used to treat chronic illnesses in older patients from A (indispensable), B (beneficial), C (questionable) to D (avoid). Applying FORTA to hospitalized geriatric patients leads to improvement of medication quality (Wehling et al. 2016).

A "*brown bag check up*" (i.e., asking the patient to bring all medications to the visit) is the single most efficient medication review and should be included in the CGA. It is an effective means of helping patients to derive maximum benefit from their medicines, of identifying medication-related problems, and of reducing wastage of medicines (Nathan et al. 1999). Review all medication bottles. Throw away expired medications. Provide patients with a pill box and a large font typed medication list with clear directions and indications.

Benefits of CGA

The CGA has been demonstrated to be superior to clinical judgment, even by experienced clinicians, when used to evaluate older cancer patients for fitness status (Tucci et al. 2009). Multiple studies have suggested a spectrum of benefits that arise from the utilization of CGA in older cancer patients (Table 2). A prospective multicentric study on the large-scale feasibility and usefulness of CGA in clinical oncology showed that CGA

Table 2 Benefits of the CGA in older cancer patients

Detection of unknown geriatric syndromes
Help in treatment decision making
Help in the risk stratification of patients prior to potentially high-risk therapy
Prediction of complication and side effects from cancer treatment
Identification of new deficits during the treatment trajectory
Devise treatment strategies to mitigate geriatric syndromes
Estimation of mortality risk
As the basis for the design of discharge planning

detected unknown geriatric problems in 51% of patients ≥70 years. When the physician was aware of the assessment results at the time of decision making, geriatric interventions were planned in 25.7%, and the treatment decision was influenced in 25.3% of the patients (Kenis et al. 2013). CGA is used in treatment decision making by clinicians, helping to risk stratify patients prior to potentially high-risk therapy. It has a role in predicting complications and side effects from cancer treatment (Hurria et al. 2011; Extermann et al. 2012; Corre et al. 2016). During the cancer treatment trajectory CGA may be used as a tool to identify new deficits such as decline in functional activity levels, and devise treatment strategies to mitigate such deficits. A number of studies have shown the use of CGA in the estimation of survival (Klepin et al. 2013; Stotter et al. 2015; Antonio et al. 2016). The online e-prognosis indices incorporate CGA elements to estimate mortality risk (Yourman et al. 2012). It may provide an effective approach to the management of pain and psychological status in the hospitalized older cancer patient (Rao et al. 2005).

Methods of Administering a CGA

CGA ideally includes an interdisciplinary team of specialized professionals to perform each assessment. Though it can take up to 2 h, most studies that measured time to administer, did it under an hour (Puts et al. 2012). An argument often used against the implementation of CGA in an oncology setting is that it is resource intensive and time consuming (Overcash et al. 2005). There are multiple ways of overcoming this problem. One way is by the use of screening tools to tease out the subset of patients that would need a full CGA, as recommended by the SIOG taskforce (Decoster et al. 2015). However, none of the published assessment tools was recommended by the task force. A review of Table 1 makes it evident that many of the tools used in CGA can be self-report tools. Having patients complete those tools on their own followed by the clinician conducting the other performance-based assessments is another way of overcoming this barrier.

Clinician Interview

A study with 30 cancer patients undergoing chemotherapy or radiotherapy was conducted in 1996. They were given a specifically structured multidimensional questionnaire (MACE) three times during 1 week by two different physicians. They collected information on demographics, socioeconomic status, cognitive status, depression, physical performance, disability, and tumor characteristics. They demonstrated that structured evaluation of functional status is feasible and reliable (Monfardini et al. 1996). A number of studies have since been done where the CGA was implemented by clinicians either in the inpatient setting (Basso et al. 2008) or in the outpatient clinic setting (Molina-Garrido and Guillen-Ponce 2011).

Self-administered

The feasibility of performing a cancer specific GA was studied in 2005. It included the following domains: functional status, comorbidity, cognition, psychological status, social functioning and support, and nutritional status. It was administered to cancer patients receiving chemotherapy at Memorial Sloan-Kettering Cancer Center (New York, NY) or the University of Chicago (Chicago, IL) (Hurria et al. 2005). KPS, TUG, and Blessed Orientation-Memory-Concentration

test were performed by a health care provider. It showed that the GA could be completed by the majority of patients without assistance.

Snail Mail Surveys

A 2002 self-reported assessment study at the Durham Veterans Affairs Medical Center included 266 male patients. They mailed out to these patients a survey that assessed 10 domains (demographics, comorbid conditions, activities of daily living, functional status, pain, financial well being, social support, emotional state, spiritual well-being, and quality of life). 76% of the patients who received their surveys and kept their appointments returned the assessment tool demonstrating that it can be conducted in an outpatient cancer community using a self-report format (Ingram et al. 2002).

Email/Electronic

The Geriatrics division at MSKCC assessed the feasibility of performing an electronic CGA, the *Electronic Rapid Fitness Assessment (eRFA)* (Shahrokni et al. 2017). The questionnaire was emailed to the patients once a geriatric appointment was scheduled. In 2015, 636 older patients with cancer (median age, 80 years) completed the eRFA during preoperative evaluation. The median time to completion was 11 min. Only 13% of patients needed someone else to complete the assessment for them. A tool to assess cognition and the TUG were performed by a clinician at the clinic appointment. This study demonstrated the feasibility of an electronic CGA. The eRFA is now used at MSKCC on a routine basis.

Another study from the City of Hope Comprehensive Cancer Center looked at computer-based GA in older cancer patients via two methods of electronic data capture compared with paper-and-pencil data capture. It too showed that delivering a computer-based GA is feasible, reliable, and valid (Hurria et al. 2016).

Conclusions

As the incidence of cancer increases with age and the geriatric population continues to expand, it is critical to develop strategies to provide optimal care for older cancer patients. It is important to distinguish functional from chronologic age and to evaluate physiologic reserves, risk of treatment complications, and probability of survival. Identifying remediable conditions and addressing them could improve therapeutic tolerability, quality of life, and overall survival. All older cancer patients should undergo CGA and the results should be analyzed relative to morbidity, mortality, and other outcomes. The availability of self-administered paper or electronic formats makes this increasingly feasible. If impediments to performing a CGA still exist, screening tests could be used. However, those found to be at risk on the screening test, should be further evaluated with a full CGA.

Frailty in Cancer Patients

Siri Rostoft

Contents

Abstract

An older cancer patient who is frail has reduced tolerance to treatment such as chemotherapy and surgery and is at increased risk of toxicity and complications. The term *frailty* is defined as an increased vulnerability to stressors due to a multisystem reduction in reserve capacity. Frailty is linked to higher chronological age and comorbidities but is considered a distinct concept. By identifying frailty in a cancer patient, the treating physician gets a more precise estimation of individual vulnerability compared to looking at chronological age alone. Recognizing frailty has consequences for treatment decisions in the oncology setting because frailty summarizes health status. A patient who is frail has a limited life expectancy compared to a fit patient with the same chronological age. When interpreting clinical trials in older cancer patients, reporting of patient frailty in addition to age is necessary because it is relevant for evaluating generalizability to clinical practice. Unfortunately, frail patients are often excluded from clinical trials.

VES-13	Vulnerable Elders Survey-13

Introduction

An older cancer patient who is frail has reduced tolerance to treatment such as chemotherapy and surgery and is therefore at increased risk of toxicity and complications. The term *frailty* is defined as an increased vulnerability to stressors due to a multisystem reduction in reserve capacity. Frailty is linked to higher chronological age and comorbidities but is considered a distinct concept. By identifying frailty in a cancer patient, the treating physician gets a more precise estimation of individual vulnerability compared to looking at chronological age alone. Recognizing frailty has consequences for treatment decisions in the oncology setting because frailty summarizes health status.

Case Vignette

A 69-year-old male was admitted to the cancer unit at his local hospital because of locally advanced rectal cancer. According to guidelines, the proposed treatment was preoperative radiochemotherapy followed by surgery. In his medical records, it was noted that he had hypertension and that he was overweight.

He was treated as an inpatient, and 1 week into treatment he became noncooperative and aggressive, pulled out his i.v. lines, and refused to get out of bed. The attending oncologist suspected acute delirium and called the geriatrician to get some advice.

The geriatrician was surprised that acute delirium had developed in an otherwise healthy 69-year-old male undergoing chemoradiotherapy. However, when looking more closely into the premorbid functional and cognitive status of the patient, it became evident that he fulfilled the criteria for frailty: A discussion with his daughter revealed that he was dependent in basic activities of daily living and needed home nursing four times a day. He was able to ambulate in his own house, but he never went out of the house, and he had fallen several times during the last months. He had gradually (over years) developed problems with his short-term memory and was now unable to pay his bills or engage in social activities. The information of his premorbid functional and cognitive status was highly relevant in the context of a newly diagnosed rectal cancer. The risk of delirium is increased in patients with pretreatment cognitive impairment (Fong et al. 2015). The risk of further functional decline is high (Covinsky et al. 2011). The risk of chemotherapy toxicity is higher when there is mobility reduction, falls, or need for assistance with medication (Hurria et al. 2011). The risk of complications after surgery is much higher in patients who are frail before surgery (Kristjansson et al. 2010). Furthermore, long-term survival is poor in frail individuals with rectal cancer (Ommundsen et al. 2014).

Definition and Identification of Frailty in Cancer Patients

Frailty is defined as a state of increased vulnerability toward stressors due to a multisystem reduction in reserve capacity (Morley et al. 2013). In the context of older patients with cancer, a frail patient has increased risk of toxicity of medical cancer treatment and radiation therapy and an increased risk of postoperative complications after cancer surgery (Feng et al. 2015; Handforth et al. 2015). Frailty is more prevalent with increasing age, but high chronological age does not necessarily lead to frailty. Thus, by estimating a person's level of frailty, one gets a more precise quantification of vulnerability than by looking at chronological age alone (Hubbard and Woodhouse 2010). Frailty is

associated with other negative outcomes such as institutionalization, functional decline, and mortality (Morley et al. 2013).

Even though there is an agreement in the literature about how to define frailty, there is no standardized way of identifying frailty in an individual patient. The two most commonly used methods are the physical frailty phenotype and the accumulation of deficits theory (Huisingh-Scheetz and Walston 2017). In the phenotypic frailty model, which was proposed by Fried and colleagues, the patient is assessed in five dimensions: weight loss, physical activity, exhaustion, grip strength, and walking speed (Fried et al. 2001). A person who scores poorly (below the 20 percentile of the normal population) in at least three of these five dimensions is considered frail, while a person who scores poorly in two dimensions is categorized as pre-frail. This way of assessing frailty is closely linked to sarcopenia (loss of muscle mass and function) and functional status, but does not take into account comorbidity and cognitive function. In this theory, underlying physiological decline contributes to frailty and leads to comorbidities. Rockwood and colleagues, on the other hand, have suggested to assess frailty based on counting the number of deficits across a variety of health indicators such as functional status, cognitive function, comorbidities, emotional and nutritional status, as well as social support (Mitnitski et al. 2001). The more that is wrong with the person, the frailer the person is, and in the end the system fails entirely. In this model, comorbidities and disability are deficits associated with aging that eventually leads to a physiological decline. By performing a geriatric assessment (GA), it is possible to identify the number of deficits in a patient across multiple areas.

In the oncology setting, the clinical definition of frailty suggested by Dr Balducci is still referenced. Dr Balducci outlined three treatment groups of older cancer patients that could be identified from a geriatric assessment (GA) – fit, intermediate, and frail. He suggested that the fit elderly should receive treatment similar to younger patients, while frail elderly should be offered mainly palliative care. The intermediate patients would need an individualized approach (Balducci and Extermann 2000). Balducci's criteria for defining the frail older patients were based on the criteria originally presented by Winograd et al. (1991). The Winograd frailty criteria were impairment of single activities of daily living (ADL), imbalance/dizziness, impaired mobility, chronic disability, weight loss, falls during the last 3 months, confusion, vision or hearing impairment, depression, malnutrition, mild or moderate dementia, urinary incontinence, social or family problems, polypharmacy, and prolonged bed rest. Several of these elements, such as falls, confusion/delirium, and incontinence, are considered *geriatric syndromes*. Geriatric syndromes result from shared risk factors such as high age, cognitive impairment, functional disability, and reduced mobility. Such risk factors lead to falls, delirium, and functional decline and may in turn lead to frailty (Inouye et al. 2007).

Another way of assessing frailty with a single physical performance assessment has been proposed: measuring usual gait speed (Clegg et al. 2015). This can be done by asking a patient to walk 4 m at his or her usual pace and then calculating the speed. A slow gait speed is most commonly defined as less than 0.8 m/s (Odden et al. 2012). Slower walkers or persons not able to complete a 4 m walk test are considered frail. In a recent study, slow gait speed was identified as a predictor of early death in older patients with cancer independent of cancer site and cancer extension, with a hazard ratio of 5.6 (95% confidence interval (CI) 1.6–19.7) (Pamoukdjian et al. 2017). Another example of a single indicator of frailty is multiple falls. In patients undergoing elective colorectal surgery, the incidence of postoperative complications was 100% in patients who had experienced three or more falls in the last 6 months (Jones et al. 2013).

Frailty Tools and Screening

With a variety of tools to choose from, the question of how to assess frailty in the oncology setting is frequently raised. Selecting the right tool will depend on the setting, first of all whether the

setting is clinical practice or research. In general, the screening tools based on phenotypic frailty model work well as pure risk assessment tools, while tools that evaluate various domains of a GA may identify areas that need further investigation and can be optimized or treated, such as malnutrition or depression. A GA is thus able to identify both *if* and *why* a patient is frail.

The most frequently tested screening tools for frailty in geriatric oncology are the geriatric-8 (G8) and the Vulnerable Elders Survey-13 (VES-13) (Luciani et al. 2010; Soubeyran et al. 2014). The G8 is based mainly on a tool called the Mini Nutritional Assessment, and adding ADL questions to the original screening increases its performance (Petit-Moneger et al. 2016). VES-13 is mainly a scoring of functional status. A comprehensive review of frailty screening tests in cancer patients from 2012 concluded that none demonstrate the optimal combination of high sensitivity and negative predictive value and an acceptable specificity for predicting abnormal GA to be considered for favored use (Hamaker et al. 2012). However, it should be noted that none of the tested screening tools in that review included a physical performance measure. It has been shown that screening tools that include objective physical performance measures, such as gait speed or grip strength, have better predictive ability than those without (Woo et al. 2012). Thus, it is recommended that a frailty screening tool should include a simple physical performance measure. In the clinical setting, physicians may consider adding Mini-Cog to screen for cognitive impairment in addition to the frailty screening (Tsoi et al. 2015).

A proposed flowchart for screening for frailty in cancer patients is presented in Fig. 1.

Data Regarding Frailty in Oncology

The exact prevalence of frailty in cancer patients is difficult to assess due to a variety of definitions of frailty in different studies. According to a systematic review from 2015, the prevalence of frailty in oncology varies from 6% to 86%, while the prevalence of pre-frailty is between 13% and 79% (Handforth et al. 2015). In any case, frailty was independently associated with all-cause mortality and treatment complications across different tumor and treatment types. The data linking frailty to postoperative complications across different types of surgery and cancer are solid (Huisingh-Scheetz and Walston 2017). In a prospective cohort of 178 patients over the age of 69 years who were electively operated for colorectal cancer, being frail assessed by the Balducci criteria increased the risk of postoperative complications with an odds ratio of 2.97 (95% CI 1.61–5.50) (Kristjansson et al. 2010). In the same cohort, 5-year survival was 24% in frail patients compared to 66% in non-frail patients (Ommundsen et al. 2014). Neither postoperative morbidity nor survival was related to patient age. A recent systematic review in older surgical cancer patients confirmed that frailty is an important predictor of negative outcomes across different tools and settings (Huisman et al. 2017). For chemotherapy toxicity and radiotherapy fatigue, there are fewer studies looking at frailty, although components of a GA predict toxicity and mortality from chemotherapy (Hurria et al. 2011; Extermann et al. 2012). Among patients over 65 years with cancer, neither the G8 nor the Groningen Frailty Indicator predicted serious events following the first cycle of (radio)chemotherapy (Baitar et al. 2014). However, G8 predicted 1-year survival (Soubeyran et al. 2014). In a study of older patients with stage III or IV colorectal cancer undergoing chemotherapy, VES-13 significantly predicted mortality (Ramsdale et al. 2013). Radiotherapy fatigue was associated with both phenotypic frailty and GA in well-functioning older women with breast cancer (Denkinger et al. 2015).

In conclusion, it seems that at least half of older patients with cancer have either pre-frailty or frailty, and frailty should therefore be assessed routinely. However, establishing a common definition of frailty in oncology that allows for

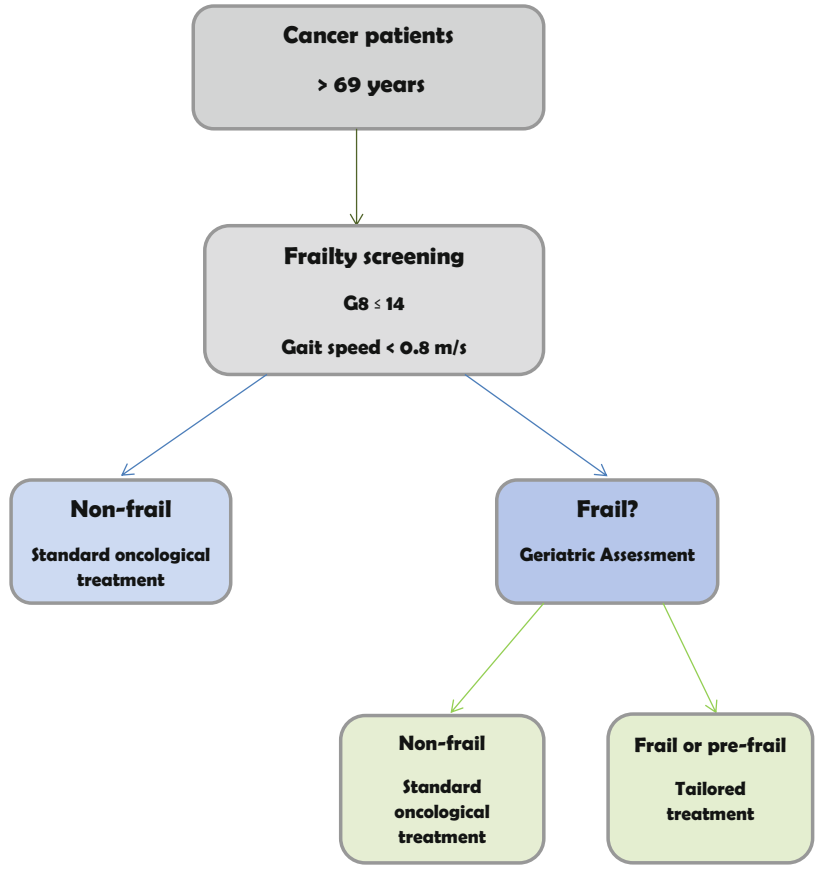

Fig. 1 Proposed flowchart for frailty screening in cancer patients

comparison of datasets is necessary in order to make further advances in this field.

Other Clinical Implications of Identifying Frailty in a Patient with Cancer

Frailty identifies vulnerability that may influence treatment decisions, but there are other clinical implications of identifying frailty in an older patient with cancer that deserves mentioning.

Cognitive impairment: Identifying cognitive impairment in cancer patients is important for several reasons. Firstly, cognitive impairment may influence decision-making capacity. If cognitive testing prior to treatment initiation reveals reduced decision-making capacity, caregivers need to be involved in the decision process.

Secondly, cognitive impairment increases the risk of acute confusional state (delirium) in relation to surgery and chemotherapy. An increased risk of delirium could be communicated to the patient and caregiver in order to reduce the stress of experiencing delirium. Delirium may also be prevented by multifactorial interventions with an odds ratio of 0.47, 95% CI 0.38–0.58, as described in a recent systematic review and meta-analysis (Hshieh et al. 2015). Establishing a baseline cognitive status before initiating cancer treatment is particularly valuable in cases where cognitive symptoms appear during the treatment trajectory. If no one assessed cognitive status before treatment, it is difficult to entangle whether the cognitive symptoms result from the cancer

treatment. Identifying cognitive impairment may also influence the treatment trajectory by identifying when it is necessary to establish services that ensure safety – such as home nursing for safe handling of medications and treatment-related toxicities.

Functional impairment: If frailty is identified as a consequence of functional impairment, the patient is at risk for further functional decline due to cancer and cancer treatment. In such cases, a physical therapist could be consulted in order to minimize further functional decline through specific exercise. Because functional decline happens gradually, establishing a baseline before treatment is essential in order to reveal changes in physical functioning. Older patients tend to prioritize maintaining their independence over survival (Fried et al. 2002; Akishita et al. 2013), and thus assessing functional status throughout the treatment trajectory is as important as assessing tumor-related factors. Furthermore, functional impairment is a consistent predictor of treatment complications and mortality – independent of tumor-related factors.

How to Manage Frailty in Older Cancer Patients

Apart from being a valuable predictor of clinical outcomes, little is known about how to specifically manage frailty in cancer patients. Frailty intervention trials are mainly studying a combination of exercise and micronutrients, macronutrients, nutritional supplement, or food regimens in order to reverse frailty, and such trials are not specific to older patients with cancer (Manal et al. 2015). Intuitively, a management plan for frail older cancer patients should be based on deficits identified through a GA and include optimization of comorbidities and polypharmacy, exercise to prevent functional decline, nutritional support to avoid weight loss, psychological support in case of emotional distress, and home care if cognitive impairment is identified in order to minimize the risk of poor compliance or treatment complications.

Summary

Frailty of pre-frailty is present in approximately half of older cancer patients. Frailty is a valuable predictor of clinical outcomes, and assessing frailty is essential in order to determine risk of treatment complications and life expectancy. Frailty is associated with higher age, but not all older patients are frail. Thus, determining a patient's level of frailty is necessary in order to avoid both over-and undertreatment of older patients with cancer.

Geriatric Interventions in Oncology

Abstract

Cancer care for older adults is complex. Frequently older adults have coexisting medical and social issues that complicate cancer treatment and require additional attention. A geriatric assessment (GA) can aid in detecting concurrent medical, psychological, and social issues and has been shown to be feasible in the oncology setting. Results of the GA can be used to develop goal-directed interventions for impairments that are detected. Although the development of GA-based management interventions is common practice by geriatricians in the non-cancer population, it is not yet routine practice for older adults with cancer. Emerging data in small, pilot studies suggest that it is feasible to develop GA-guided management interventions in the oncology setting, although the optimal model for care delivery and potential benefit of such interventions remains unclear. Multiple ongoing studies are evaluating the benefit of GA-guided management interventions for older adults with cancer. In this chapter, the role of GA in oncology with resultant GA-based management interventions is reviewed.

Introduction

Cancer disproportionately affects older individuals, and with the aging of our population, there will be an increasing number of older adults

diagnosed with cancer (Siegel et al. 2015). (▶ Chap. 1, "Population Trends in Aging and Cancer") As chronologic age increases, health status becomes progressively heterogeneous (Mohile et al. 2011; Koroukian et al. 2006). Thus patients with the same chronologic age may not be similar with regard to physiologic age and tolerance to cancer therapies. A geriatric assessment (GA) is recommended to assess an older patient's fitness for cancer therapy (Hurria et al. 2012). (▶ Chap. 25, "Comprehensive Geriatric Assessment (CGA) for Cancer Patients") GA is a compilation of assessment tools to evaluate areas that commonly affect older adults. Typically, GA involves evaluation of a patient's physical function, comorbidities, cognition, psychological status, social support, nutritional status, and medication review. In the oncology setting, GA has been shown to be feasible to incorporate into routine care in both the academic and community setting; it has been shown to influence decision-making by oncologists, and elements of the GA are predictive of chemotherapy toxicity (Hurria et al. 2005, 2011, 2016; Williams et al. 2014; Hamaker et al. 2014; Extermann et al. 2011). In older adults without cancer, geriatricians utilize the GA to develop targeted management interventions to improve outcomes, although there is limited data on the benefit of such GA-guided interventions in oncology care. Within the geriatric oncology community, furthering the evidence base on interventions in oncology care is a focus of future research (Mohile et al. 2016; Magnuson et al. 2016a). A few small, pilot studies have assessed the feasibility of incorporating GA with management interventions into oncology care, and other studies have evaluated the benefit of interventions in a single GA domain in older adults with cancer. Here we provided an updated review of current evidence of GA with management interventions in oncology care.

Geriatric Assessment in the Oncology Setting

It is feasible to utilize GA in routine oncology clinical practice. Hurria and colleagues developed a cancer-specific GA (Hurria et al. 2005). This cancer-specific GA is completed independently by the patient and includes evaluation of functional status, comorbidity, cognition, psychological status, social support and functioning, and nutritional status. In the pilot study evaluating feasibility, the majority of patients were able to complete the assessment without assistance, and the mean time to completion was 27 min. The GA has been shown to be feasible to use in both academic and community oncology settings (Williams et al. 2014; Chapman et al. 2014). Elements of the GA have been shown to be predictive of chemotherapy toxicity (Hurria et al. 2011, 2016; Extermann et al. 2011) (▶ Chap. 29, "Predictive Tools for Older Cancer Patient Management"). Extermann and colleagues developed a chemotherapy toxicity risk prediction model, the Chemotherapy Risk Assessment Scale for High-Age Patients (CRASH) score (Extermann et al. 2011). The CRASH score was subdivided into risk factors for hematologic and non-hematologic chemotherapy toxicity. Elements of the GA that were predictive of hematologic toxicity included laboratory values (lymphocyte count, aspartate aminotransferase level, and lactate dehydrogenase level), Instrumental Activities of Daily Living (IADL) score, diastolic blood pressure, and Chemotox score (toxicity of chemotherapy regimen). Elements of the GA that were predictive of non-hematologic toxicity were laboratory values (hemoglobin, creatinine clearance, and albumin), self-rated health status, Eastern Cooperative Oncology Group (ECOG) performance status, mini-mental status score, mini-nutritional assessment score, and Chemotox score. Another study by the Cancer and Aging Research Group (CARG) also developed a chemotherapy toxicity risk prediction tool based upon GA results and other patient and treatment variables (Hurria et al. 2011). Factors that were predictive of chemotherapy toxicity included age >71, cancer type (gastrointestinal and genitourinary conferred higher risk), chemotherapy dosing (standard versus dose reduced), number of chemotherapy drugs (mono- versus polychemotherapy regimen), laboratory values (hemoglobin, creatinine clearance), hearing impairment, history of falls in the past 6 months, limited ability to ambulate one block, the need for

assistance in taking medications, and decreased social activities because of physical or emotional health. The CARG model was subsequently validated in a second cohort of patients as well (Hurria et al. 2016). Geriatric evaluation has also been shown to influence treatment decisions for older cancer patients (▶ Chap. 60, "Decision Making and Safety Issues in Older Cancer Patients"). Hamaker and colleagues performed a systematic review to summarize data on the effects of geriatric evaluation on treatment decisions for older cancer patients (Hamaker et al. 2014). Ten studies were included, with the initial treatment plan modified in a median of 39% of patients after geriatric evaluation. The majority of these treatment changes resulted in less intensive treatment. All but one study also reported on recommendations for geriatric-related interventions and found that over 70% of subjects received recommendations for interventions.

GA with Management Interventions

GA can identify areas of potential concern, or "impairments," in one or more of these domains for a particular patient. There is extensive research in older adults without cancer evaluating the utility of specific goal-directed interventions to address impairments identified on GA and the impact of such interventions on a variety of outcomes. Several studies have been performed on community-dwelling subjects without cancer. The DEED II study was a randomized, controlled trial of comprehensive GA and multidisciplinary intervention for older adults discharged from the emergency department (ED) (Caplan et al. 2004). In this study, 739 patients aged ≥75 who were discharged from an Australian ED were randomized to a comprehensive GA and home follow-up versus usual care. Investigators determined that subjects who received the intervention had a lower rate of readmissions to the hospital during the 30 days following their initial ED visit and a lower rate of ED visits during an 18-month follow-up period. Patients in the intervention group also maintained a greater degree of physical and mental function as well. Frese and colleagues performed a study of in-home preventive comprehensive geriatric assessment in Germany (Frese et al. 2012). In this study, 1620 community-living subjects aged ≥70 underwent a home visit with a GA followed by recommendations for their primary care provider. Investigators observed a 20% reduction in mortality and a 22% lower risk of nursing home admission at follow-up (average 6.2 years after randomization). Stott and colleagues also evaluated a home-based geriatric assessment and intervention program for patients aged ≥65 who were high risk for hospital readmission (Stott et al. 2006). The intervention involved a comprehensive GA and home-based nursing, occupational therapy, physiotherapy, and geriatric medical review. Investigators observed that patients randomized to the intervention had improvement in the basic and extended activities of daily living, as compared to a decline in the control group.

Other studies have focused on the evaluation of GA with management in the inpatient setting or the inpatient to outpatient transition. Nikolaus and colleagues performed a randomized trial of comprehensive GA and post-discharge home intervention in 545 older adults admitted to a geriatric hospital (Nikolaus et al. 1999). In this study, the intervention group was observed to have a decreased length of stay and lower rates of immediate nursing home placement, although there was no difference in survival or readmissions between the two groups. Cohen and colleagues evaluated the impact of an inpatient and outpatient GA in 11 Veterans Affairs medical centers (Cohen et al. 2002). Patients were randomly assigned to receive either inpatient geriatric unit care versus usual inpatient care, followed by either outpatient care at a geriatric clinic versus usual outpatient care. No significant effects were observed on overall survival; however the intervention group did have less functional decline and improvement in mental health. A meta-analysis of randomized controlled trials of comprehensive GA in the hospital setting was performed in 2011, identifying 22 eligible trials evaluating 10,315 participants in six countries (Ellis et al. 2011). The result of this meta-analysis showed that in the non-cancer setting for hospitalized patients, comprehensive GA

increases patients' likelihood of being alive and in their own homes after an emergency admission to the hospital, and patients were less likely to die or experience deterioration and were more likely to experience improved cognition. However, at present, there is limited data on the utility of GA-guided interventions in older cancer patients.

Several other studies in the non-cancer setting have evaluated the impact of interventions in a single GA domain and shown to improve outcomes. The physical function domain has the most extensive amount of research. In 2014, a meta-analysis was performed to evaluate the impact of exercise in older adults and included 19 studies (Gine-Garriga et al. 2014). Investigators determined that when compared with control, exercise was shown to improve gait speed and the short physical performance battery, an objective measure of physical function. In Finland, a study of 605 community-dwelling older adults age >75 evaluated the impact of GA-based intervention on the ambulation (Tikkanen et al. 2015). Investigators determined that the intervention reduced decline in the ability to ambulate for subjects who were frail or pre-frail. Lihavainen and colleagues performed a randomized, controlled trial evaluating the effects of comprehensive GA with targeted intervention on mobility in subjects age ≥75 (Lihavainen et al. 2012). In this study, 781 subjects were randomized to either GA with multifactorial intervention lasting 2 years or usual care. The intervention had a positive effect on mobility, with a lower percentage of patients with mobility limitation in the intervention group at 1-year and 2-year follow-up. GA-based interventions have also been shown to reduce the risk of falling in community-dwelling older adults. In 2012, a Cochrane review was performed of randomized trials of interventions to reduce falls in community-dwelling older adults including 159 trials (Gillespie et al. 2012). Investigators determined that group and home-based exercise programs and home safety assessment and modifications reduce rate of falls and risk of falling. Luger and colleagues evaluated the feasibility and impact of a home-based physical training, nutritional and social support program on nutritional status, and frailty in older adults in Austria (Luger et al. 2016). The intervention was delivered by volunteers and consisted of six strength exercises and discussion about nutrition and compared to an active control group consisting of social contact. Investigators determined that the intervention was feasible and resulted in improvements in mini-nutritional assessment score, although was not significantly different from the control arm suggesting that the social support alone improved outcomes. Nykanen and colleagues evaluated the effects of individual dietary counseling as part of a comprehensive GA in community-dwelling subjects aged 75 and older (Nykanen et al. 2014). Investigators observed that nutritional counseling resulted in an increase in mini-nutritional assessment scores as well as serum albumin.

In the non-cancer setting, interventions that target multi-domains are felt to be superior as compared to mono-domain, particularly with regard to interventions on frailty and physical function measures. A systematic review was performed evaluating the effects of multi-domain compared to mono-domain interventions in subjects aged ≥65 and included 12 studies which supported this assumption as well (Dedeyne et al. 2017).

GA with Management Interventions in Oncology Care

Given the limited data regarding GA with management interventions in oncology care, a Delphi study was performed to develop consensus among US-based geriatric oncology experts regarding the incorporation of GA and management interventions into clinical care (Mohile et al. 2015). Thirty participants were included; the majority used GA in clinical care with the remainder involved in geriatric oncology research. The expert consensus panel met consensus for how GA could guide non-oncologic interventions and cancer treatment decisions in multiple domains and an algorithm for GA-guided management interventions was developed. A summary of assessment tools and interventions recommended is provided in Table 1. An expert consensus panel with guideline

Table 1 Summary of GA assessment tools and potential management interventions for consideration (Mohile et al. 2015)

GA domain	Assessment tool	Potential management intervention
Physical function/objective physical performance	Gait speed Activities of daily living Instrumental activities of daily living Timed up and go Short performance physical battery	Physical therapy Occupational therapy Home safety evaluation Evaluate fall risk Refer to social work Exercise Rehabilitation Nursing/home health Modify treatment regimen Evaluate fall risk Assure presence of social support Improve functional status prior to treatment Avoid aggressive therapy Recommend personal emergency response service Assess comorbidity/medication Modify dosage of standard Modify delivery of standard
Cognition	Montreal cognitive assessment Blessed orientation-memory-concentration Caregiver burden/support Mini-Cog	Involve caregiver Assess/minimize medications Delirium prevention Refer to social work Assess capacity and ability to consent to treatment Identify health-care proxy Cognitive testing/neuropsychology referral Ensure caregiver involved and present with patient Assess safety of treatment Limit complexity of treatment Modify therapy delivery Avoid aggressive therapy
Psychological	Hospital anxiety and depression scale Mental Health Inventory	Refer to social work Counseling Refer to psychiatry/psychology Consider medication therapy Support programs Spiritual care
Nutrition	History of recent unintentional weight loss Mini-nutritional assessment	Nutrition consult Make specific dietary recommendations Oral care Supplements Refer to social work
Social support	Medical outcomes study survey Social support from medical history	Social work referral Nursing/home health Transportation assistance Caregiver management Home safety evaluation Support groups Spiritual care Psychiatry/psychology Assess patient safety/tolerability Assess caregiver support Modify treatment regimen Consider less aggressive treatment Modify therapy delivery

development was also performed with European-based oncologists regarding the optimal assessment method and interventions recommended for commonly employed domains of the GA (O'Donovan et al. 2015).

In oncology, a select few studies have evaluated GA-guided interventions for older adults with cancer. A randomized, pilot study conducted by Puts and colleagues evaluated the impact of GA with integrated care plan in improving outcomes in 60 older patients with advanced beast, gastrointestinal and genitourinary cancer (Puts et al. 2016). Eligible patients were aged $\geq$70 and randomized to receive usual care versus GA with implementation of tailored, evidence-based interventions using a standardized intervention protocol. The study team implemented GA-guided interventions, and patients were assessed at 3 and 6 months to assess intervention fidelity and outcomes, including quality of life and modification of the cancer treatment plan. Investigators determined that there was less decline in quality of life in the intervention group at the 3-month follow-up time point. A phase III study is planned to further evaluate the intervention. A second pilot study by Magnuson and colleagues also evaluated the effect of GA with management recommendations in a randomized fashion (Magnuson et al. 2016b). In this study, patients aged $\geq$70 with advanced solid tumor malignancy were randomized to receive either GA with management recommendations or usual care. In this study design, the study coordinator administered and scored the GA and then utilized an established algorithm to identify appropriate management interventions based upon impairments identified on GA. Recommendations for GA-guided interventions were then relayed to the primary oncologist who was responsible for implementation. In this study design, the assessment and development and implementation of GA-guided management were done independent of a geriatrician or geriatric oncologist. Investigators designed the study to develop a model of care that could implement GA-guided management independent of a geriatric provider given the limited number of providers available with geriatrics expertise. In this pilot study, it was determined that it was feasible to use an algorithm to guide GA management recommendations; however it was observed that the rate of implementation of the recommendations by the primary oncologists was low, at only 34%. There was no difference in outcomes between the control and intervention groups with regard to toxicity rates, hospitalizations, or treatment changes.

A British study evaluated the impact of GA with management in older adults with cancer receiving chemotherapy that was high risk for complications (Kalsi et al. 2015). Eligible subjects were aged $\geq$70 and determine to be high risk based upon a screening questionnaire (CGA-GOLD). Subjects underwent evaluation by a geriatrician with implementation of geriatric management interventions, and outcomes were compared to a historical observational cohort. Investigators observed that patients who underwent geriatric evaluation with management interventions were more likely to complete their cancer treatment and experienced fewer treatment changes as compared to the historical observational cohort, although rates of chemotherapy toxicity were not different between the two groups. Although this was not a randomized study, it does suggest that it is feasible to develop and implement GA-based interventions by a geriatrician in the oncology setting.

Other studies in geriatric oncology have evaluated interventions in a single GA domain. A study in the Netherlands investigated the utility of a preoperative geriatric consultation with individualized treatment plan targeting risk factors for delirium as well as daily visits by a geriatric nurse during hospitalization in older adults undergoing elective surgical procedures for solid tumor malignancies (Hempenius et al. 2016). Investigators determined that the geriatric intervention did not improve outcomes of mortality, rehospitalization, ADL functioning, cognitive functioning, QOL, or return to prior living situation at 3-month follow-up. A systematic review of studies evaluating physical and nutritional preoperative interventions in older adults with colorectal cancer determined that none of the interventions significantly reduced length of stay, mortality, or readmission rates (Looijaard

et al. 2017). A randomized, controlled trial in France evaluated the impact of a nutritional intervention in older adults at risk of malnutrition during chemotherapy (Bourdel-Marchasson et al. 2014). Patients age ≥70 with solid tumor malignancy at risk of malnutrition and receiving chemotherapy were randomized to receive an intervention consisting of diet counseling to increase energy intake, as compared to usual care. Investigators determined the intervention was effective at increasing caloric intake, but did not impact mortality or chemotherapy outcomes. Other studies have evaluated the impact of a social support intervention for older adults with cancer. McCorkle and colleagues performed a randomized, controlled intervention study evaluating the impact of a home care intervention on survival in postsurgical cancer patients aged ≥60 (McCorkle et al. 2000). The intervention lasted 4 weeks and was comprised of three home visits and five telephone contacts providing clinical assessments, monitoring, and teaching to patients and caregivers. Investigators determined that overall survival was improved in the intervention group as compared to controls, with effects most noticeable in individuals with advanced disease. Goodwin and colleagues evaluated the impact of a nurse case management support in older women with breast cancer (Goodwin et al. 2003). In this multicenter, randomized study, subjects were aged ≥65 with newly diagnosed breast cancer. Women were randomized to receive a nurse case manager intervention for 12 months following diagnosis, versus usual care. Investigators determined that women receiving the intervention were more likely to receive breast-conserving surgery and radiation therapy as well as breast reconstructive surgery. Women with advanced cancer were also more likely to receive chemotherapy in the intervention group. At 2 months post-surgery, women randomized to the intervention group were more likely to have return of normal arm function and report a sense of "choice" in their treatment. Investigators also determined that women with indicators of poor social support were most likely to benefit from the case management intervention.

GA with management intervention has also been shown to improve equality of life and pain management for older cancer patients. In a subset analysis of a larger geriatric assessment intervention study, 99 patients with cancer were analyzed. Investigators determined that patients randomized to inpatient geriatric assessment had improved quality of life at time of discharge (Rao et al. 2005). Patients were also more likely to receive evaluation by consultative services as well as physical and occupational therapy (Nipp et al. 2012).

GA can also be used to intervene on treatment decisions and help identify the appropriate level of cancer therapy for an individual. The ESOGIA-GFPC-GECP 08-02 study was a multicenter, phase III study evaluating the utility of using GA to allocate cancer therapy in patients age ≥70 with advanced non-small cell lung cancer (Corre et al. 2016). Patients were randomized to GA-guided treatment decision (standard doublet-based chemotherapy for "fit" patients, single-agent docetaxel for "vulnerable," and best supportive care for "frail" patients) versus treatment allocation based upon performance status and age (platinum-based doublet if aged ≤75 and Eastern Cooperative Oncology Group [ECOG] performance status [PS] of 0–1, single-agent docetaxel for aged >75 or ECOG PS of 2). Patients randomized to GA-guided therapy had experienced less treatment toxicity and had lower rates of treatment failures. Overall survival was not different between the two groups, despite 23% of patients in the GA-guided arm receiving best supportive care only (all patients in the usual care arm received chemotherapy). Although this study did not evaluate traditionally geriatric supportive care interventions, it did demonstrate the potential benefit of using GA to guide management decisions about cancer therapy (Gajra et al. 2016).

Although early data suggests a possible benefit from GA-based management in oncology care, it is unclear the optimal model of care for delivery of such interventions. This topic was discussed at a geriatric oncology conference, "Design and Implementation of Intervention Studies to Improve or Maintain Quality of Survivorship in Older and/or Frail Adults with Cancer" in 2015

(Mohile et al. 2016; Magnuson et al. 2016a). Multiple options for clinical trial design exist, each with specific benefits and limitations. For example, a clinical trial could be developed to explore a comprehensive approach with a multicomponent intervention targeting all impaired GA domains identified for a particular subject. Alternatively, trials could be designed to investigate the benefit of a particular intervention (e.g., nutritional supplements) or the benefit of multicomponent interventions in a single GA domain (e.g., for individuals with impaired nutrition, a multicomponent intervention including nutritional supplements, nutritional counseling, exercise, etc.). Additionally models of care should be explored, such as development and delivery of interventions by an independent geriatrics team versus the primary oncology team, or physician-based development of interventions versus a team approach with geriatric-specific nursing and other allied health professionals.

Currently, there are multiple ongoing trials to further evaluate the benefit of GA with management intervention in older cancer patients. A large, phase III study in the United States of GA with algorithm-guided management intervention in community-based oncology practices is underway (NCT02054741). A second, large, phase III randomized study of approximately 1200 patients in France is also underway, which will evaluate the effect of a multidimensional GA and interventions tailored for the patient on overall survival and quality of life (NCT02704832) (Soubeyran et al. 2016). Disease-specific studies are also underway. A randomized phase II trial, GERICO, is evaluating the benefit of GA and management intervention before and during chemotherapy in older adults with colorectal cancer (NCT02748811) (Lund et al. 2017). The benefit of GA and geriatrician involvement in treatment planning, geriatric therapeutic intervention, and follow-up is also being evaluated in older adults with head and neck cancer (EGeSOR, NCT02025062) (Brugel et al. 2014). Another large, phase III study is evaluating how GA with management recommendations influences communication between older cancer patients and their oncologists (NCT02107443).

In summary, older adults represent an increasing proportion of oncology patients. Often these individuals have coexisting medical, psychological, or social concerns that require attention and management concurrent with their cancer treatment. A GA can be used to detect these potential issues and has been shown to be feasible to implement the GA in both academic and community oncology settings. GA has been shown to influence decision-making when developing an oncology treatment plan, and elements of the GA are predictive of chemotherapy toxicity. GA can be used to develop specific management interventions for identified impairments. There is considerable data in the non-cancer population about the feasibility and utility of GA-guided management, as outlined above, and it is reasonable to extrapolate this data to the oncology setting for older adults with cancer. Preliminary evidence suggests that it is likely feasible to incorporate GA with management recommendations into oncology care, although the optimal model of care for delivery remains unclear. Multiple studies are ongoing to evaluate the feasibility, benefit, and optimal model for delivering GA-guided management interventions in cancer care.

Organizing the Clinical Integration of Geriatrics and Oncology

28

Silvio Monfardini

Contents

Abstract

The management of cancer in the elderly requires attention to the oncological aspects as well as to those age-associated. Due to the complexity of the clinical aspects on both sides, the practice of the interdisciplinarity involving Clinical Oncologists, Geriatricians, and other actors is needed, but this is difficult to be achieved without a proper organization with dedicated time and space, since this integrated activity cannot rely only on good will.

A structured approach to the problem has been attempted through the so-called Geriatric Oncology Programs with different characteristics in various countries on the basis of the local health organization and available resources.

No uniform universal model can then be proposed; therefore, here the most common models have been presented as possible alternatives to those who would like to enter in this field. A description of the activities carried out in various countries may also help in

Introduction

Due to the progressive aging of the population, cancer in the older person has become an increasingly common global problem. More than half of all tumors occur over 65 years with 70% of cancer deaths in people older than 65 years (Yancic and Ries 2000). The projected increase of older cancer patients in the next decades due to the aging of the population will pose more challenges on the health care. But this does not simply mean an expansion of our cancer care resources, rather the need of a care centered on the peculiar needs of elderly cancer patients (Holmes and Allbrand 2013). Taking care of older patients with cancer will require a competence in dealing with comorbidity and disability, understanding that age-associated conditions have a significant influence on the therapeutic approach and impact on survival. And recalling that the desired outcome of treatment by elderly cancer patients are different from those of adult patients, since by the old patients the emphasis is more often placed on the maintenance of quality of life rather than on survival. This means that the increasing and peculiar needs of management of cancer in the elderly should require solutions taking into account a specific patient-oriented care.

Significant progress has been made in recent years to identify specific problems in the elderly cancer population with the development and validation of the Comprehensive Geriatric Assessment (CGA). However, this approach does not substitute for the Geriatricians contribution, but, at the contrary, calls for their presence and intervention in several clinical situations. While the needs of older cancer patients can be optimally addressed by the integration of Geriatrics with Oncology, the majority of patients worldwide in the routine practice is not managed with this interdisciplinary approach, as was already underlined some few years ago (Monfardini and Aapro 2007).

Conceptual Models of Integration

Although there is presently no widely accepted and uniform clinical model for the delivery of cancer care to frail and vulnerable elderly, in the year 2006 an International Society of Geriatric Oncology (SIOG) Task Force report on the organization of the clinical activity of Geriatric Oncology (Monfardini et al. 2007) mentioned that ideally a dedicated Geriatric Oncology Program should have the following Goals:

- To provide comprehensive care through a multidisciplinary approach that considers age-associated conditions which influence cancer management
- To conduct clinical trials in representative older patients
- To reduce adverse outcomes such as nursing home placement and hospitalizations
- To allow patients to continue to live in their primary area of life either at home, hospice, or in nursing home
- To educate health professionals, the public, older patients, and their families about cancer therapy and research

The International Society for Geriatric Oncology (SIOG) launched then in 2011 an initiative to define what, in the experts' opinion, should be the top ten priorities for the development of Geriatric Oncology worldwide (Extermann et al. 2011). Concerning in particular the clinical practice, the first stressed issue was again that of developing interdisciplinary Geriatric Oncology Clinics, especially in academic institutions and comprehensive cancer centers.

In theory, the interdisciplinary approach for each tumor type should take place at the initial therapeutic decision (tumor board), also during the therapy administration, as well as during the follow up. It is assumed that this approach may

allow the best therapeutic choice and the appropriate geriatric interventions.

The team of the health professional should be composed essentially by Clinical Oncologists (Medical Oncologist, Surgical Oncologist, Radiotherapist) and Geriatricians, but also ideally by the Dietician/Nutritionist, Social worker, Nurse, Physiotherapist, Pharmacist, Palliative Care Therapist (Hurria 2014), and of course Primary Care Physician.

In any hospital or academic Institution where the units and/or services of Clinical Oncology (Surgery, Medical Oncology, Radiotherapy) and Geriatrics are present, these physician and nurses could be involved in the development of the clinical activity of Geriatric Oncology. Other units and services may be required to cover optimally the request for supportive therapy, nutrition, and palliation.

This model can vary depending on the needs of the individual patient, family, and caregiver; the availability and expertise of the involved professionals; and support services (Cohen 2009).

Working Examples of Integration

Efforts for the integration of Geriatrics with Oncology are present in all continents but with different degrees of development. The most important results have been achieved in countries where the decisions taken by the Governments has been that of funding and supporting the multidisciplinary clinical activity and research on cancer in the elderly. This happened principally in the USA and in France, but many other efforts in other Countries deserve also to be mentioned.

USA and Canada

In the USA, the initial effort began in the year 2001 with the Geriatrics/Oncology Training Program Development Grant supported by the ASCO with the John A. Hartford Foundation. The emphasis was put on a dual training in Oncology and Geriatrics.

The Recipients of the Geriatrics/Oncology Training Program Development Grant were the Boston Medical Center, the Duke University Medical Center, the Johns Hopkins University, the Northwestern University, the Universities of California, of Chicago, of Colorado, of Michigan, of Rochester, and of Texas. In each of these centers, a training Program Director was appointed.

After 4 years in 2005, the emphasis on the development of Geriatric Oncology was placed on research and acquisition of data with the Grants to NCI–NIA (National Institute of Aging) designated Cancer Centers to study age-integrated aspects. The establishment of these initiatives provided a marked impulse to the development of the research and of the clinical multidisciplinary activity in the field of Geriatric Oncology.

A further step in the USA was the development in the year 2010 of the U13 conference series of Cancer and Aging Research Group NCI-NIA and the Alliance Clinical Trials in Oncology (2010–2014). The U13 grant, "Geriatric Oncology Research to Improve Clinical Care," was a cooperative conference grant between the Cancer and Aging Research Group in collaboration with the Geriatrics and Clinical Gerontology branch of the National Institute on Aging (NIA) and the National Cancer Institute (NCI). The mission of this conference grant program was to provide a forum for a multidisciplinary team of investigators in Geriatrics and Oncology to review the present level of evidence in Geriatric Oncology, identify areas of highest research priority, and develop research approaches to improve clinical care for older adults with cancer. One of the most important contributions of this conference were the recommendations on designing therapeutic clinical trials for older and frail adults with cancer issued in 2014 (Hurria et al. 2014) and subsequently those at improving the quality of life and survivorship of older and frail adults with cancer (Mohile et al. 2016).

Since research in the field of Geriatric Oncology requires integration of the clinical activity between Oncologists and Geriatricians, the availability of all these grants at the beginning of this millennium have been acting as a potent

leverage for the development of Geriatric Oncology Programs.

Several centers in Canada and the USA have developed Geriatric Oncology clinics or consultation services (Soto-Perez-de-Celis et al. 2017). But looking at the present situation, a consistent diversity of designed activities exists across the USA. Some centers provide consultative Geriatric services with Oncology care provided by an Oncologist (McGill University; Memorial Sloan Kettering; Thomas Jefferson University; University of Chicago; University of Rochester; University of Toronto). For example at the specialized oncology care and research in the elderly (SOCARE) of the Rochester and Chicago University through a pretreatment assessment, the risks and benefits of multiple treatment options are evaluated and weighed. In the preoperative setting, a geriatric evaluation prior to cancer surgery is carried out, while in the adjuvant setting risks and benefits of adjuvant therapy are quantified. During the survivorship management of geriatric-related conditions is also provided (Magnuson et al. 2014).

Others centers provide comprehensive care including assessment, treatment, and follow-up of cancer patients within a dedicated Geriatric Oncology team such as the Moffitt Cancer Center, where the Senior Adult Oncology Program of Balducci and Extermann (Overcash 2013) was the first to be developed in the early 1990s. At Moffit, there is in fact a separate clinic within the center with physicians, nurse, pharmacist, social worker, dietitian, and support staff. CGA is performed by a nurse. Cases are discussed at weekly team meeting. Other features of this program are the external grant funding, the fellows training activity, and the international visiting scholarship.

Many other centers consist of Geriatricians or Geriatric Oncologists providing services within a larger cancer center (City of Hope; Royal Columbian Hospital; University of Alabama).

The development of these Geriatric Oncology Programs nationwide has given a big impulse to the production of publications essential to guide the clinical practice, as for example in the case of the development of tools to estimate chemotherapy toxicity in adults, such as the Chemotherapy Risk Assessment Scale for High-Age Patients (CRASH) (Extermann et al. 2012) and the Cancer and Aging Research Group (CARG) tool (Hurria et al. 2011).

Latin America

Geriatric Oncology Clinics on a consultative model with Geriatricians performing the Geriatric assessment and make recommendations to the treating Oncologist exist in Brazil, five in the city of S Paulo and one in Recife (Soto-Perez-de-Celis et al. 2017).

In Mexico, only one multidisciplinary clinic is located in Mexico City (Soto-Perez-de-Celis et al. 2017).

France

The Oncogeriatric Coordinations Units (UCOG)

In Europe, France has been the first country focusing on the need for older cancer patients to be followed though a cooperation between Clinical Oncologists and Geriatricians. Here, the 2003–2008 Cancer Control Plan enabled the selection, via calls for proposals from the French National Cancer Institute (INCa), of 15 pilot *Oncogeriatrics units designed to bring Oncologists and Geriatricians together around the older cancer patien*t (Brechot 2013).

The specific organization for older people with cancer was enhanced and extended during the 2009–2013 Cancer Control Plan, with a new INCa call for proposals enabling the deployment of oncogeriatric coordination units (UCOG) headed by an Oncologist and a Geriatrician in every region. This scheme currently comprises 24 UCOG. The objective of this specific organization was to provide appropriate care to every cancer patient aged $\geq$75 years receiving care in the facilities authorized to

treat cancer. The UCOG were encharged the following roles:

- To develop collaboration between Geriatricians and Oncologists
- To structure care in all countries to disseminate, in the region under their control, recommendations for good practice in oncogeriatrics
- To develop professionals and encourage training in Oncogeriatrics for all professionals involved (Oncologists, organ specialists, Geriatricians, general physicians, pharmacists, nurses, mobile geriatrics units)
- To encourage specific research projects in oncogeriatrics, with dedicated clinical trials for this population
- To inform elderly patients, their families, and the general public of the advances made in cancer care, also in older patients, the importance then of early and reliable diagnosis, and insisting on the participation in clinical trials allowing access to innovative treatments

At the first evaluation in 2010, an increase in the use of the CGA was noted, however, with a great heterogeneity among the different Pilote Units and many patients not benefitting from this organization (Brechot 2013).

The next step of the Program consisted in selecting 376 health facilities that had admitted 80% of older people with cancer. Of these 376 facilities, 277 were contacted by the UCOG. Among the actions conducted by UCOG in these facilities, training of health professionals in the G8 geriatric prescreening test (Soubeyran et al. 2014) constituted the first phase of training in oncogeriatric care. G8 training was established in 173/277 facilities contacted by the UCOGs (Brechot and Balandier 2015).

University Training

Three university diplomas and two inter-university diplomas were established providing specific teaching in Oncogeriatrics.

Also an optional certificate in oncogeriatrics as part of medical studies was developed in Paris. An active role in the University training was played by the UCOG, coordinators in 46% of them being responsible for university training in oncogeriatrics. In total, 830 health professionals were trained in this context in the year 2013. Thus 399 (48%) Geriatricians and 66 (8%) Oncologists had this training as well as 92 general physicians (11%) and 85 pharmacists (10%).

Training as Part of Continuing Professional Development (CPD)

Nineteen hundred health professionals had oncogeriatrics training in 2013 as part of CPD. Of these, 29% were Geriatricians, 12% Oncologists, 14% general physicians, and 17% nurses. As for the university training, Geriatricians were much more numerous than Oncologists.

The positive consequence of this activity was that in several public and private facilities, an effective cooperation between Oncologists and Geriatricians took place.

The Geriatrician's participation in organ multidisciplinary consultations made possible, via the simultaneous presentation of oncological and geriatric assessments, to share proposals for care. Private Oncologists were noted increasingly moving into the Oncogeriatrics field.

The main difficulty, however, identified by the UCOG in trying to spread the practice of geriatric oncology to the surrounding regional hospital was the lack of funding for the geriatric consultation, since this was not covered by any specific official pricing. The assessment activity for this population was thus less valued, impeding so the geriatric assessments. This could then be poorly developed in some regional hospitals, despite the motivation of the physicians.

Research

The establishment of the UCOG provided a marked impulse to the oncogeriatric research. The number of older patients entered in a clinical trial made a strong progress in the last few years. The enrolled cases were over 800 in 2008, while in 2013, a total of over 5380 older patients were enrolled in clinical trials, 4710 in institutional trials, and 670 in an industry-sponsored trials. Although an INCa report on the Geriatric Oncology publications after the

birth of the UCOG is not yet available, the increase of the scientific articles and proffered papers at the main international meetings (ASCO, ESMO, SIOG) produced in France by the clinicians of these units has been impressive.

Other European Countries

In Europe, other successful models of care delivery and cooperation between Clinical Oncologists and Geriatricians have been developed in Belgium, Holland, Norway, and Switzerland, but with less governmental support and on a less larger scale than in France. In Belgium, the national cancer plan has provided significant financial support for geriatric assessment projects in 30 hospitals. In Netherlands, collaboration between Oncologists and Geriatricians exist mostly in general hospitals, as well as a formalization of education programs: a foundation for Geriatric Oncology is active with taskforces aimed at research activity, care, and education programs with one center of Geriatric Oncology and collaboration between Geriatricians and Oncologists in several centers. In Norway, there are three centers, including one at a geriatric and another at a surgical site, where clinical cooperation of Geriatricians with Clinical Oncologist and research activity is carried out. In Switzerland, there are three centers with an activity of Geriatric Oncology, two at a geriatric site, with weekly multidisciplinarity discussions and research activity (Soubeyran et al. 2014; Monfardini et al. 2013). In Italy, a considerable activity in the field of Geriatric Oncology is carried out on a goodwill base in 12 Medical Oncology units and in two Geriatrics units. The cooperation of Medical Oncologists with Geriatricians, in few hospitals where they are present, is good, but without structured periodical case discussion. The research activity is in some units the most prominent strength point (Brechot and Balandier 2015; Monfardini et al. 2012a).

Spain has three Geriatric Oncology clinics (two in Madrid and one in Cuenca).

Ireland has two pilote Geriatric Oncology Programs ongoing respectively in Waterford and Dublin.

In Greece there are two Geriatric Oncology clinics (Patras and Heraklion).

Israel

In Israel, two Geriatric Oncology clinics have been created within tertiary medical centers (Soto-Perez-de-Celis et al. 2017).

Australasia

Australia

Geriatric Oncology services have been established in Adelaide, Perth, Brisbane, Canberra, Melbourne, and the Gold Coast. These clinical services operate slightly differently in accordance with available local infrastructure and skills of the clinicians. The majority of these teams are hospital based, but service delivery is also available to ambulatory outpatients (Soto-Perez-de-Celis et al. 2017).

Concerning New Zealand, only in Hamilton has been developed a program for older cancer patients.

Singapore

There is a Geriatric Oncology clinical service at the National Cancer Centre Singapore.

Possible Models in Different Situations and Settings

Different Situations

For the practice of interdisciplinary activity of Geriatric Oncology, at least three different solutions for different situations have been followed worldwide. These have been published (Wildiers et al. 2014) or simply presented at SIOG meetings (Hurria 2016).

Geriatric Oncologist

The Geriatric Oncologist is the treating physician for cases where the Geriatric Oncology expertise is needed. The CGA is performed by him/her and therapeutic recommendations are given after oncological multidisciplinary discussion, if indicated systemic therapy is administered in the Geriatric Oncology Unit. This type of organization has the major advantage that geriatric expertise is centralized. The other advantage provided by this approach is that of having the patient followed during all his disease trajectory. However, the disadvantage is that this model can only reach a limited number of patients who are willing and able to travel to the Geriatric Oncology unit for consultation. Also the lack of financial incentives might drive general Oncologists not to refer patients. And a general Geriatric Oncologists might miss the details, rapidly evolving knowledge in the broad field of Oncology.

Geriatric Consultation

A consultation is provided to the Clinical Oncologist referring patients to the Geriatricians: this means to bring Geriatric consultation teams to the patients. These remain under supervision of their treating Oncologists. As a consequence, geriatric assessment result and recommendations are provided to the clinical Oncologist and selected patients can also be referred to appropriate specific geriatric programs.

This model has the potential advantage of reaching a large proportion of older patients with cancer with the consequence of a cross-fertilization of Oncology and Geriatric principles. However, if not well applied, treating Clinical Oncologists might not know what to do with CGA results. It may also be difficult to provide multiple geriatric consultations through all the disease trajectory of the old patient. On the Geriatrician's side, a possible limitation can be that of being involved with other multiple role within their Institutions and to suffer from a time constraint due to overwhelming number of elderly cancer patients. Of course, this approach can be easy if Geriaticians and Clinical Oncologists are present in the same hospital, more difficult if they work in the same city but in different hospital, and apparently impossible if Geriatrics does not exist in a region or in a country, as may happen in Europe. To overcome this difficulty, teleconferences with geriatric consultation on special cases may be of help in these instances.

Geriatric Oncology Team Collaboration with the Treating Clinical Oncologist or Shared Care Model

The Geriatrician or the Geriatric Oncologist performs the geriatric assessment and provides the therapeutic recommendations and geriatric interventions. The therapeutic and care plan is provided through a multidisciplinary team discussion with the participation of the treating specialist. The Geriatric Oncology team can then provide a concurrent care across the disease trajectory. This approach implies a periodical assessment and multidisciplinary discussions with different specialists. Therefore, it requires a well-established organization since there should be, where needed, also the participation of nurse, social workers, pharmacists, palliative and supportive care specialist and a general practitioner.

Since the nurse is often a core member of the multidisciplinary team, it has been stressed that the leadership role of the Geriatric Oncology nurse should be extended to the construction and ongoing maintenance of the multidisciplinary activity (Overcash 2013).

The choice of the model preference should be given to the best-designed model of activity that fits with the local health care.

Different Settings

For which cases, when, and where the interdisciplinary activity should be carried out?

Cases with Interdisciplinary Approach Needed

Not all cases of elderly with cancer need to be seen by the Geriatricians (Holmes and Allbrand 2013), while probably all oncological cases encountered by Geriatricians should be seen by Clinical

Oncologists. To identify which cases should be seen by Geriatricians, several screening tests have been developed, and on these a detailed and a thorough review updating the SIOG recommendations has been made by De Coster et al. (2014). However in this review considering the G8 (the screening test mandatory for all EORTC trials and the most used tool in Europe), the percentage of abnormal screening test ranges, according to the various Authors, from 68% to 82% of all older patients. This means that out of ten screened patients, only two or three could be spared of the geriatric evaluation. Then not all cases, but the majority of patients could need a full geriatric evaluation.

Timing

The time of the interdisciplinary activity is initially that of the therapeutic decision. Also during the treatment of systemic treatment or after surgery, a reassessment may be necessary, although the optimal timing in these instances has never been clearly established. Often it happens that patients receive a mutidisciplinary consultations not before the oncologic decision but during therapy (Lazarovici et al. 2011). Concerning the follow up period after the end of treatment, it has been stressed that in elderly cancer survivors an assessment of persistent and coexisting health problems should be carried out. This approach should imply a referral to Geriatricians and a relationship of Clinical Oncologists with Geriatricians. Therefore, a clinical dialogue between Oncology and Geriatric specialists other than cross-training of clinical researchers should be encouraged (Rowland and Bellizzi 2014). However, in this field, issues are still open concerning delivering optimal post-treatment care (Monfardini et al. 2017).

The possibility of following older patients at a variety of time points, during their oncological trajectory has been, however, shown by the specialized Oncology Care and Research in the Elderly (SOCARE) clinic (Magnuson et al. 2014).

Place

The place of the interplay should be that of the Units of Clinical Oncology (Medical, Surgical Oncology, and more rarely Radiotherapy) within a general Hospital, an Academic Center or a Comprehensive cancer center. Attention should also be paid to the possibility of bringing Oncology into Geriatrics. There can be in fact a setting (Geriatric Department, Geriatric or Medicine Unit) where Geriatricians can propose for consultation cancer patients to Medical Oncologists. In this situation, Geriatricians are not "reduced to make simple assessments, their opinion and proposals being ignored" (Sifer-Rivière et al. 2011). This can provide a definite advantage for the management of the old frail cancer patient (Monfardini et al. 2012b).

Since nursing homes also hosted older cancer patients, the possibility of bringing also here Medical Oncologists for consultation should not be missed (Cutolo et al. 2012).

Suggestions/Recommendations for Starting a Geriatric Oncology Program

The possible partners to be involved in the development of a Geriatric Oncology Program should be made aware by the proponent of the dimension of the problem of cancer in the elderly. For this goal, a considerable amount of epidemiological information is available in the English literature: the demographic change has consisted in a rapid increase of the population of adults older than 65 years of age. Since older patients with cancer, particularly those older than age 70 years, have specific health needs, the possible partners should be convinced that Geriatric Oncology is no longer a niche field with only a few dedicated clinician and researchers but instead an established field of activity. And that this activity takes place in several countries worldwide.

They should be informed that a scientific society – The SIOG – as a multidisciplinary society that unites experts in the field of Geriatric Oncology from throughout the world has been founded and is active since the year 2000. Concerning the clinical practice, the SIOG aims then at integrating geriatric evaluation (including comorbidities) into Oncology decision-making and has been

so providing guidelines for all tumor types. To implement this process, interdisciplinary Geriatric Oncology clinics should be developed.

The common discussion of the most difficult and interesting cases has been acting as a leverage of many Geriatric Oncology Programs. If the participants are convinced of the usefulness of case discussion and keep on in carrying it periodically, this can be the core business of this activity. Since this work requires an extra time, the health administrators should be convinced that this activity produces better clinical results. Also sparing on the costs is possible by reducing treatment complications and readmissions to the hospital, as well as the admission to the nursing homes, even if at this time no published information is available on this issue. Raising public awareness on the problem of cancer in the elderly will help in achieving the support of administrators.

A positive stepwise progression could be suggested for Medical Oncologists willing to establish a Geriatric Oncology Program through these successive phases:

1. If a Medical Oncologist is interested in Geriatrics (Geriatric Oncologist), he could initially collect the information on the CGA domains (ADL, comorbidity, MMS, GDS) before deciding on treatment.
2. This Geriatric Oncologist could then have somebody else (e.g., a nurse) collecting for him the information on G8 and/or CGA. He should also look the availability of a geriatric consultation for a help in the interpretation of the results of the collection of the CGA items and for a deeper Geriatric assessment, as well as for the planning of the geriatric interventions and supportive therapy.
3. This Geriatric Oncologist should then try to have an integrated framework consisting in a formally established and recognized relationship with the Geriatricians (interdisciplinary case discussion at the tumor board) and scheduled case conferences.
4. The further progression should be that of having a fully established multidisciplinary activity, possibly funded. This program should carry out of clinical, training, and research projects with scheduled case and research interdisciplinary discussion in connection with other specialists (Surgical Oncologists, Radiotherapists, nurses, social workers, pharmacists, palliative and supportive care specialists, and general practitioners). The Program should be coordinated by a Medical Oncologist, or by a Medical Oncologist and a Geriatrician.

If the possible proponent of a Geriatric Oncology Program is a Geriatrician, it should be firstly taken into account that recruiting other Geriatricians may be difficult, since there is a Geriatricians shortfall in Europe but also in the USA.

But, there is often a more insidious handicap such as the fact that the Geriatrician's tools and know-how may be often perceived ambiguously by the Clinical Oncologists, who may be unclear as to the Geriatricians role. On their side, Geriatricians may feel confined to the periphery of organization of cancer treatment and being involved with other multiple role within their Institutions suffer from a time constraint due to an overwhelming number of elderly cancer patients (Sifer-Rivière et al. 2011). Mainly for this reason on the Geriatricians side, it has been stressed a proper selection of cases to be proposed to the Geriatricians (Karnakis et al. 2016). Karnakis et al. have in fact quite well presented the point of view the Geriatricians who have been embarking in the organization of a Geriatric Oncology Program in a large Cancer Center. To them, the major challenges in establishing collaboration in Geriatric Oncology are the evaluation of the resources of the center, to know the role of each member of the team, to establish a good communication both within the team and with the patients, to determine the referral criteria, and to use the screening tests to select which patients can benefit the most from the multidisciplinary evaluation and a thorough GA. Their conclusion is also that multidisciplinary care models must be studied and standardized, according to the sociocultural and healthcare services of each country.

Finally, since the practice of Interdisciplinarity may not be easy at the beginning, it is important

that Clinical Oncologists in starting a collaboration get acquainted with the minimum basic principles of Geriatrics, and the same for Geriatricians concerning the basic oncological information. And that at both sides is in advance clarified what, in discussing clinical cases, Clinical Oncologists can ask to Geriatricians and vice - versa, as for example has been attempted in the Treviso SIOG advanced courses (Colloca and Monfardini 2017).

Predictive Tools for Older Cancer Patient Management

29

Ki Hyang Kim and Martine Extermann

Contents

Abstract

Because older cancer patients are very heterogeneous, decision-making is difficult for physicians. Predictive tools can help provide objective data support to inform treatment decisions. Such tools exist to predict tolerance to chemotherapy, estimate treatment benefit in view of other life-limiting conditions, or assess surgical risk, for example. In this chapter we will review several of them: the Chemotherapy Risk Assessment Score for High-age patients (CRASH score), the Cancer and Aging Research Group score (CARG), various proposed risk stratification models for surgical risk, and the Lee-Schonberg Index.

Keywords

Predictive tools · CRASH score · CARG score · Geriatric oncology · Clinical decision-making

Introduction

Oncology care entails complex decisions. This is even more the case in older patients, who are very heterogeneous in terms of health, functional, psychological, social, cultural, and economic status

(Puts et al. 2015). Yet, decision analysis studies demonstrate that oncologists have a hard time integrating more than three to four variables in their decisions (Magnuson et al. 2016; Hurria et al. 2016; Huisman et al. 2016; Luciani et al. 2013; Yourman et al. 2012; Extermann 2011). Furthermore, geriatric assessment (GA) is a key component of decision-making in older cancer patients. GA includes functional status, comorbidity, cognition, psychological state, social support, nutritional status, and a review of medications (Hurria 2015; Extermann 2010; Inouye et al. 1998; Lee et al. 2006). For these various reasons, predictive tools to summarize the information and assist benefit and risk prediction can be highly useful in geriatric oncology. In geriatric oncology practice, brief decision tools were developed to assess robustness or frailty for chemotherapy by integration of geriatric instruments (Extermann 2010, 2012; Extermann et al. 2012; Hurria et al. 2011). This chapter reviews predictive tools for older cancer patient management: chemotherapy and surgery.

Chemotherapy Toxicity Predictive Tools in Older Cancer Patients

Tailoring chemotherapy to the tolerance of a patient is a frequent challenge in geriatric oncology. However, it is often difficult to estimate clinically the extent of that risk. Historically, oncologists tend to underdose chemotherapy in older patients (Field et al. 2008; Shepherd et al. 1994). This topic has therefore seen quite a bit of research. Several studies, both prospective and retrospective, have demonstrated the association of various parameters with toxicity from chemotherapy. Yet few have led to formal externally validated indexes. Two such indexes are available to date for older patients.

The Chemotherapy Risk Assessment Scale for High-Age Patients (CRASH) Score

The CRASH score predicts grade 4 hematologic and grade 3 or 4 non-hematologic toxicity. This study was a prospective, multicenter study of patients aged $\geq$70 years who were starting chemotherapy. In total, 562 patients were accrued, and 518 patients, who were 2:1 randomly assigned to the derivation cohort or the validation cohort, were evaluated. The median age of participants was 75.5 years.

Baseline variables tested represented four categories: (1) clinical variables included age, sex, body mass index (BMI), diastolic blood pressure, comorbidity measured with the Cumulative Illness Rating Scale-Geriatric (CIRS-G), and polypharmacy; (2) laboratory variables included white blood count, hemoglobin, lymphocyte count, aspartate aminotransferase, creatinine clearance, albumin, and lactate dehydrogenase (LDH); (3) geriatric and functional assessment variables included self-rated health, Eastern Cooperative Oncology Group Performance Status (ECOG-PS), the Lawton 9-item Instrumental Activities of Daily Living (IADL), nutritional assessed with the Mini Nutritional Assessment (MNA), cognition assessed with the Folstein Mini-Mental Status (MMS), and depression assessed with the Geriatric Depression Scale (GDS)-short form; and (4) cancer-specific variables included disease stage, bone marrow invasion, prior chemotherapy, and response. Tumor type was not included because (1) tumor type has minimal influence on the patient chemotherapy toxicity risk (Extermann et al. 2002); (2) no good system exists for grouping tumor types to predict chemotherapy toxicity; (3) the main effects on the patients' general condition are likely better accounted for by measuring other factors (e.g., performance status); (4) the toxicity of the chemotherapy regimens varies over time and practice settings for a given tumor type; and (5) the group had validated a method for ranking the toxicity of chemotherapy regimens (Chemotox) valid across tumor types: the MAX2 index (Table 1) (Extermann et al. 2004). The MAX2 index describes the overall risk of severe toxicity of a regimen using the highest frequency of both grade 4 hematologic toxicity and grade 3–4 non-hematologic toxicity reported in the published literature. It correlates with the overall risk of severe toxicity in ECOG trials (Fig. 1) (Extermann et al. 2004).

As different predictors were identified for hematologic and non-hematologic toxicity, the CRASH score was developed along two sub-scores: hematologic score and non-hematologic score. The hematologic score included a clinical variable, diastolic blood pressure; a laboratory variable, LDH; a geriatric and functional assessment variable, IADL; and the toxicity of the regimen. The non-hematologic score included geriatric and functional assessment variables: ECOG-PS, MMS, MNA, and the toxicity of the chemotherapy (Table 2). Items are rated on a 0–2 point scale, and summing the points stratifies patients into four risk categories (low, medium-low, medium-high, and high). The CRASH score is available online (www.moffitt.org/eform/crashscoreform). The CRASH score was validated by two methods which were bootstrap internal validation of 200 randomly selected samples from the derivation cohort of 331 patients and independent sample validation of 187 patients. Figure 2 showed risk percentage of grade 4 hematologic toxicity and grade 3 or 4 non-hematologic toxicity based on each validated methods. The risk of hematologic toxicity was 7% in the low-risk categories and 100% in the high-risk categories ($p < 0.001$). The risk of non-hematologic toxicity was 33% in the low-risk categories and 93% in the high-risk

Table 1 The MAX2 index (Extermann et al. 2012)

(Most frequent grade 4 hematological toxicity + most frequent grade 3 + 4 non-hematological toxicity)/2
25% grade 4 neutropenia, 13% grade 3 + 4 diarrhea MAX2 = (0.25 + 0.24)/2 = 0.19 Notes Alopecia is not counted When only white blood cell nadirs are reported, ANC is extracted as follows: 0.6∗G3 + 4 leucopenia, if G4 leukopenia <30% 0.8∗G3 + 4 leucopenia, if 30% above
The formula that correlates the MAX2 index with actual risk of severe toxicity (Chemotox) is:
All patients $\text{Prob} = \frac{\exp(-0.94+6.16*\text{MAX2})}{1+\exp(-0.94+6.16*\text{MAX2})}$
Patients >70 years old $\text{Prob} = \frac{\exp(-0.94+8.30*\text{MAX2})}{1+\exp(-0.94+8.30*\text{MAX2})}$

Abbreviation: MAX2, the average of the highest frequency of both grade 4 hematologic toxicity and grade 3/4 non-hematologic toxicity (the "maximum 2" toxicities)

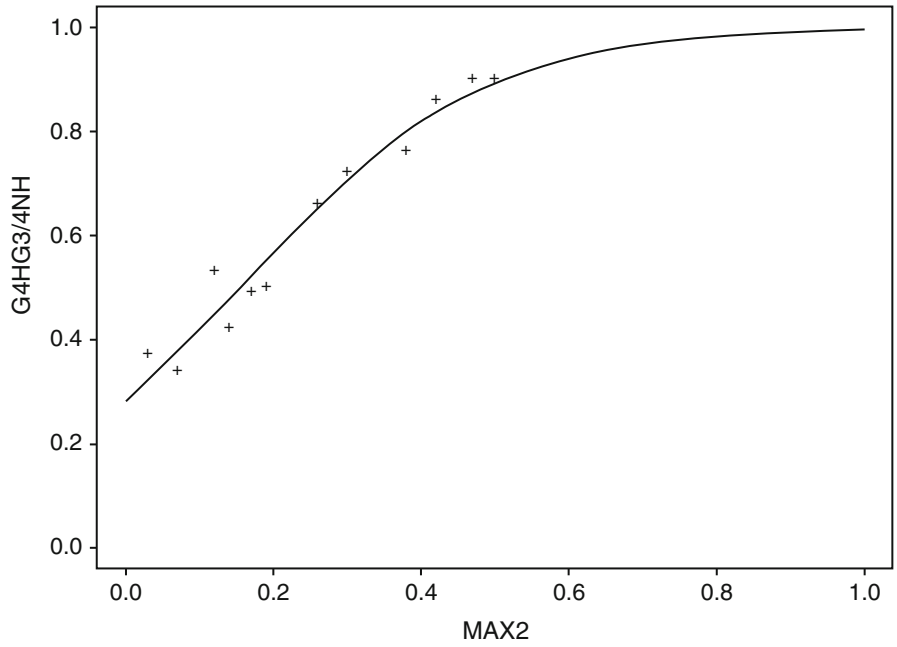

Fig. 1 MAX2 index correlation graph in ECOG trials (Extermann et al. 2012)

Table 2 CRASH (Chemotherapy Risk Assessment Scale for High-Age Patients) score (Extermann et al. 2012)

Points			
Predictors	0	1	2
Hematologic score			
Diastolic BP	≤72	>72	
IADL	26–29	10–25	
LDH (if UUN 618 U/L; otherwise, 0.74L[a] UNL)	0–459		>459
Chemotox[a]	0–0.44	0.45–0.57	>0.57
Non-hematologic score			
ECOG-PS	0	1–2	3–4
MMS	30		<30
MNA	28–30		<28
Chemotox[a]	0–0.44	0.45–0.57	>0.57

Abbreviation: BP, blood pressure; Chemotox, toxicity of the chemotherapy regimen; ECOG-PS, Eastern Cooperative Oncology Group Performance Status; IALD, Instrumental Activities of Daily Living; LDH, lactate dehydrogenase; MMS, Mini-Mental Health Status; MNA, Mini Nutritional Assessment; ULN, upper limit of normal
[a]Percent of risk of severe toxicity of a chemotherapy based on the MAX2 score (see Table 1)

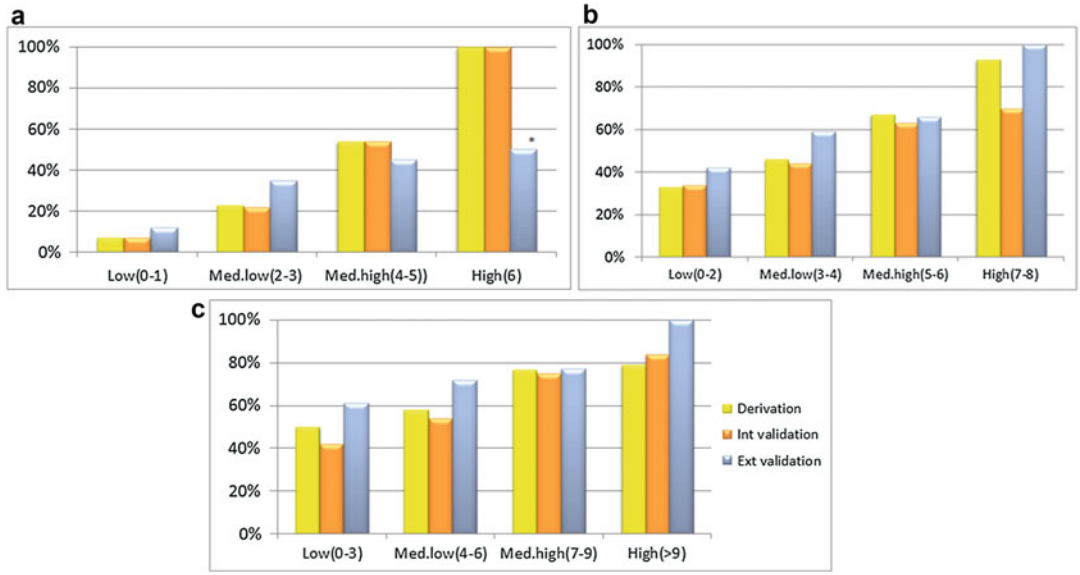

Fig. 2 The percentage of patients who experienced grade 4 hematologic toxicity (**a**), grade 3 or 4 non-hematologic toxicity (**b**), and combined toxicity (**c**) according to the CRASH score. Med indicates medium. ∗ indicates only two patients (Extermann et al. 2012)

categories ($p < 0.001$). However, in the combined risk category, the low-risk categories were 50% and the high-risk categories were 79% ($p < 0.001$). In a validation study of the CRASH score in an Italian cohort, the CRASH score was significantly associated with hematologic toxicity ($p = 0.005$) (Luciani et al. 2015). Another French study showed that the CRASH score was validated in non-Hodgkin lymphoma (Fargeas et al. 2014; Trarieux-Signol et al. 2013). One should note that even patients in the low-risk categories of the CRASH score have a residual risk of severe toxicity and therefore should be adequately monitored.

The Cancer and Aging Research Group (CARG) Chemotherapy Toxicity Assessment

The CARG score predicts the risk of grade 3–5 hematologic and non-hematologic toxicities. This study was a prospective, multicenter study of patients age ≥65 years who were starting chemotherapy. In total, 500 patients were evaluated. The mean age of participants was 73 years.

Baseline variables tested included (1) sociodemographic factors (age, sex, education, marital status, household composition, employment status, race/ethnicity), (2) study site, (3) cancer type (breast, GI, genitourinary, gynecologic, lung, and other), (4) cancer stage, (5) chemotherapy dosing (standard or dose reduced), (6) number of chemotherapy drugs (mono- or polychemotherapy), (7) line of treatment, (8) chemotherapy duration, (9) receipt of primary prophylaxis WBC growth factor, (10) prechemotherapy laboratory value (WBC, hemoglobin, liver function tests, albumin, creatinine clearance), and (11) the geriatric assessment measures (Table 3) (Hurria et al. 2005, 2011). The geriatric assessment measure included a healthcare provider portion and a patient portion. The healthcare provider portion had the patient's Karnofsky Performance Status (KPS), the Timed Up and Go measure (a performance-based measure of functional status), and the Blessed Orientation-Memory-Concentration test (a screening measure of cognitive function). The patient portion had self-reported measures of functional status, comorbidity, medications nutrition, psychological state, and social support/function (Hurria et al. 2016).

The CARG investigators identified geriatric variables associated with prognosis and narrowed down the relevant items within each to design a score that included 11 questions: factors obtained in everyday oncology practice – patient age, number of chemotherapy drugs, dosing, and laboratory values – and factors not used in everyday oncology practice-geriatric assessment questions (Table 4) (Hurria et al. 2011, 2016). The CARG score calculates the sum of the scores. The total risk score ranges from 0 (lowest toxicity risk) to 19 (highest toxicity risk). The total risk score was divided into three categories: low risk (0–5 points), medium risk (6–9 points), and high risk (10–19 points). Figure 3 shows the risk percentage of grade 3–5 hematologic and non-hematologic toxicity. The lower-risk category had a 30% risk of chemotherapy toxicity, and the high-risk category had a 83% risk ($p < 0.001$). The CARG score was validated using internal and external validation model (Hurria et al. 2011, 2016). Internal validation used the tenfold cross-validation process. External validation was performed in 250 patients who were over 65 years old. The results showed a risk of 36.67%, 62.41%, and 70.18% in the low-, medium-, and high-risk groups, respectively (Hurria et al. 2016). Another group compared the CARG tool, the VES-13, and oncologist judgment in men with prostate cancer and found lower toxicity than predicted (Alibhai et al. 2017). Analogous to the CRASH score, patients in the low-risk group still have a residual risk of severe toxicity and need proper monitoring.

Although some parameters of the CRASH score and CARG score have differences (Table 5), these two scores are available methods in oncology practice to stratify the personal risk of chemotherapy toxicity in older cancer patients. They can be useful notably as dilemma breakers when conflicting clinical impressions make a physician hesitate between treatments. More work needs to be done to define decision thresholds or changes in supportive care linked to this risk stratification. Extending the validation of these tools to targeted therapies and immunotherapies would also be a useful development. The impact of those scores on the efficacy and outcomes of chemotherapy beyond toxicity also needs additional study.

Predicting the Risk of Perioperative Complications

Although surgery is an effective cancer-ablative therapy, the increase in complication rate, mortality, length of hospital stay, and intensive care unit admission with age is a barrier to treatment for

Table 3 Measures in the Geriatric Assessment Questionnaire (Hurria et al. 2011)

Domain	Measure	No. of items	Description	Range of scores
Functional status	Activities of Daily Living (subscale of MOS physical health) (Stewart 1992)	10	Measure limitation in a wide range of physical functions (from bathing/dressing to vigorous activities such as running)	0–100 (higher score: better physical function)
	Instrumental Activities of Daily Living (subscale of the OARS) (Fillenbaum and Smyer 1981)	7	Measure ability to complete activities required to maintain independence in the community (shopping, meal preparation, making telephone calls, money management)	0–14 (higher score: less need for assistance)
	Karnofsky Self-Reported Performance Rating Scale	1	Global indicator of patient function determined by patient self-report ranging from "normal" to "severely disabled"	40–100 (higher score: better physical function)
	Karnofsky Physician-Rated Performance Rating Scale (Loprinzi et al. 1994)	1	Global indicator of patient function determined by physical report ranging from "normal" to "dead"	0–100 (higher score: better physical function)
	No. of falls in the last 6 months	1	Indicates number of times fallen in the last 6 months	0–100 (higher score: better physical function)
Comorbidity	Physical Health Section (subscale of the OARS) (Fillenbaum and Smyer 1981)		Presence/absence of 13 comorbid illness: number of comorbid illness	
Psychological state	Hospital Anxiety and Depression Scale (Zigmond and Snaith 1983)	14	Assesses the level of depression and anxiety experienced in the past week	0–100 (higher score: poorer psychological state)
Social activity	MOS Social Activity Survey (Stewart 1992)	4	Measure the degree in which physical or emotional problems interfere with level of social activity	0–100 (higher score: better social activity)
Social support	MOS Social Support Survey: Emotional/Information and Tangible Subscales (Sherbourne and Stewart 1991)	12	Measure the perceived availability of social support	0–100 (higher score: better social support)
Nutrition	Body mass index	1	Weight in kg/(height in m)^2	
	Percent unintentional weight loss in last 6 months	1	(Unintentional weight lost in the last 6 months/baseline body weight) × 100	

Abbreviations: MOS, Medical Outcomes Study; OARS, Older American Resources and Services

older patients (Korc-Grodzicki et al. 2014). Especially, emergency surgery due to delay of cancer diagnosis causes an increase in mortality and morbidity of this population (Korc-Grodzicki et al. 2014). Optimizing perioperative management is important to increase long-term survival in this population. The data show that elderly patients who survive the first year after surgery have the same cancer-related survival as younger patients (Dekker et al. 2011). Geriatric surgical patients are heterogeneous and have various vulnerabilities. Therefore, to develop assessment tools to predict various vulnerabilities in these populations is a challenge. The comprehensive geriatric assessment (CGA) is a multidisciplinary, multidimensional assessment tool to analyze a

Table 4 CARG (Cancer and Aging Research Group) scoring tool to calculate chemotherapy toxicity risk (Hurria et al. 2016)

Variable	Value/response	Score
Age of patient	≥72 years	2
	<72 years	0
Cancer type	GI or GU cancer	2
	Other cancer type	0
Planned chemotherapy dose	Standard dose	2
	Dose reduced upfront	0
Planned no. of chemotherapy drugs	Polychemotherapy	2
	Monochemotherapy	0
Hemoglobin	<11 g/dL (male), <10 g/dL (female)	3
	≥11 g/dL (male), ≥10 g/dL (female)	0
Creatinine clearance (Jelliffe, ideal weight)	<34 mL/min	2
	≥34 mL/min	0
How is your hearing (with a hearing a gearing aid, if needed?)	Fair, poor, or totally deaf	2
	Excellence or good	0
No. of falls in the past 6 months	≥1	3
	None	0
Can you take your own medicine?	With some help/ unable	1
	Without help	0
Does your heath limit you in walking one block?	Somewhat limited/ limited a lot	2
	Not limited at all	0
During the past 4 weeks, how much of the time has your physical health or emotional problems interfered with your social activities (like visiting with friends, relatives, etc.)?	Limited some of the time, most of the time, or all of the time	1
	Limited none of the time or a little of the time	0

Abbreviation: GI, gastrointestinal; GU, genitourinary

biologic age of the elderly. This tool helps to identify who is at risk for postoperative adverse events and provides a possible opportunity to implement perioperative interventions (Korc-Grodzicki et al. 2014). The International Society of Geriatric Oncology recommends that CGA should be used in older patients with cancer to detect unaddressed problems (Extermann et al. 2005). Several studies showed the importance of the geriatric assessment (Table 6).

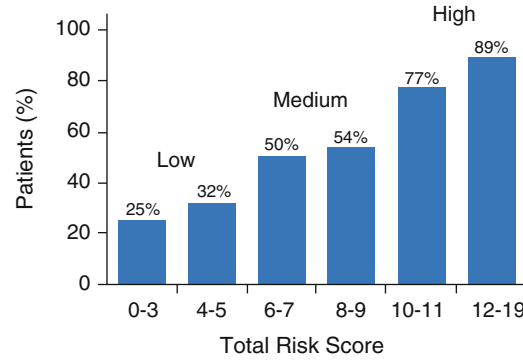

Fig. 3 Risk of grade 3–5 toxicity based on the CARG score (Hurria et al. 2011)

Table 5 Comparison of the CARG score and CRASH score

Parameter	CARG score	CRASH score
Number/ age	500 patients/ ≥65 years	518 patients/ ≥70 years
Geriatric assessment	Cancer-specific CGA, KPS	ECOG-PS, MNA, IADL, Folstein MMSE, GDS
Predictors chosen	Tumor type and stage included	Tumor type not included
Chemo adjustment	Tumor type, standard dose, poly/monotherapy	MAX2, dose, and regimen of chemotherapy

CARG, Cancer and Aging Research Group; CRASH, Chemotherapy Risk Assessment Scale for High-Age Patients

The practice guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society recommends the preoperative assessment of geriatric patients; these are summarized in checklist form (Table 7) (Chow et al. 2012). It is important to assess the decision-making capacity in older cancer patients. Cognitive ability should be assessed, and short tools such as the Mini-Cog maybe helpful in quickly screening out cognitive issues (Oresanya et al. 2014). After that, the physician could have patients articulate their personal treatment goals (Oresanya et al. 2014). In patients treated with major thoracic and abdominal surgery, preoperative impaired cognition, low albumin level, previous falls, low hematocrit level, any functional dependence, and a high burden of comorbidities were related to 6-month mortality

Table 6 Geriatric assessment as predictor of surgical outcomes in elderly patients (Korc-Grodzicki et al. 2014)

Reference	Age (years)	No. of patients	Type of surgery	Predictor	Outcome
Robinson et al. (2009)	68–80	110	Elective surgery requiring postoperative ICU admission	Impaired cognition, recent falls, lower albumin, greater anemia, functional dependence, and increased comorbidities	6-month postoperative mortality and post-discharge institutionalization
Robinson et al. (2012)	67–79	186	Elective surgery requiring postoperative ICU admission	Cognitive impairment	Increased postoperative complications, length of stay, and long-term mortality
Preoperative Assessment of Cancer in the Elderly (PACE) (Audisio et al. 2008)	≥70	460	Cancer surgery for solid tumors	Disability, fatigue, and abnormal performance status	Postoperative complication
Dale et al. (2014)	80% were older than 60	76	Pancreaticoduodenectomy for pancreatic tumors	Fried's exhaustion	Major complications, longer hospital stay, and ICU admissions
Large et al. (2013)	≥65	49	Radical cystectomy for bladder cancer	Cognitive impairment and older age	Post-cystectomy delirium
Fukuse et al. (2005)	60–84	120	Thoracic surgery, multiple causes	Functional dependency and cognitive impairment	Postoperative complications
Makary et al. (2010)	65–94	594	Multiple surgeries	Frailty	Postoperative complications, length of stay, and discharge to skilled nursing or assisted living facility
Kim et al. (2013)	≥65	141	Multiple surgeries	Functional dependency, poor nutrition, and cumulative impairment in geriatric assessment	In-hospital death, post-discharge institutionalization, adverse in-hospital events, and prolonged length of stay
Revenig et al. (2013)	19–86	189	Oncologic, urologic, and general surgery procedures	Intermediately frail or frail on the Hopkins Frailty Score	30-day postoperative complications
Huisman et al. (2014)	Older than 70	180	Elective surgery for solid tumor	Timed Up and Go test	30-day postoperative complications

and post-discharge institutionalizations (Robinson et al. 2009).

In the Preoperative Assessment of Cancer in the Elderly (PACE) study, poor health in relation to functional dependency, fatigue, and abnormal performance status was associated with a 50% increase in the relative risk of postoperative complications (Audisio et al. 2008). PACE is used as a

tool for surgical risk assessment in onco-geriatric patients (Audisio et al. 2005). PACE included these factors: Mini-Mental Status, Satariano's modified index of comorbidities, Activities of Daily Living (ADL), Instrumental Activities of Daily Living (IADL), Geriatric Depression Scale (GDS), Brief Fatigue Inventory (BFI), Eastern Cooperative Oncology Group Performance Status (ECOG-PS), American Society of Anesthesiologists (ASA) physical status system, physiological and Operative Severity Score for the Enumeration of Mortality and Morbidity (POSSUM) and in the elderly (Elderly POSSUM) (Audisio et al. 2005). In the patients aged 65 and older, a lower Mini-Mental Status score and older age were related with the development of post-cystectomy delirium (Large et al. 2013). Table 8 shows results of PACE interim analysis with 30-day morbidity (Ramesh et al. 2006). In patients treated with pancreaticoduodenectomy, older age and worse scores in geriatric assessment were related with longer hospital stays and surgical intensive care unit admission (Dale et al. 2014). These tools are to identify high-risk patients and improve communication between the surgeon and patients. However, they are still limited in their use in real practice because of the resources and time needed to complete them (Korc-Grodzicki et al. 2014; Chow et al. 2012). Another study showed that a preoperative multi-domain frailty measure based on a CGA was useful compared to the frailty measure based on physical phenotype of frailty in predicting postoperative complications (Kristjansson et al. 2012). In the UK, Enhanced Recovery after Surgery (ERAS) programs have

Table 7 Checklist for the optimal preoperative assessment of the geriatric surgical patient in elderly patients

In addition to conducting a complete history and physical examination of the patient, the following assessments are strongly recommended:
Assess the patient's cognitive ability and capacity to understand the anticipated surgery.
Screen the patient for depression.
Identify the patient's risk factors for developing postoperative delirium.
Screen for alcohol and the other substance abuse/dependence.
Perform a preoperative cardiac evaluation according to the American College of Cardiology/American Heart Association algorithm for patients undergoing noncardiac surgery.
Identify the patient's risk factors for postoperative pulmonary complications and implement appropriate strategies for prevention.
Document functional status and history of falls.
Determine baseline frailty score.
Assess patient's nutritional status and consider preoperative interventions if the patient is at severe nutritional risk.
Take an accurate and detailed medical history and consider appropriate perioperative adjustment and monitor for polypharmacy.
Determine the patient's treatment goals and expectations in the context of the possible treatment outcomes.
Determine patient's family and social support system.
Order appropriate preoperative diagnostic tests focused on elderly patients.

Table 8 PACE (Preoperative Assessment of Cancer of the Elderly) interim analysis with 30-day morbidity

Components	Complications (64 patients)	No. of complications (149 patients)	*p*
Median (IQR)			
Comorbidities	2 (0–3)	1 (0–2)	0.024
MMS	28 (27–30)	28 (26–30)	0.917
GDS	3 (1–6)	2 (1–4)	0.018
BFI	2.2 (0.2–4.4)	1.2 (0–4.4)	0.156
Number of patients (%)			
PS = 0	30 (46.9)	122 (81.9)	<0.0001
ADL (Dependent)	38 (59.4)	55 (36.9)	0.005
IADL (Independent)	38 (59.4)	114 (76.5)	0.443
ASA = 1 or 2	29 (45.1)	72(49.0)	0.449

Abbreviation: ADL, Activities of Daily Living; ASA, American Society of Anesthesiologists' scoring system; BFI, Brief Fatigue Inventory; GDS, Geriatric Depression Scale; IADL, Independent Activities of Daily Living; IQR, interquartile; MMS, Mini-Mental State; PS, performance status

been implemented to optimize recovery for elective surgical patients (Parks et al. 2015). According to the type of surgery, it delivers optimal recovery and discharge for patients from preoperative stage to postoperative stage. Also, it includes nutritional status, mobility, monitoring, and analgesia. In a Cochrane review, although it was mentioned that the quality of data was low, the ERAS group had a significant risk reduction for all complications and shorter length of hospital stay than conventional methods care groups in colorectal surgery (Parks et al. 2015; Spanjersberg et al. 2011). Another asystemic review data showed that ERAS programs may reduce length of hospital stay for colorectal surgery between 0.5 and 3.5 days compared with standard care (Parks et al. 2015; Paton et al. 2014).

Frailty Identifying Tools

The definition of frailty has been a debate until now. Many authors have reported a set of scales and screening tools for defining this syndrome. Frailty can be thought of as a decreased physiological reserve across multiple organ systems, broadly (Partridge et al. 2012). The most commonly used in oncology are Fried frailty criteria and the Balducci frailty criteria (National Comprehensive Cancer Network 2015). Fried defines frailty as the clinical syndrome with three or more of the following conditions: unintentional weight loss (10 Ib or more in the past year), self-reported exhaustion, weakness (grip strength), slow walking speed, and/or low physical activity (Fried et al. 2001; Hamaker et al. 2012). However, Kristjansson et al. evaluated frailty for 74 elderly colorectal cancer patients in both Fried and Balducci frailty criteria (Kristjansson et al. 2008). It showed that 9 patients were frail in Fried frailty criteria and 28 were in Balducci frailty criteria. Fried frailty was not measured in the same way as Balducci criteria. The Balducci criteria were originally offered as a concept to identify vulnerable or frail patients and predicted quality of care in older cancer patients based on component of CGA (age >85, dependence in one or more ADLs, three or more major comorbid conditions, and one or more geriatric syndromes) (Balducci and Stanta 2000). The concept has been operationalized by various groups, most frequently using grade 3 or 4 on the Cumulative Illness Rating Scale-Geriatric (CIRS-G) to define a severe comorbidity. Table 9 presents examples of this adaptation. These "Balducci criteria" have proven surprisingly robust in the oncology context, including when compared to Fried frailty criteria to predict complications from surgery (Kristjansson et al. 2010, 2012) or to the oncologists' clinical judgment to choose chemotherapy for high-grade lymphoma (Tucci et al. 2009). According to the Balducci criteria, Mohile et al. evaluated 12,480 community-dwelling individuals aged 65 years and older. Mohile et al. found that the cancer patients had more commonly frailty than the non-cancer patients (80% vs. 73%, $p < 0.001$) (Mohile et al. 2009). Although both frailty measures were available for prediction of OS, the Balducci frailty criteria were more useful than the modified version of the Fried frailty criteria in predicting postoperative complications in a prospective study that compared the Balducci frailty criteria and the modified version of Fried frailty criteria in 176 patients (age 70–94 years) who underwent elective surgery for colorectal cancer (Kristjansson et al. 2012; National Comprehensive Cancer Network 2015). Other measures of frailty exist and can be used as part of a geriatric assessment (GA). Groningen Frailty Index (GFI), Vulnerable Elders Survey (VES-13), Triage Risk Screening Tool (TRST), and the Geriatric 8 (G8) are used as screening tools (Huisman et al. 2016).

Predictive Tools for Life Expectancy

An accurate estimate of a patient's life expectancy is important to make a clinical decision in managing older cancer patients. The life expectancy of the healthy person is different from that of frail person. For example, the average life expectancy of a healthy 90-year-old woman is still more than 2 years longer than the life expectancy of a same age person with moderate dementia, repeated falls, dependence in one or more ADL, or severe

Table 9 Examples of operationalization and use of the Balducci criteria

Study	Age	ADL dependence	Comorbidity	Geriatric syndrome	Outcome
Soubeyran et al. (2011)	≥70	ECOG-PS 3–4	Severe/low LVEF, CrCl, cytopenia	N	Efficacy of COP-based regimen in NHL
Monfardini et al. (2005)	>80	Y	≥3 grade 3 CIRS-G or 1≥ grade 4 CIRS-G	Y	Efficacy of vinorelbine and prednisone in NHL
Tucci et al. (2009)	>80	Y	≥3 grade 3 CIRS-G or ≥1 grade 4 CIRS-G	Y	Response/survival in DLBCL
Olivieri et al. (2012)	>85	Y	≥1 grade 3 CIRS-G or 3≥ grade 2 CIRS-G	Y	Tailored therapy in DLBCL
Spina et al. (2012)	≥70	Y/IADL	Selected group (fit vs. unfit vs. frail)	N	Tailored therapy in DLBCL
Balducci and Stanta (2000)	>85	Y	3 + major	Y	N
Kristjansson et al. (2010)	≥70	Y	≥3 grade 3 CIRS-G or 1≥ grade 4 CIRS-G	Y	Post-op 30 days complications in colorectal cancer
Corsetti et al. (2011)	>80	Y/IADL	≥3 grade 3 CIRS-G or 1≥ grade 4 CIRS-G	N	AML response/overall survival

Abbreviation: Y, yes; N, no; LVEF, left ventricular ejection fraction; CrCl, creatinine clearance; COP, cyclophosphamide, vincristine, and prednisone

comorbid conditions (Balducci and Stanta 2000). Many prognostic indices were developed but several are of limited quality. A team at the University of California San Francisco conducted a systematic review of 21,593 titles (Yourman et al. 2012). They could identify 16 indices that predict risk of mortality from 6 months to 5 years for older adults in a variety of clinical settings: the community (6 indices), nursing home (2 indices), and hospital (8 indices) (Yourman et al. 2012). They assembled them into a convenient online tool for clinical practice named ePrognosis (eprognosis.ucsf.edu/). For oncology patients, taking out the points related to the cancer intended for treatment (points would still be counted for second tumors), it offers a practical estimate of the non-cancer mortality of the patients.

Recent work has tried to identify predictors of early death in older patients with cancer. In a study which enrolled a total of 348 patients in France, patients were scheduled for first-line chemotherapy and previously untreated patients greater than 70 years of age (Soubeyran et al. 2012). This study showed that high-risk early death predictors (<6 months) after initiation of chemotherapy treatments were male gender, advanced tumor stage, a low Mini Nutritional Assessment (MNA) score ≤23.5, and long Timed Get Up and Go (GUG) >20 s (Soubeyran et al. 2012). Another study showed predictor factors of early death in older patients with cancer during 100 days (Boulahssass et al. 2014). A total of 547 patients were analyzed, and a geriatric comprehensive assessment (CGA) has been done. Predictors of early death at 100 days were poor nutritional status with MNA <17, metastatic cancers, and gait speed <0.8 m/s (Boulahssass et al. 2014).

Future Needs

These predictive tools include various perspectives. However, there are some limitations to expect that these predictive tools would improve patient's outcomes. There are no validated methods for management based on predictive tool score that have been shown to improve outcomes. In view of chemotherapy toxicity tools, current tools have not been validated with recently approved targeted or immunologic therapies to inform dose modification. These predictive tools were not considered according to goals of cancer treatment (curative vs. palliative intent). Predictive tools have not been routinely incorporated into clinical trials. Future studies should consider these points.

Conclusions

Older cancer patient management is difficult because older persons are heterogeneous in health, function, psychological, social, culture, and economic status. Predictive tools could help the treatment decisions of older cancer patients. This chapter reviewed predictive tools of chemotherapy toxicity, perioperative management, life expectancy, and frailty. We could use these CGA-based tools to decide the management of older cancer patients. First of all, it is important that physicians consider the life expectancy and frailty level of their patients. They could use the ePrognosis for predicting a life expectancy. Frailty is not definitely defined, but the most commonly used tools in oncology are the Fried frailty criteria and the Balducci frailty criteria. Predictive tools for chemotherapy toxicities include two validated scores: the CRASH score and the CARG score. For perioperative management, several CGA-based systems are available, although standardized tools are still lacking. Predictive CGA-based tools often involve some time to be administered and calculated. However, this is time well spent if they contribute to improve the targeting of cancer treatment in older patients. Future developments should bring shorter instruments, and clinical multidisciplinary trials will help develop pathways using these tools more systematically.

Abstract

Myelodysplastic syndrome (MDS) is a heterogeneous, clonal hematologic malignancy of the elderly defined by morphologic dysplasia and ineffective hematopoiesis, resulting in uni- or multilineage cytopenias. Driven by genetic mutations and immune deregulation, MDS patients commonly present with cytopenias, which manifest in transfusion dependency, bleeding, and/or recurrent infections, and eventually progress into acute myeloid leukemia (AML). The International Prognostic Scoring System (IPSS) and revised IPSS (R-IPSS) are paramount in risk-stratifying patients and guiding treatment decisions, which include observation, erythropoiesis-stimulating agents (ESA), hypomethylating agents (HMA), immunosuppressive therapy, lenalidomide, and allogeneic hematopoietic stem cell transplant (allo-HSCT). Allo-HSCT remains the only curative treatment modality in MDS and should be considered in the elderly population in the right setting. While genetic mutations play an important role in prognosis, none are MDS-defining or guide treatment decisions to date. Novel therapies are being investigated in clinical trials, including oral HMAs, checkpoint inhibitors, TGF-beta inhibitors, and targeted therapies.

Introduction

Myelodysplastic syndrome (MDS) is a clonal hematologic malignancy characterized by morphologic dysplasia, ineffective hematopoiesis, and a predisposition to progress to acute myeloid leukemia (AML). Uni- or multi-lineage cytopenias and bone marrow hypercellularity are present in early stage MDS, as a consequence of increased apoptosis and proliferation of hematopoietic stem cells. As the disease progresses, hematopoietic cell maturation is further impaired and the proportion of myeloblasts increases. Alterations at the genetic and epigenetic level, altered innate immunity, and immune deregulation play an important role in the pathogenesis of MDS. MDS can present as an indolent disorder initially; however, progressive cytopenias can result in symptomatic anemia,

transfusion dependency, recurrent infections, and bleeding. Eventually, patients progress into AML or develop fatal complications due to the underlying cytopenias (Vardiman et al. 2009).

Epidemiology

MDS is a rather common hematologic malignancy. Based on Surveillance, Epidemiology, and End Results (SEER) data, the age-adjusted incidence rate of MDS is 4.8 per 100,000 population per year (Ma et al. 2007). MDS is a disease of the elderly with a median age of onset of 72 years. It has a preponderance to affect males with a male to female ratio of 1.8 to 1. These statistics are similar in Europe, while the Asian MDS population has a younger age, lower incidence, and can present as pathologically distinct subtypes (Strom et al. 2008; Komrokji 2006). Similar incidence rates are reported for white, black, and Hispanic populations, representing 4.9, 4.1, and 3.7 MDS cases yearly per 100,000 capita, respectively. MDS has a higher frequency in the elderly population with a yearly incidence as high as 55.5 per 100,000 in patients over the age of 80 (Ma et al. 2007).

Etiology

The etiology of MDS is believed to be multifactorial. Factors such as senescence, genetic predisposition, environmental triggers, and immunologic derangements play a role and accumulate to the multi-hit sequence of events that culminate to the development of MDS.

Another well-known but uncommon risk factor is familial MDS or MDS in the setting of a genetic predisposition (Churpek et al. 2013). Certain bone marrow failure syndromes, including dyskeratosis congenital, Fanconi anemia, Shwachman-Diamond syndrome, and severe congenital neutropenia, are predisposing conditions for the development of MDS (Churpek et al. 2013). Two molecularly distinct familial MDS syndromes have been described in the literature. A familial platelet disorder with a propensity to develop myeloid malignancy, associated with an autosomal-dominant RUNX-1 germline mutation manifesting as thrombocytopenia and MDS/AML has been recognized (Liew and Owen 2011). Another familial MDS/AML syndrome associated with GATA2 mutation is inherited in an autosomal dominant pattern but with variable penetrance (Ostergaard et al. 2011).

Environmental risk factors that stimulate the development of MDS include exposure to benzenes and cigarette smoking (International Agency for Research on Cancer 2012; Schnatter et al. 2012; Tong et al. 2013). One meta-analysis demonstrated an odds ratio of 1.81 in active smokers and 1.67 in former smokers compared to non-smokers (Tong et al. 2013). According to a European study, a history of infections and autoimmune diseases also increased the probability of acquiring MDS with odds ratios of 1.3 and 2.1, respectively (Kristinsson et al. 2011).

In the current era of chemotherapy and radiation, it has become evident that these exposures in itself contribute to MDS pathology. Treatment-related MDS (t-MDS) is a recognized entity and comprises up to one fifth of all MDS cases (Park and Koeffler 1996; Smith et al. 2003). t-MDS is characterized by complex cytogenetics, has an increased risk of progressing to AML, and portends a dismal overall prognosis. Certain chemotherapeutic agents have a stronger carcinogenic potential and incidence can vary anywhere from 1% in adjuvant breast cancer chemotherapy to 15% in refractory lymphoma patients receiving multiple lines of chemotherapy (Park and Koeffler 1996; Smith et al. 2003). The overall carcinogenic effect is multifactorial and depends upon the age of the patient, the class of antineoplastic agent, and the duration of cytotoxic therapy. There are two distinct subtypes of t-MDS, characterized by different mechanisms, cytogenetic profiles, and latency periods. Type I t-MDS develops after a latency period of 3–5 years post exposure to alkylating agents. Monosomy 5 and monosomy 7 are often seen on the cytogenetic level. Type II t-MDS arises shortly after exposure to topoisomerase II inhibitors and evolves rapidly into AML. Cytogenetically, type II t-MDS is typified by chromosome 11q23 derangements involving the MLL gene (Bennett et al. 2004). Radiation-induced MDS

tends to have a better prognosis than chemotherapy-related MDS, with outcomes comparable to de novo MDS (Nardi et al. 2012).

Diagnosis

In order to make the diagnosis of MDS, a complete blood count (CBC) with differential, peripheral blood smear, bone marrow aspirate or touch prep, Wright-Giemsa stain, iron stain, bone marrow biopsy, and bone marrow karyotype are imperative.

Sustained cytopenia in the absence of correctable causes such as nutritional deficiencies is required for diagnosis of MDS. Cytopenia is defined by an absolute neutrophil count $<1.8 \times 10^9$/L, hemoglobin <10 g/dL, platelet count $<100 \times 10^9$/L. Milder thresholds for cytopenia are permitted if definitive diagnostic criteria for MDS are met. Milder hematological parameters include hemoglobin <12 g/dL in females and <13 g/dL in males or platelet count $<150 \times 10^9$/L (Arber et al. 2016). In addition, one of the following criteria has to be fulfilled: (1) presence of uni- or multilineage cytologic dysplasia involving ≥10% of cells, (2) demonstration of increased myeloblasts (5–19%), or (3) a specific cytogenetic abnormality in the setting of persistent unexplained cytopenia (Arber et al. 2016; Valent et al. 2007).

Secondary causes of cytopenia and dysplasia need to be excluded clinically. Cytologic dysplasia must affect at least 10% of the cell lineage. Table 1 summarizes the classic dysplastic changes in the peripheral blood and bone marrow that define myelodysplasia.

In case of excess marrow blasts, bone marrow recovery or growth factor effect needs to be ruled out. The percentage of myeloblasts in the bone marrow is calculated as a percentage of the total cells regardless of the amount of erythroid precursors present, which is a change per the 2016 revised World Health Organization (WHO) criteria (Arber et al. 2016). While the aspirate blast count remains the gold standard, CD34 immunostaining can be useful in cases with fibrosis or suboptimal aspirate (Malcovati et al. 2014).

Table 1 Dysplastic features in peripheral blood and bone marrow characteristic of MDS (Padron and Komrokji 2015)

Cell lineage	Peripheral blood	Bone marrow
Erythroid	Poikilocytosis Anisocytosis Nucleated red blood cells Basophilic stippling	Multinuclearity Nuclear fragments Megaloblastoid changes Cytoplasmic abnormalities Ringed sideroblasts Increased erythroblasts
Myeloid	Hypolobulation Nuclear sticks Ring-shaped nuclei Hypogranulation	
Megakaryocytic	Micromegakaryocytes Large mononuclear forms Multiple small nuclei	

Approximately 50% of all MDS patients have a karyotype abnormality. Per the WHO 2016 criteria, there are several MDS-defining cytogenetic abnormalities recognized as diagnostic for MDS in the presence of sustained cytopenia. These cytogenetic profiles are summarized in Table 2 with their relative frequencies (Arber et al. 2016).

Iron stains are imperative to determine the degree of ring sideroblasts. Reticulin stains address medullary fibrosis, which can be of prognostic value. Bone marrow core biopsy adds additional information to the bone marrow aspirate and is a key in establishing the diagnosis. Bone marrow core biopsy determines cellularity, identifies dysmegakaryopoiesis, and can home clusters of abnormal localization of immature precursors (ALIP). ALIPs represent immature cells such as myeloblasts and promyelocytes displaced from the paratrabecular space to the intertrabecular areas, forming abnormal clusters (Malcovati et al. 2006; Della Porta et al. 2009).

Of note, flow cytometric abnormalities are not sufficient for diagnosis of MDS but can support the diagnosis when suspected by other observations. Similarly, MDS-type mutations are not defining MDS but may support the diagnosis in the right clinical context (Arber et al. 2016).

Table 2 MDS-defining cytogenetic abnormalities per the World Health Organization (WHO) 2016 criteria and its relative incidences in primary MDS and therapy-related MDS (Arber et al. 2016)

Cytogenetic profile	Primary MDS	Therapy-related MDS
Unbalanced		
−7 or del(7q)	10%	50%
−5 or del(5q)	10%	40%
i(17q) or t(17p)	3–5%	
−13 or del(13q)	3%	
del(11q)	3%	
del(12p) or t(12p)	3%	
del(9q)	1–2%	
idic(X)(q13)	1–2%	
Balanced		
t(11;16)(q23;p13.3)		3%
t(3;21)(q26.2;q22.1)		2%
t(1;3)(p36.3;q21.2)	1%	
t(2;11)(p21;q23)	1%	
inv(3)(q21q26.2)	1%	
t(6;9)(p23;q34)	1%	

+8, -Y, and del(20q) are common cytogenetic abnormalities in MDS; however, they can occur in non-malignant conditions and hence are not MDS-defining karyotypes

Differential Diagnosis

Up to one fifth of MDS cases are hypocellular, also known as hypoplastic MDS, and often pose a challenge upon clinicians in distinguishing these from aplastic anemia. Idiopathic cytopenia of unknown significance (ICUS) is a term that defines cases with sustained cytopenia(s) with dysplasia affecting less than 10% of any cell lineage in the absence of cytogenetic abnormalities. Patients without cytopenia or cytogenetic aberrations and a mild degree of dysplasia below 10% are recognized as idiopathic dysplasia of unknown significance (IDUS) (Steensma 2012).

Classification

French-American-British (FAB) Classification

MDS was originally classified under the French-American-British or FAB classification, which included two subtypes. This was expanded in 1982 to five distinct entities consisting of refractory anemia (RA), refractory anemia with ring sideroblasts (RARS), refractory anemia with excess blasts (RAEB), RAEB in transformation (RAEB-t), and chronic myelomonocytic leukemia (CMML) (Bennett et al. 1982).

Original WHO Classification

The WHO later established the WHO classification which refined the existing FAB classification. Categories of refractory cytopenia with multilineage dysplasia (RCMD) and RCMD with ring sideroblasts (RCMD-RS) were coined, delineating groups with dysplasia in either myeloid or megakaryocytic cell lineages in addition to erythroid dysplasia. RAEB was further subdivided into RAEB I (5–9% blasts) and RAEB II (10–19% blasts), while RAEB-t was omitted from the classification (Bennett 2000; Komrokji and Bennett 2003). The blast percentage to diagnose progression to AML was decreased from a threshold of 30% to 20% (Bennett 2000; Komrokji and Bennett 2003; Vardiman et al. 2002). A new entity, the 5q minus syndrome, was introduced, which is a less aggressive form of MDS characterized cytogenetically by isolated del(5q) and less than 5% myeloblasts in the bone marrow. MDS/myeloproliferative neoplasm (MPN) overlap syndromes were recognized, including CMML-1, CMML-2, juvenile myelomonocytic

leukemia (JMML), and atypical chronic myeloid leukemia (aCML) (Bennett 2000; Komrokji and Bennett 2003; Vardiman et al. 2002). CMML-1 is defined as 0–4% blasts and/or promonocytes in the peripheral circulation or <10% in the bone marrow, while CMML-2 represents 5–19% blasts and/or promonocytes in the peripheral circulation or <20% in the bone marrow (Bennett et al. 2002).

2008 Revised WHO Classification

In 2008, a revision of the WHO classification took place resulting in further modification of the categories. Refractory cytopenia with unilineage dysplasia (RCUD) was introduced as a separate category, which includes patients with peripheral monocytopenia or bicytopenia. MDS unclassified (MDS-U) was defined as a group of MDS disorders that did not meet criteria for other categories, including unilineage dysplasia with pancytopenia, cytogenetic evidence of MDS without overt dysplasia, RCUD or RCMD with 1% circulating blasts. Per the WHO 2008 revisions, RAEB-1 also comprised variants that have 2–4% circulating blasts and RAEB-2 included those that have 5–19% circulating blasts. The identification of Auer rods was determined to be diagnostic for RAEB-2 or CMML-2 regardless of the blast count. Refractory anemia with ring sideroblasts and thrombocytosis (RARS-T) was a novel category for patients with RARS with persistently elevated platelet count over 450,000/mm^3 (Vardiman et al. 2008). Myeloid neoplasm with eosinophilia was added as a distinct category consisting of CMML patients with eosinophilia and genetic mutations in platelet-derived growth factor receptor alpha (PDGFRα) or beta (PDGFRβ) (Orazi et al. 2008).

2016 Revised WHO Classification

In 2016, the most recent revision of the WHO criteria was published. A detailed overview of the updated classification is summarized in Table 3. While the prognostic impact of molecular mutations is recognized, most data are still too immature to determine how to incorporate mutational data into the existing morphologic classification. New data, however, help refine definitions of MDS with isolated del(5q) and MDS with ring sideroblasts (MDS-RS). Isolated del(5q) syndrome can have one additional cytogenetic abnormality without affecting its prognosis, with the exception of −7 and del(7q). TP53 mutation confers a poor prognosis in patients with 5q minus syndrome treated with lenalidomide. Hence, TP53 mutation testing or p53 immunostaining is recommended in all patients with del(5q) syndrome for prognostic purposes (Mallo et al. 2011; Jadersten et al. 2011; Germing et al. 2012). MDS-RS has a strong association with mutant SF3B1, a RNA splicing factor. SF3B1 is mutated in 70–80% of MDS with >15% RS and is rarely mutated in MDS lacking RS. SF3B1 appears to be an early founding mutation and is associated with a prolonged survival (Papaemmanuil et al. 2011; Patnaik et al. 2012; Bejar et al. 2012; Malcovati et al. 2011, 2015; Woll et al. 2014). MDS-RS is expanded to include RARS, cases with RS and multilineage dysplasia, cases with SF3B1 mutation and ≥5% RS, and cases with ≥15% RS if SF3B1 wildtype or unknown.

Acute erythroid leukemia was omitted as a category and was mostly merged with MDS with excess blasts. RCUD was renamed to MDS with single lineage dysplasia (MDS-SLD), RCMD to MDS with multilineage dysplasia (MDS-MLD), RARS, and RCMD-RS were replaced by MDS-RS with SLD and MDS-RS with MLD, respectively. RAEB was changed to MDS with excess blasts (MDS-EB) (Arber et al. 2016).

MDS-U is redefined as a heterogeneous group consisting of MDS-SLD with pancytopenia, low-grade MDS with exactly 1% circulating blasts measured on two separate occasions, and MDS with an MDS-defining cytogenetic abnormality without excess blasts or dysplasia.

MDS-EB is defined as ≥5% blasts in the marrow or ≥2% blasts in the peripheral blood and is subdivided into MDS-EB-1 and MDS-EB-2 based on marrow and peripheral blood blast percentages. Increased blast levels are a very strong indicator of aggressive behavior in MDS, independent of cytogenetics, cytopenias, and mutations (Malcovati et al. 2014).

Lastly, a new WHO category was added: myeloid neoplasms with germline predisposition. This category includes conditions with pre-existing

Table 3 The World Health Organization 2016 revised classification of MDS

Classification	Dysplastic lineages	Cytopenias[a]	Ring sideroblasts as % of marrow erythroid elements	BM and PB blasts	Cytogenetics by conventional karyotype analysis
MDS with single lineage dysplasia (MDS-SLD)	1	1 or 2	<15%/<5%[b]	BM <5%, PB <1%, No Auer rods	Any, unless fulfills all criteria for MDS with isolated del(5q)
MDS with multilineage dysplasia (MDS-MLD)	2 or 3	1–3	<15%/<5%[b]	BM <5%, PB <1%, No Auer rods	Any, unless fulfills all criteria for MDS with isolated del(5q)
MDS with ring sideroblasts (MDS-RS)					
MDS-RS with single lineage dysplasia (MDS-RS-SLD)	1	1 or 2	≥15%/≥5%[b]	BM <5%, PB <1%, No Auer rods	Any, unless fulfills all criteria for MDS with isolated del(5q)
MDS-RS with multilineage dysplasia (MDS-RS-MLD)	2 or 3	1–3	≥15%/≥5%[b]	BM <5%, PB <1%, No Auer rods	Any, unless fulfills all criteria for MDS with isolated del(5q)
MDS with isolated del (5q)	1–3	1–2	None or any	BM <5%, PB <1%, No Auer rods	del(5q) alone or with 1 additional abnormality except −7 or del(7q)
MDS with excess blasts (MDS-EB)					
MDS-EB-1	0–3	1–3	None or any	BM 5–9% or PB 2–4%, No Auer rods	Any
MDS-EB-2	0–3	1–3	None or any	BM 10–19% or PB 5–19% or Auer rods	Any
MDS, unclassifiable (MDS-U)					
With 1% blood blasts	1–3	1–3	None or any	BM <5%, PB = 1%,[c] No Auer rods	Any
With single lineage dysplasia and pancytopenia	1	3	None or any	BM <5%, PB <1%, No Auer rods	Any
Based on defining cytogenetic abnormality	0	1–3	<15%[d]	BM <5%, PB <1%, No Auer rods	MDS-defining abnormality
Refractory cytopenia of childhood	1–3	1–3	None	BM <5%, PB <2%	Any

From Arber et al. (2016)
BM bone marrow, *PB* peripheral blood
[a]Cytopenias defined as: hemoglobin, <10 g/dL; platelet count, $<100 \times 10^9$/L; and absolute neutrophil count, $<1.8 \times 10^9$/L. Rarely, MDS may present with mild anemia or thrombocytopenia above these levels. PB monocytes must be $<1 \times 10^9$/L
[b]If *SF3B1* mutation is present
[c]One percent PB blasts must be recorded on at least two separate occasions
[d]Cases with ≥15% ring sideroblasts by definition have significant erythroid dysplasia and are classified as MDS-RS-SLD

platelet disorders (germline RUNX1, ANKRD26, and ETV6 mutations), with associated organ dysfunction (germline GATA2 mutation among other syndromes), and without a preexisting platelet disorders or organ dysfunction (germline CEBPA and DDX41 mutations). It is imperative to sequence

non-hematopoietic tissue to distinguish a germline mutation from a somatic one. Newly arising mutations can occur in adulthood in the absence of a positive family history. MDS/AML with DDX41 germline mutation typically presents in adulthood (Czuchlewski and Peterson 2016; West et al. 2014).

Clonal Hematopoiesis of Indeterminate Potential

Clonal hematopoiesis of indeterminate potential (CHIP) is defined as the presence of an MDS-type mutation in the absence of MDS-related cytopenias. The somatic mutation involves a gene that is recurrently mutated in hematologic malignancies and has an allele fraction of at least 2%. The allele burden is characteristically of a low fraction. These individuals typically have normal blood counts, but can have mild cytopenias not meeting criteria for MDS, or cytopenias related to other causes. Somatic mutations in hematopoietic cells affecting DNMT3A, TET2, ASXL1, TP53, JAK2, and SF3B1 have been described in a proportion of otherwise healthy older individuals (Jaiswal et al. 2014; Genovese et al. 2014; Xie et al. 2014; Steensma et al. 2015). The frequency of these somatic mutations increases with age and averages 10% in the population over age 70. The presence of such somatic mutation is associated with an increased risk of acquiring a hematologic malignancy and an increased overall mortality, with the latter most probably attributed to the increased risk of coronary heart disease and ischemic stroke (Jaiswal et al. 2014). Patients with cancer who have CHIP are at increased risk of developing therapy-related myeloid neoplasms (Gillis et al. 2017).

Pathogenesis

MDS is a clonal disorder driven by underlying genetic abnormalities. Approximately one-half of MDS patients carry chromosomal alterations, with del(5q), monosomy 7, del(7q), and trisomy 8 being the most well described. While certain chromosomal deletions and duplications are critical in the evolution of the disease, particular gene mutations have been proven to play a major role in the disease pathway as well. As high as 90% of MDS patients will have evidence of clonal genetic abnormalities. An array of such somatic mutations has been uncovered, affecting epigenetic regulators (TET2, ASXL1), RNA splicing (SF3B1, SRSF2, U2AF1), transcription factors (RUNX1, ETV6), tyrosine kinase signaling (RAS), and tumor suppressor genes (TP53) (Papaemmanuil et al. 2013). Figure 1 depicts the diversity of commonly mutated genes in MDS and their relative frequencies in the different categories of the MDS spectrum.

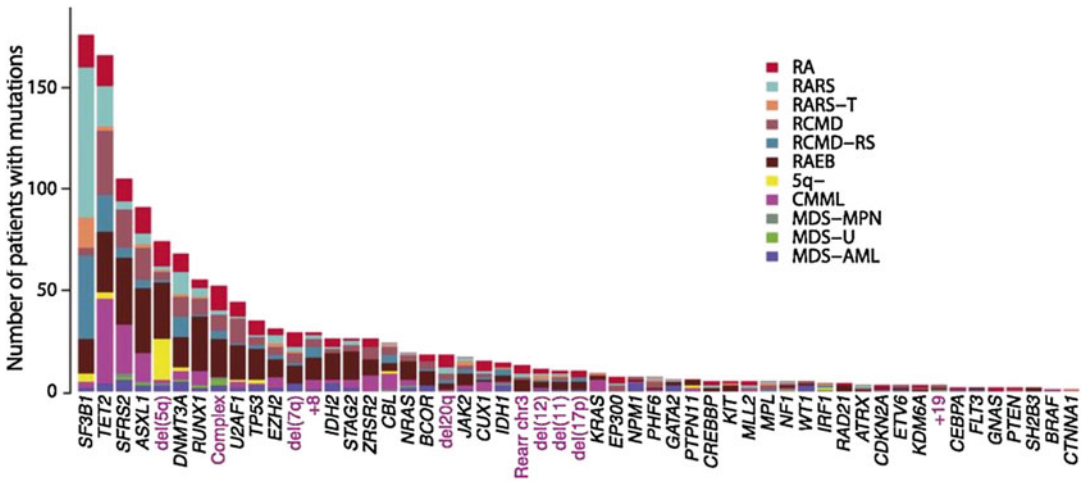

Fig. 1 Relative frequencies of driver mutations by MDS subtype. (From Papaemmanuil et al. (2013))

Inactivating TET2 mutations lead to DNA methylation and epigenetic repression, and are among the most frequently mutated genes (Ko et al. 2010). The ASLX1 gene is also frequently mutated in MDS and acts as an epigenetic regulator (Grossmann et al. 2010; Gelsi-Boyer et al. 2009; Bejar et al. 2011; Jankowska et al. 2011). Up to date, there is no MDS-defining mutation however. RNA splicing mutations occur early in the disease pathogenesis and are prognostic (Wu et al. 2012; Meggendorfer et al. 2012; Itzykson et al. 2013). SF3B1 and SRSF2gene mutations are associated with ring sideroblast subtypes and monocyte expansions (CMML), respectively (Papaemmanuil et al. 2011; Meggendorfer et al. 2012). Emerging data have shown that the type of gene mutation and number of genetic events affect the clinical course of MDS and its progression to AML, and hence impact survival (Walter et al. 2012). It has been well described that these and certain other genetic alterations are driver mutations resulting in overt MDS.

Immune dysregulation has been hypothesized to contribute to the pathogenesis of MDS. Evidence demonstrates that adaptive and innate immunity are deregulated in MDS and its resulting inflammatory changes may act as a driver in its pathogenesis. Inflammation in itself may be permissive for the emergence of a mutational burden or alternatively, an expanded clone may fuel inflammatory changes. Furthermore, studies have demonstrated a strong correlation between chronic immune stimulation and autoimmune diseases with MDS development (Kristinsson et al. 2011; Miller et al. 1994; Kulasekararaj et al. 2013; Tabata et al. 2010).

Dysregulation of T-cell lymphocytes is another hallmark of the disease. Nearly half of all T-cells are clonal and the majority of T-cells have impaired telomerase activity, which may explain their early senescence (Zou et al. 2009; Epling-Burnette et al. 2007; Yang et al. 2013). Proliferation of effector memory T-regulator cells portends a worse prognosis and manifests as anemia and elevated blast count (Mailloux et al. 2012). Upregulation of the innate immunity system leads to activation of nuclear factor kappa B (NF-κB), which further stimulates the inflammatory milieu in MDS (Wei et al. 2013; Dimicoli et al. 2013). Myeloid-derived suppressor cells (MDSC) are critical components in innate immunity. MDSCs act as effector cells and infiltrate the bone marrow in MDS. As MDSCs oversecrete hematopoietic inhibitory cytokines, their expansion results in ineffective hematopoiesis (Chen et al. 2013).

5q Minus Syndrome

The 5q minus syndrome, also known as deletion (del) 5q syndrome, is a genetically and phenotypically distinct entity within the spectrum of MDS. The 5q minus syndrome encompasses approximately 5–15% of MDS cases and is encountered more commonly in females. Bone marrow biopsy shows a preponderance of megakaryocytes with hypolobated nuclei. Clinically, these patients present with refractory anemia with or without thrombocytosis. They have a relatively indolent disease course and have an overall better prognosis compared to other categories of MDS (Giagounidis et al. 2004). Genetically, del 5q syndrome is characterized by an isolated deletion of part of the long arm of chromosome 5 in hematopoietic stem cells. Specifically, it is the result of haploinsufficiency of multiple genes located within the critical deleted region (CDR) at 5q32 (Boultwood et al. 2002). Of the 40 genes located within CDR, only haploinsufficiency of RPS14 inactivates erythroblast expansion in del 5q MDS samples, while overexpression of RPS14 results in restoration of erythropoiesis (Ebert et al. 2008). Haploinsufficient RPS14 results in defective ribosome assembly, which leads to accumulation of MDM2, and ultimately causes p53 stabilization. Inactivation of p53 in del 5q murine models confirmed the restoration of hematologic abnormalities (Barlow et al. 2010).

Clinical Presentation

The initial manifestation of MDS typically consists of cytopenia affecting one or multiple cell lines. As cytopenias progress, patients become symptomatic with infections, fatigue, or bleeding. The hallmark is macrocytic anemia. It is important to exclude alternative causes of macrocytic anemia including cyanocobalamin deficiency, folic acid deficiency,

among other etiologies. Thrombocytopenia and platelet dysfunction affect up to 65% of all MDS patients and is more prevalent in patients with high risk MDS. Platelet dysfunction is evidenced by a prolonged bleeding time and an increase in atypical megakaryocytes. Fatal bleeding events have been documented in up to 24% of patients (Kantarjian et al. 2007a; Raman et al. 1989).

While over one-third of all MDS patients will eventually transform into AML with a high fatality rate, the vast majority of patients will succumb to cytopenia complications. MDS patients are at increased risk of infections due to a multitude of factors including neutropenia, granulocyte dysfunction, and iron overload in the setting of transfusion dependency (Boogaerts et al. 1983). Common infections include bacterial pneumonias and skin abscesses; however, opportunistic infections with Mycobacterium avium-intracellulare, *Aeromonas hydrophila* endocarditis, bacterial thyroiditis, and Epstein-Barr virus hepatitis have been documented (Tsukada et al. 1994; Ong et al. 1991; Pomeroy et al. 1991). Autoimmune diseases and autoimmune cytopenias can be profound. In particular, Coombs-positive autoimmune hemolytic anemia, Sweet syndrome, seronegative arthritis, cutaneous vasculitis, necrotizing panniculitis, and polymyalgia rheumatica may arise (Al Ustwani et al. 2013; Fain et al. 2011; Enright and Miller 1997; Sanz et al. 1990).

MDS/MPN overlap syndromes, predominantly CMML, may manifest with hepatosplenomegaly, lymphadenopathy, or pleural effusions (Parikh and Tefferi 2013). RARS-T subtypes can develop substantial thrombocytosis which results in an elevated rate of thromboembolic events, comparable to patients with essential thrombocythemia (Malcovati et al. 2009).

Risk Stratification Models

As with any disease process, appropriate risk stratification and prognostic assessment is a crucial initial step in the management of MDS, particularly in the elderly population. By stratifying patients into subgroups, one is better able to get a sense of the disease trajectory thus allowing physicians the opportunity to appropriately tailor therapy. In general, the goal of therapy in low-risk patients is to alleviate symptomatic cytopenias, decrease MDS-associated complications, and most importantly, improve quality of life. In contrast, the goal of therapy in the more advanced high-risk population is to alter the natural history of the disease by delaying the potential of progression to acute myeloid leukemia in an effort to extend survival and preserve an optimal quality of life. Having open, frank discussion with elderly patients regarding their prognosis, goals, and values is critical to fostering honest communication and guiding treatment decision agreements between patients and providers.

While several prognostic models for MDS exist, the two most widely used prognostic stratification systems are the International Prognostic Scoring System (IPSS, Table 4) (Greenberg et al. 1997) and the revised-IPSS (R-IPSS, Table 4). The Global MD Anderson model (Table 4) developed in 2008 is another frequently used prognostic model and is particularly useful as it can be applied to MDS/MPN overlap syndromes (Greenberg et al. 1997; Voso et al. 2013).

The International Prognostic Scoring System

The IPSS remains the most widely used staging system in MDS. This system has been adopted by community oncology physicians, implemented in many clinical trials and remains an integral part in determining the timing of allogeneic stem cell transplant (allo-HSCT). This scoring system was developed from a multivariate analysis of an untreated cohort of more than 800 patients with MDS and incorporates bone marrow and peripheral blood blast percentage, using previously defined FAB cut points, the number of cytopenias, and cytogenetic patterns (Greenberg et al. 1997). There are four prognostic categories: low, intermediate-1, intermediate-2, and high; the IPSS low-risk category comprises low and intermediate-1–risk groups and the IPSS high-risk category includes intermediate-2 and high-risk (see Table 4). The overall survival (OS) in the low-risk group ranges from 3.0 to more than 5.5 years,

while the OS for the high-risk group averages about a year (Greenberg et al. 1997).

While the IPSS has remained a commonly used prognostic model, it is important to note that the IPSS-predicted outcomes are only relevant to the time of initial disease diagnosis and/or de novo disease, rather than patients who are experiencing disease progression. In addition, another shortcoming of the IPSS is that it does not account for the severity of the cytopenias and the cytogenetic risk groups are not comprehensive. Furthermore, the IPSS was only studied in patients with MDS, so this scoring system is not applicable to patients with t-MDS or those with MDS/MPN overlap syndromes (Voso et al. 2013; Greenberg et al. 2012).

The Revised IPSS

The R-IPSS emerged in 2012 as a refinement to adjust for the deficiencies of the original IPSS, as

Table 4 Risk stratification models in MDS

IPSS			R-IPSS			Global MDAS		
Variable	Score		Variable		Score	Variable		Score
BM blasts (%)			**BM blasts (%)**			**PS > 2**		2
<5	0		<2		0	**Age (year)**		
5–10	0.5		>2 to <5		1	60–64		1
11–20	1.5		5–10		2	≥65		2
21–30	2.0		>10		3			
Karyotype[a]			**Karyotype**[b]			**Platelets** (109/L)		
Good	0		Very good		0	<30		3
Intermediate	0.5		Good		2	30–49		2
Poor	1		Intermediate		4	50–199		1
			Poor		6			
			Very poor		8			
Cytopenia[c]			**Hgb (g/dL)**			**Hgb < 12 g/dL**		2
0/1	0		≥10		0	**BM blasts (%)**		
2/3	0.5		8 to <10		1	5–10		1
						11–29		2
			<8		1.5	**Transfusion**		1
			ANC ≤ 0.8		1	**WBC ≥20 × 109/L**		2
			Platelets			**Karyotype**		
			≥100		0	Chromosome & Abn or complex ≥3 Abns		3
			50–100		0.5			
			<50		1			
Risk Group	**Sum Score**	**OS (year)**	**Risk Group**	**Sum Score**	**OS (year)**	**Risk Group**	**Sum Score**	**OS (mos)**
Low	0	5.7	Very good	0–2	8.8	Low	0–4	54
Int-1	0.5–1	3.5	good	3–5	5.3	Int-1	5–6	25
Int-2	1.5–2.0	1.1	Int	6–7	3.0	Int-2	7–8	14
High	≥2.5	0.4	Poor	8–9	1.6	High	≥9	6
			Very poor	10–18	0.8			

Hgb hemoglobin, *WBC* White Blood Cell count, *ANC* absolute neutrophil count, *BM* bone marrow, *OS* overall survival

[a]Good is normal, -Y, del(5q), del(20q). Intermediate is other karyotypic abnormalities. Poor is complex (≥ three abnormalities) or chromosome 7 abnormalities

[b]Very good –Y, del(11q). Good is normal, single del(5q), del(12q), del(20q), or double including del(5q). Intermediate includes single del(7q), +8, I (17q), +19, or any double not including del(5q). Poor includes der(3q), monosomy 7, double including −7/7q, or three abnormalities. Very poor is more than three abnormalities

[c]Hgb <10 g/dL; ANC <1800/μL; platelets <100,000/μ ≥ L

previously outlined (Greenberg et al. 2012). These changes included incorporating a more comprehensive risk assessment based on cytogenetic risk groups, by refining the myeloblasts cutoffs and accounting for the degree of cytopenias in each cell lineage (Voso et al. 2013). The R-IPSS identifies five risk groups: very low, low, intermediate, high, and very high. Several groups have validated the R-IPSS, and it is currently incorporated in the NCCN guidelines (Voso et al. 2013; Mishra et al. 2013).

The Global MD Anderson Model

The MD Anderson Cancer Center risk model was developed in 2008 and represents a more flexible risk model that can be applied at any time during the disease course, unlike the IPSS and R-IPSS (Greenberg et al. 2012). In light of the fact that the MD Anderson model can be used throughout disease course, it does take into account the effects of therapy. In addition, it can be further used to subdivide patients who were initially classified as lower-risk by IPSS into different risk groups with variable outcome. Those models have been validated in several studies (Mishra et al. 2013; Kantarjian et al. 2008), and the MD Anderson risk model was found to be predictive for overall survival and AML transformation, offering a better discrimination for the lowest risk patients. As previously stated, this model can be used in the MDS/MPN overlap syndromes (Kantarjian et al. 2008; Hugo et al. 2009; Komrokji et al. 2012).

Other Risk Models

The lower risk MD Anderson risk model score (LR-MDAS) was developed and validated for patients with lower risk MDS; however, this model is not as commonly used in clinical practice at this time. The WHO based prognostic scoring system (WPSS) is another dynamic model utilized more commonly in Europe (Garcia-Manero et al. 2007; Malcovati et al. 2007).

Comorbidities and Frailty in MDS

Patients with MDS often suffer from other medical comorbidities, which might affect survival, performance status, and limit therapeutic options. This is a realistic challenge because the median age of MDS patients is older than 70 years. In a retrospective review among 600 patients, investigators applied the adult comorbidity evaluator (ACE-27) comorbidity to discern the effect on outcome. The median survival was 31.8, 16.8, 15.2, and 9.7 months for those with none, mild, moderate, and severe comorbidities, respectively ($P < 0.001$). A prognostic model including age, IPSS, and comorbidity score predicted median survival of 43.0, 23.0, and 9.0 months for lower-, intermediate-, and high-risk groups, respectively ($P < 0.001$) (Naqvi et al. 2011).

The Italian group added further refinement by developing an MDS-specific comorbidity index (MDS-CI). Cardiac disease (HR, 3.57; $P < 0.001$), moderate to severe liver disease (HR, 2.55; $P = 0.01$), severe pulmonary disease (HR, 2.44; $P = 0.005$), renal disease (HR, 1.97; $P = 0.04$), and history of solid tumors (HR, 2.61; $P < 0.001$) were found to independently affect the risk of nonleukemic death, and diabetes and cerebrovascular disease did not retain prognostic value. Patients were stratified into three risk groups based on those comorbidities with distinctly different outcomes. The MDS-CI is a flexible model that was predictive of outcome within each subgroup of WPSS (Della Porta et al. 2011).

It is important to keep in mind the difference between comorbidities and frailty in elderly patients. A large cohort of patients with Frailty was assessed by clinical judgment and also with a combination of physical measures such as hand grip strength and ability to get out of a chair 10 times and walk 4 m. Using a schema developed by Rockwood and associates, known as the Clinical Frailty Scale (CFS), patients were assigned scores of 1–9. A score 1 indicates very fit, 4 indicates vulnerable, and 8 indicates very severely frail. Frailty was found to correlate only modestly with Eastern Cooperative Oncology Group (ECOG) performance status ($r = 0.39$; $p < 0.0001$), less with comorbidity as assessed

by the MDS-specific comorbidity index (MDS-CI28; $r = 0.33$; $p < 0.0001$), and minimally with age-adjusted IPSS-R ($r = 0.12$; $p = 0.03$). Frailty improved the prognostication of the IPSS-R in all but the highest-risk group. Frailty was independently associated with survival (hazard ratio [HR] 2.7; 95% CI, 1.7–4.2). Moreover, incorporation of frailty improved MDS risk stratification by 30% (Buckstein et al. 2016).

Molecular Alterations

The heterogeneity of MDS has been elucidated and appreciated even prior to the advent of next-generation sequencing (NGS) and karyotypic analyses and techniques. Important somatic mutations to remember include ASXL1, EZH2, RUNX1, ETV6, and TP53, as these have all been shown to have less favorable outcomes in MDS patients (Bejar et al. 2012; Haferlach 2012). Of particular significance, TP53 alterations carry the worst prognostic significance. Additionally, a study published in *Blood* in 2013 showed that the number of somatic mutations effects prognosis with more than three mutations carrying a particularly unfavorable prognosis in patients with MDS (Papaemmanuil et al. 2013; Garcia-Manero et al. 2007). To date, SF3B1 is the only mutation shown to have a more favorable outcome (Haferlach 2012), and this is the most common mutation observed in patients with ring sideroblast MDS subtypes.

Incorporating somatic mutations into prognostic models enhances their utility; in fact, presence of any of the aforementioned somatic mutations has been demonstrated to upstage patients risk category in the IPSS or R-IPSS (Nazha and Bejar 2017).

Management of MDS: Low, High, and Intermediate Risk

Managing MDS is complicated by the advanced age of the majority of patients, their preexisting nonhematologic comorbidities and their comparative inability to tolerate intensive treatments compared to the younger population. The choice of therapy and treatment indications is based upon the IPSS and/or R-IPSS along with other parameters like performance status, age, patient preference for therapy, frailty, and comorbidities. At this point in time, molecular mutations do not drive treatment decisions but rather they play a role in the prognostication of patients. As further knowledge is elucidated about the significance of certain mutations, there is likely to be changes regarding incorporating these into treatment decisions and tailoring therapy for specific individuals, particularly in the elderly population.

To date, the only curative therapy for MDS remains allo-HSCT. This modality of therapy should be discussed with all elderly patients with a good performance status who have high-risk disease, in addition to those patients with low-risk disease that is refractory to treatment.

The first step in the treatment of the elderly population with MDS requires confirming the diagnosis ad subtype. This may require examination from an experienced hematopathologist at a large tertiary center familiar with MDS. Next, it is of paramount importance to risk-stratify patients, by using the aforementioned indices and molecular profiling, into low and high risk for management decisions. Once patients are stratified into groups, the subsequent step prior to discussion of therapy is to determine if the patient is an allo-HSCT candidate. Only after that should management and therapy options be discussed. A formal geriatric assessment for comorbidities and frailty should be incorporated to tailor therapy accordingly.

Low-Risk

Low-risk MDS patients include those with IPSS low, intermediate-1, and R-IPSS very low, low, and intermediate. The goal of therapy in these patients is to mitigate symptomatic cytopenias. This differs from the goal in high-risk patients, which aims to modify the natural history of the disease. Asymptomatic low risk patients are generally followed

clinically with close observation. Supportive care is an important component of all MDS patients, particularly in the elderly population.

Low-Risk Patients with Isolated del (5q) Syndrome

Patients with isolated del(5q) represent a rare entity but a favorable prognosis, as they respond well to treatment with lenalidomide. In a landmark NEJM publication, 67% of patients with del(5q) treated with lenalidomide had transfusion independence with at least 50% of patients going into a complete cytogenetic remission (List et al. 2006). The dose of lenalidomide is 10 mg po continuously or 10 mg po daily for 21 days of a 28-day cycle. Subsequent placebo controlled study confirmed those observations. Patients who achieve transfusion independence and or cytogenetic response derive survival advantage and less likely to progress to AML (List et al. 2014).

Initially, patients are started on 10 mg once daily dose; however, a majority of patients develop treatment related cytopenias within a few weeks, which then requires holding the drug for 2–3 weeks and restarting at a lower dose. It is important to note, however, that treatment related cytopenias predict a more favorable response. It is crucial to monitor blood counts weekly for the first 8 weeks of therapy. Other common side effects of lenalidomide include scalp itching, pruritic or non-pruritic rash, diarrhea, muscle cramping of the legs, and hypothyroidism.

Low-Risk Patients Without Isolated del (5q) Syndrome

As shown in Fig. 2, low-risk patients with a low erythropoietin level (EPO) <500 μU/mL and a low red cell transfusion burden (<2 units/month) have a 61–74% response rate to erythropoietin-stimulating agents.

Hypomethylating agents (HMA) such as Azacitidine (AZA) or Decitabine (DAC) are also used in the low-risk MDS population after failure of an ESA agent or those patients with serum EPO >500. It is important to note that HMAs do not improve counts immediately; therefore, it is important and considered standard practice to continue with at least 4–6 cycles of HMAs prior to rendering them a treatment failure. When using AZA in the lower-risk subpopulation, many favor a 5-day schedule, rather than the 7-day schedule used for higher risk patients (Lyons et al. 2009). Outcome after HMA failure is poor in the elderly, and they should be considered in patients with bi/pancytopenia and those with higher risk features (Jabbour et al. 2010, 2015).

Lenalidomide in non-del5q patients yields lower response rates compared to del5q patients. However, because of this drugs ability for some patients to attain red cell transfusion independency, it remains an option for patients with pure anemia. Recent studies demonstrated higher and more durable response rates when combined with ESA (Zeidan et al. 2015).

Immunosuppressive therapy (IST) with ATG (equine or rabbit) with or without cyclosporine is most effective in the younger population (<60yo), HLA-DR15+, hypoplasia, normal cytogenetics, and those with a PNH clone (Sloand et al. 2008). If patients are appropriately selected, durable trilineage responses can be observed.

High-Risk

The most important item to assess prior to assessing prognostic score or initiating any kind of therapy in high-risk patients is transplant eligibility. As such, every provider treating high-risk MDS patients should ask "is this patient allogeneic transplant eligible?" This is very important to initially assess, as most patients with MDS are ineligible for transplant given their advanced age, performance status, and underlying non-hematologic comorbidities (Fig. 3).

High-Risk, Transplant Ineligible

For all high-risk patients, including the elderly population, AZA 75 mg/m^2 $\times$ 7 days is considered the standard of care. This is based upon the AZA-001 phase III trial that revealed an improved median OS of 24.5 months versus 15 months with conventional care alone (i.e., best supportive care, low-dose cytarabine or intensive chemotherapy) (Fenaux et al. 2009). Another study comparing low-dose DAC to best supportive care in high-risk elderly

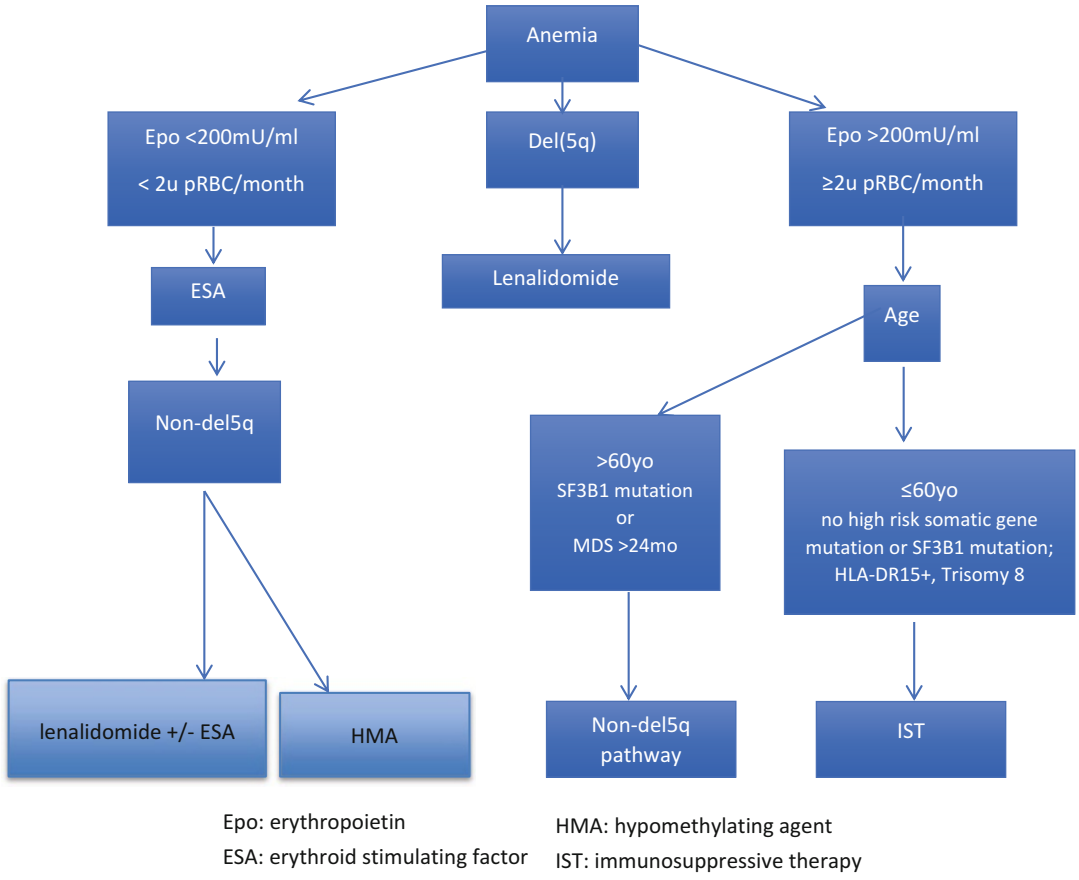

Fig. 2 Anemia management in low-risk MDS. *Epo* erythropoietin, *ESA* erythroid stimulating factor, *HMA* hypomethylating agent, *IST* immunosuppressive therapy

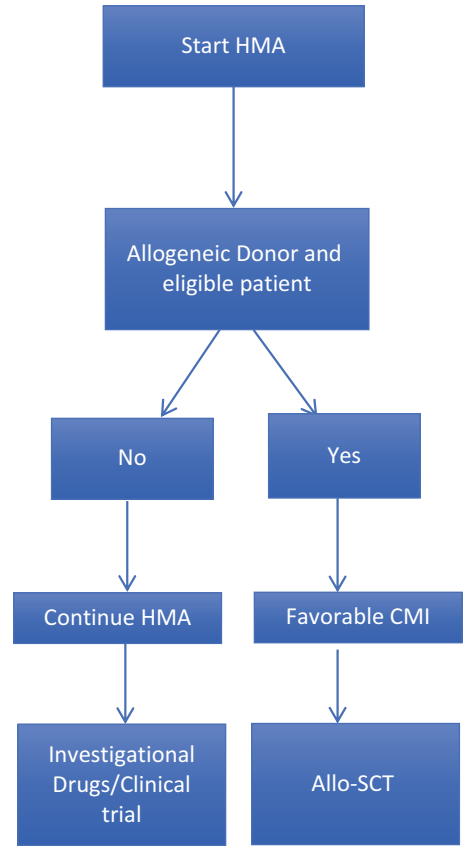
(60–90yo) transplant and intensive chemotherapy ineligible patients showed no statistically significant improvement in OS, but did improve PFS and AML transformation at 1 year (33% w/BSC to 22% with DAC) (Lubbert et al. 2011). Decitabine treatment was associated with improved patient-reported quality of life (QOL) parameters. Decitabine used at 20 mg/m^2 IV for 5 days every 28 days as outpatient was reported to have median overall survival of 19–20 month (Kantarjian et al. 2007b). It is crucial to allow 4–6 cycles of HMA therapy, patients with stable disease or better should continue on therapy as some patients will achieve better response later and even those with stable disease have better outcome than those who progress on therapy. Rarely, intensive chemotherapy can be utilized in this subset of patients as well, although these patients tend to have a lower response rate and shorter duration of remission.

High-Risk, Transplant Eligible

Since allo-HSCT is the only curative therapy for MDS, all patients who are <75 years of age with limited comorbidities should be considered for transplant at the time of initial diagnosis (Rowe et al. 2004). Currently, there remains inconclusive evidence that treatment prior to allo-HSCT improves outcomes. HMA compared to induction is an acceptable therapeutic option prior to allo-HSCT and often is used as a bridge to allo-SCT. As discussed below, the most important predictor of response to transplant is the disease status (blast percentage) and cytogenetics going into transplant (Damaj et al. 2012).



HMA: hypomethylating agents

Allo-SCT: allogeneic hematopoietic stem cell transplantation

Fig. 3 High-risk MDS treatment algorithm. *HMA* hypomethylating agents, *Allo-SCT* allogeneic hematopoietic stem cell transplantation

Low-dose HMA maintenance therapy (32 mg/m^2 × 5 days) posttransplant can be well tolerated although definitive clinical trial is warranted to confirm benefit of HMA maintenance (Jabbour et al. 2009).

It is important to note that a particular subset of high-risk patients, those with a TP53 mutation, have a particularly poor prognosis and to date, the benefit of allo-HCT has not been elucidated. For these patients, a clinical trial would be preferable (Lindsley et al. 2017).

Relapsed/Refractory Disease

There is a general paucity of effective treatments for the management of recurrent or refractory MDS. As such, patients with recurrent or refractory disease should be encouraged to participate in clinical trials whenever possible (Prebet et al. 2011). Any risk patient with HMA failure generally has a poor outcome (Garcia-Manero et al. 2013).

Intermediate-Risk R-IPSS

The intermediate-risk R-IPSS patients represent a challenging subset of patients. At this time, there is no defined consensus regarding the optimal treatment of patients with intermediate-risk MDS. As such, the management of this group of patients is ill-defined and is individualized based upon other factors such as age, LDH, ferritin, and perhaps somatic mutations (Tefferi et al. 2017). A choice among the therapeutic options, particularly in the intermediate-risk patients, must take into consideration the patients' own preferences and interpretation regarding what ascertains a reasonable quality of life, survival, and individualized goals.

The Role of Allogeneic Stem Cell Transplant

At this time, allo-HCT remains the only potentially curative therapy for patients with MDS. Unfortunately, as the median age of patients with MDS is 72 years old, most of these patients – even the higher risk patients – are ineligible for allo-HCT given other medical comorbidities and the baseline transplant-related mortality. It is interesting to note that since 2008, when Medicare began to provide coverage for the procedure in MDS patients, the number of allo-HCT performed in the United States for patients with MDS, particularly those older than 60 years, has significantly increased over the last decade.

The timing of allo-HCT is of paramount importance in MDS but is incompletely defined. In general, early transplant is recommended for all-comers with higher risk MDS to maximize survival potential, whereas for lower-risk MDS patients delaying allo-HCT until disease progression is often the norm as this is associated with prolonged OS in this subset of patients (Cutler et al. 2004). A subsequent study utilizing data from reduced intensity allo-HCT in the elderly (60−70yo) population confirmed the recommendation of early allo-HCT for high-risk disease and delayed allo-HCT for those patients with lower-risk MDS (Koreth et al. 2013). It is important to note, however, that age is *not* the most important predictor of outcome after allo-HCT. A retrospective multicenter analysis of 1333 MDS patients ≥50 years, the 4-year estimated treatment-related mortality (TRM) was 36% in the 50–60-year-old cohort, and 39% in patients older than 60 years (Lim et al. 2010). Interestingly, age is not the most important predictor of outcome after allo-HCT, rather it is the disease status prior to transplant (Damaj et al. 2012; Cutler et al. 2004).

Therapies on the Horizon

MDS is a particularly challenging entity given the heterogeneity of this disease and the complicated elderly patients that compromise the majority of those afflicted. Newer and more efficacious therapies are needed to advance the overall outlook of elderly patients with MDS. In higher risk MDS patients, new HMA such as oral azacitadine, oral decitabine, and SGI-110 are being tested in clinical trials. Checkpoint inhibitors are currently in clinical studies in combination with HMA or after HMA failure.

In the lower risk MDS population, novel TGF-B inhibitors luspatercept and sotatercept showed promising results in patients with ring sideroblasts. Those molecules are fusion trap proteins that neutralize activin receptor ligands (Platzbecker et al. 2017; Komrokji et al. 2014).

Targeted therapies including splicing inhibitors, IDH-2 inhibitors, and p53 modulators are being investigated in clinical trials.

Contents

Abstract

Acute myeloid leukemia (AML) is a disease of older adults, and approximately 58% are diagnosed in those aged ≥65 years. Outcomes in older adults with AML are poor due to a combination of factors including disease biology, under-referral, undertreatment, and poor treatment tolerability. For selected older patients with AML, treatment is associated with improved survival. The optimal treatment for older patients with AML is unclear. While

intensive induction chemotherapy has been used for the last few decades, it has been associated with high treatment-related morbidity and mortality. In the last decade, many advances in the treatment of AML have been made, including the use of targeted agents and novel combinations of lower-intensity treatments, the latter of which may have better tolerability and similar or better efficacy compared to intensive chemotherapy. Nonetheless, to help personalize therapies for older adults with AML, it is important to assess individual fitness through the use of a geriatric assessment. Improving outcomes of older adults with AML will rely on both development of novel therapies and targeting therapy to their physiologic fitness and disease biology.

Keywords
Acute myeloid leukemia · Older adults · Geriatric assessment

Introduction

Acute myeloid leukemia (AML) is an aggressive cancer of the myeloid linage of leukocytes. It is of particular interest to geriatric oncologists as it is a disease of older adults which has been characterized by dramatic age-related outcome disparity. There is no consensus regarding optimal therapy for older adults (frequently defined as ≥60 or ≥ 65 years). Older adults are commonly treated differently than younger patients due to concerns related to both decreased treatment efficacy and lower treatment tolerance. Available evidence supports an individualized approach to treatment accounting for both the heterogeneity of tumor biology and the variability of patient characteristics which better define physiologic age and resilience. A recent expansion of therapeutic strategies spanning more and less intensive treatment approaches provide opportunities to improve outcomes for older adults with AML.

Epidemiology

AML is a disease most commonly diagnosed in older adults. The median age at diagnosis is between 68 and 72 years; approximately 57% are ≥65 years and 33% are ≥75 years. The Surveillance, Epidemiology, and End Results (SEER) Program estimates 19,520 new cases in 2018 in the United States with 10,670 deaths from the disease (SEER 2019).

Risk factors for the development of AML include a history of preceding myelodysplastic syndrome (MDS) or myeloproliferative neoplasms (MPNs), exposure to certain chemotherapy drugs (alkylating agents, topoisomerase II inhibitors, and nitrosoureas), radiation, benzene exposure, and a history of Down's syndrome. The majority of diagnosed cases of AML, however, are not associated with any known risk factor.

Diagnosis and Risk Stratification

The presentation of AML can vary and initial symptoms are non-specific. The most common objective findings are anemia, thrombocytopenia, and/or leukopenia. Fatigue, dyspnea, bleeding, fever, and infection are common presenting symptoms secondary to cytopenias. Leukemic infiltration of tissues outside the bone marrow such as the liver, spleen, skin, lymph nodes, and central nervous system (CNS) can manifest a variety of other symptoms specific to the site of involvement. Some patients present with severe leukocytosis, which can produce symptoms of leukostasis due to the large blast fraction in the peripheral blood. Peripheral blood findings range from pancytopenia with or without circulating blasts cells to severe leukocytosis with circulating blasts often accompanied by anemia and thrombocytopenia.

Diagnosis of AML depends primarily upon detection of an abnormal accumulation of leukemic blasts of myeloid lineage ≥20% in the bone marrow. Additionally, presence of certain genetic abnormalities t(8;21), inv(16), or t(15;17) and myeloid sarcoma are considered diagnostic of AML regardless of marrow blast count. AML classification by genetic abnormality is presented in Table 1 (Döhner et al. 2017).

Table 1 Risk stratification by genetics for acute myeloid leukemia per European Leukemia Network 2017

Risk category	Genetic abnormality
Favorable	t(8;21)(q22;122.1); *RUNX1-RUNX1T1*
	inv(16)(p13.1q22) or 1(16;16)(p13.1; q22); *CBFB-MYH11*
	Mutated NPM1 without FLT3-ITD or with FLT3-ITD[low(a)]

Outcome and Treatment Disparity by Age

Outcomes for older adults are poor. In the United States, a 5-year relative survival reported by Surveillance, Epidemiology, and End Results (SEER) Program is 46.3%, 26.3%, 10.8%, and 2.7% for ages 20–49, 50–64, 65–74, and > 75 years, respectively (SEER 1988–2014). While survival rates have improved over time, the magnitude of improvement decreases with increasing age and has remained fairly stagnant for those diagnosed above age 75 (representing approximately one-third of newly diagnosed patients) (SEER, Fig. 1). Clinical trial data have also documented low 5-year survival estimates among adults aged ≥65 years (<10%) (Appelbaum et al. 2006). The Alliance for Clinical Trials in Oncology recently published long-term outcomes of patients treated intensively who did not undergo allogeneic transplantation post-remission and showed a complete remission rate of 60.3% among older patients (>60 years, N = 944) and a 10-year disease-free survival rate of 2.4% (Vasu et al. 2018).

Population-based data have indicated that a large proportion of older adults with newly diagnosed AML receive no antileukemic therapy at all (Medeiros et al. 2015; Oran and Weisdorf 2012). For example, SEER data indicated that only 40% of adults ≥65 years of age received any antileukemic therapy within 3 months of diagnosis (years 2000–2010). Forty percent of the population were aged >80 years, and only 20% received any therapy in this age group (Medeiros et al. 2015). Indicators of poor performance (i.e., claims for oxygen, wheelchair, home health supplies, skilled nursing; poor performance indicators) and comorbidity were associated with lack of therapy. However, it is notable that indicators of poor performance were only present in 13% of the population and only a quarter had such a comorbidity. In a more recent analysis (2000–2013), it appears that the percentage of older patients who received antileukemic therapy has increased from 37% to 55% (Medeiros et al. 2018).

Importantly, receipt of any treatment is associated with improved survival. Swedish registry data has also observed a survival advantage for older adults who receive therapy for AML (Juliusson 2011; Juliusson et al. 2009). In general, these population-based studies do show a trend for increased use of antileukemic therapy over time among older patients, particularly among those between ages 65 and 80 years. Given the recent availability of new therapies, it is likely that the proportion of older adults receiving any antileukemic therapy will continue to increase in the coming years. However, it will be important to continue observing practice patterns in the community and to pay close attention to those aged ≥75 years.

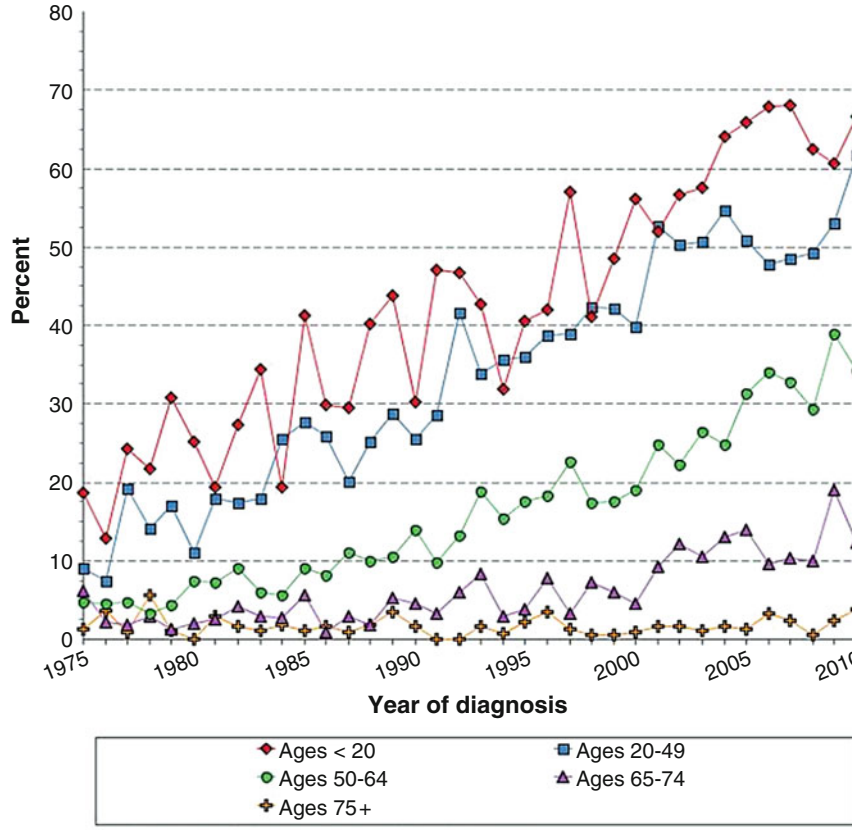

Fig. 1 Surveillance, epidemiology, and end results (1975–2014) 5-year relative survival for newly diagnosed acute myeloid leukemia by year of diagnosis and by age

Age-Related Changes in Tumor Biology

Age-related changes in tumor biology contribute to poor outcomes for older adults. Older adults with AML are less likely to have favorable cytogenetic abnormalities (i.e., t(8;21), t(15;17), and inv(16)) compared to younger patients. In addition, they are more likely to have unfavorable cytogenetic abnormalities (i.e., chromosome 5 and 7 abnormalities and/or complex karyotypes) (Appelbaum et al. 2006; Grimwade et al. 2001; van der Holt et al. 2007). Unfavorable cytogenetic abnormalities are associated with decreased rates of remission and decreased overall survival (OS) (Appelbaum et al. 2006; Grimwade et al. 2001; Farag et al. 2006; Frohling et al. 2006; Gupta et al. 2005). Other risk factors include expression of a multidrug resistance (MDR1) phenotype which are more commonly seen in older patients with AML (Leith et al. 1997). This membrane-associated glycoprotein actively pumps out conventional chemotherapies such as anthracyclines reducing intracellular concentrations, compromising treatment efficacy. Older patients are also more likely to harbor unfavorable mutations in their leukemic clone when compared to younger patients. This was particularly true for mutations in the tumor suppressor gene *TP53* and the epigenetic regulator *DNMT3A*. Mutations in both of these genes were independent predictors of adverse prognosis among older adults (Tsai et al. 2016). Finally, older adults are more likely to present with secondary AML, often with a

preceding hematologic disorder such as myelodysplastic syndrome, which is associated with lower remission rates and higher rates of relapse (Godwin and Smith 2003).

Studies have demonstrated the influence of these risk factors on remission rates for older adults. For example, a study of older adults with newly diagnosed AML treated with intensive induction therapy conducted by the Southwest Oncology Group demonstrated that patients with none of these adverse risk factors (i.e., de novo AML, MDR1-negative phenotype, favorable or intermediate cytogenetics) had high complete response (CR) rates (81%), while those with multiple risk factors (i.e., secondary AML, MDR1-positive phenotype, unfavorable cytogenetics) had extremely low CR rates (12%) (Leith et al. 1997). Another study of older patients with favorable cytogenetics (t(8;21), inv. (Tsai et al. 2016)) demonstrated remission rates of 80% and 5-year survival of 30% (Prebet et al. 2009), resulting in some consensus that this uncommon subgroup should be offered intensive therapy if their Eastern Cooperative Oncology Group (ECOG) performance status is <3.

The majority of older adults fall into the category of cytogenetically normal AML. This category is, however, molecularly diverse. The prognostic implication of gene mutations (i.e., FMS-like tyrosine kinase-3 internal tandem duplication (*FLT3-ITD*), nucleophosmin 1 (*NPM1*), CCAAT-enhancer-binding protein alpha *(CEBPA)*, DNA methyltransferase *3 (DNMT3)*, isocitrate dehydrogenase *1* (*IDH1)* and *IDH2*, Wilms tumor suppressor gene 1 (*WT1*)), and gene overexpression (i.e., erythroblast transformation-specific-related gene (*ERG*), brain and acute leukemia, cytoplastic (*BAALC*)) is an area of active research (Becker et al. 2010; Marcucci et al. 2012; Mendler et al. 2012; Schwind et al. 2010, 2011; Whitman et al. 2012; Whitman et al. 2010; Eisfeld et al. 2018). The most well-defined molecular risk factors are *FLT3-ITD* mutation (poor prognosis), *NPM1* without *FLT3-ITD* mutation (good prognosis), and biallelic *CEBPA* mutation without *FLT3-ITD* (good prognosis). The prognostic implications of these mutations appear similar across ages. Molecular changes have been observed between older and younger patients, and analysis of gene expression data comparing younger and older patients has demonstrated age-specific dysregulation of oncogenic pathways (Rao et al. 2009).

Treatment

Induction Chemotherapy

The standard treatment for older adults with AML is an ongoing debate. Induction chemotherapy with anthracycline and cytarabine (given over 7 and 3 days, respectively) has been a standard upfront treatment for AML since the 1970s (Yates et al. 1973). In the CALGB study published by Rai et al., it was established that 7 days of cytarabine administered as a continuous confusion along with 3 days of daunorubicin given as intravenous injection was superior to 5 + 2 (Rai et al. 1981). The CR rate was 59% in patients aged <60 years and 45% in patients aged ≥60 years. In 1989, Löwenberg et al. confirmed the benefits of intensive chemotherapy in patients aged ≥65 years (Lowenberg et al. 1989). In this trial, patients who received 7 + 3 vs. supportive care had a superior CR (58% vs. 0%) and median survival (21 weeks vs. 11 weeks, P = 0.015).

Since then, various other strategies have been investigated with the goal of improving outcomes. These strategies include the use of different anthracyclines (e.g., idarubicin or mitoxantrone) (Rowe et al. 2004; Goldstone et al. 2001; Pautas et al. 2010; Lowenberg et al. 1997, 1998), new agents added to standard 7 + 3 (e.g., etoposide, midostaurin, or gemtuzumab) (Goldstone et al. 2001; Baer et al. 2002; Cripe et al. 2010; Castaigne et al. 2012; Stone et al. 2017; van der Holt et al. 2005), alternative agents (e.g., clofarabine alone) (Foran et al. 2015), novel combinations (e.g., clofarabine with cytarabine) (Faderl et al. 2006; Burnett et al. 2017), various doses of anthracycline and cytarabine (Pautas et al. 2010; Lowenberg et al. 2009; Dillman

et al. 1991), and growth factors (Rowe et al. 2004; Lowenberg et al. 1997; Godwin et al. 1998; Stone et al. 1995). Some of these strategies have yielded improvement in outcomes although the majority did not (Table 2).

In terms of the types and doses of anthracycline, Löwenberg et al. compared daunorubicin 45 mg/m^2 vs. 90 mg/m^2 given with cytarabine in patients aged 60–82 years; CR rates were 54% vs. 64% (P = 0.002) (Lowenberg et al. 2009). No difference in OS, 30-day mortality, or adverse events was noted. Nonetheless, in subgroup analyses, patients aged 60–65 years who received higher dose of daunorubicin (90 mg/m^2) had improved CR (73% vs. 51%) and 2-year OS (38% vs. 23%, P < 0.01). On the other hand, Pautas et al. did not demonstrate superiority of daunorubicin 80 mg/m^2 vs. idarubicin 12 mg/m^2 given over 3 or 4 days (Pautas et al. 2010). In fact, the CR rate was lower in the daunorubicin arm (70% in the daunorubicin arm vs. 83% in the 3-day idarubicin arm vs. 78% in the 4-day idarubicin arm, P = 0.04) (Pautas et al. 2010). Burnett et al. also failed to show any difference in the daunorubicin 60 mg/m^2 vs. 90 mg/^{2} arm (over a quarter were aged ≥60 years) (Burnett et al. 2015). Taken together, daunorubicin 60–90 mg/m^2 or idarubicin 12 mg/m^2 can be considered for patients aged ≥65 years.

In recent years, emerging studies have demonstrated the utility of adding targeted agents to intensive chemotherapy. Castaigne et al. demonstrated that in patients aged 50–70 years, adding gemtuzumab ozogamicin, an anti-CD33 antibody conjugate, during induction on days 1, 4, and 7 and during consolidation for two doses at 3 mg/m^2 improved OS (34.0 months vs. 19.2 months, P = 0.0368) (Castaigne et al. 2012). Burnett et al. also showed that adding gemtuzumab at 3 mg/m^2 on day 1 of induction chemotherapy improved survival (Burnett et al. 2012). However, both studies did not show a difference in CR rates.

Another targeted agent is midostaurin, a multikinase inhibitor with activity against FLT3. In a study of patients aged 18–60 years, Stone et al. showed that midostaurin added to standard induction chemotherapy for those with a FLT3 mutation improved median OS (74.7 months vs. 25.6 months, P = 0.009), compared to chemotherapy alone (Stone et al. 2017). CR was similar (58.9% vs. 53.5%, P = 0.15). Even though the trial did not include older patients, midostaurin was approved by the US Food and Drug Administration (FDA) for use in all patients with FLT3 mutations.

Even with intensive chemotherapy, the outcomes of older patients with AML are poor, especially in those with secondary or therapy-related AML (Granfeldt Ostgard et al. 2015). In this population, a liposomal capsulation of cytarabine and daunorubicin, known as CPX-351, was evaluated. Lancet et al. compared CPX-351 to standard 7 + 3 in patients aged 60–75 years with secondary AML, therapy-related AML, or AML with MDS-related cytogenetic abnormalities (Lancet et al. 2018). CPX-351 improved the median OS and remission rate compared to standard 7 + 3 (median OS, 9.6 months vs. 6.0 months, P = 0.003; remission rate, 47.7% vs. 33.3%, P = 0.016). It is worth noting that the time taken to neutrophil and platelet count recovery in the CPX-351 arm was longer (around 35 to 37 days vs. 26 days in the 7 + 3 arm), which may translate to a longer hospitalization.

Lower-Intensity Treatments

Intensive chemotherapy is associated with an early mortality rate of 10–30% in older adults (Foran et al. 2015; Lowenberg et al. 2009; Kantarjian et al. 2006, 2010). Therefore, it is typically reserved for patients who are considered "fit" and have no major comorbidities. In addition, some older patients may prioritize receiving treatments in the outpatient setting. Therefore, lower-intensity treatments that are outpatient, such as low-dose cytarabine and hypomethylating agents (azacitidine and decitabine), have been actively investigated.

Tilly et al. compared low-dose cytarabine (LDAC) to intensive chemotherapy in patients aged ≥65 years (Tilly et al. 1990). CR was 32% in the low-dose cytarabine group vs. 52% in the intensive chemotherapy group, though OS was

[d]Single-arm study

similar. Burnett et al. compared low-dose cytarabine to hydroxyurea in patients with AML or MDS (most patients were aged ≥60 years) not considered "fit" for intensive treatment (Burnett et al. 2007). CR was 18% in the low-dose cytarabine group vs. 1% in the hydroxyurea group ($P < 0.00006$), with improvement in OS noted in the former group (odds ratio (OR), 0.60; 95% CI, 0.44–0.81). These studies supported that the utility of low-dose cytarabine in older patients with AML was not considered candidates for intensive chemotherapy.

Additional low-intensity options are the hypomethylating agents, azacitidine and decitabine. These drugs are cytidine and deoxycytidine analogues, respectively. Unlike cytarabine, these agents are incorporated into the growing DNA strand and do not cause DNA polymerase stalling or replication fork collapse. Once incorporated into the newly synthesized DNA strand, DNA methyltransferases become covalently attached when they attempt to methylate them. This adduct is recognized by the base excision repair machinery, and its resolution results in the degradation of the DNA methyltransferase. The result is a cell depleted of DNA methyltransferase and hypomethylated DNA leading to aberrant gene expression and differentiation or apoptosis (Stresemann and Lyko 2008).

These agents have demonstrated activity in older adults with AML (van der Helm et al. 2013; Gardin and Dombret 2017) and have been shown to be superior to conventional care regimens (Dombret et al. 2015). Overall, these agents have demonstrated a lower CR rate but increased tolerability and comparable survival when compared to intensive chemotherapy (Gardin and Dombret 2017).

Fenaux et al. compared azacitidine with conventional care regimens (CCR, best supportive care only, low-dose cytarabine, or intensive chemotherapy) in patients (72.7% were $\geq$ 65 years) with low bone marrow blast count AML (median, 22.5–27.0%) (Fenaux et al. 2010). Compared to CCR, those who received azacitidine had improved median OS (24.5 months vs. 16.0 months, $P = 0.005$) and fewer days in hospital (26.0 days vs. 50.9 days per patient year, $P < 0.0001$). CR was not different between the azacitidine and CCR groups (18% vs. 16%, $P = 0.80$). Of note, the median OS was also not different between patients who received azacitidine vs. intensive chemotherapy (not reached vs. 14.2 months, $P = 0.97$), although the study was not powered to detect a difference (Fenaux et al. 2010). Dombret et al. further evaluated azacitidine vs. CCR in patients aged $\geq$65 years with high bone marrow blast count (>30%) (Dombret et al. 2015). Compared to CCR, those who received azacitidine had improved median OS, though this was not statistically significant (10.4 months vs. 6.5 months, $P = 0.1009$). When adjusted for subsequent AML therapy, azacitidine was superior compared to CCR. Overall response rate (CR + CRi) was not different between the azacitidine vs. CCR groups (27.8% vs. 52.1%, $P = 0.5384$). Kantarjian et al. compared decitabine vs. supportive care or low-dose cytarabine in patients aged $\geq$65 years (Kantarjian et al. 2012). Like azacitidine, after censoring for subsequent AML therapy, decitabine was found to be superior to its comparative arm (median OS: 8.5 vs. 5.3 months, $P = 0.044$). CR was higher in the decitabine arm (17.8 vs. 7.8%, $P = 0.001$). To date, there is no published randomized trial powered to compare low-dose therapy vs. intensive therapy although such a study is ongoing (NCT02172872).

Recently, novel combinations with lower-intensity therapies have been tested leading to new drug approvals specific to older adults. Two combination therapies with LDAC have been recently approved in the United States. The first of these is an oral hedgehog pathway inhibitor, glasdegib. This was tested in a randomized trial of older patients with AML not fit for intensive chemotherapy (97.7% were $\geq$ 65 years; 53% had ECOG performance status of 2). The study showed a doubling of survival for patients treated with combination compared to LDAC alone (4.9 months vs. 8.8 months, $P = 0.0004$) (Cortes et al. 2019). This led to the approval of this combination for older AML patients unfit for intensive therapy due to comorbidities or age. The B-cell leukemia/lymphoma 2 (BCL2) antagonist venetoclax was also tested in combination with LDAC in a single-arm phase I/II study of 82 patients (median age not reported) with previously untreated AML that were unfit for induction chemotherapy (Wei et al. 2018a). The phase I portion of the study determined the recommended phase II dose of venetoclax to be 600 mg daily given continuously. The combination resulted in a CR/CRi rate of 54% with a median survival not yet reached at the time the abstract was presented (Wei et al. 2018b). These data led to the approval of venetoclax in combination with LDAC for the treatment of unfit patients with AML. Finally, the combination of venetoclax with either azacitidine or decitabine for older adults not fit for chemotherapy was conducted. In this phase Ib study of 145 previously untreated, unfit patients, the recommended venetoclax dose was determined to be 400 mg daily (DiNardo et al. 2019). The overall CR/CRi rate was 67% for all doses tested. The median survival was a remarkable 17.5 months given the median age of the patients was 74 (DiNardo et al. 2019). These outstanding results led to the approval of this combination by the FDA for the treatment of unfit patients with AML and may result in this combination becoming the standard of care for these patients. In elegant translational experiments on AML cells taken from treated patients, it was determined that the combination of venetoclax and azacitidine acts by impairing the activity of complex II of

the electron transport chain leading to disruption of oxidative phosphorylation (ox/phos) and apoptosis particularly in the leukemia stem cell population (Pollyea et al. 2018). Of note neither agent alone has this activity; it is only the combination that results in ox/phos inhibition.

While recent approvals have included a specific indication for "unfit" adults, the criteria for "unfitness" vary among trials and remain to some extent dependent upon physician perspective. To a large extent, "unfitness" in this context has been described by chronologic age >75 years. The trial testing glasdegib did include additional specific criteria including PS 2, heart disease, and creatinine >1.3. No characterization of functional status was required except that patients were excluded if PS was >3.

Extrapolating Clinical Trial Data

In reviewing available clinical trial data to support treatment decisions for older adults, consideration must be given to how results can be extrapolated to patients seen in practice. Careful attention should be paid to inclusion and exclusion criteria in addition to characterization of patients. It is well known that those older adults who are enrolled on clinical trials are typically healthier than patients seen in practice (Hurria et al. 2015; Scher and Hurria 2012; Singh et al. 2017; Levit et al. 2018). In the case of AML, referral bias is also an important consideration. Clinical trials commonly enroll patients from referral centers, yet most older adults with AML are never referred (Alibhai et al. 2009a). Referral bias and unmeasured confounders (related to the patients themselves or the environment in which they are treated) can influence treatment outcomes at a high-volume referral center vs. smaller-volume community practice (Ostgard et al. 2016; Juliusson et al. 2012).

Post-remission Therapy

No studies have demonstrated the benefits of post-remission therapy vs. no therapy in older patients. However, most clinical trials evaluating induction therapies have incorporated post-remission therapies given a high risk of relapse in these patients (Cassileth et al. 1988). Therefore, it is an accepted standard to administer consolidation therapy to older patients with AML. Consolidation therapy usually consists of chemotherapy, allogeneic stem cell transplant, or both.

Mayer et al. showed that patients who received high-dose cytarabine (3 gm/m^2) every 12 hours on days 1, 3, and 5 for four courses had the best OS and disease-free survival, compared to lower doses (100 mg/m^2 or 400 mg/m^2 given continuously over 5 days) (Mayer et al. 1994). However, only 29% of patients aged >60 years were able to tolerate four courses, and 45% were able to receive more than one course. Central nervous toxicity occurred in 32% of these patients; 40% had permanent disability. Gardin et al. compared a single intensive consolidation course (i.e., second course of induction therapy) vs. a 6 monthly course of daunorubicin/idarubicin and cytarabine at lower doses. The latter regimen appears to be better in terms of disease-free survival and OS (Gardin et al. 2007). In contrast, Schlenk et al. showed that consolidation with idarubicin and etoposide was better than oral maintenance with the same drugs over a year (Schlenk et al. 2006). Stone et al. showed that a combination of cytarabine at higher dose and mitoxantrone was no better than cytarabine alone at a lower dose given over 4 months (Stone et al. 2001).

Overall, the aforementioned studies suggest that cytarabine may be beneficial in older patients with AML who achieve CR after induction chemotherapy, although the exact dosing and frequency are unclear. There are various regimens used in clinical trials and practice. The National Comprehensive Cancer Network recommends several strategies: cytarabine at 100–200 mg/m^2/day over 5–7 days for one to two cycles with or without anthracycline or intermediate-dose cytarabine at 1.0–1.5 gm/m^2/day for 4–6 doses given for 1–2 cycles for those who were not CD-33 positive, did not have FLT3 mutation, and did not have secondary or therapy-related AML (National Comprehensive Cancer Network 2018). In these patients, gemtuzumab, midostaurin, or CPX-351 should be incorporated as part of the consolidative treatments.

Allogeneic hematopoietic stem cell transplant (allo-HSCT) is generally considered in younger patients who have high-risk cytogenetics and potentially in those with intermediate-risk cytogenetics (Oliansky et al. 2008). However, the lack of evidence for allo-HSCT in older adults, coupled with the high treatment-related mortality, has contributed to its low utilization. With improvement in conditioning regimens and supportive care, an increasing number of older patients are considered for allo-HSCT (Muffly et al. 2017). Several studies have suggested improvement in outcomes in older patients with AML who underwent allo-HSCT (Muffly et al. 2017; Rashidi et al. 2016; Devine et al. 2015). Nonetheless, studies are needed to select older patients who will most benefit from this highly intense treatment.

Acute Promyelocytic Leukemia (APL)

Acute promyelocytic leukemia (APL) represents a unique AML subset. Treatment recommendations differ for APL. Patients with APL were largely excluded from the trials reviewed above and therefore warrant separate discussion. APL is defined by a translocation between chromosomes 15 and 17, which leads to fusion of the promyelocytic leukemia (*PML*) gene with the retinoic acid receptor α (*RARα*) gene and results disruption of normal cell differentiation (Sanz et al. 2019). This block to differentiation is the result of the fusion gene, PML-RARα, no longer able to bind to physiological levels of retinoic acid recruiting transcriptional repressors to genes normally activated by the wild-type RARα receptor (The and Chen 2010). APL is less common among older adults (only approximately 30% are over age 60) (Chen et al. 2012), but the response and cure rates are higher than in most AML subtypes with induction regimens that include use of all-*trans* retinoic acid (ATRA) that overcomes the differentiation block by providing pharmacological levels of ATRA to force binding to the fusion receptor resulting in the restoration of gene activation. A clinical feature of APL is presentation with bleeding secondary to disseminated intravascular coagulation, which is a frequent cause of early death. When the diagnosis is suspected, treatment with ATRA should begin immediately.

APL is a curable disease. Treatment options have expanded in the past decade which is particularly relevant for older patients. Common curative treatment regimens include induction therapy with ATRA+anthracycline (for patients with high-risk disease defined by white cell count greater than 10,000) versus ATRA+arsenic trioxide (ATO) induction (chemotherapy-free regimen for intermediate and low-risk disease). A paradigm changing randomized trial compared ATRA+chemotherapy induction with ATRA+ATO alone in 156 patients with low- and intermediate-risk disease and showed CR rates of 95% versus 100% (ATRA+ATO) with a 2-year event-free survival of 86% and 97%, respectively (Lo-Coco et al. 2013). Consolidation therapy post induction is recommended with ATRA+ATO where available. The role of maintenance therapy is less clear. This treatment option provides highly effective therapy with lower toxicity rates providing an option for most older adults diagnosed with APL.

Survival rates for APL have been improving over time although there remains a persistent age-related survival disparity. For example, in a report from the Netherlands, relative 5-year survival rates for those 61–70 years of age at diagnosis improved from 38% (2001–2006) to 54% (2007–2012), while those for aged over 70 increased from 16% to 37% during those years (Dinmohamed et al. 2016). Early death rates (typically defined as 30-day mortality) are high for all ages in population-based data but significantly worse among those diagnosed at an older age, with poor performance status, or comorbidity (Lehmann et al. 2011). Registry data from Sweden reported an early death rate of 15% for ages 16–50 and 50% for those over age 60 years (Lehmann et al. 2011). It is expected that this age-related gap in outcomes may continue to improve with use of chemotherapy-free regimens, but it remains critical that older adults are diagnosed in a timely manner, offered therapies, and carefully monitored to address unique supportive care needs during management.

Individualizing Therapeutic Decisions

Risk Prediction Models

A critical issue when making treatment decisions for older adults with AML is estimating risks and benefits of therapy. Several models have been developed to inform risk stratification particularly when considering intensive therapy. Most of these incorporate chronologic age, tumor biology characteristics, and oncology performance status (PS). For example, a model predicting early mortality (death within 8 weeks of induction) among patients 70 years of age or older receiving intensive therapy includes age > 80, complex karyotype, poor ECOG performance status ≥2, and elevated creatinine (>1.3 mg/dl) (Kantarjian et al. 2010). Early mortality rates were 16%, 31%, 55%, and 71% for patients with none (28%), 1 (40%), 2 (23%), or ≥ 3 (9%) of these risk factors, respectively (Kantarjian et al. 2010). A model developed to predict OS after induction includes chronologic age, karyotype, NPM1 mutation status, white blood cell count, lactate dehydrogenase (LDH) levels, and CD4 expression (Rollig et al. 2010). Three-year OS rates of 39.5%, 30%, 10.6%, and 3.3% illustrate the impact of favorable, good intermediate, adverse intermediate, and high-risk categories based on this model. Another validated web-based application predicts CR and early death using both laboratory and clinical variables (body temperature, age, secondary leukemia or antecedent hematological disease, hemoglobin, platelet count, fibrinogen, and LDH). CR rate predictions range from 12% to 91% if cytogenetic information is available (Krug et al. 2010). More recently, two additional models were developed. The first model was developed to predict therapeutic resistance. Factors including age, performance status, white blood cell count, secondary AML, cytogenetic risk, and *FLT3*-ITD/*NPM1* mutation status were independently associated with failure to achieve CR despite no early death (area under receiver operator characteristic curves of 0.78). The second model was the AML composite model (AML-CM) which includes albumin levels, platelet counts, and LDH level, in addition to comorbidities as assessed in the hematopoietic cell transplantation-specific comorbidity index (HCT-CI) (Sorror et al. 2017). Four risk groups were derived, and 1-year survival among patients aged 60–75 years were 86% (scores 1–4), 50% (scores 5–6), 46% (scores 7–9), and 23% (scores ≥10). All of the above models demonstrate that outcomes for older adults vary widely and provide a foundation for improving risk stratification at the time of diagnosis. With the exception of the AML-CM, each model relies on chronologic age as a surrogate for measureable underlying impairments (i.e., comorbidity, physical function, cognition) that if accounted for may further improve estimates of reserve capacity during or after treatment (Loh and Klepin 2018a).

Assessing Fitness: A Role for Geriatric Assessment

Characterization of "fitness" is central to personalizing therapies for older adults with AML. To do so the heterogeneity of aging needs to be measured including assessments of patient-specific characteristics such as comorbidity and functional status. Clinical trials have incorporated knowledge gained from characterizing the biologic diversity of AML but have not routinely adopted rigorous characterization of the diversity of the older adult population. Older age is a risk factor for poor outcomes but remains a surrogate marker for other unmeasured characteristics. Older adults of the same chronologic age present with varying comorbidity, functional status, emotional health, cognitive performance, polypharmacy, social support, and presence of geriatric syndromes. These factors can influence aspects of care including communication, decision-making, treatment tolerance/resilience, treatment responsiveness, and survival.

Performance of standardized, validated measurement of patient characteristics can inform fitness in the context of specific therapies. For the purposes of this discussion, fit older adults could be considered robust enough to treat similarly to a middle-aged patient. Frailty, on the other hand, is characterized as a state of decreased physiologic

reserve associated with adverse health outcomes usually arising from decreased organ reserve, lack of activity, poor nutritional intake, stress, and/or physiologic changes of aging. In geriatric medicine, frailty is most commonly assessed using a phenotype method such as the Fried Frailty Index (weight loss, weakness, slow gait speed, low physical activity, and exhaustion) (Fried et al. 2001) or using a cumulative deficit burden approach (Rockwood and Mitnitski 2007). The implications of frailty may differ in hematology practice as it relates to treatment decisions (Abel and Klepin 2018). For example, a phenotypically frail person is unlikely to tolerate aggressive therapy but may tolerate and benefit from low-intensity therapy depending upon the toxicity profile. Frailty is also not a static process. In some cases frailty may improve with therapy if the disease was a primary contributor to the phenotype. Alternatively, frailty can develop as a consequence of treatment complications. Finally, there is a middle category of patients, who meet neither extreme, often termed "vulnerable," "unfit," or "pre-frail." These patients may benefit from aggressive supportive care targeting specific vulnerabilities to enhance fitness or prevent frailty.

Current evidence has not defined a gold standard for assessment of fitness, "unfitness," or frailty categorization in AML. Recent studies, which have tested new drugs in "unfit" older adults, maintained some subjectivity. Several studies left characterization of "unfit" to the discretion of physicians and/or patients. Common criteria cited include age $>$ 75 years and comorbidity (Dombret et al. 2015; DiNardo et al. 2019). Most studies have continued to exclude those patients with the worst performance status (ECOG $\geq$3) even when testing less-intensive therapies (DiNardo et al. 2019). Most clinical trials do not routinely characterize comorbidity although many studies investigating the relationship between comorbidity and outcomes in AML have shown a relationship between increased comorbidity burden and worse outcomes (Sorror et al. 2017; Wass et al. 2016; Sorror et al. 2007; Etienne et al. 2007; Giles et al. 2007).

Geriatric assessment is a promising strategy to improve characterization of older patients enrolled on clinical trials and treated in practice. Geriatric assessment is a method used to evaluate multiple characteristics in a standardized fashion and commonly includes physical function, comorbidity, cognitive function, psychological state, social support, polypharmacy, and nutritional status. This robust assessment strategy could help define fitness, "unfitness," or frailty in AML studies (Loh and Klepin 2018b; Loh and Klepin 2018c). Geriatric assessment is recommended by the National Comprehensive Cancer Network, the International Society of Geriatric Oncology (SIOG), and the American Society of Clinical Oncology (ASCO) guidelines statement due to the growing evidence that it can predict chemotherapy toxicity and survival in varied settings (Mohile et al. 2018; NCCN 2019; Extermann et al. 2011; Hamaker et al. 2014a; Hurria et al. 2011; Soubeyran et al. 2012; Wildiers et al. 2014).

There are data to support use of geriatric assessment in the AML setting. Pretreatment geriatric assessment is feasible to perform for newly diagnosed AML patients and detects vulnerabilities not otherwise captured (Deschler et al. 2013; Klepin et al. 2011). A single institution study assessing older patients ($\geq$60 years of age) with good ECOG performance status considered fit to receive intensive therapy found the following impairments when performing bedside geriatric assessment: cognitive impairment (24%), depression (26%), distress (50%), activity of daily living (ADL) dependence (34%), impaired objectively measured physical performance (31%), and significant comorbidity (40%) (Klepin et al. 2011). In this cohort (N = 74) testing, the utility of inpatient geriatric assessment prior to intensive chemotherapy, baseline impaired objectively measured physical performance (assessed using the Short Physical Performance Battery [SPPB], score $<$9), and cognitive impairment (modified Mini-Mental State Exam score $<$77) were independently associated with worse survival (Klepin et al. 2013). The SPPB is a validated measure of lower extremity function that predicts disability, hospitalizations, and mortality among older patients with demonstrated reliability across varied populations

(Guralnik et al. 1994, 1995, 2000; Ostir et al. 2002; Studenski et al. 2003; Volpato et al. 2011). The European Medicines Agency recommends use of the SPPB as a frailty measure (European Medicines Agency 2018). The SPPB consists of a short walk (4 m at usual speed), five repeated chair stands, and three balance tests. Gait speed is as a robust marker of frailty and may be an alternate strategy to use in practice (Studenski et al. 2011).

The utility of geriatric assessment data has been shown in the non-intensive setting as well (Sherman et al. 2013; Molga et al. 2018). A multi-site observational study evaluated pretreatment geriatric assessment among patients with MDS or AML who were treated with best supportive care, hypomethylating agents, or intensive therapy per clinician discretion. Three characteristics were associated with worse survival among those receiving low-intensity therapy or best supportive care: assistance with activities of daily living (ADLs), high fatigue score, and impaired PS (Sherman et al. 2013). These three variables were used to create a frailty score ranging from 0 (low risk), 1–2 (intermediate), and 3 impairments (high risk) which predicted survival. A multi-site study designed to validate this frailty score in the setting of non-intensive therapy has been completed in Europe (Grishina et al. 2015).

While larger studies are ongoing, evidence is sufficient to support incorporation of brief validated assessment tools, ideally a geriatric assessment, to characterize patients both in clinical trials and in practice. Available evidence supports assessing physical function, comorbidity, cognition, and fatigue (Abel and Klepin 2018; Hamaker et al. 2014a, 2017). Integration of core measures to assess fitness can facilitate personalized treatment planning (Abel and Klepin 2018; Hamaker et al. 2014a, 2017).

Quality of Life, Survivorship, and Communication

When making a treatment decision, it is important to consider patients values and to inform patients on expectations for both disease control and quality of life. This communication is made more difficult by both a lack of data on key quality of life outcomes (i.e., functional independence, time spent at home (El-Jawahri et al. 2015), emotional well-being, financial considerations) and the stressful circumstance in which these conversations need to be undertaken. Characterization of how patients feel and function during and after AML therapy is limited largely to observational studies, and data collection in this setting is challenging due in part to attrition (Buckley et al. 2018). This is consistent with studies of older adults with cancer in varied settings; therapeutic trials do not routinely assess functional and QOL outcomes (Hamaker et al. 2014b; Wildiers et al. 2013). Observational studies have provided some insights, highlighting both short-term negative functional consequences of AML treatment and observations of improved QOL and functional resilience among older adult survivors (Aaldriks et al. 2013; Alibhai et al. 2007, 2009b; Klepin et al. 2016; Timilshina et al. 2019; Kayastha et al. 2018). Continued attempts to collect and compare outcomes that can inform "quality" are needed to inform treatment decisions. Finally, communication challenges faced by providers and patients at the time of AML diagnosis are significant. A small study was conducted among AML patients who were enrolled within 72 hours after initiating therapy and their oncologists. Older patients with AML consistently overestimated both the risks and the benefits of treatment they were receiving compared to estimates provided by their oncologists (Kayastha et al. 2018). Studying the decision-making process from the perspective of patients, caregivers, and their providers is important to ensure that patient-centered decisions are optimized (Loh et al. 2018).

Future Strategies

There is no one-size-fits-all treatment strategy for older adults with AML. While outcomes remain suboptimal, treatment options are expanding. Individualized treatment decisions required careful characterization of patient fitness to tolerate a given therapy and targeting of therapy to the

unique disease biology. Rapid advances in the field will be supported by testing of therapies which target biologic disease subsets and account for patient subsets (fit, vulnerable, frail).

Abstract

The typical patient with chronic lymphocytic leukemia (CLL) is old. For proper choice of therapy, older adults with CLL in need of treatment must be examined towards biological characteristics of their disease (presence or absence of 17p deletion or TP53 mutation) and their age (presence or absence of comorbidities or geriatric syndromes). Comorbidity scores and geriatric assessments could be supportive during fitness evaluation. Chemoimmunotherapy is a standard of care for older adults with previously untreated CLL lacking 17p deletion and TP53 mutation/dysfunction. Choice of the chemotherapy backbone (chlorambucil, bendamustine, fludarabine) and the antibody (rituximab, ofatumumab, obinutuzumab) depends on the fitness of the patient. The kinase inhibitor ibrutinib is a new therapeutic option in such patients and the treatment of choice for older adults with previously untreated CLL harboring 17p deletion or TP53 mutation. In addition to ibrutinib, idelalisib plus rituximab and venetoclax are preferred therapies for older adults with relapsed or refractory CLL. Readministration of chemoimmunotherapy is an option in older adults with late recurrence of CLL.

Chronic lymphocytic leukemia · Age · Comorbidity · Geriatric assessment · Chemoimmunotherapy · Antibody · Kinase inhibitor

Introduction

The incidence of chronic lymphocytic leukemia (CLL) in western countries is 4–6 per 100.000 men and women per year, but it increases by more than tenfold with advancing age. Therefore, individuals affected by this disease are typically old. The median age of newly diagnosed subjects is 71 years – with approximately 25% of patients being older than 75 years and 10% being older than 85 years at the time of diagnosis (Howlader et al. 2016). The absolute number and the relative proportion of older adults with CLL are expected to rise during the next decades. Such patients differ considerably from younger ones with regard to several aspects, thereby posing growing challenges to physicians and medical staff involved in the care of CLL. This chapter will discuss features of the disease as well as features of aging in older adults with CLL, followed by a review of the currently available evidence regarding the optimal management in this patient population.

Disease Features in Older Adults with CLL

Similar to younger subjects, disease courses vary remarkably between individual older adults with CLL. In daily practice, some patients will present with indolent and asymptomatic CLL without any need of antileukemic therapy over many years, while others will suffer from rapidly progressive and symptomatic CLL with unsatisfying responsiveness to conventional treatment efforts. According to the observational data, older adults with CLL will present with advanced disease stage twice as often as younger patients. In a Spanish study of 949 subjects with CLL, Binet stage C and Rai stage III–IV was found at rates of 10% and 12% among patients older than 70 years, respectively, but only of 5% in patients younger than 70 years (Baumann et al. 2014). A study of 2487 North American patients with newly diagnosed CLL found Rai stage III–IV in 11% of patients over 75 years but only 4–6% below that

age (Shanafelt et al. 2010). Molecularly defined poor risk features such as presence of a deletion of the short arm of chromosome 17 (del(17p)) or a mutation/dysfunction of the tumor suppressor gene p53 (TP53mt) appear more frequent in older than in younger patients with CLL. A recent study of 909 subjects with CLL demonstrated continuous increase of frequency rates of del (17p), TP53mt, or other adverse prognostic markers such as unmutated IGHV (immunoglobulin heavy chain variable region) gene with each age decade, being lowest in patients younger than 60 years (3%) and highest in patients over 90 years (21%) (Truger et al. 2015). Overall, these data suggest that advanced disease stage and unfavorable risk are more frequently observed among older than younger patients with CLL. Nevertheless, the majority of older adults with newly diagnosed CLL will still present with early or intermediate disease stages and lack of high risk features.

Aging Features in Older Adults with CLL

Physiological decline of functional organ reserve (e.g., aging-driven decline of the glomerular filtration rate or reduction of the hematopoietic stem cell pool in the bone marrow), pathological occurrence of aging-related chronic diseases (e.g., cardiovascular, musculoskeletal, or neurodegenerative disorders), as well as of geriatric syndromes such as polypharmacy, delirium, dementia, depression, sarcopenia, frailty, falls, immobility, and loss of autonomy are the most important determinants of an older person's biological age. There is great interindividual variation in the presence of such aging features among older adults with CLL. For instance, an observational study in 373 unselected patients with newly diagnosed CLL reported presence of at least one major comorbidity (i.e., chronic artery disease, stroke, cardiac disease, diabetes mellitus, chronic obstructive lung disease, or secondary malignancy) in 46% of the examined subjects. Another 43% had one or more milder comorbidities such as hypertension, joint disease, hyperlipidemia, or peptic ulcer but none of the major comorbidities. The remaining 11% neither had major nor minor concurrent diseases and thus were free from any comorbidity (Thurmes et al. 2008). The prevalence of geriatric syndromes in older adults with CLL has not been studied so far and thus is not well known. However, it can be assumed that these can be found in older patients with CLL at least at similar frequencies than in equally aged community-dwelling populations.

Management of Older Adults with CLL

Diagnosis

There are no data suggesting age-specific differences in the morphological or immunological phenotype of CLL. Independent of age, establishing the diagnosis of CLL therefore should follow general guidelines that have been published – with no further management specifically needed in patients of advanced age (Hallek et al. 2008; Eichhorst et al. 2015; Zelenetz et al. 2016). In brief, diagnosing CLL in an older adult presenting for example with B-symptoms, lymphocytosis, lymphadenopathy, or hepatosplenomegaly requires a blood count including differential, blood smear microscopy, and flow cytometry of the blood.

Prognostication

Advancing age in patients with CLL naturally comes with a growing risk to die from other health problems than from the hematological malignancy. Hypothetically, CLL-specific risk factors such as clinical stage, serum or antigen markers, cytogenetic aberrations, and gene mutations therefore could have differential survival impact in younger versus older individuals. However, recent data suggest that key CLL-specific risk factors such as advanced Rai/Binet stage, elevated serum β2-microglobulin (β2M), unmutated IGHV gene, and del(17p)/TP53mt maintain their prognostic value in older adults with CLL, even if these present with

increased comorbidity and lower performance status: Rai/Binet stage, β2M, IGHV mutational and del(17p)/TP53mt status are integral elements of the CLL International Prognostic Index (CLL-IPI), a newly proposed tool to estimate survival in patients with CLL (International CLL-IPI Working Group 2015). Recently, the CLL-IPI was evaluated in older adults with CLL specifically. In one study of 691 older patients (median age 74 years) with increased comorbidity and previously untreated CLL, CLL-IPI performed well with regard to the prognostication of overall survival as well as progression-free and treatment-free survival (Goede et al. 2016b). CLL-IPI was also found prognostic in another study of 460 subjects with previously treated CLL of whom half at least were older and had increased comorbidity (Soumerai et al. 2016). Among the known risk factors in CLL, so far del(17p)/TP53mt is the only one considered not just prognostic but also predictive for treatment failure.

Next to CLL-specific risk factors, patient-related factors such as comorbidity and geriatric syndromes may determine an older patient's overall prognosis as well as the tolerability and feasibility of the antileukemic therapy. For instance, renal comorbidity as reflected by a reduced creatinine clearance has been shown to increase the risk of hematological toxicity during treatment with purine analogues (Martell et al. 2002). In one study, overall comorbidity burden, as measured by the Cumulative Illness Rating Scale (CIRS), also showed some correlation with tolerability of purine analogue-containing chemotherapy and chemoimmunotherapy (Goede et al. 2012). A growing number of studies demonstrate that patients with CLL and multiple or severe comorbidities survive shorter than those with only mild or without comorbidities (Goede et al. 2012, 2014a; Baumann et al. 2014). The reason for shorter overall survival in comorbid subjects are not just more frequent deaths from coexisting conditions but also from CLL – apparently because therapy is more difficult to administer in these individuals compared to those without comorbidity. One study in older adults with CLL and increased comorbidity found associations between overall survival and the presence of geriatric syndromes such as cognitive decline, reduced gait speed, or poor performance in activities of daily living (Goede et al. 2016a).

In conclusion, prognostication in older adults with CLL is complex. Even in the era of molecularly defined CLL-specific risk factors, assessment of the Rai or Binet stage (Rai et al. 1975; Binet et al. 1977) remains important and of prognostic value. This requires careful palpation of lymph nodes, liver, and spleen, as well as measurement of hemoglobin and platelets. Imaging of cervical, thoracic, abdominal, or pelvic lymph nodes by computer tomography normally will not render treatment decisions and thus is not mandatory in routine practice. Potential benefits of computer tomography must be carefully weighed as many older adults with CLL will present with subclinical chronic kidney insufficiency and hence a risk of contrast media-induced renal failure. The del(17p)/TP53mt status must be assessed prior to treatment in all older adults with CLL, because it will render treatment decisions. Assessment of other molecularly defined CLL-specific risk factors is optional, but some (i.e., β2M, IGVH) are essential for calculation of the CLL-IPI, which appears a valuable prognostic tool not just in younger but also in older adults with CLL. Some recently identified gene mutations in CLL (*ATM, NOTCH1, SF3B1, BIRC3*) (Zent and Burack 2014) as well as other gene mutations such as *KRAS* or *POT1*, which might be particularly prognostic in older adults with CLL in the context of chlorambucil-based chemoimmunotherapy (Herling et al. 2016), remain to be further studied before being routinely used for prognostication in general and in this patient population particularly. Next to the assessment of CLL-specific risk factors, thorough evaluation of comorbidities and geriatric syndromes is needed (Stauder et al. 2017). This requires comprehensive history taking and physical examination as well as laboratory tests (e.g., estimation of the creatinine clearance). Further investigations such as electrocardiography, echocardiography, or bodyplethysmography might be performed if considered appropriate and potentially treatment decision-rendering. A systematic approach to comprehensively assess the comorbidities and

geriatric syndromes in an older adult with CLL is geriatric assessment which sometimes enables physicians to identify health issues that otherwise would have remained undetected (e.g., potentially inadequate medication, mild cognitive impairment, depression, delirium, sarcopenia, risk of falls) (Hamaker et al. 2014b). Such findings could not just be helpful when deciding for the antileukemic treatment regimen but also might drive geriatric interventions to fight geriatric syndromes in a systematic way (Hamaker et al. 2014c). Geriatric assessment therefore can be recommended in older adults with CLL provided that a proper logistical infrastructure exists. Resources can be spared by implementation of geriatric screening or geriatric consultation prior to a more comprehensive assessment (Hamaker et al. 2014a; Schiphorst et al. 2016). Importantly, results of geriatric screening and assessment in older adults with CLL always must be interpreted in context with other findings. Thus, compulsory treatment algorithms based on these diagnostic techniques alone cannot be defined at the present time.

Indication for Treatment

Treatment indications for CLL have been published in general guidelines and are similar for younger and older patients (Hallek et al. 2008; Eichhorst et al. 2015; Zelenetz et al. 2016). In brief, antileukemic therapy is indicated in patients with CLL-driven symptoms or/and advanced disease stage. However, in older adults with CLL, attribution of symptoms to CLL sometimes might be difficult, because these could also be caused by coexisting conditions (e.g., weight loss could be either due to progressive CLL or depression, peptic ulcer, etc.; fatigue could be CLL-related or due to heart failure, lung emphysema, etc.; anemia could be due to subtotal bone marrow infiltration by CLL cells or chronic blood loss, vitamin deficiency, myelodysplasia, etc.). In symptomatic patients with significant comorbidities but early or intermediate disease stage, unspecific symptoms therefore must be carefully dissected and judged before triggering the start of antileukemic treatment.

Choice of Front-Line Treatment

There is a considerable number of therapies available for treating older adults with previously untreated CLL in routine practice, namely chemotherapy alone, chemoimmunotherapy, and kinase inhibitors. Novel treatment combinations and compounds are currently evaluated in ongoing clinical studies, but this section will focus on approved front-line therapies applicable in this patient population outside of trials. Table 1 summarizes the main results of randomized trials which have been performed specifically in older adults with CLL and which are the basis of current treatment recommendations.

Since the introduction of monoclonal antibodies targeted against the CD20 antigen expressed on CLL cells (i.e., rituximab, ofatumumab, obinutuzumab), administration of chemotherapy alone has become an uncommon treatment approach in older adults with CLL. Today, this strategy is reserved only to those patients who do not tolerate an antibody. Available chemotherapeutic drugs for single-agent therapy are chlorambucil, bendamustine, and fludarabine. In a randomized study (CLL5) performed by the German CLL Study Group (GCLLSG), treatment with fludarabine of older adults with CLL did not result in prolongation of overall survival compared to chlorambucil therapy (Eichhorst et al. 2009). A comparison of bendamustine with chlorambucil is only available from a randomized study in younger patients, reporting longer progression-free survival with bendamustine but no overall survival benefit (Knauf et al. 2009). Combined chemotherapy of CLL with fludarabine and cyclophosphamide was investigated in randomized trials, but these did not enroll many older subjects.

Chemoimmunotherapy with fludarabine, cyclophosphamide, and rituximab (FCR) is the currently most efficacious treatment of CLL and – as shown by the CLL8 study – life-prolonging compared to combined chemotherapy without rituximab (Hallek et al. 2010; Fischer et al. 2016; Thompson et al. 2016). The FCR regimen therefore represents the current standard of care for younger and fit patients with CLL. FCR is

applicable in carefully selected older subjects who present with excellent fitness and without any comorbidities. However, there is cumulative evidence that in comparison to younger subjects a majority of older patients will tolerate FCR less well, even if fitness is good (Ferrajoli et al. 2005; Hallek et al. 2010; Kovacs et al. 2015). Adverse events, treatment delays, dose reductions, and premature discontinuation of therapy are all more frequently observed in older than younger patients. Dose-attenuated FCR regimens have been suggested (e.g., FCR-lite, Q-lite, FCR3) in order to save treatment toxicity and to improve treatment feasibility. Two randomized phase 2 trials have compared dosed-attenuated FCR with standard dose FCR (Mulligan et al. 2014) and chlorambucil plus rituximab (R-CLB) (Nikitin et al. 2013), respectively (Table 1). Results were encouraging, but since these trials were rather small (less than 50 patients per arm), dose-attenuated FCR regimens have not become a broadly accepted treatment standard in older adults with CLL so far.

A phase 3 study of the GCLLSG (CLL10) mainly enrolled young and fit patients and compared chemoimmunotherapy with bendamustine and rituximab (BR) to FCR (Eichhorst et al. 2016a). This trial demonstrated inferiority of BR to FCR with regard to its primary endpoint progression-free survival (medians: 42 versus 55 months). Importantly, no differences in progression-free survival were observed between study treatments when analyzed solely for the subgroup of patients being at least 65 years or older. Moreover, BR showed significant better tolerability than FCR in this subgroup as well as in the total study population. Rates of grade 3–4 neutropenia (59% versus 84%) and of grade 3–4 infections (27% versus 39%) were lower with BR compared to FCR. A randomized phase 2 study (MABLE) compared BR with R-CLB in older adults with CLL (Michallet et al. 2015) and found BR superior with regard to complete response rates (24% vs. 9%) representing the trial's primary endpoint. Progression-free survival was longer with BR, but there was no difference in overall survival. The rate of grade 3–5 infections was twice as high as with R-CLB (19% vs. 10%). Both studies used BR with the standard dose (i.e., 90 mg/m^2 body surface). To date, there are no solid trial data

Table 1 Randomized clinical trials in older adults with CLL with primary endpoints and main result[a]

Trial	Type	Compared treatments (patient number per arm)	Primary endpoint	Result (medians or rates)	Hazard ratio (95% confidence interval)
Front line

[a]Table contains published randomized trials with median age over 65 years

F fludarabine, *C* cyclophosphamide, *R* rituximab, *CLB* chlorambucil, *B* bendamustine, *O* ofatumumab, *G* obinutuzumab (GA101), *IBRUT* ibrutinib, *IDELA* idelalisib, *PFS* progression-free survival, TOX toxicity rate, *CYC* rate of six completed treatment cycles, *CRR* complete response rate, *NR* not reported, *NR* not reached

available for dose-adapted BR schedules (e.g., 70 mg/m^2 body surface) in older adults with CLL. The combination of bendamustine and ofatumumab (BO) also lacks specific evaluation in this patient population. In a nonrandomized phase 2 study conducted in younger patients (Flinn et al. 2016), response rates or BO were close to those observed with BR, and no superiority for BO over BR has been shown so far.

A phase 3 study in older adults with CLL and moderately increased comorbidity (COMPLEMENT-1) compared chemoimmunotherapy of chlorambucil and ofatumumab (O-CLB) with chlorambucil alone (Hillmen et al. 2015). Progression-free survival as the primary endpoint was significantly longer with O-CLB than with chlorambucil (medians: 22 versus 13 months), but there was no overall survival benefit. Grade 3–5 infections and infusion-related reactions (IRR) each were observed in 10% of patients treated with O-CLB. A large phase 3 study conducted by the GCLLSG in older adults with CLL and significantly increased comorbidity (CLL11) compared chemoimmunotherapy with chlorambucil and obinutuzumab (G-CLB) with R-CLB (Goede et al. 2014b). G-CLB was found significantly superior with regard to progression-free survival as the trial's primary endpoint (medians: 29 versus 15 months) and also time to next treatment (medians: 51 versus 38 months). Furthermore, a trend in overall survival benefit for G-CLB was observed (Goede et al. 2015a). Additionally, there was a comparison of G-CLB and R-CLB each with chlorambucil alone in this study. Both chemoimmunotherapies showed overall survival benefit over chemotherapy with chlorambucil (Goede et al. 2015b). Grade 3–5 infections occurred at a rate of 10–15% in all three study arms. Grade 3–4 IRR were more frequent during treatment with G-CLB than with R-CLB (20% vs. 4%).

The kinase inhibitors ibrutinib and idelalisib (in combination with rituximab) initially have been explored in older adults with CLL in small, nonrandomized trials (O'Brien et al. 2014, 2015). Notably, both compounds showed activity in patients with del(17p)/TP53mt which was an indicator of treatment failure in the above mentioned chemoimmunotherapy trials. A phase 3 study (RESONATE-2) compared ibrutinib to chlorambucil in older adults with CLL (Burger et al. 2015), with ibrutinib showing superiority over chlorambucil with regard to the primary endpoint progression-free survival (medians: not reached versus 19 months) as well as overall survival. No patients with del(17p)/TP53mt were enrolled. Diarrhea and fatigue were the most frequent adverse events observed with ibrutinib, while myelotoxicity was mild. It must be noted that ibrutinib could cause specific toxicities. Several studies including RESONATE-2 have reported new onset of atrial fibrillation at rates of 5–10%; particularly in patients with preexisting cardiovascular comorbidity (Byrd et al. 2014; Burger et al. 2015). Ibrutinib inhibits platelet aggregation which could induce bleeding. The risk of ibrutinib-induced hemorrhage (which mostly occurs as skin and less frequently as cerebral or gastrointestinal bleeding) appears increased in patients taking anticoagulants. Ibrutinib is metabolized in the liver via CYP3A4. This could result in drug-drug interactions if medication is taken that is metabolized via the same hepatic enzyme system (e.g., clarithromycin, voriconazole) (Finnes et al. 2015). According to current knowledge, the kinase inhibitor must be taken permanently which may cause adherence problems in older adults with CLL (Maddocks et al. 2015). Idelalisib has not yet been explored in randomized fashion in older adults with previously untreated CLL. Importantly, recent studies of idelalisib in younger patients with untreated CLL reported serious accumulation of autoimmunity-mediated colitis, hepatitis, and pneumonitis (Lampson et al. 2015), as well as infections by pneumocystis jirovecii and cytomegaly virus (FDA Alert 2016).

Based on this evidence, recommendations for the front-line therapy of CLL in older adults have been published by national and international organizations (Eichhorst et al. 2015, 2016b; Zelenetz et al. 2016). Such recommendations are displayed in Table 2. At present, chemoimmunotherapy is a broadly accepted standard of care for older adults with previously untreated CLL lacking del (17p)/TP53mt. Older patients with good fitness

Table 2 Summary of NCCN and ESMO recommendations for front-line treatment of older adults with CLL in need of therapy[a]

NCCN 2016 recommendations

[b]To be considered in fit older patients with previous history of infections

[c]Only if not suitable for ibrutinib

(i.e., no or only mild comorbidities, no geriatric syndromes) are suitable for more intense chemoimmunotherapies (e.g., standard dose BR, standard dose FCR only in very fit patients). Less fit patients (i.e., with significant comorbidity or geriatric syndromes) are candidates for chlorambucil-based chemoimmunotherapy (e.g., G-CLB). Dose-modified BR or FCR is possible, but the level of evidence is considerably lower. The main risks of chemoimmunotherapy in older adults with CLL are infusion-related reactions and infections due to myelosuppression. Therapy usually is stopped after six treatment cycles, and a treatment-free time period of 3–5 years can be expected. Ibrutinib is a newly available treatment option in these patients. Lack of infusion-related reactions and myelotoxicity are key advantages while risk of bleeding, drug-drug interactions, nonadherence, late-onset complications, and potentially nonresponse to chemoimmunotherapy after disease progression are of disadvantage. Chemoimmunotherapy shows unsatisfying treatment results in older adults with CLL and presence of del(17p)/TP53. These patients therefore should be treated upfront with ibrutinib. Idelalisib plus rituximab should only be used if patients are not suitable for ibrutinib and always with proper prophylaxis for pneumocystis jirovecii and cytomegaly virus infection/reactivation.

Choice of Further-Line Treatment

Therapies that can be used in older adults with previously treated CLL in routine practice are chemoimmunotherapy, ibrutinib, or idelalisib (in combination with rituximab) which block BTK and PI3K, respectively and venetoclax which block the antiapoptotic protein BCL2. Ongoing clinical studies explore novel agents (e.g., acalabrutinib, duvelisib, ublituximab) and combinations. The focus of this section will be therapies approved for further-line treatment in older adults with CLL outside of trials, however. Main results of two corresponding randomized trials are shown in Table 1.

The number of randomized trials investigating chemoimmunotherapy in relapsed or refractory CLL is small – with none of those having been conducted specifically in older subjects. Greater

evidence in this patient population exists for kinase inhibitors. A phase 3 study (RESONATE) compared ibrutinib with ofatumumab in heavily pretreated patients of whom a larger proportion was of advanced age (Byrd et al. 2014). Ibrutinib proofed superior to ofatumumab with regard to progression-free survival as the primary endpoint (medians: not reached versus 8 months) and overall survival. Benefits from ibrutinib were observed in all subgroups including patients with del(17p)/TP53mt. Specific adverse events of ibrutinib were bleeding and atrial fibrillation (see section "Choice of Front-Line Treatment"). Another phase 3 study (116) compared idelalisib plus rituximab with rituximab alone in older adults with CLL and significantly increased comorbidity (Furman et al. 2014). Progression-free survival as the trial's primary endpoint was longer with the combination treatment (medians: not reached versus 6 months). Again, benefits were seen across subgroups including patients with del(17p)/TP53mt. Diarrhea was the most frequent toxicity in the idelalisib arm. Autoimmunity-induced hepatitis and pneumonitis were also recorded. In contrast to front-line therapy, long-term study results suggest that idelalisib plus rituximab is a safe treatment of relapsed or refractory CLL. In non-randomized trials, venetoclax demonstrated remarkable activity in relapsed or refractory CLL, even in patients who had del(17p)/TP53mt (Roberts et al. 2016; Stilgenbauer et al. 2016). So far, there are no specific data available for venetoclax monotherapy in older adults with pretreated CLL. An important toxicity of venetoclax is tumor lysis syndrome which needs special consideration in older adults with CLL and preexisting renal comorbidity.

Recommendations for further-line therapy of CLL in older adults made by national and international organizations (Eichhorst et al. 2015, 2016b; Zelenetz et al. 2016) are shown in Table 3. Readministration of chemoimmunotherapy is an option if the CLL has not reoccurred within the first 24–36 months from the start of front-line treatment and still lacks del(17p)/TP53mt. Irrespective of del(17p)/TP53 status, older adults with earlier recurrence of CLL should be treated with ibrutinib or idelalisib plus rituximab. Both kinase inhibitors are administered until disease progression. Ibrutinib and idelalisib

failure, respectively, may be followed by a switch to the other kinase inhibitor or treatment with venetoclax.

Conclusion

Future research likely will result in further changes of the management of older adults with CLL. New molecularly defined risk factors (e.g., gene mutations) are expected to improve prognostication in general and in this patient population specifically. Fitness evaluation in older adults with CLL is a moving target and will depend on the particular toxicity profiles of treatments becoming available. Geriatric consultation, screening, and assessment likely will stay important; maybe less for the choice of antileukemic therapy, but for the stratification of older adults with CLL towards supportive geriatric interventions. Several ongoing clinical trials in CLL are specifically designed for older patients and explore novel combination treatments (e.g., venetoclax plus CD20 antibody) (Fischer et al. 2015). Together with recommendations and guidelines for older adults with CLL provided by national and international organizations, this chapter will need to be constantly adapted to these ongoing developments.

Chronic Myelogenous Leukemia and Myeloproliferative Disorders in Older Adults

33

Raul Cordoba, Valentin Garcia-Gutierrez, and Juan M. Alonso-Dominguez

Contents

Abstract

Chronic myeloid leukemia (CML) and other myeloproliferative neoplasms are more often diagnosed in people aged above 65. CML is more common in older adults, frequently diagnosed among people aged 65–74. Given the large proportion of older adults with these diseases, it is of interest to pay higher attention in special physiologic and comorbidity

conditions found in older people. Plenty of data can be obtained from clinical trials in these diseases about tolerance, side effects, and outcome in elderly people when compared with younger people. Comorbid conditions are now being assessed in these chronic myeloproliferative diseases, with a strong correlation with toxicity and survival. Quality of life may also be improved with the new target therapy strategies approved not only in CML but also in primary myelofibrosis patients.

Keywords
Chronic myeloid leukemia · Myeloproliferative neoplasms · Polycythemia · Essential thrombocytosis · Myelofibrosis

Introduction

Chronic myelogenous (also known as *myeloid*) leukemia (CML) is a pluripotent hematopoietic stem cell neoplasm characterized by *BCR-ABL1* fusion gene, which is derived from a balanced translocation between the long arms of chromosomes 9 and 22, t(9;22)(q34;q11), also known as the Philadelphia (Ph) chromosome. The resultant hybrid oncogene is transcribed as a chimeric *BCR-ABL* mRNA, which is translated into a functional abnormal protein. *ABL1* encodes a non-receptor tyrosine kinase that phosphorylates substrate proteins via its SH1 domain, affecting crucial cellular activities such as increased proliferation, loss of stromal adhesion, and resistance to apoptosis. The *BCR-ABL1* gene results in two critical events in the disease: it provides a unique biomarker for the diagnosis of the disease and, second, it is susceptible to drug targeting. Tyrosine kinase inhibitors (TKIs) block the ATP-binding pocket of ABL1 kinase domain, inhibiting phosphorylation and resulting in cell death (Apperley 2015).

Other entities different than CML are the myeloproliferative neoplasms (MPNs), previously known as myeloproliferative diseases (MPDs). They are a group of diseases of the bone marrow in which excess cells are produced. The concept of myeloproliferative disease was first proposed in 1951 by the hematologist William Dameshek (Dameshek 1951). In the most recent World Health Organization (WHO) classification of hematologic malignancies, this group of diseases was renamed from "myeloproliferative diseases" to "myeloproliferative neoplasms" (Arber et al. 2016). This reflects the underlying clonal genetic changes that are a salient feature of this group of disease (Tefferi and Vainchenker 2011). The categories of MPNs have not significantly changed since the 2008 fourth edition of the WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues, but discoveries of new mutations and improved understanding of the morphologic features of some entities have impacted the diagnostic criteria for the disease entities. In recent years, new data have suggested the need for revisions to the diagnostic criteria for the *BCR-ABL1*-MPNs (Barbui et al. 2015). New findings have been demonstrated to have diagnostic and/or prognostic importance like *JAK2*, *MPL* mutations, and in particular the *CALR* mutation, providing proof of clonality, diagnostic importance, and influence prognosis or the need to differentiate "true" essential thrombocythemia (ET) from prefibrotic/early primary myelofibrosis (prePMF).

Chronic Myeloid Leukemia

Epidemiology

In the National Cancer Institute "Surveillance, Epidemiology, and End Results Program," the number of new cases of CML in the United States was 1.8 per 100,000 men and women per year, and the number of deaths was 0.3 per 100,000 men and women per year. These rates are age-adjusted and based on 2009–2013 cases and deaths. CML is more common in older adults and among men, with a median age at diagnosis of 64 years old. CML is most frequently diagnosed among people aged 65–74. Forty-nine percent of cases are diagnosed in people over 65, so it is of interest to pay higher attention in special physiologic and comorbidity conditions found in older people (Howlader et al. 2016).

In order to establish the incidence of CML in Europe, a large population-based study (EUTOS study) was conducted in 20 European countries with a sample of 92.5 million adults (Hoffmann et al. 2015). The standardized incidence per 100.000 inhabitants in all countries was 1.10 for males and 0.82 for females. For both sexes, the yearly incidence rose from a minimum of 0.39 new cases in very young adults to a maximum of 1.52 in senior adults of 70 years and more. This study showed important differences when comparing data from "real life" with pivotal treatment studies, with main differences concerning age, with a median of 55 years in the EUTOS population study and 46–51 years for company-sponsored trials.

Presentation

CML is a triphasic disease: most patients are diagnosed in the "chronic phase," in which symptoms can be fairly easily controlled but without effective medical intervention will progress through a period of increasing instability known as "accelerated phase" to terminal transformation to an acute leukemic-like illness or so-called blast crisis (Apperley 2015).

CML patients are usually asymptomatic at diagnosis and are discovered incidentally. Commons symptoms at diagnosis include fatigue, night sweats, and weight loss and are normally due to hypercatabolic symptoms, splenomegaly, anemia, or platelet dysfunction. Hyperleukocytosis has been related in men with priapism. Most patients will present with splenomegaly (50–90%) at diagnosis, and painless hepatomegaly may be present in up to half of the patients. Thrombotic and hemorrhagic complications are not as frequent as in the other MPNs, observed only in less than 5% of patients.

Diagnosis
