Once CML is suspected, regardless of the age of the patient, specific test must be performed to confirm the diagnosis (see Table 1). Most cases of CML in chronic phase can be diagnosed from peripheral blood findings combined with detection of t(9;22)(q34.1;q11.2) or, more specifically, BCR-ABL1 by molecular genetic techniques. However, a bone marrow aspirate is essential to ensure sufficient material for a complete karyotype and for morphologic evaluation to confirm the phase of disease (Arber et al. 2016). Roughly, 90% of new patients are diagnosed in the chronic phase. The definitions of acceleration and blast crisis are largely dependent on the proportion of blasts in the blood and bone marrow but vary in the two commonly used systems: the World Health Organization (WHO) classification and the European LeukaemiaNet (ELN). The major difference in WHO classification is in blast cells percentage, where for WHO is 15–19% for accelerated phase and $\geq$20% for blast crisis. ELN definitions are those that have been internationally shared and used in almost all recent major studies of CML. Other parameters to distinguish CML phases are basophils, thrombocytopenia, increasing spleen size, extramedullary disease, appearance of other cytogenetic abnormalities, or extra Ph chromosome during treatment or extramedullary disease (Baccarani et al. 2013, 2015).

Table 1 Test to be performed in CML newly diagnosed patients (Adapted from Apperley 2015)

Mandatory diagnostic tests for chronic myeloid leukemia
Blood count with blood film differential. This will typically show a so-called left shift of the myeloid series with the presence of immature myelocytes and metamyelocytes, basophils, and eosinophils. These must be accurately quantified as the results contribute to accurate identification of disease stage and prognostic scoring systems
Blood count with blood film differential. This will typically show a so-called left shift of the myeloid series with the presence of immature myelocytes and metamyelocytes, basophils, and eosinophils. These must be accurately quantified as the results contribute to accurate identification of disease stage and prognostic scoring systems
Cytogenetics and karyotyping by G banding: fluorescent in situ hybridization is not sufficient at diagnosis as it is unable to identify chromosomal abnormalities in addition to the t(9;22) translocation
Reverse transcriptase PCR for BCR-ABL1 mRNA transcripts

Definition of disease is regardless the age, and all patients should be properly diagnosed according to current criteria.

Treatment

The goal of therapy in CML is to achieve a complete cytogenetic response. New treatment strategies with TKIs avoid the use of both chemotherapy and allogeneic transplantation in a clear majority of patients. TKIs are extremely well tolerated and are suitable therapies for older patients, despite frailty status. The choice among the different options would be guided according to patient's comorbidities.

It is crucial to establish the phase of the disease because it will have impact on treatment decisions and prognostic implications. Treatment recommendations are different when accelerated phase and blast crisis are recognized at baseline, prior to any treatment, or during the treatment of chronic phase. Patients presenting in accelerated phase are well responsive and should be treated with TKIs, better with the more potent second-generation TKIs. They are eligible for allogeneic stem cell transplantation (SCT) only if not achieving an optimal response. But this strategy is restricted only to young patients and the rare "fit" older patient with CML.

In contrast, young patients presenting in blast crisis are in high risk of progression, and all of them should be considered eligible for a SCT procedure, except older people. The patients who progress from chronic phase to accelerated phase or blast crisis are less sensitive to any subsequent treatment, and they should be treated with a TKI and considered for SCT only if they are young and fit enough, a strategy not possible to be done in older people.

Over the last decade, with the incorporation to new treatment strategies in CML like TKIs, the expected overall survival of patients with CML has reached the general population at the same age interval (Bower et al. 2016). Therefore, the expected prevalence of the disease is increasing year by year. In the United States, the prevalence of CML is increasing from about 70,000 in 2010, 112,000 in 2020, 144,000 in 2030, 167,000 in 2040, to 181,000 in 2050 when it will reach a near plateau prevalence (Huang et al. 2012). This dramatic improvement in the prevalence of CML will have two major consequences: first, a significant increasing in the budget we will have to spend to treat our CML patients since nowadays expert guidelines recommend maintaining treatment indefinitely; and second, the progressive aging of patients with CML, implying necessarily having to deal with the treatment of leukemia with a multidisciplinary approach within the different pathologies that our geriatric patients will have to deal with. Understanding the relationships between comorbidity, treatment outcomes, and patient's health-related quality of life (HRQOL) is thus essential to robustly inform clinical decision-making (Uemura et al. 2016).

In CML, age was considered a prognostic factor in Sokal score (Sokal et al. 1984) and Hasford score (Hasford et al. 1998). Sokal score which was generated with four variables representing percent blasts, spleen size, platelet count, and age provided a useful representation of risk status in CML population. It was possible to identify a lower-risk group of patients with a 2-year survival of 90%, subsequent risk averaging somewhat less than 20%/year and median survival of 5 year, and an intermediate group and a high-risk group with a 2-year survival of 65%, followed by a death rate of about 35%/year and median survival of 2.5 year (Barbui et al. 2011a). Hasford score, developed in patients treated with interferon alfa, was generated with six covariates: age, spleen size, blast count, platelet count, eosinophil count, and basophil count. Three distinct risk groups were identified, with median survival times of 98 months (40.6%), 65 months (44.7%), or 42 months (14.6%) (Tefferi et al. 2014a). In the era of TKIs, a new risk score has been developed: EUTOS score (Hasford et al. 2011). The strongest predictors for the achievement of complete cytogenetic response at 18 months were spleen size and percentage of basophils. Spleen size is measured in cm under the costal margin, basophils as their percent in peripheral blood. Age was not predictable of outcome in CML patients in the era of TKIs any longer.

Several approaches have been tested in order to minimize toxicities of TKIs and improve the quality of live in CML patients. In clinical trials where elderly patients, with optimal and stable response, were changed to a regimen of intermittent imatinib (1 month on and 1 month off), imatinib-associated side effects were reduced in 50% with no progressions or death due to CML (Russo et al. 2015). The Spanish group of CML has also recently published how decreasing imatinib dose to 300 mg in patients with sustained deep responses can improve tolerability and preserves efficacy (Cervantes et al. 2016). But probably, the most interesting approach in this sense is the probability of discontinuing treatment to get what it has been called as "operational cure" in CML. Several clinical trials (and more ongoing) including more than 2000 patients have shown how around 50% of patients in deep and stable molecular response can safely cease their therapy without relapsing. Furthermore, those who are unsuccessful in their cessation attempt can safely reestablish remission after restarting their TKI therapy. However, there is no evidence enough to recommend treatment strategies out of clinical trials unless there are important side effects. New data from clinical trials ongoing will hopefully allow hematologists to give further recommendations for such important question as how much time of exposure to TKI is needed before stopping treatment or when to restart treatment after losing response (Hughes and Ross 2016). But there are still no data regarding discontinuation strategies in elderly population.

For resistant or intolerant imatinib patients, dasatinib and nilotinib are the current options, with probabilities to obtain complete cytogenetic responses of around 50%. However, after 5 years of treatment, only 70% of patients remained in the study, which means that most of these patients would need to have treatment change in a third-line strategy. It is important to note that nilotinib dose on label in second line is 400 mg BID (300 mg BID in first line). For patients' intolerance or resistance to second-generation TKIs (2GTKIs), current recommendations recommend treatment change to a different 2GTKI (nilotinib, dasatinib, or bosutinib) or ponatinib.

Treatment patterns, overall survival, healthcare resource use, and costs in elderly patients with CML using second-generation tyrosine kinase inhibitors as second-line therapy have been analyzed. Despite similar adherence, dasatinib patients were more likely to start on the recommended dose and to have dose reductions than nilotinib patients. Fewer nilotinib patients discontinued or switched to another TKI than dasatinib patients. Nilotinib patients had longer median OS and lower mortality risk, fewer inpatient admissions, fewer emergency room visits, and fewer outpatient visits than dasatinib patients (Smith et al. 2016). But of notice, more cardiovascular adverse events have been seen in elderly population when compared with younger people. Regarding dasatinib treatment, Charlson comorbidity index and adult comorbidity evaluation-27 (ACE-27) scores might predict treatment compliance and development of pleural effusions in elderly patients with CML when treated with second-line dasatinib (Breccia et al. 2011). Bosutinib has shown in second line after imatinib failure results similar to dasatinib or nilotinib in the same indication with a good safety profile. In third line, after failing to imatinib and nilotinib or dasatinib, probabilities to obtain complete cytogenetic responses are around 25%. Most frequent side effects related to bosutinib are gastrointestinal (diarrhea and hepatotoxicity) which are generally well managed, not being these side effects a common reason for treatment discontinuation (Cortes et al. 2016). Ponatinib is at this moment the most effective treatment for patients resistant to previous 2GTKIs, with probabilities achieving complete cytogenetic responses around 50%. Ponatinib is the only effective drug for patients harboring the T315I mutation. However, the use of ponatinib has been related with 30% probabilities of suffering cardiovascular events. For these reasons, current recommendations are to start with lower dose in cardiovascular high-risk patients (30 or even 15 mg) and decrease dose once complete cytogenetic responses have been achieved. At this moment, this approach is being tested in clinical trials (Fava and Saglio 2016).

Philadelphia-Negative Chronic Myeloproliferative Neoplasms

Polycythemia Vera

Regarding the other MPNs, median age of patients at diagnosis of polycythemia vera (PV) is approximately 60 years (Tefferi et al. 2013). The reported annual incidence of PV increases with advanced age and varies from 0.710 to 2.6 per 100,000 inhabitants in Europe and North America. Most reports indicate a slight male predominance, with the male-female ratio ranging from 1 to 2:1 (Campo et al. 2008).

In 2016, the World Health Organization (WHO) modified the criteria required to be diagnosed of PV. Currently, major criteria are hemoglobin >16.5 g/dL or hematocrit >49% in men/hemoglobin >16 g/dL or hematocrit >48% in women, morphology showing a panmyelosis, and presence of a JAK2 mutation (V167F or exon 12 mutations). There is only one minor criterion: serum erythropoietin (EPO) level below the normal range. In order to be diagnosed of PV, all three major criteria are required or the two first major criteria and the minor criteria. Although recommended in every patient, biopsy may not be required in cases with sustained absolute erythrocytosis (hemoglobin levels >18.5 g/dL or hematocrit >55.5% in men/hemoglobin >16.5 g/dL or hematocrit >49.5% in women) if a JAK2 mutation is detected and EPO level diminished (Arber et al. 2016). Therefore, in an elderly and/or unfit patient who fulfilled these criteria, the bone marrow biopsy could be spared.

A recent study carried out in Mayo Clinic found that life expectancy in patients with PV was inferior to that of an age- and sex-matched control population, with estimated median survivals of 14 years for PV. A survival score, developed with a cohort of 1545 patients, classified patients into three groups. Age greater than 67 years classified patients directly in the high-risk group with a median survival of 10.9 years compared to 27.8 years in the low-risk group. Age greater than 61 years was also found to be an independent prognostic marker for development of leukemia (Barbui et al. 2011a).

Polycythemia is the main alteration in the complete blood count, but leukocytosis with neutrophilia and thrombocytosis may also be present. Patients with PV might also have leukocytosis, splenomegaly, and microvascular symptoms, palpitations, atypical chest pain, paresthesias, erythromelalgia, thrombosis, bleeding, and pruritus (usually after bathing and other constitutional symptoms (e.g., fatigue)). In nearly 20% of patients, an episode of venous or arterial thrombosis is documented in the medical history and may be the first manifestation of PV, even prior to rise in hemoglobin levels (Dameshek 1951). Leukemic or fibrotic transformation rates at 20 years are estimated at 10–20% for PV (Tefferi et al. 2014a). There is no way to cure the disease or prevent the development of leukemia or post-PV myelofibrosis; consequently, the current therapy in PV is aimed at lowering the risk of thrombosis (Tefferi and Barbui 2015). The risk classification system in these disorders is shaped according to thrombosis risk. Low-dose aspirin must be given to every patient diagnosed of PV (Landolfi and Marchioli 1997). In case of major hemorrhagic events, antiaggregant therapy should be discontinued. In case of a first episode of thrombosis, indefinite anticoagulation should be the best approach. Several studies in PV have identified age older than 60 years and previous thrombosis as the main predictors of vascular complications (Marchioli 2005). Hence, cytoreductive therapy should be administered in patients older than 60 years or who have suffered from any arterial or venous thrombotic event (Barbui et al. 2011a). As in younger patients, in elderly patients hematocrit should be kept below 45% (Marchioli et al. 2013). Either hydroxyurea or IFN-α is first-line cytoreductive therapy at any age (Barbui et al. 2011a). Second-line treatment for intolerant or resistant patients include the first-line option not administered or, in case of prior hydroxyurea administration, the JAK2 inhibitor ruxolitinib (Vannucchi et al. 2015). Pipobroman, busulfan, and ^{32}P are other second-line therapies reserved for patients with short life expectancy (Barbui et al. 2011a).

Essential Thrombocythemia

Essential thrombocythemia (ET) is a MPN that involves primarily the megakaryocytic lineage. More than one half of the patients are asymptomatic at the time of diagnosis when a markedly elevated platelet count is discovered at the time of a complete blood count. The remaining patients may present at the clinics with the same symptoms explained in PV. Median age at diagnosis is 67 years, and the female-to-male (F/M) ratio was 2.6:1 (Jensen et al. 2000).

No major changes have been done in the 2016 revision to the WHO classification of myeloid neoplasms, besides the inclusion of new molecular markers. Hence, all four major criteria are required to be diagnosed of ET: a platelet count >450.000/microL; a trephine biopsy morphology showing an increased number of enlarged, mature megakaryocytes with hyperlobulated nuclei and no significant fibrosis; not meeting criteria for other myeloid neoplasm; and the presence of any of the three driver mutations (*JAK2* V617F, *CALR*, or *MPL* found in 50–60%, 19–22%, and 1–3% of patients, respectively) (Pardanani et al. 2006; Kong et al. 2016). In around 15% of patients, no mutation in these genes is detected (i.e., are triple negative). In such cases, clonal marker is required or absence of evidence for reactive thrombocytosis (Dameshek 1951). In general, *JAK2* V617F mutations are found in older patients compared to those who carry a *CALR* mutation, probably due to the association of type-1 *CALR* mutations to younger patients (Tefferi et al. 2014b, c).

Life expectancy is reduced in ET compared to that of an age- and sex-matched control population, although it is higher than in PV patients, with a median survival of 20 years (Tefferi et al. 2014a).

Arterial or venous thrombotic events occur in around 25% of patients, either previous or after ET is diagnosed (Colombi et al. 1991). As described in PV, therapy is aimed at reducing the risk of thrombosis and, in turn, is guided by the thrombotic risk of the patient. Hence, patients older than 60 years or with a previous record of arterial or venous thrombosis might receive cytoreductive treatment. Prophylactic low doses of aspirin should be individualized according to patient's risk. It seems that cases with JAK2 mutation are at higher risk of thrombosis rather than cases with CALR mutation, where the risk is much lower (Barbui et al. 2011b). In case of major hemorrhagic events, antiagregant therapy should be discontinued. Hydroxyurea is the first-line cytoreductive therapy, but tolerance is much worse in older people. Moreover, the incidence of skin lesions like ulcers is higher in older people. Anagrelide is the recommended second-line therapy for ET. In older people, cardiac function should be closely monitored due to secondary tachycardia induced by the inhibition of phosphodiesterase and ulterior myocardiopathy. IFN might be considered an experimental therapy (Barbui et al. 2011a). Although a non-leukemogenic drug is preferred after hydroxyurea treatment, due to an increase of the incidence of leukemia evolution, in case of short life expectancy, pipobroman, busulfan, or ^{32}P could be administered (Barbui et al. 2011a; Najean and Rain 1997).

Primary Myelofibrosis

Primary myelofibrosis (PMF) is a clonal proliferation of a pluripotent hematopoietic stem cell, in which the abnormal cell population releases several cytokines and growth factors in the bone marrow that lead to marrow fibrosis and stroma changes (Barosi 1999). Some patients initially diagnosed of PV or ET eventually develop this disease, denominated post-PV myelofibrosis (post-PV MF) or post-ET myelofibrosis (post-ET MF). PMF is the least frequent among the chronic myeloproliferative diseases. One study reported an estimated incidence of 1.5 per 100,000 per year. PMF occurs mainly in middle-aged and older adults. The median age at presentation is 67 years (Mesa et al. 1999).

In order to be diagnosed of PMF, a patient must also show, at least, one of the following: anemia, leukocytosis, palpable splenomegaly, increased LDH, or leukoerythroblastosis. Around 12% of patients carry a triple-negative mutation status (i.e., negative for *JAK2*, *CALR*, or *MPL* mutations). In order to diagnose these patients, a search for the most frequent accompanying mutations (e.g., ASXL1, EZH2, TET2, IDH1/IDH2,

SRSF2, SF3B1) must be carried out (Dameshek 1951). Unfortunately, mutations in some of these genes have been reported in around 5% of elderly people, associated to clonal premalignant hematopoiesis, which could reduce the reliability of these additional criteria in this group of patients (Xie et al. 2014).

Surveillance is reduced compared to that of an age- and sex-matched control population with a median survival of 6 years (Tefferi et al. 2014a). Several scores, namely, IPSS, DIPSS, and DIPSS plus, have been developed in order to predict for survival. In all of them, age greater than 65 was found to be an adverse prognostic factor (Passamonti et al. 2010; Gangat et al. 2011; Cervantes et al. 2009).

The only curative treatment is allogeneic hematopoietic stem cell transplantation. Regrettably, old adults cannot benefit from this therapeutic option. A few years ago, ruxolitinib, a JAK2 inhibitor, was approved by the FDA for treatment of patients with intermediate-2 or high-risk MF according to IPSS score and also for intermediate-1 risk group by the EMA. Ruxolitinib effectively reduces spleen volume and constitutional symptoms compared to best available therapy. The median duration of spleen response is 3.2 years. Although crossover was allowed between arms, there is a trend to statistically significant differences in overall survival at 5 years. Most frequent adverse events observed with ruxolitinib were thrombocytopenia, anemia, and an increased risk of infections (Harrison et al. 2016).

In order to improve the anemia, usually below 10 g/dl, the therapeutic options available include erythropoiesis-stimulating agents, androgens, immunomodulators, splenectomy, and prednisone. Therapeutic options for symptomatic splenomegaly, apart from ruxolitinib, include cytoreductive drugs, mainly hydroxyurea, splenectomy, and splenic radiation (Cervantes 2014).

Age and Comorbidities

Comorbid health conditions such as heart disease, pulmonary disease, diabetes, and arthritis are commonly present in elderly patients (Extermann 2000). The variety of comorbid conditions and their individual severity, as well as the cumulative impact of these conditions, have the potential to uniquely impact the cancer patient's treatment and prognosis (Yancik et al. 2001; Janssen-Heijnen et al. 2005). In a recent study carried out to demonstrate that comorbid health conditions disproportionately affect elderly cancer patients, 27,506 newly diagnosed cancer patients were analyzed to examine the prevalence and severity of comorbid ailments by age. Hypertension was the most common comorbidity in all patients, diabetes was the second most prevalent comorbidity in middle-aged patients, and previous solid tumors were the second most prevalent condition in patients aged 74 and older. Moreover, the prevalence and severity of comorbid conditions like dementia and congestive heart failure increased with age. A subgroup analysis also demonstrates that with increasing age, the proportion of patients who present with mild comorbidities decreases, while the proportion of patients who present with moderate and severe comorbidities increases (Piccirillo et al. 2008).

In this regard, comorbidity is being assessed in patients with CML. Charlson comorbidity index predicts poor outcome in CML patients treated with tyrosine kinase inhibitor (Uemura et al. 2016). Although the Sokal and Hasford scoring systems are well-known prognostic models specific to CML, it has not been established whether they can effectively predict outcomes in elderly CML patients with comorbidities. The Charlson comorbidity index (CCI) has been explored in studies in CML patients and was found that cases with a CCI score >3 had significantly poorer survival after diagnosis and CCI score was inversely associated to overall survival. It has been demonstrated in prospective clinical trials. In the CML study IV of the German CML Study Group, the influence of comorbidities on remission rate and overall survival in patients with CML was studied. Higher CCI was significantly associated with lower OS probabilities. And even more important, in the multivariate analysis, CCI was the most powerful predictor of OS, which was still valid after removal of its age-related components. Comorbidities have no impact on treatment

success but do have a negative effect on OS, indicating that survival of patients with CML is determined more by comorbidities than by CML itself (Saussele et al. 2015).

In a small study, comorbidities and polypharmacy impact on complete cytogenetic response in CML elderly patients. The CCI and the polypharmacy were correlated to the obtained cytogenetic response. The majority of complete cytogenetic response was obtained by patients who presented a low score of CCI and did not take any other drugs other than TKI (Iurlo et al. 2014).

Of interest is a recent study of the Surveillance, Epidemiology, and End Results cancer registry performed in 1466 patients with CML with a mean age of 78 years treated with imatinib where elderly patients with CML had greater mortality and greater rates of myocardial infarction, stroke, pulmonary embolism, and peripheral arterial disease than did noncancer patients. The event rates were not elevated among the TKI-treated (primary imatinib) patients, suggesting that the vascular events risk in these patients with CML was driven primarily by the underlying factors associated with CML (Lang et al. 2016).

In PMF, there is a study about comorbidities and outcome. Comorbidities were assessed using the adult comorbidity evaluation-27 (ACE-27). In a large cohort of 349 patients, approximately 64% of patients had at least 1 comorbid condition; cardiovascular diseases were the most common up to 63%. Comorbidities had a significant negative impact on survival. Patients with severe comorbidities had twice the risk of death as those with no comorbidities (Newberry et al. 2014).

Age and Polypharmacy in CML Older Patients

The prevalence of polypharmacy increased with age, and from the age of 70 years, two thirds of all drug users were polypharmacy users, defined as taking more than three drugs. Drug use was 50% more prevalent among women than men, but over the age of 70, the sexes did not differ in the prevalence of major polypharmacy. Many different drug combinations were found, and among major polypharmacy users, two thirds had their own unique drug regimen, different from all other drug users. Cardiovascular drugs and analgesics were often involved in polypharmacy among the elderly, while asthma drugs, psychotropic drugs, and antiulcer drugs were predominant among young individuals exposed to polypharmacy. The higher risk for major polypharmacy was substantially increased for individuals treated for cardiovascular diseases, anemia, and respiratory diseases (Bjerrum et al. 1998).

In a specific study of imatinib and polypharmacy in very old patients with CML, the effects on response rate, toxicity, and outcome have been evaluated. Polypharmacy was reported in one third of patients, and drugs more frequently used were antiplatelets, diuretics, proton pump inhibitors, ACE inhibitors, beta blockers, calcium channel blockers, angiotensin II receptor blockers, statins, oral hypoglycemic drugs, and alpha blockers. Comparing patients exposed to polypharmacy to those without, no difference was observed pertaining to the dosage of imatinib, cytogenetic, and molecular responses and hematological and extra-hematological toxicity (Iurlo et al. 2016).

Age and Quality of Life in CML Older Patients

Two thirds of CML patients aged 60 years presented with at least one comorbidity condition at diagnosis. The presence of comorbidity was associated with important impairments in both physical and mental health domains. This negative association with poor health-related quality of life (HRQoL) outcomes was particularly remarkable in patients who reported two or more comorbid conditions. Elderly patients with comorbidities should be more closely monitored due to their poorer HRQoL outcomes, representing a specific population who can benefit the most from supportive care programs (Efficace et al. 2016).

Patients with PMF have significant debilitating symptoms, physical disabilities, and HRQoL. In clinical trials, ruxolitinib treatment has been associated with PMF-associated symptoms improvement from baseline compared with the control group receiving best available therapy (BAT) where symptoms were the same or worsened. Ruxolitinib also resulted in significantly higher response rates in global health status/QoL and Functional Assessment of Cancer Therapy-Lymphoma (FACT-Lym) summary scores versus BAT at most time points (Harrison et al. 2013).

Real-World Patients Versus Clinical Data Trial

Elderly patients are underestimated in clinical trials, and final results are extrapolated into all patients in real life. Many exclusion criteria of the clinical trials will have a possible selection bias compared with the real life. In a very interesting study, authors evaluated patient characteristics of those that could not be enrolled in nilotinib and dasatinib trials. Up to 13.5% of CML patients should have been excluded by both trials because of polycomorbidities, severe cardiomyopathy, age > 80 with frailty, drug abuse, or other severe concomitant diseases. In addition, some patients should have been excluded in dasatinib trials due to isolated chronic obstructive bronchopulmonary disease, and other patients should have been excluded in nilotinib trials due to isolated diabetes, arrhythmia, and acute myocardial infarction > 6 months before CML diagnosis, chronic pancreatic disease, and peripheral arterial obstructive disease. On the whole, 17.4% of patients would have been excluded by dasatinib trial and 22.7% by nilotinib trial. The patients potentially not eligible for both trials were significantly older and with imatinib had a worse outcome compared with patients potentially eligible. Therefore, an automatic transposition of results available in clinical controlled trials into the frontline real-life management of elderly CML patients should be regarded with caution (Latagliata et al. 2015).

Conclusion

Older patients with CML and other MPNs are at higher risk of suffering from other comorbidities that may impact in the general outcome. The age is by itself an adverse prognosis risk factor in many of these MPNs. The polypharmacy and preexisting medical conditions may influence the follow-up of these patients and should be monitored more closely. Data from clinical trial, where older people are underrepresented, must be taken with caution in order to minimize toxicity and enhance adherence to treatment.

Abstract

Multiple myeloma (MM) is a plasma cell malignancy of older adults and incidence is expected to increase in the coming years. Despite substantial improvements in patient survival, the disease remains incurable. Early mortality is most common in adults 70 years and older. Novel therapeutics and autologous stem cell transplant (ASCT) have led to improvement in survival; however, transplant eligibility remains a challenge especially in the older adult population. Understanding geriatric assessment evaluations can aid in identifying patients at risk for increased morbidity and mortality in older adults with MM. Novel treatment combinations have improved disease control while balancing efficacy with toxicity for the older adult. Here we explore the diagnostic criteria, staging systems, cytogenetic abnormalities, treatment approach, and geriatric assessment in older adults with MM.

Keywords

Multiple myeloma · Autologous stem cell transplant · Geriatric assessment

Introduction

Multiple myeloma (MM) is a plasma cell malignancy of older adults and accounts for 15% of all hematologic malignancies in the United States (Siegel et al. 2016). The median age of diagnosis is 69 years, and in the next 15 years MM incidence is expected to double (Surveillance Epidemiology, and End Results (SEER) 2017; Smith et al. 2009). Novel therapeutics and routine use of autologous stem cell transplant (ASCT) have led to substantial improvements in patient survival. However, the disease remains incurable (Kumar et al. 2014). MM deaths, overall, are highest in patients aged 75 years and greater, and early mortality is most common in those 70 years and older (Kumar et al. 2014; Warren et al. 2013). MM incidence is more common in men (1.4:1) and African Americans. MM has no clear genetic predisposition, although the risk of developing MM is 3.7-fold higher for a first-degree relative with the disease (Greenberg et al. 2012). MM is a clinical diagnosis, whereby a neoplastic proliferation of plasma cells in the bone marrow results in end organ damage. Older adults diagnosed with MM receive multidrug systemic induction therapy to obtain disease control. Eligible patients may proceed to an ASCT or those who are not eligible complete induction therapy, followed by maintenance therapy or low-dose treatment to sustain disease remission. Here we explore the diagnostic criteria, staging systems, cytogenetic abnormalities, treatment approaches, and geriatric assessment in older adults with MM.

Diagnosis of Multiple Myeloma

Laboratory Testing

Cases of MM were first reported in the late 1800s and coined "Multiple Myeloma" by J. Van Rustizky (1873). Early cases described bone pain with spontaneous fractures, abnormal X-rays, proteinuria, wasting, loss of appetite, and edema. Plasma cells were identified to originate in the bone marrow, and Wright identified these cells to be the cause of multiple myeloma in 1900 (Wright 1900a, b). The advent of bone marrow aspiration and its utilization in patients with anemia and skeletal abnormalities led to increased recognition of this entity (Kyle 2000). End organ damage that defines the clinical entity of MM includes anemia, hypercalcemia, bone disease, and/or renal dysfunction (Table 1) (Rajkumar et al. 2014). Here we discuss these clinical

Table 1 CRAB-E criteria

C	Hyper**C**alcemia	Symptomatic or asymptomatic elevation in serum calcium (>11.5 mg/dL or >2.75 mmol/L)
R	**R**enal failure	Serum creatinine >2 mg/dL (>117 μmol/L) or creatinine clearance <40 mL/min
A	**A**nemia	Normocytic normochromic anemia with hemoglobin <10 mg/dL
B	**B**one lesions	One or more osteolytic lesions noted on imaging
E	Myeloma Defining **E**vents	≥60% clonal bone marrow plasma cell percentage >1 focal lesions (5 mm or more) noted on magnetic resonance imaging (MRI) Involved: Uninvolved serum light chain ratio ≥100

Adapted from: Rajkumar et al. (2014)

abnormalities in the context of the aging adult in the modern era.

Anemia

Identifying anemia due to underlying myeloma requires a degree of clinical suspicion. Anemia is common as one ages, where one in five older adults are identified to have anemia (see ▶ Chap. 19, "Hematopoiesis and Aging"). The most common cause of anemia in older adults is secondary to nutritional deficiencies, chronic renal disease, or inflammation and the remaining one-third have unexplained anemia. A small proportion of "unexplained" anemia is a result of malignancies and bone marrow disorders, including MM. MM related anemia is a myelophthisic process where the plasma cells replace normal hematopoiesis. Anemia is a major clinical manifestation of MM and is present in about 70% of newly diagnosed patients. Causes include marrow replacement or suppression and erythropoietin deficiency from concomitant renal failure (Kyle 2000). The presence of moderate to severe anemia should prompt thorough investigation with a detailed history, complete blood counts, chemistry for serum creatinine, red cell indices, reticulocyte counts, peripheral smear, iron studies including ferritin, and tests for cobalamin to exclude nutritional deficiencies. Chronic renal disease is found in 17% of anemic patients; hence a careful evaluation for myeloma is warranted in a patient with anemia and new or unexplained renal dysfunction (Guralnik et al. 2005; Kyle et al. 2003; Baz et al. 2004). Anemia is a risk factor for adverse outcomes in older adults with cancer. Anemia is associated with decreased survival, functional immobility leading to falls, increased cardiovascular mortality, and decreased chemotherapy tolerance in older adults with cancer (Ferrucci and Balducci 2008).

Renal Dysfunction

Nearly half of patients diagnosed with MM have renal insufficiency (RI) at presentation. RI can be multifactorial secondary to direct tubular injury and fibrosis by toxic monoclonal light chains (cast nephropathy) or other contributing factors such as hypercalcemia, dehydration, hyperuricemia, direct plasma cell infiltration, proximal tubular dysfunction, or amyloid deposition. The International Myeloma Working Group (IMWG) proposed the use of the Modification of Diet in Renal Disease (MDRD) equation for calculation of renal dysfunction in patients with chronic renal disease (Kooman 2009; Levey et al. 2005). A renal biopsy is confirmatory of cast nephropathy or can identify amyloid deposition but is not mandatory in many cases. A 24-h urine collection is essential with urine protein electrophoresis and immunofixation to quantify the amount of monoclonal protein present. RI in myeloma is associated with poor prognosis and significant morbidity, if not reversed (Dimopoulos et al. 2010). Early recognition and treatment can help prevent progression to end-stage renal failure and decrease need for renal replacement therapy. Treatment may include rehydration and prompt chemotherapy initiation. Other measures to decrease paraprotein deposition and cast nephropathy such as plasmapheresis have been used (Leung et al. 2008). Renal function declines with aging, although there is wide variability in

age-related renal loss and/or renal disease (Weinstein and Anderson 2010) Therefore it is of critical importance to differentiate RI secondary to MM from renal dysfunction of other etiologies.

Radiographic Imaging

Bone pain and fractures are hallmarks of MM clinical presentation. Earliest autopsies of patients with MM revealed significant destruction and thinning of the bones (Kyle 2000). Mechanisms of bone involvement include direct invasion, marrow replacement, and dysregulation of bone microenvironment. A complete bone survey with x-rays is recommended for the diagnostic evaluation of lytic bone lesions but could underestimate bony involvement in older adults with osteoporosis (Gleeson et al. 2009). Differentiating benign compression fractures from malignant disease secondary to myeloma can be a challenge, as diffuse myelomatous involvement on MRI has been noted in 29% of those with compression fractures (Kusumoto et al. 1997). If a bone lesion nature is in question (benign vs malignant), a bone biopsy of the suspected lesion is recommended. Moreover, newer imaging modalities including MRI, ^{18}F- FDG PET, CT, and PET/CT scans are more sensitive for detecting MM bone lesions in comparison to skeletal radiography (Regelink et al. 2013). The IMWG criteria has since been revised to allow for osteolytic lesions >5 mm or more diagnosed by MRI, low-dose whole body CT, PET-CT as criteria for end-organ disease. PET-CT is increasingly being incorporated for extramedullary myeloma disease detection, however there is lack of strict reporting criteria for PET-CT, and PET portion alone is not adequate for the diagnosis of multiple myeloma (Cavo et al. 2017).

Hypercalcemia

Hypercalcemia is present in 28% of the patients at the time of diagnosis with nearly half requiring emergent treatment (Kyle et al. 2003). Hypercalcemia is due to bone destruction from osteoclastic activation by tumor cells. It can be asymptomatic or present with wide symptoms ranging from nausea, anorexia, polyuria, polydipsia, constipation, weakness, confusion to stupor. The presenting feature can be challenging in an elderly patient with multiple medical comorbidities. A high serum blood calcium level should be confirmed with an ionized calcium. Calcium binds with IgG monoclonal protein and can result in a spurious increment of measured calcium without hypercalcemia (Annesley et al. 1982). Hypercalcemia impacts overall survival where survival decreased with Ca levels of $\geq$12 mg/ml (Carbone et al. 1967).

Monoclonal Proteins and Light Chains

Myeloma proteins can be classified by immunoglobulin class and light chain identification. Immunoglobulins IgG (52%) and IgA (21%) are most common, followed by light chain disease Kappa (κ) and Lambda (L) (16%), and paraproteins IgD and IgM are rare (2.5%) (Kyle et al. 2003). Characterization of the type of immunoglobulin and presence of light chains is important in assessing chemotherapy response and survival (De Bergsagel et al. 1965). Patients with an M protein burden may also have a higher incidence of bone lesions and hypercalcemia (Report on the first myelomatosis trial 1973). Most patients have serum monoclonal protein with or without urine protein, and 3% of patients have neither, classifying them as nonsecretory myeloma. Identification of monoclonal protein (M protein) in serum and urine is usually done by protein electrophoresis. Immunofixation (IFE) techniques in serum and urine are more sensitive and can identify smaller amounts of monoclonal protein. Quantification of the amount of proteinuria in a 24-h period should be done in the initial evaluation. Quantitative analyses of serum immunoglobulins and serum free light chains are sensitive for screening and are followed for treatment response (Table 2) (Kyle et al. 2003; Kastritis et al. 2014; Drayson et al. 2001).

Table 2 IMWG response criteria

Response category	Response criteria
Stringent complete response	Complete response as defined below plus normal serum free light chain (SFLC) ratio and absence of clonal plasma cells in the bone marrow by immunohistochemistry
Complete response	Negative immunofixatiaon on the serum and urine, disappearance of any soft tissue plasmacytomas and ≤5% plasma cells in the bone marrow
Very good partial response	Serum and urine monoclonal protein (M protein) detectable by immunofixation but not electrophoresis or ≥90% reduction in serum M protein plus urine M protein level <100 mg per 24 h
Partial response	Reduction of serum M protein by ≥50% plus 24 h urinary M protein by >90% or to <200 mg per 24 h[a]
Minimal response	≥25% but ≤49% reduction of serum M protein and reduction in 24 h urine M protein by 50–89% In addition to the above listed criteria, if present at baseline, a ≥50% reduction in the size of soft tissue plasmacytomas is also required
Stable disease	Not meeting criteria for complete response, very good partial response, partial response, minimal response, or progressive disease
Progressive disease	Any one or more of the following criteria: Increase of 25% from lowest confirmed response value in one or more of the following criteria: Serum M protein (absolute increase must be ≥0.5 g/dL) Urine M protein (absolute increase must be ≥200 mg/24 h) In patients with inadequate serum and urine M proteins for response assessment, the difference between involved and uninvolved FLC levels (absolute increase must be >10 mg/dL) In patients with inadequate serum and urine M proteins and SFLC's, bone marrow plasma cell percentage irrespective of baseline status (absolute increase must be ≥10%) Appearance of a new lesion(s), ≥50% increase from nadir in of >1 lesion, or ≥50% increase in the longest diameter of a previous lesion >1 cm in short axis; ≥50% increase in circulating plasma cells (minimum of 200 cells per μL) if this is the only measure of disease

[a]Additional criteria apply Adapted from International Myeloma Working Group Response Criteria for Multiple Myeloma (Kumar et al. 2016)

Beta 2 Microglobulin (β_2M)

Serum β_2M in combination with serum albumin emerged as the single, most important prognosticating factor in the 1980s during the development of the International Staging System (ISS). It was noted to be elevated in advanced disease independent of renal function and could be followed over time. Decreased survival was noted in cases of high β_2M (Cassuto et al. 1978; Norfolk et al. 1980; Bataille et al. 1983). β_2M reflects tumor mass burden and renal function and possibly immune function, but exact biology remains to be explored (Bataille et al. 1986; Jacobson et al. 2003; Durie et al. 2003). The Southwest Oncology Group stratified patients into low, intermediate, and high-risk categories with the inclusion of age and serum albumin similar to ISS (Durie et al. 1990).

Lactate Dehydrogenase (LDH)

Lactate Dehydrogenase is a nonspecific marker of cell turnover found when the enzyme converts pyruvate to lactate in the process of aerobic glycolysis and is increased during hypoxia, tissue injury, and necrosis. It has been shown that higher than normal serum LDH is suggestive of disease aggressiveness with high tumor proliferation rate and the presence of extramedullary disease. High LDH also has been associated with decreased overall survival with both chemotherapy and newer MM agents especially in elderly patients

(Dimopoulos et al. 1991; Terpos et al. 2010; Anagnostopoulos et al. 2005).

Bone Marrow Evaluation and Cytogenetics

Bone marrow biopsy and aspiration is required for evaluation and diagnosis. Bone marrow immunohistochemistry confirms the presence of monoclonal plasma cells and flow cytometry can identify clonal plasma cells. Chromosomal analysis by fluorescence in situ hybridization and conventional karyotyping identify prognostic chromosomal abnormalities. Two main types of cytogenetic abnormalities are trisomies (hyperdiploid) and translocation of the immunoglobulin heavy chain (IgH) gene (nonhyperdiploid). Trisomies include extra copies of chromosomes, mainly odd numbered chromosomes 3, 5, 7, 9, 11, 15, and 17 (Fonseca et al. 2009). Clinically relevant chromosomal abnormalities and their effects on multiple myeloma are listed (Table 3). Gene expression profiling may also add prognostic information but is not widely available (Anderson et al. 2015). Deletion (Kyle et al. 2003) is frequently associated with t(4;14) and del(17p). These abnormalities are associated with decreased event-free survival (EFS) and overall survival (OS), in combination. Translocation t(4;14) and del(17p) along with a high β2M are associated with decreased EFS and OS. Stratification of these cytogenetic abnormalities (CA) is also shown in Table 3 (Avet-Loiseau et al. 2007; Fonseca et al. 2004; Dispenzieri et al. 2007; Kumar et al. 2009).

Staging

Durie-Salmon Staging System (DSS)

Durie and Salmon were the first to classify myeloma into stages based on tumor burden in 1975 (Durie and Salmon 1975). Further characterization of these stages by blood urea concentration, hemoglobin levels, and performance status identified worse prognosis to be associated with higher blood urea concentration, lower hemoglobin, and, understandably, poor performance status (Prognostic features in the third MRC myelomatosis trial 1980). These findings were also reported in the long-term follow-up of the first and second myeloma trials (Merlini et al. 1980; Buckman et al. 1982). The Durie and Salmon staging system incorporated monoclonal protein type and level, calcium, the number of bony lesions, and later divided into substages: substage A with serum creatinine >2 mg/dL, and substage B with ≥ 2 mg/dL, with low and high-risk patients respectively. This staging system did not account for observer bias during evaluation of skeletal metastases. Other classifications adopted other prognostic factors like Sβ2M along with serum albumin, the rate of bone resorption, to overcome observer bias (Bataille et al. 1986; Merlini et al. 1980).

International Staging System (ISS)

The International Staging System was developed incorporating β_2M, renal function, and serum albumin into a three-stage system, which provided the most statistically significant results, and was validated consistently. It was noted that ISS stage I overall survival corresponded to Durie-Salmon stage IA; but interestingly, DSS stage IIA also had similar overall survival at 58 months. All poor-risk DSS substage B patients with a serum creatinine of ≥ 2 mg/dL had worse overall survival which was similar to ISS stage III with Sβ_2M $\geq$ 5.5 mg/L. β_2M in combination with serum albumin emerged as the most important prognosticating factor (Greipp et al. 2005).

Revised-International Staging System (R-ISS)

Cytogenetic abnormalities (CA) detected by FISH play an important role in overall prognosis with standard-risk myeloma having an overall survival (OS) of 50.5 months, and high risk with

Table 3 Chromosomal abnormalities in multiple myeloma

Abnormality	Chromosome	Incidence	Genes	Cytogenetic risk
Trisomies of odd chromosomes (hyperdiploid)	3, 5, 7, 9, 11, 15, 17 (with exception of 1, 13, and 21)	42%	Many	Standard risk (OS: 7–10 yrs)
Chromosome 13 deletion Del(13)	13	48%	Many	Close association with t(4;14)(p16;q32); adverse prognosis only in association with t(4;14) del (17p)
Translocations				
Immunoglobulin heavy chain (IgH)	t(11;14)(q13;q32)	21%	*CCND1* -cyclin D1	Standard risk (OS: 7–10 yrs) K-RAS mutations common
	t(6;14)(p21;q32)	2%	*CCND3* -cyclin D3 gene	
	t(4:14)(p16;q32)	14%	*FGFR-3, MMSET*	Intermediate risk (OS: 5 yrs)
	t(14;16)(q32;q32)	5%	*C-MAF*	High risk (OS:<2–3 yrs)
	t(14;20)(q32;q11)	2%	*MAFB*	
MYC translocation	8	13%	Encodes transcription factor that regulates cell proliferation and apoptosis	Adverse prognosis (median OS: 20.2 months)
Gains and losses				
Gain(1q21)	1	43% 78% in relapsed MM	Amplification of long arm is usually associated with deletion of short arm of chromosome 1 and strongly associated with chromosome 13 deletion	Intermediate risk (med OS: 5 yrs) Increases risk of progression from smoldering myeloma to multiple myeloma; decreased postrelapse survival
Del(1p)	1	18%		High risk (OS: 3 yrs)
Monosomy 17 del(17p13)	17p13– locus for tumor suppressor gene	11%	Loss of heterozygosity of TP53	High risk (OS: 3 yrs)

Adapted from: Fonseca et al. (2009), Avet-Loiseau et al. (2007), Fonseca et al. (2004), Dispenzieri et al. (2007), Kumar et al. (2009)

median OS of 24.5 months (Fonseca et al. 2009). Efforts to improve the ISS, included characterization of CA into low, intermediate, and high-risk groups (Neben et al. 2010; Boyd et al. 2012; Avet-Loiseau et al. 2013). It was noted that very few patients had a nonsignificant cytogenetic analysis that did not impact the prognostication. The Revised-ISS, established in young and elderly patients with newly diagnosed multiple myeloma, identified similar median OS in elderly population (≥65 years of age) (median OS not reached in stage I, 70 months in stage II, and 46 months in stage III); but patients ≥65 years of age constituted only 35% of the population evaluated (Palumbo et al. 2015a). Comparisons among the three staging systems are shown in Table 4.

Treatment Stratification

Treatment for MM is often stratified into transplant eligible and transplant ineligible strategies. This approach historically was based upon age (+/−65y.o.) and presumed tolerance of ASCT. Transplant "eligibility" is an active and important area of myeloma investigation. ASCT is established, in younger populations, to improve survival over nontransplant therapy (Attal et al. 1995; Cavo et al. 2016a) and has PFS advantages

Table 4 Comparison of myeloma staging systems

	DSS 1975		ISS 2005		R-ISS 2015	
Stage	Criteria	OS Median	Criteria	OS Median	Criteria	OS Median
I	Low cell mass ($<0.6 \times 10^{12}$ cells/m^2 BSA) All: 1. Hg >10 g/ml 2. Calcium ≤12 mg/ml 3. Bone lesions: None or solitary plasmacytoma 4. Low M component (a) IgG <5 g/ml (b) IgA <3 g/ml (c) UPEP<4 g/24 hr	A: 69 months B: 22 months	β_2M <3.5 mg/L Serum albumin ≥3.5 g/dL	62 months	Standard risk cytogenetic abnormalities (no high risk) Normal LDH	Not reached
II	Intermediate cell mass ($0.6–1.2 \times 10^{12}$ cells/m^2 BSA) Neither stage I or III	A: 58 months B: 34 months	Not stage I or III	44 months	Not R-ISS stage I or III	83 months
III	High cell mass ($>1.2 \times 10^{12}$ cells/m^2 BSA) Having ≥1: 1. Hg <8.5 g/ml 2. Calcium >12 mg/ml 3. Advanced lytic bone lesions 4. High M component production: (a) IgG >7 g/ml (b) IgA >5 g/ml (c) UPEP >12g/24 hr	A: 45 months B: 24 months	β_2M ≥5.5 mg/L	29 months	High risk cytogenetic abnormalities [(del (17p) and/or t(4;14) and/or t(14;16)] Or High LDH (>upper limit of normal)	43 months

Adapted from: Durie and Salmon (1975), Prognostic features in the third MRC myelomatosis trial (1980), Greipp et al. (2005), Palumbo et al. (2015a)
Substage A (serum creatinine <2 mg/ml), substage B (serum creatinine ≥2 mg/ml)
β_2M <3.5 mg/L but serum albumin <3.5 g/dL or Sβ_2M − 3.5 to <5.5 mg/L irrespective of serum albumin level

over delayed transplant in the novel era (Attal et al. 2015). However, ASCT is feasible and an efficacious component of therapy for older patients with myeloma as well but is underutilized (Wildes et al. 2015a). In the novel area, older adults mobilize sufficient numbers of hematopoietic stem cells and can tolerate transplant with excellent outcomes (Wildes et al. 2015b) leading to the largest growth in myeloma transplant. In contrast, historic reports depict conflicting tolerance, response rates, and survival[48] potentially leading to referral bias. Novel therapeutics and routine use of ASCT have led to substantial improvements in overall response rates and durable remissions for the MM population as a whole (Kumar et al. 2014; Harousseau et al. 2010; Cavo et al. 2010). Nonetheless, applying data from clinical trials based on chronologic age alone has left the clinician with questions on who is and who is not eligible for transplant.

Eligibility for transplant is subjective and variable by transplant institution but is dependent on

age, comorbidities, and underlying health status. Some adults with MM are not candidates for ASCT due to advanced age (≥80), comorbidities, frailty, or personal preference. Studies have shown that patients with advanced comorbidities have inferior outcomes posttransplant (Saad et al. 2014a). Weight loss prior to transplant and lower physical function is associated with a longer transplant length of stay (Rosko et al. 2018). Psychosocial health has also shown to play an important role in ASCT outcomes, where anxiety and depression are associated with inferior outcomes and may play a role in overall survival (Richardson et al. 2018). Optimizing specific factors, such as physical function or nutrition, prior to transplant may aid in the improving health outcomes for older adults. Suggested minimal recommendations for transplant eligibility include an assessment of comorbidities by testing end organ function (e.g., electrocardiogram, ECHO, and pulmonary function testing), psychosocial support (e.g., screens for anxiety, depression, caregiver support, and financial assessment), cognitive health (screen for cognitive impairment), and MM response (e.g., bone marrow testing, skeletal survey, SPEP, FLC, and UPEP). Additional assessments of transplant eligibility that may influence outcomes include nutritional status, physical function (subjective or objective testing), and contributions of polypharmacy; this approach is further outlined in section "Geriatric Assessment in Multiple Myeloma."

Transplant Ineligible Therapy for MM in the Older Adult

Melphalan-Based Therapy

The therapeutic backbone of melphalan and prednisone (MP) was the standard for older adults with MM. A relatively effective drug, oral melphalan was the foundation of therapy for non-ASCT candidates but was avoided in ASCT candidates due to the effect on stem cell mobilization (Alexanian et al. 1969). The addition of novel agents to MP has resulted in improvements in overall survival. Thalidomide was first added to MP (MPT) and confirmed a survival advantage in randomized trials for older adults (Palumbo et al. 2006). Subsequently, with the advent of novel agents, both bortezomib and lenalidomide have been examined in combination with melphalan and are considered a standard frontline therapy for aging adults (Mateos and San Miguel 2013). Older adults with MM are vulnerable to adverse events associated with multidrug combinations, which can lead to dose reductions or cessation of therapy and is associated with poorer outcomes (Palumbo et al. 2015b). Strategies for selecting 2-drug therapy vs. 3-drug therapy is aimed at disease control while balancing for treatment toxicity and accounting for factors related to aging.

Immunomodulatory Drugs (IMiD)-Based Therapy

The addition of thalidomide to MP is associated with improved response rates, depth of response, progression-free survival, and overall survival (OS). However, nonhematological toxicity is increased with the addition of thalidomide to MP (Palumbo et al. 2013). Thalidomide, although efficacious, has fallen in usage due to the advent lenalidomide (Palumbo et al. 2006; Facon et al. 2007a). Lenalidomide is a second generation IMiD developed as a more potent, less toxic analog of thalidomide. Lenalidomide has been studied alone and with combination therapy. Studies show that melphalan, lenalidomide, and prednisone (MPR) with or without lenalidomide maintenance prolongs progression-free survival and OS compared to MP, with a toxicity profile that compares favorably with MPT (Zweegman et al. 2016; Gay et al. 2010). Two-drug options are also favorable; continuous treatment with Rd. (lenalidomide and dexamethasone), in comparison with MPT, is associated with a survival advantage and fewer toxicities (Benboubker et al. 2014). When pairing therapy with dexamethasone, older adults with MM do not benefit from higher dosages of dexamethasone and weekly dexamethasone is recommended over high-dose dexamethasone (40 mg once weekly over 40 mg 4 days on/5 days off) as the latter results in inferior progression-free and overall

survival (Rajkumar et al. 2010). Lenalidomide is associated with mild myelosuppression as part of its adverse event profile, whereas thalidomide is associated with more peripheral neuropathy, fatigue, and constipation (Gay et al. 2010). Recent studies suggest that three-drug regimens may be superior to two-drug regimens in terms of disease response and survival (Durie et al. 2017). Others are investigating dosage attenuation of standard regimens (VCD-lite and RVD-lite) in older adults to attenuate toxicity while maintaining efficacy (O'Donnell et al. 2015).

Bortezomib-Based Therapy

Bortezomib is a proteasome inhibitor and is also a standard frontline therapy in older adults. Twice weekly bortezomib in addition to MP (VMP) improves overall survival compared to MP but is associated with peripheral neuropathy (Mateos et al. 2013). Bortezomib alone (VD) and in combination (VTD, VMP) has been evaluated in older adults ineligible for transplant and have shown that response rates, PFS and OS were similar, yet toxicities were more common with VTD (Niesvizky et al. 2015). Bortezomib, Lenalidomide, and dexamethasone (VRD) induction therapy in comparison to Rd. alone has been shown to have survival advantages for newly diagnosed MM patients and with the exception of peripheral neuropathy, had balanced side effect profiles (Durie et al. 2017). Bortezomib is the preferred agent in those with renal failure and results in prompt disease control and potential for renal recovery. Complete renal response (CRrenal) with resolution of RI to normal creatinine and glomerular filtration rate is more frequent with newer treatment regimens containing bortezomib (71%) than with conventional chemotherapy (41%) or with immunomodulatory therapy (45%) (Dimopoulos et al. 2010). Other combination regimens that substitute conventional melphalan for Cytoxan (VCD, CyBorD) have also been evaluated and show excellent responses compared to Rd. or CRD and are well tolerated (Jimenez-Zepeda et al. 2015; Kumar et al. 2010). Peripheral neuropathy is a significant concern for aging adults with myeloma, several studies have demonstrated that once weekly administration and subcutaneous administration of bortezomib reduces toxicity by roughly 30% while preserving efficacy (Mateos et al. 2010a; Mateos et al. 2010b; Bringhen et al. 2010).

Next Generation Therapy

Balancing efficacy and managing toxicity is a challenge for older adults with myeloma. Recent studies suggest that three-drug regimens may be superior to two-drug regimens (SWOG S0777), in terms of disease response and survival (Durie et al. 2017). Others are investigating dosage attenuation of standard regimens (VCD-lite and RVD-lite) in frail older adults to attenuate toxicity while maintaining efficacy (O'Donnell et al. 2015). Studies such as these may help to better define the optimal induction regimens for seniors who will not undergo ASCT. Therapy selection for older adults is evolving, and questions remain on how to sequence newer agents such as the monoclonal antibodies – daratumumab and elotuzumab. Daratumumab is a CD38 targeted antibody that causes myeloma cell death through a variety of immune-mediated mechanisms and is under active investigation as a frontline agent [NCT02541383, NCT02252172, NCT02874742, NCT02195479, NCT02951819]. Elotuzumab is a first-in-class humanized immunostimulatory monoclonal antibody targeted against signaling lymphocytic activation molecule F7 (SLAMF7, also called CS1) and is approved for relapsed disease, in combination with lenalidomide and dexamethasone (Lonial et al. 2015; Wong et al. 2015). Studies are ongoing to explore how monoclonal antibodies can best be incorporated into MM therapies across the board.

Autologous Stem Cell Transplant in Older Adult with MM

Disparities in OS for older MM patients are multifactorial; under-utilization of ASCT in this population has been a significant contributing factor (Al-Hamadani et al. 2014). Recently, ASCT utilization has improved, and

consequently, overall survival for older adults has also improved. Large registry studies from the European Group for Blood and Marrow Transplantation (EBMT) have shown the proportion of ASCT recipients ≥65 years old increased from 3% (1991–1995) to 18.8% (2006–2010). Over these same time periods, the percentage of patients aged 65–69, alive at 2 years, increased from 55% to 83%, with comparable trends seen for patients aged ≥70 years (Auner et al. 2015a; Sánchez-Ortega et al. 2016). A similar analysis was conducted by the Center for International Blood and Marrow Transplant Research (CIBMTR), where 11,430 patients receiving ASCT reported similar 1-year non-relapse mortality for patients above and below age 70. Increasing age, however, was associated with worse overall survival yet MM-specific mortality rates were similar across age groups (Sharma et al. 2014).

High-dose melphalan followed by ASCT improves overall survival and PFS among fit patients <65 years old compared with delayed transplantation (Palumbo et al. 2014; Cavo et al. 2016b; Attal et al. 1996). Under-utilization for transplant may be a result of conflicting data in older adult ASCT studies. The largest older adult ASCT study was the Intergroupe Francophone du Myélome (IFM) 99–06 study, where 447 patients were randomized to either receive MP, MPT, or tandem ASCTs using a reduced dose of melphalan at 100 mg/m2 (MEL100). Early death was reported in 7% of patients in the MP group, 2% in the MPT group, and 9% in the MEL100 group. MPT was associated with a significant OS benefit compared with both MP and MEL100 (Facon et al. 2007b).

In contrast to these results, more recent prospective evaluations, registry studies, and multiple single-center retrospective analyses have yielded more favorable results in older adult ASCT (Wildes et al. 2015a; Sánchez-Ortega et al. 2016; Sharma et al. 2014; Garderet et al. 2016; Gertz et al. 2007; Siegel et al. 1999; Kumar et al. 2008; Merz et al. 2014). The Mayo Clinic evaluated outcomes of ASCT patients above and below 65 years of age. Older patients were more likely to receive a reduced dose of melphalan (30% vs. 5%), similar overall response rate (97% vs. 98%), similar time to progression (29 months vs. 18 months), and no differences in OS (not reached vs. 53 months) (Kumar et al. 2008). Likewise, the German Myeloma Study group reported on 202 patients aged ≥60 who underwent ASCT where 97% of patients received MEL200, with 21% receiving tandem transplants, and there was no significant difference in mortality by day 100, and age was not a risk factor for adverse outcome (Merz et al. 2014). The feasibility of MEL200 in selected elderly patients was further supported by retrospective studies, where advancing age was not predicative of worse PFS post-ASCT (Bashir et al. 2012; Huang et al. 2017). The optimal dose strategy of high dose melphalan in older adults undergoing ASCT is unclear. Many studies have reported MEL200 without significant differences in treatment toxicity compared to younger patients; furthermore, higher dosages of melphalan may partially explain improved outcomes, compared to other studies using lower dosages of melphalan (Auner et al. 2015b). Nonetheless, melphalan 140 mg/m^2 is commonly used in older adults in an effort to preemptively reduce risk of transplant toxicity (Sharma et al. 2014; Huang et al. 2017).

Risk Stratification

Geriatric Assessment in Multiple Myeloma

As the MM population ages, a rigorous approach assessing the underlying health status aims to balance therapeutic efficacy while minimizing adverse events. A valuable tool to identify and resolve occult health factors is a Geriatric Assessment (GA) (see ▶ Chap. 25, "Comprehensive Geriatric Assessment (CGA) for Cancer Patients"). A GA is a global evaluation of the health of older adults, comprising a multidimensional evaluation of functional status, fall history, social support, cognitive and psychologic status, sensory loss, nutritional status, and comorbidities. Emerging data suggests that use of a Geriatric Assessment (GA) aids in the clinical

Table 5 Geriatric evaluation for older patients

Domains	Common geriatric tools	Assessment and intervention(s)
Comorbidity	Hematopoietic cell transplantation-comorbidity index (HCT-CI) Geriatric syndromes	Remote cancer Urinary problems Visual or hearing impairment Cardiac dysfunction Prior renal impairment Osteoporosis Falls
Function	Instrumental activities of daily living (IADL) Timed up and go (TUG) Short physical performance battery (SPPB) Grip strength 4-meter walk Brief fatigue inventory (BFI)	Evaluation of active and passive range of motion in all extremities. Examination during weight transfer, sit to stand times, gait, posture, timed up and go, and transfers. Recommendations to promote movement, reduce pain, restore function, and prevent disability. Education on prevention of fall risk.
Social support and function	Medical outcomes study-social support survey (MOS-SSS)	Evaluation of social support and caregiver dynamics Assessment of home safety, coping abilities to deal with health status, and spiritual/cultural/religious support Evaluation of socioeconomic status and appropriate recommendations for insurance coverage, employment status, appointment transportation, lodging for appointments, prescription pick-up location, and copay costs
Cognition	Blessed memory orientation and concentration (BOMC) Mini-mental state examination (MMSE) Montreal cognitive assessment (MoCA)	Characterization of mild, moderate, or severe cognitive impairment. Evaluation for decision making capacity, risk for delirium, and life expectancy
Psychological	Geriatric depression scale (GDS) Mental health inventory (MHI) Hospital anxiety and depression scale (HADS)	Evaluation of psychological distress including depression and anxiety, quality of life expectations, and social engagement
Nutritional status	Weight loss Body mass index Mini nutritional assessment (MNA)	Evaluation of weight loss, current diet/intake, oral supplements, appetite, and any barriers to oral intake Recommendations based on each patient's caloric needs and protein intake in the form of counseling, educational material, and supportive contact
Polypharmacy	>5 medications Beers criteria	Inappropriate medication use Review of medications (prescription and nonprescription) with side effects, purpose, interactions, high risk therapeutic classes

Adapted from: Rosko and Artz (2017)

decision-making for patients with MM. Each of these evaluations aims to identify occult factors, unique to aging, that contribute to adverse events in myeloma treatment. Table 5 depicts a set of tools often employed in a cancer specific GA. GA tools are established metrics to accurately assess the risk of morbidity and mortality in cancer populations (Pal et al. 2010; Rodin and Mohile 2007). GAs have been shown to predict mortality and toxicity, independent of performance status and age in solid tumors (Hamaker et al. 2014). Given multiple treatment options for MM and concerns for frailty and tolerance in older adults, a GA is a valuable tool. The International Myeloma Working Group (IMWG) GA based on age, comorbidities, and physical function (by ADL/IADL) can predict mortality in the nontransplant eligible MM population. Furthermore, IMWG GA scores were predictive of death independent of treatment,

cytogenetics, or stage in the MM population, and were recently validated in an older real-world MM population (Palumbo et al. 2015b; Engelhardt et al. 2016). Patient comorbidities also play a role in evaluating the risk of treatment toxicity. Formal systems such as the hematopoietic cell transplantation comorbidity index (HCT-CI) is a transplant-specific modification of the Charlson comorbidity index that has been shown to correlate with OS and readmission rates but not with nonrelapse mortality (Sorror et al. 2007; Jaglowski et al. 2014; Saad et al. 2014b). Although no GA instrument has been prospectively validated in MM to delegate therapy decisions about ASCT or otherwise, these instruments are promising. MM is a disease of the elderly; with the aging of the population, risk assessment tools will become increasingly important to allocate treatment according to patient tolerability.

Low-Grade Lymphomas (Other than CLL/SLL) in Older Patients

Contents

Abstract

The incidence of non-Hodgkin lymphomas has been progressively increasing over the last decades, especially in the elderly. Taken with an aging population, this scenario represents a growing health problem with significant implications for the care of older patients. In fact, because of comorbidities and organ dysfunctions, elderly patients are at an increased risk of therapy-related toxicity. In the setting of indolent lymphomas, even in advanced stages, there is no benefit in terms of outcome in administering early therapy. On the contrary, a "watch and wait" approach represents the standard of care, until specific treatment is indicated. In this case, an accurate evaluation could be made by the comprehensive geriatric assessment (CGA) based on age, comorbidities, and functional disabilities of daily living, which is an important tool to discriminate between fit, unfit, and frail patients.

CGA is useful to determine the patient chance of tolerating and responding to therapy, making a whole evaluation of older patients, beyond chronological age itself. The therapeutic goal for elderly patients is to find a balance between effective therapy and related toxicity; therefore, therapy regimens used for younger patients may not be always appropriate for the elderly. When treatment is indicated and feasible, the use of rituximab in combination with chemotherapy is the standard of care in first-line treatment. Furthermore, there is a remarkable number of emerging new drugs which represent valid therapeutic options in relapsed/refractory setting and may allow a chemo-free treatment; therefore, continued participation in clinical trials which include also elderly patients should be recommended.

Indolent lymphoma · Elderly · Geriatric oncology · Follicular lymphoma · Marginal zone lymphoma · Waldenström's macroglobulinemia

Introduction

The incidence of non-Hodgkin lymphomas (NHL) has been increasing by 1–2% annually over the past two decades in all age groups, mostly in the elderly. Among low-grade lymphomas accounting for approximately 40% of all NHL, the median age at diagnosis is 65 years with higher prevalence in males than females. This scenario, taken with an aging population, has significant implications for the care of older patients. Indolent lymphomas typically have a slow clinical course which does not always require treatment, even in advanced stages in whom a "watch and wait" (W&W) policy (close clinical monitoring) is applicable until therapy becomes indicated to control symptoms. In this case, several factors should be considered before starting a therapy in the elderly, such as comorbidities. It is essential to discuss and if necessary to adapt treatment strategies for this growing population of older patients, considering their biological characteristics and goals of treatment. Emerging new drugs show a favorable toxicity profile which makes them very attractive for older patients. In fact, these agents offer the opportunity to prevent chemotherapy-related myelotoxicity which still represents an obstacle to intensely treat elderly patients.

The comprehensive geriatric assessment (CGA) and the impact of aging on the care of older adults will be reviewed in this chapter, as well as disease incidence, diagnosis, and treatment approaches for low-grade lymphomas, particularly marginal zone lymphoma (MZL), follicular lymphoma (FL), and lymphoplasmacytic lymphoma/Waldenström's macroglobulinemia (LPL/WM).

Indolent Lymphomas in Older Patients: The Impact of Age

According to the latest WHO classification of lymphoid neoplasm, indolent lymphomas are categorized in several entities (Table 1, WHO 16).

An analysis conducted by the Non-Hodgkin's Lymphoma Classification Project showed among indolent lymphomas (other than CLL) that follicular lymphoma (FL) was the most frequent, followed by marginal zone lymphoma (MZL) in older patients

Table 1 WHO classification 2016, indolent lymphomas (Swerdlow et al. 2016)

Chronic lymphocytic leukemia/small lymphocytic lymphoma
Monoclonal B-cell lymphocytosis[a]
Splenic marginal zone lymphoma
Hairy cell leukemia
Splenic B-cell lymphoma/leukemia, unclassifiable[a]

(>70 years). The same analysis showed complete remission rate (CRR) decreases with age, from 68% in young patient to 45% in the elderly (The Non-Hodgkin's Lymphoma Classification Project 1997). This difference is consistent with the results of another study (Bai et al. 2003) which showed in older patients affected by indolent NHL, the overall survival (OS) decreases with increasing age and outcome and CRR worsen compared to younger patients. This could be also due to differences in disease biology by age group: elderly patients are more likely to have a diffuse disease and a more frequent extranodal presentation (Cutter et al. 2002). It is widely recognized that age greater than 60 years is an independent pretreatment adverse prognostic factor for NHL. In order to define not arbitrarily older patients, NCCN "Older Adult Oncology" (2017) divided them into three groups:

- "Young" old patients are 65–75 years of age.
- "Old" old patients are 76–85 years of age.
- "Oldest" old patients are older than 85 years of age.

Chronological age has been mainly influencing clinicians for the therapeutic decisions: in fact many elderly patients are often left untreated, and fewer of those treated received adequate intention to treat regimen (Bairey et al. 2006). Clinicians might be inclined to prescribe less toxic and lower-dose drugs, and this attitude increases the chances of failure (Caimi et al. 2010). Poorer tolerability and feasibility of standard treatments consequently determine a lower therapeutic efficacy and less disease control.

However, chronological age by itself is not reliable in estimating life expectancy, functional reserve, or the risk of treatment complications (NCCN "Older Adult Oncology" 2017).

The Comprehensive Geriatric Assessment: A Useful Tool for Evaluating Elderly Patients

Little is still known about the prevalence of comorbidities and polypharmacy in older patients with NHL, as well as the impact on tolerability and feasibility of diagnostic and therapeutic procedures (Goede 2017). This could be related to the fact that highly aged patients are usually underrepresented in the majority of clinical trials.

An adequate clinical evaluation of older patients is a very complex issue, and it should be widely noted that chronological age itself is not enough to categorize these patients and to guide their management. The concept of *fitness status evaluation* has recently emerged as a more appropriate indicator of fitness and tolerability to chemotherapy compared to chronological age.

In evaluating newly diagnosed elderly patients, age-related factors should be considered (Table 2, Ninan and Morrison 2009).

Aging means organ and tissue functions physiologically decrease (Berkman et al. 1994) conditioning a reduced tolerability to chemotherapy. In addition, comorbidities inevitably result in pharmacokinetic and pharmacodynamic changes which could interfere with absorption, distribution, metabolism, and clearance of drugs; therefore, adverse effects could be exaggerated, and treatment efficacy could be diminished. Indeed, older patients develop major toxicities (myelotoxicity, cardiotoxicity, neurotoxicity, nephrotoxicity) more frequently than younger. Next to physiological aging, the typical polypharmacy of older patients could facilitate geriatric syndromes (Goede 2017). Moreover, it is also likely that tumor biology in the elderly is more aggressive since they manifest immune system dysfunction with a decreased both humoral- and cellular-mediated immune response (Extermann et al. 1998) (see also ▶ Chap. 10, "The Biologic Interconnections Between Aging and Lymphoma" in this book).

Table 2 Factors to be considered for the care of older patients

Poor performance status
Comorbidities
Polypharmacy and interactions with immunochemotherapeutic agents
Age-related organ damage or dysfunction
Age-related alterations in pharmacokinetics and pharmacodynamics
Alterations in immunity
Differences in disease biology by age group

In view of these considerations, a careful and complete evaluation of elderly patients affected by NHL is a central issue for a better management of this population. In fact, the assessment of patient's vulnerability is indispensable in order to offer a tailored dose-intensity therapy, depending on lymphoma-related and patient-related factors. In fact, older population is considerably heterogeneous with regard to biological age and comorbidities, so the aim of the therapy may range from curative intent to palliation. When a treatment is indicated, achieving a prolonged life expectancy with minimal toxicities should be the aim of clinicians, ensuring a good quality of life.

A whole evaluation of the elderly discriminating between fit, unfit, and frail patients could be made by using the comprehensive geriatric assessment (CGA) based on age, comorbidities, and functional disabilities of daily living (Table 3) (see also ▶ Chap. 25, "Comprehensive Geriatric Assessment (CGA) for Cancer Patients" in this book).

The multidimensional assessment of the "fitness geriatric status" includes determination of performance status (Karnofsky or ECOG), functional status (ADL, activities of daily living; Katz's scale or IADL, instrumental activities of daily living; Lawton's scale), comorbidities and their optimal control (Charlson Comorbidity Index or Cumulative Illness Rating *Scale* CIRS), cognitive state (MMSE, Mini-Mental State Examination), evaluation of nutritional status and family and social support (Geriatric Depression Scale (GDS)), and, last but not least, assessment of drugs taken for other comorbidities and possible interactions with antineoplastic treatment offered (Extermann and Hurria 2007) (see also ▶ Chaps. 21, "Drug Interactions in Aging and Cancer" and ▶ 22, "Comorbidity in Aging and Cancer" in this book). Therefore, the multidimensional geriatric assessment seems to be more functional and effective in guiding therapeutic choices compared to clinical evaluation alone.

CGA could be a useful tool to detect conditions which might interfere with treatment and to estimate expected therapy-related toxicities, providing a more accurate evaluation of residual functions than chronological age alone.

Table 3 Comprehensive geriatric assessment score. (From Tucci et al. 2015)

Scale	Fit	Unfit	Frail
Adl	6	5[a]	≤4[a]
Iadl	8	7–6[a]	≤5[a]
Cirs	0 score = 3–4 <5 score = 2	0 score = 3–4 5–8 score = 2	1 score = 3–4 >8 score = 2
Age	–	≥80 FIT	≥80 UNFIT

[a]Residual functions

Of note, to date, CGA advantages have not yet been studied in low-grade lymphomas unlike aggressive lymphomas which can benefit from well-done studies in the elderly (Tucci et al. 2009, 2015) (see also ▶ Chap. 36, "Diffuse Large B-Cell Lymphomas in Older Adults" on this book). However it would be useful to include CGA in clinical trials even in indolent lymphomas, to assess whether a less intensive treatment could be beneficial for older patients.

Diagnostic and Therapeutic Management of Elderly Patients with Low-Grade Lymphomas

The clinical onset of indolent lymphomas is usually subtle. In predominantly nodal forms, lymph node enlargement, often widespread, may be the presenting feature. Coexistence of systemic symptoms (fever, sweats, and weight loss) is uncommon; sometimes mild malaise, fatigue, or a feeling of an abdominal mass (due to retroperitoneal lymphoadenopathies or massive splenomegaly) could be the first symptoms referred by the patient. In indolent primitive extranodal lymphomas, such as MALT lymphomas, clinical picture generally depends on the involved site.

Except for MALT lymphomas, other indolent lymphomas are frequently diagnosed in advanced stage. Bone marrow infiltration is common, as well as presence in the peripheral blood, especially in splenic marginal zone lymphoma (80–90%) and, to a lesser degree, in other lymphoproliferative indolent diseases.

The clinical management of low-grade lymphomas has been elaborated in expert guidelines

(Zucca et al. 2013; Zelenetz et al. 2014; Buske et al. 2013; Dreyling et al. 2013, 2016) which discuss recommended diagnostic procedures and treatment options also in the elderly.

Diagnosis always requires histological examination on excision biopsy of involved site or, if it is difficult to obtain (e.g., abdominal bulky disease), a "core biopsy" is recommended. It is essential to require histological confirmation by a skilled expert pathologist.

NHL staging is based on a careful history and physical examination to assess the patient's general conditions (performance status according to ECOG scale), pathological presence of lymph nodes, and/or hepatosplenomegaly. Laboratory tests include blood counts with differential, indexes of systemic inflammation (ESR, fibrinogen, ferritin, alpha2-globulin, C-reactive protein), liver and kidney function, dosage of serum LDH and beta2-microglobulinemia levels (which are included in several prognostic indexes), serum immunoglobulins, and immunofixation. All patients have to be screened for hepatitis virus (HBV, HCV) and HIV which, in addition to their potential pathogenetic role, may affect treatment decisions. In the case of gastric MALT lymphoma, it is also required to test for *H. pylori* by histological and/or laboratory evaluation. Diagnostic imaging should include computed tomography (CT) scans of the neck, chest, abdomen, and other sites as appropriate. As indicated by the Lugano classification (Cheson et al. 2014), FDG-PET is now recommended at diagnosis in all patients with FDG-avid lymphomas (all histologies except small lymphocytic lymphoma, lymphoplasmacytic lymphoma, and marginal zone lymphoma) (Barrington et al. 2014). Staging is completed in all patients with bone marrow biopsy and aspiration for flow cytometry and cytogenetic and molecular studies. Low-grade lymphomas are often diagnosed in advanced stage and leukemic; therefore, peripheral blood should be evaluated. Staging should be conducted in accordance with international guidelines, using the Ann Arbor system modified by the Lugano classification (Table 4; Cheson et al. 2014).

Table 4 Revised staging system for primary nodal lymphomas: the Lugano classification (Cheson et al. 2014)

Stage	Nodal	Extranodal
Limited		
I	One node or an adjacent group of nodes	Single extranodal lesions without nodal involvement
II	Two or more nodal groups on the same side of the diaphragm	I or II by nodal extent with limited contiguous extranodal involvement
II Bulky	II as above with bulky disease	Not applicable
Advanced		
III	Nodes on both sides of the diaphragm or nodes above the diaphragm with spleen involvement	Not applicable
IV	Additional noncontiguous extra-lymphatic involvement	Not applicable

For older adults eligible for chemotherapy, particularly anthracycline-containing regimens, it would be essential to obtain an accurate evaluation of cardiac function: it is well known anthracyclines cause short- and long-term cardiotoxicity and the risk for congestive heart failure is cumulative dose-related (Rahman et al. 2007).

As these procedures are associated with little morbidity, they are recommended for all patients regardless of age (Morrison 2007).

The therapeutic goal for elderly patients is to find a balance between effective therapy and related toxicity (Bairey et al. 2006); the best ideal therapy should also be brief and feasible in outpatient setting, guaranteeing a good quality of life. Considering the natural history of indolent lymphomas, it is justified to undertake a W&W approach even in advanced stages, since the probability for these patients of not requiring any treatment is up to 40% for those who are diagnosed at age $>$ 70 years (Ardeshna et al. 2003). W&W approach is the most suitable, especially for the elderly, without any toxicity or cost, since no survival benefit was shown with early treatment, including with rituximab (Ardeshna et al. 2010). In patients aged $>$90 years diagnosed with

indolent lymphomas, outcome is not influenced by treatment which therefore should be reserved only to symptomatic patients in order to relieve symptoms (Trebouet et al. 2013). In the presence of high tumor burden criteria or B symptoms or any other symptoms related to lymphoma (active disease defining criteria, Table 5), specific treatment indications arise.

Management of older patients remains particularly delicate due to their underlying fragility. Fit elderly patients should receive chemoimmunotherapy regimen as first-line treatment, such as R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone), or R-CVP (as R-CHOP without doxorubicin) or R-bendamustine (BR). The addition of rituximab to chemotherapy has dramatically improved OS and PFS (Hiddemann and Kneba 2005; Schulz et al. 2007). Since BR is effective and has less toxic side effects (Rummel et al. 2005), it can be considered as the preferred regimen in older fit patients and partially in unfit patients (StiL trial, Rummel et al. 2013, and BRIGHT trial, Flinn et al. 2014). BR is shown to be not inferior to R-CHOP in terms of PFS: in the overall study population, the median PFS was significantly longer after BR compared to R-CHOP (not reached versus 40.9 months with median follow-up of 45 months); within the subset of MZL, progression-free survival (PFS) was not different between the two treatments. BR was better tolerated than R-CHOP (lower rates of hematologic and extra-hematologic toxicities) but with more erythematous skin reactions (Rummel et al. 2013). These studies have made BR an attractive alternative option compared to R-CHOP in older or cardiopathic patients. However, data on tolerability and feasibility of BR or other schemes in "oldest" old patients (>85 years) with multiple or severe comorbidities are still lacking; thus, great caution should be used in this highly vulnerable group of patients when BR or any treatment scheme is offered.

In older patients who are candidates for combination therapy, international guidelines recommend primary prophylaxis of febrile neutropenia with G-CSF as this can reduce infectious complications which are frequent in this population.

Table 5 Available criteria for defining active disease. (Based on Chen et al. 2012)

GELF criteria	BNLI criteria
High tumor burden defined by at least one of the following: Involvement of >3 nodal sites, each with diameter > 3 cm Any nodal or extranodal (except spleen) tumor mass with a diameter of 7 cm Symptomatic splenomegaly Cytopenias (leukocytes $<1.0 \times 10^9$/L and/or platelets $<100 \times 10^9$/L) Leukemia ($>5.0 \times 10^9$/L malignant cells) Pleural effusion or peritoneal ascites B symptoms Elevated LDH or beta2-microglobulin level	Rapid generalized disease progression in the preceding 3 months B symptoms or pruritus Involvement of vital organs Renal or liver involvement Bone lesions Bone marrow infiltration (leukocytes $<1.0 \times 10^9$/L, platelets $<100 \times 10^9$/L and/or hemoglobin <10 g/dl)

In frail patient group, chemoimmunotherapy is not feasible; oral alkylating drugs (chlorambucil or cyclophosphamide) are usually able to control symptoms of disease in the most of cases. The combination rituximab plus chlorambucil is well tolerated by many frail patients, and this regimen improved CRR up to 89% (Martinelli et al. 2003). Fludarabine was demonstrated to be more efficacious than chlorambucil but with a greater hematological and renal toxicity (Leblond et al. 2013). Also low dose of steroid, low-dose irradiation, and best supportive care may be appropriate with the aim to relieve disease symptoms (Table 6).

There are a remarkable number of emerging new drugs for relapsed/refractory patients (such as lenalidomide, idelalisib, or ibrutinib) which may allow a chemo-free treatment. It is likely that these agents will be part of available treatment options, especially for vulnerable naive or treated patients.

Marginal Zone Lymphoma (MZL)

Approximately 50% of newly diagnosed patients have an older age, with median age at presentation around 65–70 years (Goede 2017). MZL is not a

Table 6 Different treatment options according to patient fitness. (Modified from Viardot and Buske, Springer, 2015)

Fitness	Aim of therapy	Treatment options
Fit	Curative intent	BR or R-CHOP[a]
Unfit	Control of symptoms	R-CVP, BR, R-FC[b], R-CBL, radioimmunotherapy, rituximab single agent
Frail	Control of symptoms	Chlorambucil, cyclophosphamide (orally), low-dose bendamustine, rituximab single-agent low-dose RT, low-dose steroid, supportive care

[a]Avoid anthracyclines in patients with cardiac dysfunction
[b]Avoid fludarabine in patients with renal impairment

single entity but a group of three different lymphomas (splenic MZL, nodal MZL, and extranodal MZL of mucosa-associated lymphoid tissue [MALT]), which differ from each other in biological and clinical features, diagnostic work-up, and therapeutic strategies.

Among MZL, extranodal MZL of MALT (EMZL/MALT lymphoma) is the most common (5–8% of all lymphomas), while splenic MZL (SMZL) and nodal MZL (NMZL) are less frequent (each of them accounting for <2% of all lymphomas) (Goede 2017).

Etiology of EMZL/MALT lymphoma may be driven by chronic antigen stimulation which could explain why MZL develop in the elderly in the majority of cases. Additional oncogenic events are essential for lymphoma growth and progression, until it becomes frankly malignant and eventually independent of antigenic drive (Suarez et al. 2006; Zucca and Bertoni 2016). Gastric MALT lymphoma (representing the most common EMZL) has a close association with infection by *Helicobacter pylori* (HP). Eradication of HP by a combination of antibiotic therapy and proton pump inhibitor should be the initial therapy for localized HP-positive gastric MALT lymphomas, resulting in lymphoma regression and long-term clinical control in most patients (Ferreri et al. 2012b; Dreyling et al. 2013). Other infectious agents has been associated to MZLs: Campylobacter jejuni may have a causal role for intestinal MALT lymphoma as well as Chlamydia spp. infection has been well documented in MZL of ocular adnexa, which is effectively treated with antibiotic therapy (Ferreri et al. 2012a).

According to other models of lymphomagenesis, chronic stimulation by HCV can promote development of MZL. This hypothesis is supported by the effectiveness of antiviral therapy in lymphoma eradication. A meta-analysis reports a significantly higher prevalence of HCV in NHL patients compared with controls, both in endemic areas for HCV and in those with low prevalence of this infection (Matsuo et al. 2004). MALT lymphoma in HCV-infected patients may regress after HCV eradication (Arcaini et al. 2007). Since antiviral treatment has a favorable impact on outcome of HCV-infected patients with indolent NHL, it should be offered as fist-line therapy in patients who have not the urge of an immediately cytoreductive treatment (Dreyling et al. 2013; Tarella et al. 2015).

Eradication treatment can be safely administered in older patients since it is considered uncomplicated or at least a low-risk regimen. Nevertheless, treatment efficacy might be compromised by nonadherence to therapy in the elderly because of their considerable polypharmacy or cognitive impairment (Goede 2017).

There are several clinical and biological factors defining outcome in MZL patients. However, for older patients, prognosis is influenced also by the increasing risk of death independent of MZL (especially cardiovascular causes). Therefore, prognostic factors and scores are likely to be unrepresentative in very old (>80 years) compared to moderately old (65–75 years) or young (< 60 years) patients (Goede 2017).

Immunochemotherapy represents the optimal option for fit and eligible patients with advanced-stage MZL. For frail elderly patients, a palliative care is represented by cytoreductive therapy with alkylating agents which have a benign toxicity profile, causing only mild to moderate myelosuppression.

Splenic Marginal Zone Lymphoma

SMZL diagnosis is often incidental. A frequent presenting feature of SMZL is peripheral lymphocytosis in asymptomatic patients. More rarely,

patients can be symptomatic for splenomegaly or cytopenias. In a minority of cases (approximately 20%), autoimmune manifestations can precede or accompany SMZL (autoimmune hemolytic anemia, autoimmune thrombocytopenia, acquired von Willebrand disease). These autoimmune disorders require specific treatment, in addition to lymphoma's therapy.

In the most of cases, SMZL has an indolent course not requiring therapy for a long time. A few patients (about 30%) might have a worse outcome, including transformation to more aggressive lymphoma (5–10%) (Arcaini et al. 2006; Olszewski and Castillo 2013; Conconi et al. 2015).

HCV infection in SMZL patients has been proposed as a model of infection-driven lymphoma genesis (Saadoun et al. 2005). The causal role of HCV is strongly supported by regression of lymphoma after eradicating HCV infection (Arcaini et al. 2014) with interferon-based antiviral treatment but also with new IFN-free regimens (Direct-Acting Antiviral, DAA) (Arcaini et al. 2015).

Definitive diagnosis of SMZL requires splenectomy and spleen histology; if not available, the diagnosis can be made on bone marrow histology, with cell morphology and flow cytometry in peripheral and marrow blood (Arcaini et al. 2016).

It does not exist for SMZL a specific validated prognostic index because of the paucity of patients and prospective trials in this rare disease. The Italian Lymphoma Intergroup (now Fondazione Italiana Linfomi, FIL) had already proposed a system of scoring for prognostic assessment of SMZL patients: it includes hemoglobin level $<$ 12 g/dl, elevated serum lactate dehydrogenase (LDH) level, and albumin level $<$ 3.5 g/dl. Patients can be divided into three risk groups: low risk (no adverse factors), intermediate risk (one adverse factor), and high risk (two or three adverse factors) (Arcaini et al. 2006). In a following international study, hemoglobin, platelet count, high LDH level, and extrahilar lymphadenopathy were identified as independent prognostic factors, dividing patients into three risk groups again: low risk (no adverse factor), intermediate risk (1–2 adverse factors), and high risk (3–4 adverse factors) (Montalban et al. 2012, 2014). These scores have been validated in an independent series of SMZL patients (Kalpadakis et al. 2014).

Consensus guidelines (Dreyling et al. 2013; Zelenetz et al. 2014) recommend treatment only in the presence of symptoms or progressive disease; otherwise, asymptomatic patients are candidates for a W&W strategy.

As first-line therapy, splenectomy should be offered in order to eliminate a significant amount of disease: in fact, the splenic sequestration is removed with consequent improvement of peripheral cytopenias; this also relieves symptomatic abdominal discomfort. Splenectomy allows the patient to remain free from treatment for many years (Thieblemont et al. 2002). This procedure should be contraindicated in cases with disseminated disease. Also in this case, CGA is useful to identify older patients with preexisting cognitive impairment who are at an increased risk to develop delirium after abdominal surgery (Ganai et al. 2007). Therefore, pros and cons of splenectomy should be carefully evaluated in this patient group, and preexisting comorbidities or geriatric syndromes have to be considered before offering a surgical procedure (Kavic et al. 2005).

A valid and less traumatic alternative to splenectomy is represented by rituximab single agent (Else et al. 2012) which should be offered in older patients with comorbidities or with contraindications to surgical procedure. Rituximab is minimally myelosuppressive, and therefore even very old patients can safely benefit.

In case of disseminated disease, combination regimen is considered as the standard.

Extranodal Marginal Zone Lymphoma

MALT lymphoma is the commonest MZL type, accounting for 5–8% of all B-cell lymphomas (Olszewski and Castillo 2013). The most frequently affected organ is the stomach; other non-gastric site (virtually all tissues) can be involved: salivary glands, orbits and conjunctiva, thyroid, lung, and other gastrointestinal (GI) sites.

Generally MALT lymphoma shows more often an indolent course; histological transformation is

less frequent than follicular lymphoma (below 10% in most series), also occurring as a late event, and independent of dissemination (Sagaert et al. 2006; Zucca and Bertoni 2016).

MALT lymphoma usually remains in a localized stage (often multifocal within the involved organ) for a long period of time. Non-gastric MALT lymphomas have overall a poorer prognosis than gastric localizations, although they generally maintain a low tendency to spread outside of the MALT-type sites. Nodal spread is a risk factor for the evolution into a more aggressive lymphoma.

Staging is based on CT scan and bone marrow biopsy (marrow infiltration occurring in 20% of cases). In primary gastric lymphoma, to run an eco-endoscopic examination which would allow an accurate assessment of infiltration degree in gastric wall is recommended. This procedure can also detect any involvement of adjacent lymph nodes (usually underestimated by other investigations) which constitutes a risk factor for the spread of lymphoma (Zucca et al. 2003).

In localized MALT lymphoma, radiation therapy may be the favored choice, also for infected patients who do not achieve a lymphoma regression following eradication therapy (Dreyling et al. 2013). Radiotherapy is not free from side effects: local toxicity is possible, but in the majority of older patients, radiotherapy is well tolerated in a similar way of younger patients (Goede 2017).

For patients with disseminated disease, there is still no clear consensus about the treatment: careful observation could be an adequate initial approach. When treatment is required, rituximab plus chemotherapy may represent the most appropriate choice, as in the other indolent NHL (Dreyling et al. 2013).

Nodal Marginal Zone Lymphoma

NMZL is a rare disease accounting for <2% of all NHL. The median age at diagnosis is lower than the other types of MZL ranging from 50 to 65 years. In the most of cases, NMZL is disseminated with nodal (usually non-bulky) and peripheral involvement. Bone marrow infiltration is present in about one third of patients, while leukemic and cytopenias are rare (Thieblemont et al. 2016). Clinical outcome is generally inferior to the other MZL. Treatment is based on the same principles used for follicular lymphoma. For localized disease, radiotherapy is the standard; in cases of low tumor burden, a watchful waiting approach is indicated, while disseminated disease requires immunochemotherapy as appropriate option.

Follicular Lymphoma

Follicular lymphoma (FL) is the commonest subtype of low-grade lymphomas, accounting for approximately 25–30% of all newly diagnosed NHL (Harris et al. 1994). The median age at diagnosis is slightly higher than 50 years which is slightly lower compared to that of other indolent lymphomas. Incidence is higher in patients older than 75 years (Smith et al. 2011).

As reported by recent international guidelines (Zelenetz et al. 2014; Dreyling et al. 2016), FL is an indolent but incurable disease which is likely to shift into an aggressive phenotype in about 15–20% of cases. Morphologically, FL is divided into three grades: 1, 2, and 3A grades behave in a more indolent manner, while grade 3B behaves more clinically aggressive, whose recommended therapy is similar to that of diffuse large B-cell lymphoma. Staging is completed in FL by whole-body FDG-PET, which sometimes upstages disease showing extranodal or occult localization. FDG-PET does not have high sensitivity for detection of bone marrow infiltration; therefore, bone marrow biopsy and aspiration for flow cytometry is always indicated. If needed, it could be added molecular studies to detect the presence (or persistence after therapy) of cells with bcl2-IgH rearrangement or t(14;18) using RQ-PCR or cytogenetic analysis, respectively.

Prognosis of FL remains heterogeneous. Once again, age over 60 years is a predictor of decreased survival. The Follicular Lymphoma International Prognostic Index (FLIPI), established in 2004 (Solal-Céligny et al. 2004), divides patients into three risk groups according to five parameters (age greater than 60 years, Ann Arbor stage III or IV, elevated serum LDH level, hemoglobin <12 g/dl, >4 nodal sites involved).

However, FLIPI was made in pre-rituximab era on retrospective data. More recently, in the rituximab era, a revised FLIPI-2 was introduced (Federico et al. 2009). This score includes five parameters: age greater than 60 years was confirmed as prognostic factor together with hemoglobin value less than 12 g/dl; increased level of beta2-microglobulin, diameter of largest lymph node, and bone marrow involvement were introduced as new prognostic factors.

Treatment of follicular lymphoma depends mainly on disease stage, and it is not guided by FLIPI and FLIPI-2. For localized stages (I–II, without bulky disease, accounting for 15–20%), treatment of choice is involved-field radiation therapy (IFRT) alone (24 Gy is indicated to obtain a curative intent; 2x2 Gy has mainly a palliative effect). IFRT allows to achieve long-term disease-free survival in about 45% of patients (Peterson et al. 2004). However, patients with low life expectancy, with severe comorbidities, or with contraindications to radiotherapy are candidates for a "W&W" policy or rituximab single agent.

For advanced stages (III, IV, or II with bulky disease), with high tumor burden or with symptoms, rituximab plus chemotherapy is considered the standard. Anyway, the choice of chemotherapy regimen should be made taking into account several factors, including age, comorbidities, and patient's will (Castellino et al. 2017). Frail elderly patients may be treated with alkylating agents for palliative intent, as in other indolent lymphomas.

Patients responding to first-line combination treatment are candidates for maintenance therapy with rituximab, which was shown to improve progression-free survival (PFS) compared to observation strategy (75% vs. 58% after 3 years) (Seymour et al. 2013; Taverna et al. 2013). Rituximab maintenance improves duration of response both in first line and in relapse setting (Salles et al. 2011), regardless of induction therapy scheme. Rituximab maintenance is able to maintain response with minimal toxicity and preserve quality of life.

The efficacy of rituximab maintenance in older patients with advanced follicular lymphoma responding to brief first-line chemoimmunotherapy has been evaluated in a clinical trial designed by Fondazione Italiana Linfomi (FIL) (Vitolo et al. 2013). This trial compared rituximab maintenance to no further treatment in elderly patients with advanced FL who had responded to a brief first-line treatment (four courses of R-FND) followed by 4 weekly doses of rituximab consolidation. This therapy scheme achieved excellent results with high complete response rate (CRR) and PFS, supporting the feasibility of this anthracycline-containing regimen in patients older than 60 years and also in those with comorbidities. No differences between the two arms were detected by OS.

Another treatment option is radioimmunotherapy with 90Y-ibritumomab tiuxetan (Zevalin), an anti-CD20 antibody conjugated with a radionuclide, recommended as consolidation therapy (Morschhauser et al. 2008). Despite its prolonged myelotoxicity which requires close monitoring especially between 4 and 8 weeks after treatment, Zevalin would remain a valid alternative option in patients not eligible for high-dose chemotherapy (HDT) and autologous stem cell transplantation (ASCT) such as elderly patients (Castellino et al. 2017).

At relapse a new biopsy is indicated, in order to exclude histological shift into more aggressive lymphoma. For elderly patients, options are a further period of "W&W" if disease relapses with low tumor burden and/or the patient is asymptomatic, second-line immunochemotherapy if feasible and lymphoma has high tumor burden, or palliative care if the patient is not a candidate for curative treatment. Rituximab should be added to salvage therapy if the duration of remission after first-line treatment has been longer than 6–12 months (Dreyling et al. 2016). In rituximab-refractory cases, obinutuzumab (an anti-CD20 antibody of second generation) plus bendamustine or CHOP demonstrated improved PFS compared to chemotherapy alone (GADOLIN trial, Sehn et al. 2016, GAUDI' trial, Radford et al. 2013).

Novel drugs are available in monotherapy or in association with chemotherapy; idelalisib (PI3K inhibitor) could be used in double refractory FL based on a phase II study (Gopal et al. 2014).

Lenalidomide single agent or in association with chemotherapy or rituximab showed high activity in FL and other indolent NHL (Fowler et al. 2014).

Lymphoplasmacytic Lymphoma and Waldenström's Macroglobulinemia

Lymphoplasmacytic lymphoma (LPL) is a rare lymphoproliferative disorder which occurs more frequently in older adults and is characterized in most of cases by the presence of a serum paraprotein associated with bone marrow infiltration by lymphoplasmacytic cells. LPL associated with serum IgM paraprotein is called Waldenström's macroglobulinemia (WM).

According to international guidelines (Buske et al. 2013), LPL/WM constitutes less than 5% of all NHL. It generally has an indolent clinical course responding to treatment, although over time, it may become refractory to chemotherapy and transform into an aggressive form. Spread to nodal and/or hepatosplenic sites is present in about a quarter of patients (15–20%), while extranodal involvement and leukemic phase are uncommon (Treon 2015). Patients could have signs and/or symptoms attributable to tumor infiltration such as cytopenias and/or to monoclonal paraprotein (hyperviscosity, cryoglobulinemia, cold agglutinin disease, neuropathy, amyloidosis).

Hyperviscosity is a central feature in WM patients, due to large size of IgM molecules and their high levels which make peripheral blood more viscous, with consequent slower transit time through capillaries (Gertz and Kyle 1995). Hyperviscosity syndrome is a clinical indication for immediate plasma exchange, regardless of IgM entity. Most commonly symptoms are represented by bleeding, less frequently by dizziness, headache, vertigo, hearing loss, paresthesias, or diplopia. Neurological deficits are not specific, ranging from confusion to dementia-like syndrome, making them difficult to recognize especially in the elderly. Neurological symptoms could also be the sign of central nervous system infiltration by the disease (Bing-Neel syndrome).

As for other indolent lymphomas, "W&W" policy is the standard approach to LPL in patients without symptoms. LPL/WM has a long natural history, and affected patients are often elderly with coexisting medical problems. The mainstay of therapy is based again on rituximab-chemotherapy combination or on the use of bortezomib (Viardot and Buske 2015). Another approach in older patients is the DRC regimen, which consists of dexamethasone, oral cyclophosphamide, and rituximab: this scheme was shown to be highly effective in treatment-naïve WM patients, with low toxicity (Dimopoulos et al. 2007). Rituximab single agent is effective, but time to response is slow and can cause a critical increase in IgM serum levels triggering hyperviscosity syndrome which requires urgent plasmapheresis (Treon et al. 2004).

New drugs acting on the BCR signaling pathway have been tested in WM since MYD88 mutations represent the most studied pathogenetic event in the majority of MW cases (Treon et al. 2012): both ibrutinib (Btk inhibitor) and idelalisib (PI3k inhibitor) are effective in patients with WM. Ibrutinib, administered as monotherapy (420 mg/die) in 63 previously treated WM patients, resulted in an overall response rate (ORR) higher than 73% and PFS at 2 years of 70%. Ibrutinib has shown to be effective in 100% of MYD88-mutated patients with a benign and manageable toxicity profile (Treon et al. 2015; Dimopoulos et al. 2017). Experiences with idelalisib in the relapsed setting are lower, but results seem to be hopeful (ORR 80%, median PFS of 22 months in a study of Gopal et al. 2014).

Conclusions

The incidence of NHL has been progressively increasing, especially in older adults, together with a steady increase of median age population. The treatment of elderly patients affected by low-grade lymphomas still remains a challenge which could be faced with integrating multidisciplinary care.

Chronological age by itself is not sufficient to guide treatment in these patients. CGA could be a useful tool in order to improve assessment of patient's vulnerability and to guide the choice of the most appropriate treatment for each individual patient. In fit older patient, regimens commonly used for younger patients are feasible. However, curative intent is not generally applicable for the most of elderly patients with NHL. For this remaining population, it would be necessary to guarantee high quality of care and a good quality of life with minimal treatment-related toxicity. In this challenging clinical setting, novel drugs are promising to obtain patient-targeted treatment, with a better tolerability and potentially a better effectiveness. In the near future, new drugs might provide for an oral chemo-free treatment, especially for vulnerable treated patients. Therefore, continued participation in clinical trials which include elderly patients should be recommended.

Diffuse Large B-Cell Lymphomas in Older Adults

Contents

Abstract

Diffuse large B-cell lymphoma (DLBCL) is the most common subtype of non-Hodgkin lymphoma in the elderly and is increasing in incidence. Although significant therapeutic advances have recently been made in the care of older DLBCL patients, based upon results of randomized clinical trials, many older patients are not eligible for such trials due to comorbidities and functional decline. Pretreatment evaluation of older patients to ascertain potential tolerance to therapy is especially important in therapeutic decisions for this population. Evaluation by performance status alone is insufficient, especially in the elderly, and consideration of the impact of comorbidities and functional/social decline needs to be included in such assessment. In this chapter, we will review approaches to therapy of the older patients with DLBCL, including initial treatment, role of maintenance therapy, use of combined modality therapy

for limited stage disease, and strategies for the relapsed/refractory older patient. We will also address the issues of prognosis, comorbidities, geriatric assessment, supportive care measures in older patients with DLBCL, and recommendations for assessment and allied care.

Introduction

Non-Hodgkin's lymphoma (NHL) is common in the elderly, with median age at diagnosis of 67 years. The incidence of this malignancy has been increasing, especially in patients >60 years of age (Thieblemont and Coiffier 2007; Howlader et al. 2012; Smith et al. 2011). Diffuse large B-cell NHL (DLBCL) is the most common NHL subtype in the elderly, with prognosis being poorer than in younger patients (Thieblemont and Coiffier 2007). Although significant therapeutic advances have been made in the past two decades for older DLBCL patients, standard therapies are complicated by comorbidities and preexistent alterations in functional status. In this chapter, we will review prognosis, impact of comorbidities, role of geriatric assessment, approaches to therapy in the treatment-naive and salvage settings, and supportive care measures for older DLBCL patients.

Demographics and Staging in Older DLBCL Patients

More elderly than younger patients are diagnosed with DLBCL (Thieblemont and Coiffier 2007). Incidence rates increase with older age, being approximately 30/100,000 per year in patients >65–70 years of age (Howlader et al. 2012; Smith et al. 2011). Median age at DLBCL diagnosis is between 70 and 75 years; approximately half the cases occur in patients ≥65 years of age, and 40% in those older than 70 years (Smith et al. 2011; Sarkozy and Coiffier 2013). The incidence is higher in men than women, approaching 2:1 in the elderly. Age at diagnosis has been shown to be a major prognostic factor in registry studies (Howlader et al. 2012; Monnereau et al. 2013; Sant et al. 2008; Marcos-Gragera et al. 2011). Net survival (NS) is survival that would be observed if cancer was the only possible cause of death and represents an indicator in population studies. In one series, 5-year NS was 47% (95% CI: 45–49), with a 40-fold decrease in 5- and 10-year NS in males >75 years of age (Monnereau et al. 2013). Among the oldest males (i.e., 65–75, versus >75 years), 5-year NS dropped from 45% (95% CI: 40–50) to 26% (95% CI: 22–31).

Histologic classification of NHL has evolved from the International Working Formulation (IWF) in 1982, to the 1994 REAL (Revised European American Lymphoma) schema, followed by the 2001 World Health Organization (WHO) classification (updated in 2008), which includes morphologic, immunophenotypic, genetic, and clinical aspects (The Non-Hodgkin's Lymphoma Pathologic Classification Project 1982; Harris et al. 1994; Jaffe 2009). Diagnostic material should be submitted for histologic, immunophenotypic, immunohistochemical, cytogenetic, and molecular analysis. Recommendations for initial evaluation, staging, and response assessment of NHL have recently been updated (Cheson et al. 2014). Although division into limited (I–II) and advanced (III–IV) stage disease remains, suffixes A and B for symptoms will no longer be used. Staging evaluation should include physical examination, complete blood count with differential, lactic dehydrogenase (LDH), hepatitis B/C serologies, CT scans of chest, abdomen, and other sites as appropriate and functional imaging with PET scan, which is more sensitive in extranodal disease sites. For elderly patients in whom scans are not feasible, CXR and abdominal ultrasound may be substituted. Bone marrow biopsy is no longer indicated for routine staging. Cerebrospinal fluid cytology may be assessed in patients at high risk of central nervous system involvement. Baseline determination of cardiac ejection fraction is necessary prior to anthracycline-based therapy.

Prognostic Factors

DLBCL is a heterogeneous disease with regard to prognosis, clinical features, and treatment outcome, related to a variety of molecular pathways and pathogenic mechanisms involved in oncogenesis. Clinical risk factors as well as biomarkers may be utilized to refine prognostication (Table 1). Adverse disease subtypes as immunoblastic morphology, activated B-cell (ABC) subtype, and Epstein Barr virus-positive DLBCL are overrepresented in elderly patients (Pfreundschuh 2010; Hofscheier et al. 2011).

Clinical Prognostic Models The International Prognostic Model (IPI) was derived and validated in the pre-rituximab era from patients receiving anthracycline-based chemotherapy (The International Non-Hodgkin's Lymphoma Prognostic Factors Project 1993). Adverse prognostic factors identified included age > 60 years, Eastern Cooperative Oncology Group (ECOG) performance status (PS) ≥2, stage III/IV disease, more than one extranodal disease site, and elevated lactate dehydrogenase (LDH). Four prognostic risk groups were defined (low, low intermediate, high intermediate, high) with 5-year survival rates of 73%, 51%, 43%, and 26%, respectively. The age-adjusted IPI has been used in elderly patients. The utility of the IPI in the rituximab /R-CHOP era was examined in several series (Sehn et al. 2007; Ziepert et al. 2010; Advani et al. 2010). In a British Columbia registry series (median age 61 years) with a revised-IPI (R-IPI) scoring system, three prognostic groups (very good, good, poor, risk) were identified, with 4-year survival rates of 94%, 79%, and 55%, respectively (Sehn et al. 2007). In another analysis of 1062 patients receiving rituximab-based chemotherapy in three prospective trials, the IPI retained significance for event-free (EFS), progression-free (PFS), and overall survival (OS) (Ziepert et al. 2010). The addition of rituximab significantly improved outcome within each IPI subgroup. The Elderly-International Prognostic Model (E-IPI), utilizing an age cutoff of 70 years, classified more patients as low risk as compared to prior prognostic classifications and found significant differences in FFS and OS in low-intermediate, as compared with low, risk patients (Advani et al. 2010). In a more recent report with a 70 year age cutoff, among factors as albumin, lymphocyte count, gender, IgG level, bulky disease, hemoglobin, and B-symptoms, only albumin was prognostic (Gang et al. 2015). This group proposed a modified prognostic index (DLBCL-PI) including age (70 years), PS, LDH, and albumin eliminating extranodal disease site(s) as a factor. For patients <70 years of age, the DLBCL-PI included PS, LDH, albumin, and more than one extranodal disease site, excluding stage. An accompanying editorial concluded that an age cutoff of 70 years is most appropriate at present (Mikhaeel 2015). Lastly, in a prospective cohort study, pretreatment quality of life was predictive of survival in R-CHOP-treated patients (Jung et al. 2012).

Table 1 Prognostic factors for outcome in older DLBCL patients

Clinical factors (age-adjusted International Prognostic Index)
Performance status
Advanced stage disease

B-cell differentiation (BCL6, FOXP1)
Angiogenesis (HIF-1α, VEGFR2)

Biomarkers, Gene Expression, and Immunohistochemical Prognostic Factors Lymphoma biomarkers most extensively studied include genes and protein products involved in apoptosis (BCL2, survivin, Fas), cell-cycle regulation (p53), cellular proliferation (Ki-67), B-cell differentiation (BCL6, FOXP1), and angiogenesis (HIF-1α and VEGFR2) (Wilson et al. 2007; Mounier et al. 2003; Adida et al. 2000; Hara et al. 2009; Xu-Monette et al. 2012; Miller et al. 1994;

Jerkeman et al. 2004; Winter et al. 2006; Barrans et al. 2004; Evens et al. 2010; Gratzinger et al. 2010). MYC gene rearrangements and MYC protein overexpression are associated with inferior outcome, as are the "double-hit lymphomas" involving aberrations of MYC and/or BCL2 and BCL6 (Savage et al. 2009; Horn et al. 2013; Vaidya and Witzig 2014).

Gene expression studies have identified the germinal center B-cell (GCB) and activated B-cell (ABC) DLBCL subtypes (Alizadeh et al. 2000; Rosenwald et al. 2002; Lenz et al. 2008a). In patients >80 years of age, 60–70% of DLBCL are of the ABC subtype (Lenz et al. 2008b; Mareschal et al. 2011; Fontan et al. 2012). Patients with the GCB compared to ABC subtype have a significantly better prognosis (5-year survival of 76% versus 16%) with anthracycline-based therapy. Another study identified three molecular signatures (germinal center B-cell [GCB], stromal-1, stromal-2 signatures) with tumor microenvironment correlation (Lenz et al. 2008b). The stromal-1 signature, characterized by genes associated with connective tissue growth factor and monocyte/macrophage lineage, correlated with significantly better prognosis compared to the stromal-2 signature, which was associated with genes involved in angiogenesis. Immunohistochemical (IHC) studies on paraffin-embedded tissue are more readily available and have been utilized as surrogates for gene expression (Choi et al. 2009; Copie-Bergman et al. 2009). However, there is no consensus of the optimal prognostic IHC panel in rituximab-treated patients.

Comorbidities in Elderly Patients

Comorbid conditions in the elderly are common, being present in >60% of patients older than 70 years (Janssen-Heijnen et al. 2005). With older age, hematopoietic reserve may be limited, with therapy-related myelotoxicity being more common. Drug pharmacokinetics and pharmacodynamics may also be altered in older patients. Delivery of therapy can be impacted, as well as disease outcome (Janssen-Heijnen et al. 2005). Subsequent dose reductions can result in lower dose intensity and a higher rate of treatment failure (Gomez et al. 1998). Assessment of end-organ dysfunction is critical to guide physicians in cancer therapy dosing. When the comorbidity index of the National Institute of Aging/National Cancer Institute was applied in a Netherlands population study of aggressive lymphoma patients, it was found that high-impact comorbidity doubled the risk of death, independent of the IPI (Janssen-Heijnen et al. 2005; Yancik et al. 1998). The Cumulative Illness Rating Scale (CIRS) has been employed in the EORTC trials to assess comorbidity, being part of the functional definition of frailty. Charlson et al. determined that number and severity of comorbid illnesses can predict survival in general medical patients admitted to an inpatient unit (Charlson et al. 1987). In a study of older cancer patients, it was found that functional status and comorbidity were independent, necessitating separate assessment for each (Extermann et al. 1998). Measures as Karnofsky score (KPS) and PS may not address geriatric issues as polypharmacy, social support, ability to use the telephone, and depression, which can predict survival in older patients. Currently available functional scales include self-reported measures as ability to complete activities of daily living (ADL) and instrumental (I-)ADL, as well as performance-based tests as get up and go and gait speed. Polypharmacy, with issues of potential drug interactions and compliance, is common in elderly patients with comorbidities. Comorbidities may also preclude clinical trial enrollment of elderly patients. In one study of older NHL patients, there were no significant differences in baseline demographics and lymphoma characteristics among patients aged 60–74 and those >75 years, except for PS (Lim et al. 2008). In multivariate analysis, lymphoma histology, PS, and stage were predictive for survival in patients <75 years of age. Among patients age ≥ 75 years, only PS was prognostic for survival. Thus PS, comorbidity, and functional status need to be independently assessed.

The impact of comorbidity in treatment planning and prognosis was examined in a retrospective review of 140 DLBCL patients >70 years of age (Sonnen et al. 2002). Treatment outcomes

were related to IPI risk stratification. The most common comorbidities were peripheral neuropathy and cardiovascular and diabetic complications. Lymphoma was the cause of death in 76% of patients. The Eindhoven Cancer Registry was examined to determine severity of comorbidity among older patients (median, 64 years) in the Netherlands (Janssen-Heijnen et al. 2005). In aggressive NHL patients, comorbidities were present in 48% of those <60 years of age and 78% of older patients. The likelihood of receiving chemotherapy for patients >60 years of age was only a third that of younger patients ($p = 0.05$). Among patients with cardiovascular comorbidity, the likelihood of receiving chemotherapy was only 40% compared to those without such comorbidity ($p = 0.04$). Likewise, receipt of CHOP-like chemotherapy was 40% for those >60 years of age compared with younger patients, after adjustment for gender, stage, and severity of comorbidity. Dose reductions were not more common in the elderly and did not occur more frequently among patients with high impact comorbidity. Hematologic toxicity was the most common reason for dose reduction. There was no difference in spectrum and incidence of toxicity comparing older and younger patients. Severity of comorbidity had no significant impact on toxicity occurrence, except for patients with cardiovascular comorbidity. In aggressive NHL, 3-year crude survival was 62% for patients age 40–60 years, and 41% for those >60 years. Survival decreased significantly with increasing IPI risk score and was significantly lower for patients with high-impact comorbidity.

With regard to cardiovascular comorbidity, certain agents as the anthracyclines have potential cardiotoxicities, including QT prolongation, myocardial ischemia, and congestive heart failure (CHF) (Aapro et al. 2011). In a Surveillance, Epidemiology, and End Results (SEER) Medicare database study, any doxorubicin use was associated with a 29% risk of CHF (Hershman et al. 2008). CHF risk increased with number of doxorubicin claims, increasing age, prior heart disease, comorbidities, diabetes, and hypertension. Patients with prior heart disease were less likely to receive doxorubicin. Those with hypertension and diabetes had 58% and 27% greater risks of developing CHF. Advanced age was predictive both for withholding doxorubicin and subsequent CHF. Those >80 years had more than twice the CHF risk as patients 65–70 years of age. In a recent publication, treatment-naïve DLBCL patients (median age 65 years) were randomized to initial therapy with R-CHOP or the same regimen with non-pegylated liposomal (NPL) doxorubicin substituted for doxorubicin (Fridrik et al. 2016). In patients with normal cardiac function, six cycles of R-CHOP had low rates of cardiotoxicity, and NPL-doxorubicin did not reduce cardiotoxicity. Screening evaluation of patients to receive cardiotoxic drugs should include assessment of risk factors as hypertension, atherosclerotic cardiovascular disease, diabetes, CHF, prior exposure to cardiotoxic drugs or thoracic radiation, and baseline electrocardiogram and either echocardiogram or MUGA scan (Eschenhagen et al. 2011). Cumulative upper doses of anthracyclines should not be exceeded (i.e., 400–450 mg/m^2 for doxorubicin; 140 mg/m^2 for mitoxantrone), and cardiac function should be serially monitored. The utility of troponins or brain natriuretic peptide for prediction and monitoring of cardiotoxicity is not clear. Potential cardiotoxicity of novel targeted agents should also be considered. In another single institution analysis of patients ≥80 years of age, 87% had at least one comorbidity, with cardiovascular disease being most common (Thieblemont et al. 2008). Stratification of patients by Charlson comorbidity index (CCI) was 0 (13.7%), 1–2 (36.6%), 3–4 (33.7%), and >4 (15.1%). Anthracycline-based therapy was administered in 32% of aggressive lymphoma patients. Lymphoma was the predominant cause of death (57.5%), with comorbidity accounting for 13.7%.

Renal dysfunction is common in the elderly and impacts choice of therapeutic agents (Nabhan et al. 2012). Recommendations for chemotherapy dosing of older patients with renal insufficiency have been published as an International Society of Geriatric Oncology (SIOG) task force guideline (Lichtman et al. 2007; Launay-Vacher et al. 2007). Additional study is needed to determine which of the available creatinine clearance

formulae (modification of diet in renal disease (MDRD), Cockcroft-Gault) is most accurate in older patients (Marx et al. 2004). Evaluation of renal function in extreme obesity or cachexia is often not valid. Most drugs utilized for DLBCL therapy as cyclophosphamide, vincristine, doxorubicin, and bendamustine have limited renal elimination, thus dose adjustments are not necessary. Nephrotoxicity of platinum derivatives limits their usage. Appropriate hydration is warranted.

Chemotherapy-induced peripheral neuropathy (CIPN) is a potential toxicity of several drugs utilized for DLBCL therapy, as platinum derivatives, taxanes, vinca alkaloids, and lenalidomide. Monitoring of neuropathy and hearing loss are recommended. There are no age-specific guidelines for dose reduction of these agents in the elderly/frail. The occurrence of CIPN is influenced by cumulative dose, co-administration of neurotoxic drugs, and presence of predisposing factors as diabetes or alcohol abuse. No agents have proven effectiveness in prevention of CIPN (Argyriou et al. 2012).

Dementia is also a significant issue in oncology care (Lichtman 2006; Extermann 2005). Cognitively impaired patients have markedly reduced survival compared to nonimpaired patients (Wolfson et al. 2001). In a SEER colon cancer database review, patients with dementia are significantly less likely to have undergone histologic diagnosis, be offered surgical resection, or adjuvant chemotherapy. The risk of toxicities that can cause delirium, as diarrhea, dehydration, or fever, is higher in impaired patients. Elective surgery is markedly preferred to emergency surgery in such patients, with improved outcome including markedly decreased mortality (Kemeny 2004).

Comprehensive Geriatric Assessment and Measures of Frailty

A multidimensional approach to geriatric assessment, incorporating functional capacities, comorbidities, cognitive function, social support, emotional status/depression, nutritional status, and polypharmacy, is important to assess biological-physiologic age, which is more important than chronological age in choosing treatment regimens and predicting tolerance to therapies. Measures as KPS/PS, ADL, and IADL are limited in scope and ability to assess multiple domains, subjective, and not good predictors in the elderly. The comprehensive geriatric assessment (CGA) is a fundamental tool in care of geriatric patients, with components of including functional assessment, comorbidities, nutritional status, cognitive function, psychological state, social support, and medication review (Table 2). Incorporation of the CGA into oncology practice has been limited by logistic and resource constraints. Hurria et al. has developed a CGA that is self-administered and feasible in the outpatient setting, with assessment across multiple domains (Hurria et al. 2011). This tool is currently being validated in both a larger prospective study and the oncology cooperative group setting. In utilizing components of CGA to better assess PS, Siegel et al. selected three functional tests validated in older populations and readily applicable in clinic, specifically "timed up and go," hand grip, and "Tinetti gait and balance test," to improve functional status assessment (Siegel et al. 2006). Screening tools, as the vulnerable elders survey (VES-13), to identify those at-risk individuals in need of more formal CGA, require prospective oncologic validation. A SIOG task force concluded that although CGA should be utilized for elderly oncology patients, a specific CGA tool cannot be recommended given available data (Extermann et al. 2005).

Table 2 Components of a comprehensive geriatric assessment

Performance status
Assessment of activities of daily living (ADL), instrumental ADL (IADL)
Comorbidities
Functional assessment
Fitness/frailty
Nutritional status
Cognitive function
Psychological state
Social support
Polypharmacy

An abbreviated geriatric assessment has been used in some NHL series. Winkelmann et al. evaluated 143 patients, median age 63 years (29% ≥70 years), and found that comorbidity and dependence in IADL were associated with overall survival, irrespective of lymphoma subtype or therapy (Winkelmann et al. 2011). Tucci et al. evaluated patients age ≥ 65 years with CGA prior to therapy, with following treatment decisions for aggressive or palliative therapy made solely by clinical judgment (Tucci et al. 2009). As CGA was able to differentiate fit versus unfit patients better than clinical judgment, they concluded that CGA is an appropriate measure to identify patients that can receive anthracycline-based therapy. In another series, doses of rituximab-based combination chemotherapy in elderly patients were adjusted based upon a modified CGA, reflecting comorbidities and activities of daily living (ADL) and instrumental IADL scores (Spina et al. 2012). More recent reports in DLBCL patients at least 70 years of age, in which measures as ADL, IADL, mini mental state examination, mini nutritional assessment, and cumulative illness rating scale were employed, found that underperformance in geriatric assessment was associated with increased mortality rates (Aaldriks et al. 2015; Tucci et al. 2015; Goede and Schulz 2015). Some, but not all, mortality was lymphoma-related, complicating these findings. Such algorithms should ideally reflect treatment feasibility and adherence, as well as the mortality endpoint, for more useful application in prospective treatment decisions.

Although there is no single definition of frailty, suggested criteria include age > 85 years, dependence in ADL, exhaustion, slow gait speed, decreased hand grip, unintentional weight loss, and decreased physical activity. These patients may have an increased incidence and severity of therapy-related toxicities, shortened survival, and may be candidates for supportive care. However, further delineation of frailty is needed, such that patients who still have remaining functional reserve are not withheld from active treatment (Balducci 2007, 2009; Balducci and Beghe 2000; Fried et al. 2001). Data has been reported from an elderly DLBCL series in which CGA identified 99 frail patients who received a variety of treatment regimens (Merli et al. 2014). Age-adjusted IPI of 2–3 and respiratory comorbidity were the only factors predictive for OS, with 5-year OS of 28%. Outcome in frail patients was poorer with rituximab-containing therapy than in fit patients.

Supportive Care Issues in the Elderly

The occurrence of chemotherapy-related toxicities has been reported from series specifically in older adults (Hurria et al. 2011; Extermann et al. 2012). A 53% incidence of grade 3–5 toxicities was reported in a series of 500 patients (mean age 73 years) receiving solid tumor chemotherapy, with pretreatment assessment including CGA, disease, laboratory, therapy-related parameters, and sociodemographics (Hurria et al. 2011). Using these pretreatment variables, a three-tiered risk-scoring system predictive of toxicity occurrence was developed. From a series of 518 patients ≥70 years planned to receive chemotherapy, a CRASH (chemotherapy risk assessment scale for high-age patients) score was prospectively developed (Extermann et al. 2012). These multidimensional risk assessment tools are useful in pretreatment evaluation of older patients, to guide dose adjustment and supportive care measures.

Older patients are at greater risk of febrile neutropenia (FN) and FN hospitalization, with its resultant increased morbidity, mortality, length of stay, and cost (Kuderer et al. 2006; Chrischilles et al. 2005). Risk is greatest in early chemotherapy cycles, with consideration of supportive care measures being warranted (Lyman et al. 2011; Balducci and Repetto 2004). Treatment outcomes may also be impacted upon by subsequent dose reductions (Lyman et al. 2011; Lyman and Delgado 2003). In one study, 17% of patients had at least one FN hospitalization, and more than 50% such hospitalizations occurred in cycles 1 or 2 of therapy. Increased risk of FN hospitalization was associated with the following baseline characteristics: age ≥ 65 years, serum albumin ≤3.5 g/dL, planned average relative dose

intensity ≥80%, baseline absolute neutrophil count (ANC) <1500/mm3, and presence of hepatic disease. Lack of early myeloid growth factor usage in Cycles 1 and 2 was also associated with a trend for increased risk of FN hospitalization. A composite risk score delineated patients at greater risk of FN hospitalization, including age > 65 years, hepatic dysfunction, renal insufficiency, and receipt of prior chemotherapy.

An Oncology Practice Pattern Study reviewed records of predominantly community-based intermediate-grade lymphoma patients receiving initial CHOP chemotherapy, and identified in multivariate analysis the following factors associated with time to first FN event: age ≥ 65 years, cardiovascular disease, renal disease, baseline hemoglobin <12 g/dl, >80% planned average relative dose intensity (ARDI), and no prophylactic myeloid growth factor use. (Lyman et al. 2003). Among patients having an FN event, half had initial occurrences by day 14 of cycle 1 of therapy. In a following study of treatment-naive elderly patients randomized to CHOP or R-CHOP therapy on the US intergroup trial, one or more FN episodes occurred in 41% of patients, with FN most often in cycle 1 (38% of events) (Morrison et al. 2017). In multivariate analysis, risk factors for FN included age > 65 years and anemia (hemoglobin <12 g/dl). Another large observational study of 1113 DLBCL receiving R-CHOP-14 OR -21 therapy reported higher FN rates in those patients ≥65 years of age, and poor adherence to FN guidelines in high risk patients (Lugtenburg et al. 2012). Models as these can be prospectively used to identify patients at greatest risk of FN and for whom prophylactic myeloid growth factor usage is best utilized.

Guidelines for myeloid growth factor usage have been developed. The European Organization for Research and Treatment of Cancer (EORTC) guidelines recommend that adverse FN risk factors, including age ≥ 65 years, be assessed prior to each treatment cycle (Aapro et al. 2006). When using regimens associated with ≥20% FN risk or dose-dense regimens, prophylactic myeloid growth factor use is recommended. When using regimens associated with 10–20% FN risk, particular attention should be given to patient-related factors that may increase such risk. Also, if reductions in dose intensity are associated with poorer prognosis, primary myeloid growth factor prophylaxis may be used to maintain full-dose therapy. According to the American Society of Clinical Oncology (ASCO) guidelines, myeloid growth factor use is likewise recommended when the FN risk is ≥20% and no other comparably effective regimen not requiring myeloid growth factor support is available (Smith et al. 2006). Primary prophylaxis is recommended in high risk patients based on age, medical history, disease variables, and therapy-related myelotoxicity. Prophylactic myeloid growth factors for DLBCL patients aged ≥65 years receiving curative regimens as R-CHOP should be utilized to reduce FN and infection incidence.

There are no specific recommendations for the use of erythrocyte stimulating agents (ESA) in older patients. Both ASCO and American Society of Hematology recommend that for patients receiving myelosuppressive chemotherapy with a hemoglobin <10 g/dL, there should be a discussion of potential harms (i.e., thromboembolic complications, shorter survival) and benefits (i.e., fewer transfusions) of ESA, with comparison to potential harms (i.e., infection, immune-mediated reactions), and benefits (i.e., rapid hemoglobin rise) of red cell transfusions (Rizzo et al. 2010a, b). ESA should be given at the lowest possible dose and discontinued after 6–8 weeks of use in nonresponders. Patients not actively receiving chemotherapy should not receive ESA, except those with low-risk myelodysplastic syndromes. They should be used with caution with treatment agents associated with an increased risk of thromboembolism.

Initial Therapy of DLBCL in the Elderly

For decades, cyclophosphamide, adriamycin, vincristine prednisone (CHOP) chemotherapy was the standard treatment for DLBCL, with complete response (CR) rates of 50% in patients age 65–75 years, and 40% in those >75 years (McKelvey et al. 1976; O'Reilly et al. 1997; Connors and O'Reilly 1997). Median remission

duration was 16 months; 50–60% of younger, and 25–30% of older, patients achieved cure. CHOP therapy became standard based on a randomized trial comparison to other regimens (m-BACOD, Pro-MACE-CytaBOM, MACOP-B), with no significant difference in efficacy (CR rate, progression-free [PFS] and overall survival [OS]), but a more favorable toxicity profile (Fisher et al. 1993). Outcome of older patients receiving full dose anthracycline-based chemotherapy was similar to younger patients. However, more toxicities and deaths from intercurrent illnesses were found in some reports (Ballester et al. 1993; Armitage and Potter 1984; Vose et al. 1988; Solal-Celigny et al. 1987; Tirelli et al. 1988; O'Connell et al. 1986). The feasibility of delivering full dose CHOP therapy to elderly patients with myeloid growth factor support was demonstrated (Campbell et al. 1999; Sonneveld et al. 1999; Jacobson et al. 2000). Subsequent trials examined the role of anthracyclines, etoposide, and alternative CHOP dosing for older patients, demonstrating the importance of anthracyclines and greater toxicity with etoposide. (Meyer et al. 1995; Sonneveld et al. 1995; Bastion et al. 1997; Tirelli et al. 1998; Pfreundschuh et al. 2004) (Table 3). These included randomization to CHOP-14 versus CHOP-21 (CR, 70% vs. 60%, respectively), as well as CHOEP-14 (CHOP plus etoposide) or CHOEP-21 (CR, 72% vs. 76%, respectively).

In the past decade, initial rituximab(R)-CHOP therapy for older DLBCL patients, as well as younger with favorable prognostic characteristics, was established as standard-of-care (Table 4) (Coiffier et al. 2002, 2010; Habermann et al. 2006; Feugier et al. 2005; Vose et al. 2001; Sehn et al. 2005; Morrison et al. 2010). In the GELA (Groupe d'Etude des Lymphomes de l'Adulte) trial, treatment-naïve DLBCL patients, age 60–80 years, were randomized to R-CHOP (rituximab on day 1 each cycle) or CHOP therapy, with CR rates of 76% and 63% (p=0.005), 10-year PFS of 36.5% and 20%, and 10-year OS of 43.5% and 27.6%, respectively (Coiffier et al. 2002, 2010; Feugier et al. 2005). Eight cycles of R-CHOP/CHOP therapy were administered to 80% and 72% of patients, respectively. Deaths due to other causes, secondary malignancies, and late relapses were comparable among the two groups. The benefit of R-CHOP (two doses of rituximab prior to cycle 1, and a single dose prior to cycles 3, 5, and 7) was also demonstrated in the US intergroup trial (Habermann et al. 2006). Responding patients (CR, partial response [PR]) had a secondary randomization to maintenance rituximab (weekly for 4 weeks, repeated every 6 months for 2 years) or observation. Overall

response rate (ORR) to induction therapy was comparable (R-CHOP, 77%; CHOP, 76%). With median follow-up of 9.4 years, the 9-year failure-free survival (FFS) was 35% (R-CHOP) and 25% (CHOP) ($p = 0.008$) (Morrison et al. 2010). Maintenance rituximab led to prolonged FFS following CHOP ($p = 0.003$), but any benefit was abrogated with R-CHOP induction ($p = 0.79$). Maintenance rituximab had no significant impact on OS (9-year OS: R-CHOP, 44%; CHOP, 37%, $p = 0.11$). With CHOP induction, median time to treatment failure (TTF) was 9.5 years with maintenance rituximab and 2.0 years with observation ($p = 0.003$). However with R-CHOP induction, median TTF was comparable with maintenance rituximab or observation (8.5 and 7.5 years, respectively, $p = 0.79$). At least six cycles of induction therapy were administered to 79% of patients.

In the RICOVER-60 trial, patients age 61–80 years were randomized to six or eight cycles of R-CHOP-14 or CHOP-14, with CR rates after six cycles of 78% and 68%, respectively (Pfreundschuh et al. 2008). Three-year event-free survival (EFS) was 67% and 47%, respectively. Benefits were also seen in PFS (73% versus 57%, $p = 0.0001$) and OS (78% versus 68%, $p = 0.0181$, respectively). Median relative doses of myelosuppressive agents received was ≥95%. Outcome was no better with eight, versus six, cycles of therapy. When CHOP-14 patients were divided into high-risk (age > 75 years and performance status [PS] >3) and standard-risk (age 60–75 years and PS < 3, or age < 60 years) subgroups, hospitalizations were more common in the high-risk group (88% vs. 68%), mainly due to infection, malnutrition, and declining PS (Tholstrup et al. 2007). The issue of central nervous system (CNS) relapse was also examined in the RICOVER-60 trial (Boehme et al. 2009). CNS prophylaxis (intrathecal methotrexate, days 1 and 5, of cycles 1 and 2) was given to patients with marrow, testicular, and upper neck/head involvement. Risk factors for CNS disease were involvement of >1 extranodal site and B-symptoms. However, with the addition of rituximab, the relative rate of CNS disease was reduced, and intrathecal prophylaxis was not beneficial except for those with testicular involvement. In the subsequent SMARTE-R-CHOP-14 trial, two doses of rituximab were administered prior to six cycles of R-CHOP (Pfreundschuh et al. 2014a). Overall, no outcome advantage was seen as compared to the RICOVER-60 results. However, in the poor prognosis patients, 3-year EFS and OS were prolonged with the added rituximab (67% versus 54%, and 80% versus 67%, respectively).

Although dose dense therapy appeared advantageous, a prospective comparison of R-CHOP-21 and R-CHOP-14 was necessary to confirm any potential benefit (Delarue et al. 2013; Cunningham et al. 2013). The GELA trial included patients aged 60–80 years with at least one other adverse prognostic factor (Delarue et al. 2013). With median follow-up of 56 months, neither 3-year PFS (R-CHOP14, 60%; R-CHOP21, 62%, $p = 0.04$) nor 3-year OS (69% and 72%,

respectively, $p = 0.7487$) differed by treatment; toxicity profile was comparable. In another trial of patients of age 18–88 years (56% >60 years), no efficacy differences were seen (2-year OS 83% with R-CHOP-14, 81% with R-CHOP-21), but grade 3/4 thrombocytopenia, febrile neutropenia, and infection were more common with R-CHOP-14 (Cunningham et al. 2013).

Risk factors for early death in older patients receiving rituximab-based regimens have been examined in SEER-Medicare databases (Olszewski et al. 2016). Among 5530 patients of median age 76 years, of whom 94% received anthracycline-based regimens, at 30 days the cumulative incidence of death was 2.2%, and the incidence of hospitalization was 23.5%. The most common causes of death were lymphoma (72%), cardiac disease (9%), and septicemia (3%). Risk factors for early death were age $\geq$ 75 years, B-symptoms, chronic kidney disease, poor functional status, prior use of walking aids or wheelchairs, and prior hospitalization or upper endoscopy. Use of myeloid growth factor support decreased early deaths in those at highest risk.

Subsequent trials have attempted to improve on the outcome achieved with R-CHOP. In a phase II trial of 64 patients (median age 68 years) treated with R-CHOP plus bevacizumab, there was no improvement in PFS, and grade $\geq$ 3 toxicities, including cardiac and gastrointestinal perforations, occurred in 81% of patients (Stopek et al. 2012). The addition of bortezomib to R-CHOP therapy has been examined in several phase II trials (Ruan et al. 2010; Offner et al. 2015). In one, with 40 DLBCL patients of median age 56 (range, 20–87) years, CR rate was 75%, with 2-year PFS and OS of 64% and 70%, respectively (Ruan et al. 2010). Outcome was similar in non-germinal center (GCB) and GCB subtypes. Another trial in which bortezomib was substituted for vincristine (VR-CAP) and compared to R-CHOP in 164 patients (median age, 59 years, with 32% >65 years) with non-GCN DLBCL, found no differences in CR rate, PFS, OS, and grade $\geq$ 3 adverse events (Offner et al. 2015). Lenalidomide plus R-CHOP therapy (R2CHOP) has also been examined (Nowakowski et al. 2014; Vitolo et al. 2014). In one study in which 64 patients, median age 65 (range, 22–87) years, received lenalidomide, 25 mg daily on days 1–10 with R-CHOP, overall response rate (ORR) was 98% (CR, 80%), with 2-year EFS and OS of 59% and 78%, respectively (Nowakowski et al. 2014). There was no difference in EFS and OS on the basis of non-GCB and GCB phenotype. A second trial was confined to 49 patients age 60–80 years, with 15 mg of lenalidomide given daily on days 1–14 with R-CHOP, with an ORR of 92% (86% CR) and a tolerable toxicity profile (Vitolo et al. 2014). Preliminary data on the combination of daily ibrutinib plus R-CHOP in a phase 1b study has been reported (Younes et al. 2014). Of the 18 DLBCL patients, all responded with CR rates in those of GCB and non-GCB subtypes of 71% and 100%, respectively.

The addition of etoposide to R-CHOP (dose-adjusted [DA]-EPOCH-R) has been studied in several phase II and III trials (Wilson et al. 2012; Garcia-Suarez et al. 2013; Purroy et al. 2015; Wilson et al. 2016). From a series of 69 patients, median age 58 (range, 23–83) years, 84% achieved a CR, and with median follow-up of 62 months, TTP and OS were 81% and 84%, respectively (Wilson et al. 2012). However, TTP and OS were more favorable in those with GCB versus non-GCB phenotype (100% and 94% versus 67% and 58%, $p = 0.008$, respectively). The regimen was well-tolerated with no significant non-hematologic grade 4 toxicities. A 2-week DA-R-EPOCH-14-like regimen was studied in 20 patients of median age 55 (range, 19–70) years, and compared to a similar population receiving the regimen every 3 weeks (Garcia-Suarez et al. 2013). Toxicity was manageable, and 3-year PFS was better with the 2-week regimen (95% versus 74%, $p = 0.08$). Another phase II trial of DA-EPOCH-R including 68 DLBCL patients found that patients with BCL2 rearrangement had a poorer outcome than those of ABC or GCB subtypes without this rearrangement (Purroy et al. 2015). Lastly, results of the large phase III intergroup trial comparing therapy with R-CHOP versus DA-EPOCH were recently reported (Wilson et al. 2016). Outcomes were similar, with 3- and 5-year EFS of 79% and

66% with DA-EPOCH-R, and 81% and 69% with R-CHOP. Three-year OS was 85% in both arms. However, grade 3/4 hematologic toxicities, febrile neutropenia, and sensory/motor neuropathy were more frequent with DA-EPOCH-R.

Alternative approaches to R-CHOP-21 for more frail and/or elderly patients have been examined, primarily in phase II trials (Table 5) (Visani et al. 2008; Corrazelli et al. 2011; Peyrade et al. 2011, 2017; Hasselblom et al. 2012; Merli et al. 2012; Musolino et al. 2011; Hainsworth et al. 2010; Zinzani et al. 2010; Fields et al. 2014; Monfardini et al. 2005; Soubeyran et al. 2011; Murawski et al. 2014; Weidmann et al. 2011; Walter et al. 2012). Dose-attenuated regimens as R-miniCHOP, DA-POCH-R, epirubicin, cyclophosphamide, vinblastine, prednione, rituximab (R-miniCEOP), and ofatumumab plus reduced dose CHOP have been both safe and efficacious in older patients (Peyrade et al. 2011, 2017; Hasselblom et al. 2012; Merli et al. 2012; Musolino et al. 2011). Other alternative regimens studied have included liposomal doxorubicin; induction R-CNOP or R-CVP for three cycles followed by maintenance rituximab in responders; four cycles of R-CHOP followed by ^{90}Y-ibritumomab tiuxetan; substitution of gemcitabine for anthracyline in a R-CHOP-like regimen; vinorelbine plus prednisone; and COP (Visani et al. 2008; Corrazelli et al. 2011; Hainsworth et al. 2010; Zinzani et al. 2010; Fields et al. 2014; Monfardini et al. 2005; Soubeyran et al. 2011). Use of dose-dense rituximab in patients aged 60–80 years did not result in an improved outcome compared with R-CHOP and had increased infectious toxicities, limiting its utility (Murawski et al. 2014). Bendamustine-rituximab (BR) has been examined in small series (Weidmann et al. 2011; Walter et al. 2012; Park et al. 2016). An ORR of 69% (CR 54%) to BR with favorable toxicity profile was demonstrated in very elderly patients (Weidmann et al. 2011). Another retrospective study examined BR as an alternative to R-CHOP in unfit DLBCL patients (Walter et al. 2012). In a recent publication in patients of median age 80 years with 52% having a PS of $\geq$2, although ORR was 78% (CR 52%), survival was short (median PFS and OS of 5.4 and 10.2 months, respectively (Park et al. 2016).

Initial "prephase treatment" with prednisone for 7 days, given alone or with 1 mg of vincristine, may be considered for DLBCL patients of all ages, but especially for the more frail elderly (Pfreundschuh 2010). An alternative prephase option is oral cyclophosphamide (400 mg on days 1, 3, 5). Use of such treatment decreases first cycle depth and duration of neutropenia, tumor lysis, and therapy-associated deaths with R-CHOP-based therapy. The benefit of prephase treatment should be weighed against preexisting comorbidities as diabetes.

In summary, six cycles of R-CHOP-21 therapy should be offered to fit older patients, with appropriate supportive care measures, as it has been demonstrated in large phase III trials that the majority of elderly patients are able to receive full-dose therapy. The use of geriatric assessment tools will be important in evaluating older/frail patients and choosing appropriate therapies. For very elderly (>80 years) patients or those unfit for R-CHOP-21, regimens with alternative agents or dose reductions demonstrate efficacy and tolerability. Such treatment, with appropriate supportive measures and close toxicity monitoring, can be more than palliative and add meaningful quality and quantity of life.

Treatment Approaches for Limited Stage Disease or Bulky Disease

Approximately 25–30% of DLBCL patients present with limited stage disease, defined as stage I or nonbulky stage II (<10 cm in greatest diameter) disease (Armitage and Weisenburger 1998). Despite treatment with involved field radiation therapy (IFRT) with CR rates approaching 90%, 5-year disease-free survival (DFS) for stage I and II disease was 50% and 20%, respectively, with relapses common outside the radiation field and in extranodal sites (Kaminski et al. 1986; Vaughan Hudson et al. 1994; Chen et al. 1979; Reddy et al. 1977; Spicer et al. 2004). Presently, sole use of IFRT may be considered for patients unfit for chemotherapy.

Trials in the pre-rituximab era included a Southwest Oncology Group (SWOG) trial in

Table 5 First-line therapy for DLBCL in older patients: alternative regimens from phase II/III trials

Reference	Therapy (*n*)	Median, age, years (range)	% pts. ECOG-PS ≥2	Efficacy	Reasons for non-CHOP therapy
Visani et al. (2008)	R-COMP-21 (20)	73 (61–82)	45%	ORR 90% CR 65%	Cardiac issues Frailty

PS = performance status; ORR = response rate; CR = complete response; DFS=disease-free survival; EFS = event-free survival; PFS = progression-free-survival; OS = overall survival

which 400 patients (median age 59 years) with stage I (68%), IE, or nonbulky stage II/IIE disease were randomized to eight cycles of CHOP or three cycles of CHOP followed by IFRT (Miller et al. 1998). In 5-year follow-up, the combined modality arm was more favorable than CHOP alone (5-year PFS 77% and 64%, $p = 0.03$; 5-year OS 82% and 72%, $p = 0.02$, respectively). However, the curves overlapped for PFS at 7 year follow-up, and for OS at 9 years, due to lymphoma relapses in the combined modality group (Miller et al. 2001). With adverse risk factors of stage II disease, elevated LDH, PS 2, and age > 60 years, 5-year OS was 95%, 77%, and 50%, for 0, 1–2, or 3 risk factors, respectively ($p = 0.01$). Five-year OS in bulky stage II disease patients (49%) was similar to that of advanced stage patients, supporting similar treatment approaches. Now with median follow-up of 17.7 years, there are no differences in PFS and OS with either approach, nor in the cumulative incidence of second malignancies (Stephens et al. 2016). Stage II/IIE disease replaced advanced stage disease in the Miller modification of the IPI (Miller 2004). In a retrospective review of 308 patients (median age 64 years) with stage I (61%) or nonbulky IIA disease who received three cycles of anthracycline-based therapy followed by IFRT, similar outcomes were seen using the Miller-modified IPI, with 5- and 10-year PFS of 94%/89% (no risk factors), 79%/73% (1–2 factors), and 60%/50% (3–4 factors); corresponding OS was 97%/89% (no factors), 77%/56% (1–2 factors), and 58%/48% (3–4 factors) (Shenkier et al. 2002).

The impact of IFRT consolidation following chemotherapy has been examined (Horning et al. 2004; Shikama et al. 2006; Reyes et al. 2005; Bonnet et al. 2007). In an ECOG trial, eight cycles of CHOP was followed by observation (n = 179) or consolidative IFRT (n = 173) achieving a CR (n = 219; 61%) or PR (n = 98; 28%)]; all PR patients received IFRT (Horning et al. 2004). Although 31% of PR patients converted to CR following IFRT, this did not impact relapse rate or OS. Comparing CR patients with CHOP and observation versus CHOP followed by IFRT, 6-year DFS was 56% and 73% ($p = 0.05$), and 5-year OS was 73% and 73% ($p = 0.24$), respectively, with no difference in 10- or 15-year OS. In another series of patients age > 70 years with stage IA/contiguous IIA nonbulky disease, three cycles of reduced dose CHOP followed by IFRT resulted in 3-year PFS and OS of 83% (Shikama et al. 2006). In a GELA trial, good risk patients (60–80 years of age, 95% with age-adjusted IPI of 0, 65% stage I, 35% stage II) received four cycles of CHOP followed by IFRT or observation, with no differences in toxicities or 5-year EFS and OS (64% and 61%, $p = 0.6$; 68% and 72%, $p > 0.05$, respectively) (Bonnet et al. 2007). Relapse patterns also varied between CHOP alone (47% exclusively initial disease site; 16% local and distant sites; 37% exclusively distant) and CHOP followed by IFRT (21%, 13%, and 66%, respectively).

Trials in the rituximab era sought to improve on survival with CHOP for three cycles followed by IFRT. In a phase II SWOG trial in which 60 patients (median age 69 years, 57% stage I disease, stage-modified IPI 1 in 70%) with ≥1 adverse risk factor received CHOP ×3 + IFRT, plus four doses of rituximab, 2- and 4-year PFS and OS were 93% and 88%, 95%, and 92%, respectively, at median follow-up of 5.3 years (Persky et al. 2008). Now with median follow-up of 12 years, 5 and 10 year OS are 82% and 67%, respectively, with a persistent pattern of relapse despite the addition of rituximab (Stephens et al. 2016). More recently, a series of 874 limited stage DLBCL patients at least 66 years of age identified through Surveillance, Epidemiology, and End Results (SEER) data who received three to four cycles of R-CHOP followed by IFRT (n = 359) or six to eight cycles of R-CHOP alone (n = 515) was examined (Odejide et al. 2015). Those receiving R-CHOP followed by IFRT had a lower likelihood of receiving second line therapy and of febrile neutropenia occurrence, compared to R-CHOP alone. However, OS was comparable in both groups, suggesting that R-CHOP + IFRT may be better tolerated in the elderly than a full course of R-CHOP.

The role of radioimmunotherapy with conjugated antiCD20 antibodies was examined in several studies (Miller et al. 2008; Witzig et al. 2015; Friedberg et al. 2014). In one, 44 patients (median age 61 years, 48% stage I disease; stage-modified IPI of 1 (66%), 2 (25%), 3 (9%)] received CHOP

×3, followed by IFRT and yttrium-90 ibritumomab tiuxetan (zevalin) consolidation (Miller et al. 2008). With a 2-year median follow-up, 2-year PFS and OS were 92% and 95%, respectively. In an ECOG study, four to six cycles of R-CHOP was followed by ibritumomab tiuxetan consolidation, and by IFRT if residual disease was present (Witzig et al. 2015). A CR was achieved by 89% of patients without the need for IFRT; 5 year PFS and OS were 78% and 94%, respectively. The impact of iodine-131 tositumomab consolidation following six cycles of R-CHOP, two cycles of CHOP, followed by I^{131} tositumomab consolidation was examined in patients with advanced or bulky stage II DLBCL patients in a SWG trial (Friedberg et al. 2014). With median follow-up of 3.9 years, 2-year PFS and OS were 69% and 77%, respectively. However, benefit from such consolidation is limited by early disease progression, deaths, and declining PS from induction therapy.

IFRT should be considered for improved local control and EFS for patients with bulky disease (≥10 cm) with equivocal positron emission tomography (PET) scan findings after chemotherapy (Pfreundschuh et al. 2006, 2011; Marcheselli et al. 2011; Held et al. 2014; Dorth et al. 2012; Phan et al. 2010; Ballonoff et al. 2008). The role of IFRT to bulky disease sites in elderly patients (age 61–80 years) was examined in the RICOVER-60 trial (Dorth et al. 2012). Patients receiving six cycles of R-CHOP, followed by two additional rituximab doses, then IFRT to sites of initial bulky (≥7.5 cm) disease and extralymphatic involvement, were compared with those who received such therapy without IFRT. EFS was superior with IFRT ($p = 0.005$), with trends toward superior PFS and OS, thus abrogating bulky disease as a risk factor. In the ongoing OPTIMAL >60 trial involving older DLBCL patients, the role of IFRT is being examined in those with a negative PET scan after induction therapy. In a retrospective review of 469 patients (40% limited, 60% advanced, stage disease) who received IFRT versus observation following R-CHOP, 5-year PFS (90% versus 75%) and OS (91% versus 83%) were superior with IFRT (Phan et al. 2010). In limited stage patients, corresponding 5-year PFS and OS were 82% and 92% versus 68% and 73%, respectively.

The role of PET scans was examined in limited stage patients, following three cycles of R-CHOP therapy (Sehn et al. 2008). Those who were PET-negative (74%) received a fourth cycle of R-CHOP; PET+ patients (26%) received IFRT. With median follow-up of 17 months, one PET-negative patient relapsed, and 2-year PFS and OS was 97%. In the PET-positive patients, 3 of 17 relapsed (all outside the radiation field), with 2-year PFS and OS of 83% and 76%, respectively. An ongoing trial is examining the role of IFRT in patients with PET-negative disease. The role of IFRT compared with involved node RT (INRT; radiation to pre-chemotherapy involved nodes with margins ≤5 cm) was studied in 288 limited stage (stage I/II, no B symptoms, bulk <10 cm) patients, of whom 56% were >60 years of age, 55% with extranodal disease, and 15% had received rituximab (Campbell et al. 2012). With median follow-up of 117 (IFRT) and 89 (INRT) months, there was no difference in TTP, PFS, or OS. The most common site of failure was distant relapse. Thus, reducing the radiation field size resulted in low marginal recurrence risk with no impact on outcome.

In summary, IFRT improves local disease control, with no excess therapy-related myelodysplasia. Second malignancy risk in the radiation field is 11–15%, but decreases with older age (Armitage et al. 2003; Mudie et al. 2006; Tward et al. 2006; Hemminki et al. 2008). Although the role for IFRT in advanced stage disease remains controversial, recent data suggests that it may benefit older patients with bulky disease.

Maintenance Therapy

Based upon data in indolent NHL, the potential role of maintenance therapy in DLBCL has been examined. Maintenance interferon alfa 2b therapy was studied in 223 DLBCL patients, half >65 years of age, with high- (80%) or high-intermediate (20%) IPI risk disease, who after attaining a CR with CHOP-bleomycin induction

were randomized to maintenance interferon (5 million units, three times weekly for a year) or observation (Aviles et al. 2001). With median follow-up of 45 months, no advantage to maintenance interferon was found. The estimated 5-year EFS and OS with maintenance therapy were 71% and 54%, respectively, compared with 69% and 54% with observation ($p = 0.2$). In another trial, 169 DLBCL patients with high-intermediate or high-risk IPI disease who achieved a CR to induction therapy were randomized to maintenance interferon alfa 2b, cyclophosphamide, and prednisone or to observation (Avilés et al. 2004). Again, no 5-year EFS and OS survival advantage was found (71% and 84% with maintenance, 63% and 83% with observation, respectively, $p = 0.2$).

The utility of maintenance rituximab was examined in the US intergroup trial, with 632 patients ≥60 years of age randomized to CHOP or R-CHOP induction therapy (Habermann et al. 2006; Morrison et al. 2010). The 451 responding patients (CR/PR) were then randomized to maintenance rituximab (weekly for 4 weeks, every 6 months, for 2 years) or observation. With median follow-up from induction and maintenance randomizations of 9.4 and 9.0 years, respectively, 9 year FFS and OS were 35% and 44% with R-CHOP, and 25% and 37% with CHOP, respectively (Morrison et al. 2010). Overall, maintenance rituximab resulted in prolonged FFS ($p = 0.014$), but not OS. Specifically, maintenance rituximab prolonged FFS after CHOP ($p = 0.003$), but not after R-CHOP induction, and had no impact on OS. Median time to failure (TTF) for CHOP plus maintenance rituximab and CHOP-observation was 9.5 and 2.0 years, respectively. With R-CHOP induction, median TTF was similar with maintenance rituximab or observation (8.5 and 7.5 years, respectively). PFS was improved in all IPI subgroups in 228 patients receiving R-CHOP induction followed by maintenance rituximab (monthly for a year, then every 3 months for the second year) (Huang et al. 2012). In another study, maintenance rituximab (weekly for 4 weeks, every 6 months for 2 years) was given to 51 elderly (median age 78 years) patients with no disease progression following three cycles of induction R-CNOP or R-CVP therapy (Hainsworth et al. 2010). With 4-year median follow-up, 2-year PFS and OS were 71% and 72%, respectively.

However, more recent data has suggested a potential role for maintenance rituximab in select patient subsets. In a phase III multicenter study, 683 patients (662 DLBCL, 21 follicular NHL grade 3B) achieving a CR with induction R-CHOP-like therapy were then randomized to maintenance rituximab (one dose every 2 months for 2 years) or observation (Jaeger et al. 2015). Overall, no advantage in EFS, PFS, and OS was seen with maintenance rituximab. However, in subgroup analysis, both EFS and PFS were superior in male patients rituximab maintenance receiving maintenance rituximab compared to observation (84.1% versus 74.4%, and 89.0% versus 77.6%, respectively). Those men with a low IPI index receiving rituximab maintenance had the best outcome. In another multicenter trial in which patients with CD20-positive B-cell NHL (152 with DLBCL) were randomized to maintenance rituximab (one dose every 3 months for 2 years) versus observation, 5-year relapse-free survival (RFS) was comparable in those with DLBCL (Witzens-Harig et al. 2015). However, men with DLBCL receiving rituximab maintenance had superior RFS and OS compared with observation (88% versus 74%, $p = 0.05$; 100% versus 88%, $p = 0.03$, respectively). The use of weekly rituximab "consolidation" (weekly for four doses) in responding patients following four cycles of R-CHOP induction was examined in 51 DLBCL patients >70 years of age (Jung et al. 2014). With median follow-up of 20.3 months, 2-year PFS and OS were 63.9% and 68.7%, respectively. In comparison to historical controls receiving six cycles of R-CHOP, such treatment was considered a reasonable compromise between safety and efficacy in this elderly population. The report that men >60 years of age have more rapid rituximab clearance than women does not explain these gender-based differences (Pfreundschuh et al. 2014b; Lunning and Armitage 2015).

In summary, although there is presently no proven role for rituximab maintenance in DLBCL induction therapy responders, recent

reports raise controversy on this issue (Lunning and Armitage 2015). There may be select subgroups, as the very elderly/frail not receiving full-dose induction therapy, or males with IPI <1, in which maintenance rituximab may confer benefit.

Management of Relapsed/Refractory DLBCL in the Elderly

Although significant advances have been made in DLBCL therapy, 30–40% of patients will have relapse or have refractory disease (Coiffier et al. 2002). These patients may be divided into three subgroups (Hamlin et al. 2003; Friedberg 2011). Primary refractory disease, with an approximate 10% incidence, is defined as <50% reduction in lesions or new lesions during induction therapy. These patients have a poor outcome, with reponses to salvage regimens uncommon. A second subgroup will achieve a PR with >50% reduction in measurable disease, but with persistent disease following induction. The third subgroup will relapse following an initial CR with induction therapy, with most relapses occurring within 2 years following induction treatment. Outcome is poor in those relapsing within a year of initial therapy. Relapsed DLBCL in the elderly is increasingly associated with non-germinal center (ABC phenotype) biology, with inferior outcomes (Feugier et al. 2005; Gisselbrecht et al. 2010; Thieblemont et al. 2011; Mareschal et al. 2011; Hans et al. 2004; Jais et al. 2008; Copie-Bergman et al. 2009). The second-line age-adjusted IPI (lactate dehydrogenase [LDH], stage, PS) may be utilized to predict outcome at relapse (Hamlin et al. 2003). In the elderly relapsed/refractory patient, treatment goals should focus not only on response but also disease control, symptom palliation, and quality of life, as durable remissions are uncommon. A minority may be suitable for high-dose salvage therapy followed by autologous stem cell rescue (HDT/ASCR) consolidation.

Patients Not Eligible for Transplant Approaches. For patients who are not transplant candidates, including most >70 years of age, induction therapy is the only curative option. In a recent meta-analysis, most salvage therapy studies have been single arm trials with small patient numbers (<50 patients), in which median OS ranged from 4–13 months (Colosia et al. 2014). At present, no standard salvage regimen has been established, with options including clinical trials (if available), single agent or combination therapies, or best supportive care, with decisions dependent on comorbidities, functional status, and goals of the given patient. Single agent rituximab has only modest activity, especially in those relapsing within 6 months of prior rituximab but may be considered in combination salvage regimens. In a GELA trial, relapsed patients had 2-year OS of 26% with median OS <9 months (Feugier et al. 2005). Those who relapsed late and had no prior rituximab had improved outcome with rituximab-containing salvage regimens, with a 2-year survival of 58%, versus 24% without rituximab ($p = 0.00067$). Toxicity concerns may limit use of R-ICE or R-DHAP in the salvage setting. However in a recent report, 32 patients (median age 75.6 years) with relapsed/refractory DLBCL who received dose-reduced ICE+/- rituximab in the salvage setting had an ORR of 53% (CR 41%) and median PFS and OS of 3.9 and 17 months, respectively, with good tolerability (Sarif et al. 2016). Other well-tolerated combination salvage regimens include CEPP(B), gemcitabine-based therapy (R-Gem-Ox), bendamustine, and CVP +/- rituximab (Rigacci et al. 2012; Horn et al. 2012; Chao et al. 1990; El Gnaoui et al. 2007; Corazzelli et al. 2009; Rodriguez et al. 2007; Yao et al. 2013; Weidmann et al. 2002; Vacirca 2009; Ohmachi et al. 2013; Coleman et al. 2008; Niitsu and Umeda 1997; Witzig et al. 2011; Zinzani et al. 2011; Witzig et al. 2009; Wiernik et al. 2008; Wang et al. 2013). In a small phase II trial of single agent bendamustine salvage therapy, ORR was 44% (CR, 17%) (Weidmann et al. 2002). The addition of rituximab to bendamustine (BR) resulted in a 51% ORR (CR, 15%) (Vacirca 2009). In another BR trial, ORR in patients ≥65 years of age was 62% (CR, 38%) (Ohmachi et al. 2013). Several oral regimens utilize single agent etoposide given continuously, and low dose "metronomic therapy" with prednisone, etoposide, procarbazine,

cyclophosphamide (PEP-C) (Coleman et al. 2008; Niitsu and Umeda 1997). Salvage single agent lenalidomide resulted in a 33% ORR and median response duration of 10 months (Witzig et al. 2009, 2011; Zinzani et al. 2011; Wiernik et al. 2008; Wang et al. 2013). Lenalidomide-rituximab therapy lead to an ORR 28% (CR, 22%) with median PFS and OS of 2.8 and 10.2 months, respectively, although grade 3/4 hematologic toxicities were common (Wang et al. 2013). Palliative radiation therapy to sites of symptomatic disease may also be considered. Treatment and supportive/palliative care guidelines for such elderly patients have been developed by organizations as NCCN, American Society of Clinical Oncology (ASCO), and International Society of Geriatric Oncology (SIOG) (Table 6) (Morrison et al. 2015a, b).

Transplant-Eligible Patients. There is limited data regarding HDT/ASCR in older patients. Feasibility of this approach is determined by functional as well as chronologic age, including assessment of comorbidities, activities of daily living (ADL), instrumental-ADL (IADL), and psychosocial support aspects. These aspects, as well as comprehensive geriatric assessment (CGA), are useful to predict overall risk of this treatment approach, as well as relapse risk, transplant-related mortality (TRM), and non-relapse mortality (NRM), which are higher in older patients (Guglielmi et al. 1998; Wildes et al. 2008; Charlson et al. 1994; Sorror et al. 2005; Raimondi et al. 2012; Hurria et al. 2011; Extermann and Hurria 2007; Deeg and Sandmaier 2010). patients reported a 5-year TRM rate was 15% and relapse rate was 66%, with DFS of 19% and OS of 30% (Lazarus et al. 2008). In a EBMTR review of 463 DLBCL patients ≥60 years of age at transplant, TRM was 1.6 times that of younger patients (Jantunen et al. 2008). Similar CIMBTR registry data found TRM to be 1.86 times that of younger patients (Lazarus et al. 2008). A 35% NRM was found in patients ≥70 year of age, compared to 8% in patients age 65–69 years. In a more recent single institution report in which 202 NHL patients (37% with DLBCL) of median age 65 (range, 60–74) years underwent HDT/ASCR, with median follow-up of 3.6 years, 3-year PFS and OS were 60% and 73%, respectively, with a 4% TRM rate (Dahi et al. 2014).

The impact of posttransplant rituximab, as compared with observation, has been reported in several randomized trials (Haioun et al. 2009; Gisselbrecht et al. 2012). Poor risk DLBCL patients, all <60 years of age, who received high-dose consolidative therapy followed by autologous transplant, were then randomized to four weekly doses of rituximab versus observation (Haioun et al. 2009). With median 4 year follow-up, there was a trend toward improved EFS in those receiving rituximab. In the Collaborative Trial in Relapsed Aggressive Lymphoma (CORAL) study, 242 patients were randomized to rituximab, given every 2 months for 1 year, or observation following transplant (Gisselbrecht et al. 2012). The 4-year EFS following transplant was comparable (52% and 53%, respectively). In the rituximab group, EFS was more favorable in women (63%) than in men (46%). Based upon these findings, this group did not recommend posttransplant rituximab in such patients.

In those older patients considered candidates for HDT/ASCR, there is no clear standard second-line therapy. Rituximab is often included in such regimens (Kewalramani et al. 2004; Vellenga et al. 2008). In the CORAL study, comparable response rates (ORR 63%) were achieved with R-ICE or R-DHAP (Gisselbrecht et al. 2010). Cisplatin-related nephrotoxicity and neurotoxicity with ifosfamide, both of which are age-dependent, are potential limitations with these regimens. Phase II trials have examined the utility of gemcitabine or oxaliplatin-based regimens (Gopal et al. 2010; Lignon et al. 2010; Rigacci et al. 2010). However with second line regimens, if the disease is not chemosensitive, outcomes are poor and consideration for clinical trials or supportive care is appropriate (Elstrom et al. 2010). In several small series of patients >70 years of age undergoing HDT/ASCR, long-term disease control (>1 year) was achieved in 48–59% (Elstrom et al. 2012; Andorsky et al. 2011). In the CORAL study, in which patients were with median age 55 (range, 19–65) years, 3-year PFS and OS were 37% and 49%, respectively (Thieblemont et al. 2011). Most relapses occurred following rituximab-based induction therapy, and within 1 year of prior therapy, with a 3-year PFS of only 23%, similar to EBMT registry data (Mounier et al. 2012).

Therapy of DLBCL in the Elderly – Conclusions

Despite treatment advances for older DLBCL patients based upon prospective randomized trials in the era of rituximab-based therapies, many patients are not eligible for such trials based on underlying comorbidities and functional deficits related to aging. Alternative regimens may be considered for those unable to tolerate R-CHOP due to comorbidities or frailty. There is presently no clear-cut role for maintenance therapy of DLBCL. In the relapse setting, only select elderly patients will be candidates for high dose treatment approaches, and treatment should be given with palliative intent in those who are not transplant candidates. Measures for more formal assessment of older patients are being developed, to include more facets than PS alone. Although potentially curative therapies should be offered to older patients when possible, pretreatment evaluation should include some formalized assessment and consideration not only of comorbidities but also of functional, social, and psychological constraints, such that safety and tolerability of a given regimen can be determined. Supportive care measures are of particular importance in the elderly. With the evolution of new novel agents, it is anticipated that continued advances will be made in the care of older DLBCL patients.

The Evolving Role of Transplant for Older Adults

37

Andrew S. Artz and Rebecca L. Olin

Contents

Abstract

In recent years, the number and percentage of both allogeneic and autologous transplants being performed in older patients has increased. These trends can be attributed to the aging of the population in general, but also improved transplant methodology making transplant safer and better tolerated. Uptake of allogeneic transplant, which is most commonly performed for acute myelogenous leukemia and myelodysplastic syndrome, has also been affected by the development of non-myeloablative conditioning regimens. Autologous transplants, most commonly performed for multiple myeloma and non-Hodgkin lymphoma, continue to play an important role in the care of the older patient, and in particular, for multiple myeloma, evidence exists to support the safety of melphalan-based autologous transplant well over the age of 70. The current challenge in the transplant field is to

understand which factors affect transplant outcomes, including disease-related and patient-related factors. While chronologic age plays a role in decision-making, physiologic fitness is likely more important. Increasing data exists to support the use of functional assessments, alone or as part of a comprehensive geriatric assessment. As well, any decision to proceed to transplant must consider the relative merits of nontransplant therapies.

Keywords
Transplantation · Stem cell · Allogeneic · Autologous

Introduction

The absolute number and relative percentage of hematopoietic stem cell transplants (HCT) performed for older patients have consistently increased over the years (Pasquini and Wang 2015; Hahn et al. 2013). In the 1990s, fewer than 10% of transplants were performed for older patients (≥50 years for allogeneic, ≥60 years for autologous). By contrast, in the more recent 2007–2013 era, 44% of autologous transplant recipients and 22% of allogeneic transplant recipients were at least 60 years of age. Moreover, the entire rise in the absolute numbers of HCT can be accounted for by patients 60 years or older.

Patients in their eighth decade of life now represent the area of fastest growth of allogeneic and autologous grafts and can have reasonable outcomes (Muffly et al. 2016; Auner et al. 2015). In a European registry of over 50,000 autologous transplants for multiple myeloma, patients aged 70 years and older represented 3% of transplants from 2006 to 2010 compared to only 1.1% one decade before (Auner et al. 2015). Similarly, Muffly reported in abstract form that 3.3% of allogeneic HCT reported to CIBMTR in 2012–2013 derived from this age group versus only 0.4% the decade before (Muffly et al. 2016).

Many factors underlie greater HCT utilization in older patients (Artz and Ershler 2010) (Table 1).

Table 1 Trends promoting hematopoietic cell transplant (HCT) for older adults

Characteristic	Example
Reduced intensity conditioning[a]	Fewer acute regimen-related toxicities
Peripheral blood stem cells	Reduces time to neutrophil engraftment Easier collection of hematopoietic cells for patients and older donors
Supportive care	
Infectious disease	Better infectious disease monitoring (e.g., CMV detection) and better treatments for opportunistic infections
Growth factors	Facilitate stem cell collection and reduce neutropenia phase post-HCT
Immunosuppression[a]	More tolerable immunosuppression reducing toxicity
Human leukocyte antigen (HLA) matching[a]	Better HLA matching reduces post-HCT complications
Donor registries[a]	Merging of registry databases electronically facilitates unrelated donor identification. Cord blood banks provide resource for unrelated cord blood
Patient health	Older adults have fewer disabilities and longer life expectancy allowing more intensive treatment
Societal attitudes	Patient and physician attitudes have shifted to expect life-prolonging treatment for older adults
Availability	More transplant centers and insurance coverage for older adults

[a]Restricted to Allogeneic HCT (Adapted from Artz and Ershler 2010)

Of note, while reduced intensity or non-myeloablative conditioning has been widely credited for the rise in allogeneic transplants, the parallel rise in autologous transplant (as myeloablative preparative regimens remain the rule) for older adults argues that other factors are at play. Improvements in supportive care, including infectious disease monitoring, prophylaxis, and treatment, have all played a key role in

expanding the use of both allogeneic and autologous transplants. Societal attitudes toward treatment of older adults are also changing. For allogeneic transplant, better HLA matching for unrelated donors has improved outcomes and availability of unrelated donors, contributing to this being the leading donor source in older patients. Finally, the demography of aging reveals an expanding number of older persons nationwide, who suffer a disproportionate burden of the incidence and mortality related to most hematologic malignancies.

Despite rising use of HCT for hematologic malignancies in older adults, only a small fraction of older patients with transplant-eligible diseases actually receive a transplant. Estimates of the percentage of older patients diagnosed with acute myeloid leukemia (AML) who ultimately undergo allogeneic transplant range from 0.8% to 6% (Ustun et al. 2013; Oran and Weisdorf 2012). Similarly, Yao estimated the utilization rate for unrelated allografts for all hematologic malignancies at 44%, 29%, and 8% among patients aged 20–44, 45–64, and 65–74 years, respectively, even after adjusting for lower rates of transplant eligibility in older adults due to comorbidities and induction mortality (Yao et al. 2013). Prospective studies of transplant in older adults and more widespread dissemination of transplant feasibility promise to further escalate utilization.

Allogeneic Transplantation

What Is the Effect of Increasing Age on Allogeneic Hematopoietic Stem Cell Transplant (alloHCT) Outcomes?

Older age historically prohibited transplant and modern evidence do still support worse outcomes in older versus younger transplant recipients. However, this gap may be narrowing. Depending on the approach used to answer this question, the question of whether increasing age affects transplant outcome is controversial and data are mixed.

In large registry studies or large database studies covering the entire age spectrum of adults, older age is consistently associated with worse transplant outcomes. The Center for International Blood and Marrow Transplant Research (CIBMTR) data demonstrates better one-year overall survival for alloHCT recipients <50 years versus ≥ 50 years, though the difference is 10% or less depending on whether the donor used is related or unrelated (Pasquini and Wang 2015). An analysis of 1853 patients aged 0.1–75 years and transplanted from 2000 to 2006 showed that risk of death not due to disease (a.k.a., nonrelapse mortality or NRM) still increases with older age. Using age groups of 20 year increments with the 0–19-year-old group as a reference point, NRM worsened over age 40 (Sorror et al. 2014).

On the other hand, smaller retrospective studies have evaluated the effect of recipient age, restricted to an older patient population, and found no difference of older age on alloHCT outcomes (Koreth et al. 2010; Sorror et al. 2011; Chevallier et al. 2012; McClune et al. 2010; Lim et al. 2010; McClune et al. 2014) (Table 2). The explanation for this discrepancy may lie in patient selection bias (older patients may be more closely scrutinized for transplant clearance) and small-moderate sample sizes of these retrospective studies. We believe for older adults consider fit for transplant, one should generally not exclude based on age alone, at least up to around age 75 years.

On a patient level, older adults have substantially worse nontransplant outcomes due to worse disease and/or greater nontreatment deaths. Studies of age differences within transplant cohorts do not inform the risks or benefits of the procedure for older patients.

Consideration of Treatment Alternatives: Transplant Versus Nontransplant Therapy

A decision to pursue allogeneic transplant for any patient must always be balanced against nontransplant alternatives and outcomes. Prospective studies comparing transplant to nontransplant

Table 2 Studies evaluating effect of age on allogeneic transplant outcomes

Study	Population	NRM	GVHD	OS
Koreth et al. (2010)	N = 158, aged 60–71, mixed indications	No effect	Lower risk of cGVHD in age > 65 vs 60–65	No effect
Sorror et al. (2011)	N = 372, aged 60–75, mixed indications	No effect	No effect	No effect
Chevallier et al. (2012)	N = 600, aged 60–71, mixed indications	No effect	No effect	No effect
McClune et al. (2010)	N = 1080, aged 40–79, AML CR1 or MDS	No effect	Borderline higher risk of cGVHD in age > 65	No effect
McClune et al. (2014)	N = 1248, aged 40–75, NHL	Worse NRM for age ≥ 55	No effect	Worse OS in age ≥ 55
Lim et al. (2010)	N = 1333, aged 50–74, MDS	No effect	NR	No effect

cGVHD chronic graft versus host disease, *NHL* Non-Hodgkin lymphoma, *MDS* myelodysplastic syndrome, *NRM* nonrelapse mortality, *OS* overall survival, *NR* not reported
Adapted from Artz and Olin (2016)

approaches have generally been restricted to younger patients (Koreth et al. 2009). Data regarding the efficacy of allogeneic transplant in an older population have largely been derived from retrospective analyses and one prospective donor versus no donor comparison. Allogeneic transplant for acute myeloid leukemia is perhaps the best studied and the most common disease in older adults for which allogeneic transplant is entertained.

Estey et al. studied consecutive AML patients >50 years of age seen at MD Anderson Cancer Center, and performed a case-control study comparing the outcomes of transplanted patients versus those who received chemotherapy (Estey et al. 2007). The analysis demonstrated longer relapse-free survival in the transplanted patients, with limitations including selection bias and small sample size. Farag et al. compared the outcomes of patients aged 60–70 with AML in first remission receiving RIC transplants reported to the CIBMTR with outcomes of patients receiving induction and consolidation chemotherapy on cooperative group trials (n = 94 versus 96, respectively) (Farag et al. 2011). Allogeneic transplant was associated with a lower risk of relapse, higher NRM, longer leukemia-free survival, but only a nonsignificant increase in overall survival. Kurosawa et al. reported a retrospective study of patients aged 50–70 with AML in first remission, using Japanese national registry data, comparing transplanted versus nontransplanted patients (n = 152 versus 884, respectively) (Kurosawa et al. 2011). Transplant was associated with lower relapse risk and longer relapse-free and overall survival. In subgroup analysis, transplant was associated with improved overall survival among patients with an eligible sibling donor, but not among patients with only an unrelated donor. Finally, Versluis et al. reported results from older patients enrolled in four successive prospective HOVON-SAKK acute myeloid leukemia trials. In multivariate analysis of 640 patients aged ≥ 60 years who achieved CR1, receipt of allogeneic transplant in CR1 was associated with improved 5-year overall survival versus nontransplant approaches, especially in intermediate and poor risk groups (mirroring results from the US meta-analysis study (Koreth et al. 2009) in younger patients) (Versluis et al. 2015).

One prospective multicenter study of allogeneic transplant in older AML patients was conducted from 2004 to 2011 through the Alliance cooperative group and the BMT CTN (CALGB 100103/BMT CTN 0502) (Devine et al. 2012). AML patients in first remission aged 60–74 underwent sibling or unrelated reduced intensity conditioning (RIC) transplant. The trial enrolled 123 patients with a median age of 64. At 2 years, DFS and OS were 39% and 46%, respectively, with TRM 14%. Acute severe

GVHD at 100 days was 3% and chronic GVHD at 2 years was 26% (similar to a large study of nonmyeloablative transplant reported by Sorror and colleagues in patients 60 years and older (Sorror et al. 2011)).

A prospective donor versus no donor comparison (a.k.a. "biologic randomization") for older patients with AML has been presented in abstract form by Niederwieser et al. (Niederwieser et al. 2014). As part of the OSHO AML 2004 trial, patients in CR1 underwent randomization based on donor availability (matched related and unrelated donors preferred, though mismatched unrelated donors allowed for high risk disease). In an analysis of 315 patients aged 60–74 years, receipt of a reduced intensity allogeneic transplant improved leukemia-free survival relative to consolidation chemotherapy (32% vs. 13% at 8 years, $p < 0.0005$), reduced incidence of relapse (40% vs. 79%, $p < 0.0001$), but produced higher NRM (28% vs. 9%, $p < 0.0001$). The improvement in overall survival after allogeneic transplant was not statistically significant (35% vs. 24% at 8 years, $p = 0.18$). In a subsequent analysis, benefit of allogeneic transplant was seen in European Leukemia Net (ELN) Intermediate-1, Intermediate-2, and High risk groups (Niederwieser et al. 2016).

These studies demonstrate that RIC allogeneic transplant in the older patient population is feasible and outcomes are encouraging; this study provides a benchmark for outcomes against which other nontransplant AML therapies can be measured.

For older patients with myelodysplastic syndrome (MDS), decision analysis has been a particularly informative approach in understanding the role of allogeneic transplant. Koreth et al. used Markov modeling to compare reduced intensity transplant versus nontransplant strategies for patients aged 60–70 (Koreth et al. 2013). For patients with low/intermediate-1 risk MDS, nontransplant therapies remain the favored approach, but for patients with intermediate-2/high risk MDS, allogeneic transplant improves both life expectancy and quality-adjusted life expectancy.

Regardless of disease type, a consideration of treatment alternatives should always include clinical trial options. In the current era of somatic mutation profiling and targeted therapies, nontransplant alternatives (as well as posttransplant maintenance options) have proliferated, at least in clinical trials. Immunotherapy represents another particularly exciting approach, generally restricted to clinical trials at present.

Assessing Candidacy for alloHCT: Disease-Specific Factors

Once a decision is made that a patient's disease type and risk should prompt preliminary consideration of alloHCT, the next step is to determine whether or not that patient is a transplant candidate. Evaluation of disease control, donor options, and social support should always occur regardless of patient age. However, older age requires a more nuanced approach to disease-specific factors, as well as patient-specific factors discussed in section "Assessing Candidacy for alloHT: Patient-Specific Factors" (Fig. 1).

Disease Prognosis

Poor disease-free survival without transplant will generally spur consideration of transplantation. Unfortunately, in older AML patients, even traditionally "good risk" prognostic factors appear to be trumped by older patient age; for example, patients with AML aged 60 and older fare considerably worse after standard induction and consolidation relative to younger patients for the same cytogenetic and molecular markers (Buchner et al. 2009; Grimwade et al. 2001; Prebet et al. 2009). Therefore, consideration of allogeneic transplant is usually warranted in older patients, and could be entertained even in AML with "good risk" prognostic markers.

Disease Control

Disease relapse remains the most common cause of transplant failure, and poorly controlled disease precludes alloHCT in a large number, if not the majority, of older patients. The tendency to de-escalate initial therapy due to older age may produce lower response rates. However, in older patients who will be receiving a reduced intensity

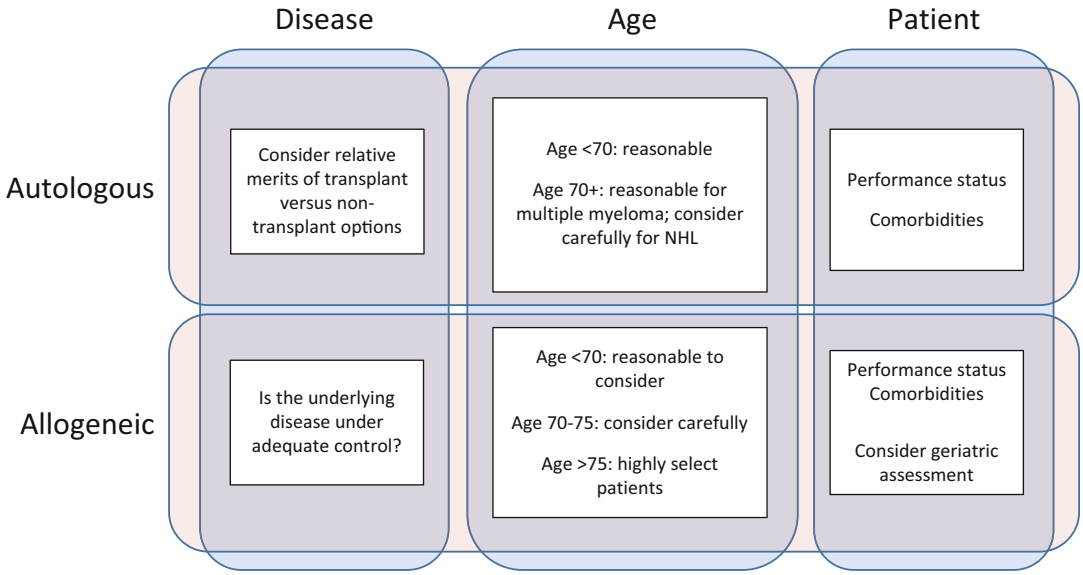

Fig. 1 Evaluation of autologous or allogeneic transplant candidacy in older patients including disease-specific and patient-specific factors (Adapted from Artz and Olin 2016)

transplant regimen, excellent disease control is paramount in reducing the risk of rapid post-transplant relapse before the graft versus malignancy effect can occur, particularly in highly proliferative malignancies. In the current era of minimal residual disease testing, more and more refined estimations of disease control is now possible. That said, it is not clear that additional therapy to achieve MRD negativity warrants the delay in time to transplant, with the associated risk of disease relapse. Overall, the best approach may be to refer for consideration of transplantation soon after diagnosis, and consider intermediate intensity preparative regimens for patients with positive MRD, if tolerated, by incorporating patient fitness as below.

Assessing Candidacy for alloHT: Patient-Specific Factors

Chronologic Age

For alloHCT, older age increases rates of TRM even adjustment for other parameters affecting treatment tolerance (Sorror et al. 2014; Muffly et al. 2014). While most patients in their 60s are now routinely offered allogeneic and autologous transplant, one should be much more cautious in patients 70 years and older and consider only the most robust adults 75 years of age or greater for alloHCT. A clinical trial is highly preferred.

Performance Status

Physician-rated performance status, most commonly measured using the Karnofsky index (KPS), performs well as a screening tool. The majority of older adults undergoing allogeneic transplant have a high KPS of $\geq$80%, making performance status a relatively coarse measure for prognostication. Performance status has been associated with TRM and overall survival after allogeneic transplant; specifically KPS $\leq$80 was associated with decreased overall survival in a large CIBMTR analysis of AML patients (Alousi et al. 2013). Older patients with KPS less than 80% should be scrutinized before offering allogeneic transplant. Patients with an inter current event or recent treatment may recover KPS but loss of performance status and delayed time to recover may still reflect impaired reserved.

Comorbidity

Hematopoietic Cell Transplantation Comorbidity Index (HCT-CI) has become the most

validated comorbidity measure for TRM and OS in alloHCT independent of age (Sorror 2009; Sorror et al. 2005, 2011, 2014, 2015; Raimondi et al. 2012; Keller et al. 2014). Sorror et al. proposed the composite Comorbidity-Age index, which can risk stratify patients based on the combination of these two variables (Sorror et al. 2014). We prefer, based on larger registry studies showing an independent effect of older age by categories, to consider age separately and inspect fitness more closely. Of note, outcomes for nontransplant therapy will also suffer in the presence of higher comorbidity (Giles et al. 2007; Sperr et al. 2010). Therefore, the decision of whether to avoid transplant based solely on high comorbidity is complex.

Considering comorbidity prior to transplant testing must account for incomplete testing and realize all data on the HCT-CI derives from the immediate pretransplant period among transplanted patients. The most common comorbidity of pulmonary will usually require pulmonary function testing for accurate assessment of respiratory function and may result in a falsely low score if PFTs are not performed. Alternatively, DLCO results may falsely elevate the HCT-CI score, depending on the specific calculation methodology (Dinkara vs. Cotes) used by each PFT lab (Coffey et al. 2013). Laboratories value may fluctuate in the pretransplant period (e.g., renal, liver) and alter the final HCT-CI score.

Higher comorbidity, such as HCT-CI of 3 and particularly 4 or more, is associated with high rates of TRM (Sorror et al. 2015). However, we caution against decisions based on the score alone and advise clinical interpretation for severity. For example, an HCT-CI score of 3 will be obtained from either an early stage breast cancer remotely resected without additional therapy or locally advanced bladder cancer after chemoradiation, though only the latter would markedly impair transplant tolerance. Finally, comorbid conditions not scored by the HCT-CI often have relevance, such as other concurrent hematologic malignancies, hip fracture, dementia, or thromboembolic disease.

Functional Status and Geriatric Assessment (GA)

Functional impairments and frailty may develop in older age without comorbidity per se. Functional status summarizes physiologic health through self-report and performance-based testing. Patient self-reported function holds consistently high predictive value in geriatrics as this offers insight into both function and environmental adaption to limitation and ultimately offers insight into life expectancy (Cruz et al. 2013). Limitations in functional status may be due to a single severe functional deficit or more commonly a combination of vulnerabilities that may not be readily apparent to the treating physician. Performance-based or objective functional status measures can isolate and quantify functional impairment, often through simple bedside tests and may promote objectively tracking changes over time.

GA represents a comprehensive health assessment designed to measure a wide variety of health domains including functional status, comorbidity, cognition, nutritional status/weight loss, social support, psychological health, and polypharmacy, among others. GA has found widespread application in the field of oncology (Wildiers et al. 2014). Brief cancer-specific geriatric assessments have been employed to predict chemotherapy related toxicity in older solid tumor patients, as well as survival in older AML patients (Hurria et al. 2011; Klepin et al. 2013). Recent evidence suggests that GA is feasible in the older stem cell transplant population, and can uncover significant vulnerabilities not captured by more traditional measures such as performance status.

The largest study of GA prior to allogeneic transplant, reported by Muffly et al., included 166 allogeneic transplant recipients aged 50–73 who were clinically deemed fit for transplant and underwent abbreviated GA; 51% were found to be prefrail and 25% were frail, using the widely accepted Fried Frailty Index (Muffly et al. 2013). Forty percent had limitations in their Instrumental Activities of Daily Living (IADL), a measure of functional status; among patients with an ECOG performance status of 0, 28% were still limited in IADL. Holmes et al. described a series of

50 clinically selected allogeneic transplant patients who underwent a more extensive GA and confirmed high prevalence of functional limitations, with 22% of patients characterized as frail (Holmes et al. 2014). Finally, Olin et al. reported a 42% incidence of IADL impairment in patients over the age of 50 undergoing allogeneic or autologous transplant, with high rates of impairment even in patients with good performance status and few comorbidities (Olin et al. 2014). By comparison, surveys of community-dwelling older adults show <10% prevalence of IADL impairment (Lin et al. 2012). Thus, even in patients who are deemed by their physician to be fit for allogeneic transplant, significant functional limitations still exist.

Evidence also suggests that such baseline functional limitations may predict transplant outcome. In one study, the presence of IADL limitation, slow walk speed, and poor mental health were each independently associated with reduced overall survival, even when adjusted for traditional prognostic factors such as age, comorbidity, and active disease (Muffly et al. 2014). Using a simple risk score with 1 point each for IADL impairment and HCT-CI score $\geq$ 3, 2-year overall survival was 63%, 29%, and 0% for 0, 1, and 2 points, respectively, among the cohort 60 years and older. The specific measure used to quantify functional limitation may be important, as another study found that the 6-min-walk test among all aged patients (an objective measure of functional status) did not add prognostic ability beyond Karnofsky performance status (Jones et al. 2015).

Other GA measures standardly include cognitive function, social support, emotional health, nutrition, and polypharmacy. Cognitive function in particular may be one of the most important and yet one of the most challenging to measure, given the time and personnel required to perform these assessments in combination with the relative insensitivity of most cognitive screening tests for subtle degrees of cognitive impairment. Estimates of the rate of cognitive impairment in the transplant eligible population range from 16% on screening tests (Holmes et al. 2014) to 67% by comprehensive neuropsychological testing (Artz, unpublished data).

Although GA in pretransplant patients reveals vulnerabilities which may predict posttransplant outcome, an unanswered question is whether pre or posttransplant intervention to improve functional status will ameliorate adverse outcomes. Although intuitively appealing, studies will be required to address such a strategy. This may involve a standardized intervention for all patients (e.g., an exercise program (Jacobsen et al. 2014)), a multidisciplinary geriatric oncology approach targeting each patient's unique vulnerabilities (Randall et al. 2016) or both. Table 3 summarizes GA domains, specific measures, and potential targeted interventions.

Donor Considerations

A matched sibling donor remains the established optimal donor for allogeneic transplant, regardless of disease type or transplant center. However, for older patients whose siblings are also older, concerns may arise about the health of the donor or the donor's hematopoietic cell regenerative capacity. Indeed, older donor age has been associated with mobilizing fewer CD34+ progenitor cells after G-CSF (Richa et al. 2009). In general, a medically cleared donor aged 50–70 will likely have an adequate collection, but there is little data on donors >70 years of age.

A CIBMTR analysis of 2172 recipients aged $\geq$50 years compared transplant outcomes using grafts from matched siblings >= 50 years versus unrelated donors <50 years suggested matched related donors are preferred (Alousi et al. 2013). Rates of both acute and chronic GVHD were higher after an unrelated allograft. For older recipients with preserved performance status (KPS of 90% or more), survival was better after matched sibling allografts. However, for recipients with KPS $\leq$80, there was no difference in outcomes between sibling and unrelated donor sources. Few related donors, however, were 70 years and older. In a registry study by Muffly et al. of alloHCT patients 70 years and older with AML, MDS, and NHL, outcomes for matched related and unrelated donors were similar (Muffly et al. 2016). Smaller series generally show at least equivalent outcomes using older sibling versus unrelated donors, with one exception (Sorror et al. 2011; De Latour et al. 2012; Kroger et al. 2013). Therefore, a matched

Polypharmacy	>5 medications or >8 medications	Hold any unnecessary medications

Adapted from Artz (2016)

sibling donor aged <70 years is currently the preferred donor for an older transplant recipient; however, for siblings >70 years, careful consideration of underlying health conditions should be pursued. We recommend a parallel unrelated donor search especially for a young well-matched unrelated donor (Kollman et al. 2016). Advance collection and cryopreservation of the stem cell product may be a useful option to ensure that the CD34+ cell yield is adequate in older donors.

In the absence of a suitable sibling or well-matched unrelated donor, "alternative" graft sources, such as haploidentical or umbilical cord blood should be considered (Kasamon et al. 2015; Rafii et al. 2016). In particular, haploidentical transplant using the Johns Hopkins approach with posttransplant cyclophosphamide offers low rates of GVHD, albeit with the possible trade-off of a higher incidence of relapse. In a recent retrospective comparison of 8/8 matched unrelated donor versus haploidentical donor transplants for AML, in which 93% of the nonmyeloablative transplants were in patients aged 51–70, haploidentical transplant was associated with lower risk of acute and chronic GHVD with no difference in survival (Ciurea et al. 2015). Since evidence suggests that younger donor age may improve outcome in the haploidentical setting, consideration may even be giving to using an older patient's grandchild as a haploidentical donor in some circumstances (Showel et al. 2015).

Allogeneic Transplant: Case Studies

A 70-year-old woman was diagnosed with AML while on an extended hiking trip to Europe with her daughter. Her medical history was notable for localized hormone receptor positive breast cancer 1 year prior, treated with surgery, radiation, and

hormonal therapy. She was otherwise healthy. At diagnosis, cytogenetics were positive for inversion 16 and molecular testing was negative for kit mutation; this was consistent with therapy related myeloid neoplasia with inversion 16, which can be seen in association with prior radiation (Andersen et al. 2002). She was treated with 7 + 3 chemotherapy. HLA typing revealed that her brother was not a match, and unrelated donor search revealed only 9/10 B-mismatched donors.

Discussion: Inversion 16 is still associated with a better prognosis in older patients with AML, compared to intermediate or poor risk cytogenetic features. However, standard chemotherapy still yields worse overall survival for older patients with inversion 16 AML compared to younger patient harboring the same cytogenetic abnormality (~30% OS at 5 years) (Grimwade et al. 2001; Prebet et al. 2009). Moreover, therapy-related disease tend to have worse outcomes. After discussing allogeneic transplant or chemotherapy alone consolidation, the patient wanted to proceed with transplant but was wary of GVHD. She was motivated by recent encouraging haploidentical transplant data, and elected to receive a transplant from her daughter.

A 75-year-old woman was diagnosed with FLT3 ITD+ AML. Her medical history was notable for diabetes. She had limited social support. She received azacitidine plus sorafenib with palliative intent, and did not undergo HLA typing.

Discussion: This patient's age would require that she have excellent functional status and medical health in order to consider transplant. In her case, her concomitant diabetes was not optimally controlled, and her limited social support appropriately concerned the patient and her treating physician. She also had a reasonable alternative treatment which involved targeting the FLT3 ITD mutation, and was interested in clinical trials of novel FLT3 inhibitors should she did not respond to azacitidine/sorafenib. This also reflects the importance of overt decisions for or against transplant early in the disease course rather than delaying until time of disease progression.

Autologous Transplant

Multiple Myeloma

Effect of Increasing Age on Autologous Transplant Outcomes:

For autologous transplant to be feasible, adequate numbers of hematopoietic stem cells must be obtained. Older patients with multiple myeloma may have more difficulty mobilizing adequate CD34+ progenitor cells than younger patients. A large cohort study of multiple myeloma patients did demonstrate an inverse correlation of age with CD34+ cell collection; however, 92% of older patients were able to collect adequate stem cells for a single autologous transplant (Morris et al. 2003). The advent of Plerixafor has improved rates of successful mobilization even further (Micallef et al. 2013).

Historically, in the era of TBI-based autologous transplants and bone marrow stem cell grafts, the rate of TRM for older patients was 25–35%. In the modern era, using a melphalan-based preparative regimen, peripheral blood stem cells and better supportive care, tolerability, and TRM have been greatly improved. As a result, the definition of "older" for patients with multiple myeloma has shifted. Modern studies investigating the safety and efficacy of patents $\geq$65 or $\geq$70 years with multiple myeloma reflect excellent tolerance with TRM in the 0–5% range. Several retrospective studies have examined the effect of increasing age on transplant outcome, with variable results (Jantunen et al. 2006; Lenhoff et al. 2006; Kumar et al. 2008; El Cheikh et al. 2011) (Table 4).

Bashir et al. published a series of 84 patients $\geq$70 years with multiple myeloma receiving a melphalan-based autologous transplant (65% received 200 mg/m^2) (Bashir et al. 2012). There was no comparator group of younger patients; however, results were impressive with an 85% overall response rate, 3% TRM, a time to

Table 4 Studies evaluating effect of increasing age on autologous transplant outcomes for multiple myeloma

	Population	ORR	TRM	TTP	OS
Jantunen et al. (2006) (Finland)	N = 22 ≥ 65 N = 79 < 65	No effect (94% ORR)	No effect (0%)	No effect (median 23 month PFS)	No effect (median 57 month OS)
Lenhoff et al. (2006) (Nordic)	N = 120 60–64 N = 294 < 60	No effect (90% ORR)	No effect (1%)	Worse EFS in 60–64 (19% at 4 years)	Worse OS in 60–64 (50% at 4 years)
Kumar et al. (2008) (Mayo)	N = 33 > 70 N = 60 < 65 (matched controls)	No effect (97% ORR)	No effect (3%)	No effect Median 28.5 month TTP	No effect Median not reached
El Cheikh et al. (2011) (France)	N = 82 > 65 N = 104 60–65	–	No effect (3.7)	Worse PFS in >65	No effect 32% @ 10 years
Sharma et al. (2014) (CIBMTR)	N = 5818 18–59 N = 4666 60–69 N = 946 ≥ 70	–	No effect (0%)	No effect (3 year PFS 33% in ≥70)	Worse OS by age but similar myeloma specific mortality (72% at 3 years for age ≥ 70)

ORR overall response rate, *TRM* treatment related mortality, *TTP* time to progression, *PFS* progression free survival, *EFS* event free survival, *OS* overall survival
Adapted from Artz and Olin (2016)

progression of 27% at 5 years, and an overall survival of 67% at 5 years. In a large CIBMTR study including over 900 patients age ≥70, 1-year NRM was 0%, PFS 33% at 3 years, and overall survival of 72% at 3 years (Sharma et al. 2014). Overall survival was worse with increasing age, but myeloma-specific survival was no difference, suggesting that age primarily influences non-myeloma mortality. While NRM and PFS were similar between older and younger patients, outcomes after relapse were worse.

Autologous Transplant Versus Other Therapy

Even in the era of novel treatments, autologous stem cell transplant is still an important therapeutic modality for multiple myeloma. In younger patients, stem cell transplant as part of first-line therapy is associated with improved survival compared to no transplant, and improves PFS when compared to delayed transplant (Cavo et al. 2016; Attal et al. 2015).

Three studies have examined the effectiveness of autologous transplant relative to nontransplant therapies in older adults ≥65 with multiple myeloma. Wildes et al. reported a retrospective study of 146 patients aged 65–77 and compared those who received stem cell transplant versus nontransplant therapy. After adjusting for other prognostic factors, stem cell transplant was associated with improved overall survival (Wildes et al. 2015). On the other hand, Offidani et al. compared outcomes of adults ≥65 who received chemotherapy followed by transplant if eligible versus chemotherapy alone if ineligible for transplant; there was no difference in PFS or OS (Offidani et al. 2010). Finally, Facon et al. reported results of a trial randomizing older patients aged 65–75 to receive melphalan and prednisone (MP) chemotherapy, MP with addition of thalidomide, or MP followed by transplant (melphalan 100 mg/m^2) (Facon et al. 2007). The winning arm was the thalidomide-containing regimen, and there was no survival benefit of chemotherapy plus transplant versus chemotherapy alone. However, the study used a low melphalan dose of 100 mg/m^2; higher doses may be tolerated in fit older patients, likely with improved efficacy.

In conclusion, while the relative benefit and morbidity of transplant for older patients with

multiple myeloma remains unclear, autologous transplant in select older patients is well tolerated with low TRM. Based on the Facon data, if a given patient is felt to require melphalan dose reduction to 100 mg/m^2, the relative merits of stem cell transplant for that patient should be reconsidered.

Determining Treatment Tolerance and Transplant Eligibility

The development of novel therapies for multiple myeloma has resulted in significantly improved survival over the past decade. However, older patients with multiple myeloma have experienced only a modest improvement in survival over this time period (Brenner et al. 2008; Pulte et al. 2011; Turesson et al. 2010). This disparity between younger and older patients is likely due to impaired treatment tolerance, as a result of comorbidities and decreased physiologic "reserve."

Whether for transplant or nontransplant therapy, assessment of the "fitness" of an older patient is paramount. In a large CIBMTR study, performance status was associated with overall survival even after controlling for other risk factors in multivariate analysis (Sharma et al. 2014). The International Myeloma Working Group recommends assessment of fitness using not only age but also comorbidities and GA (of particular use are the functional assessments to detect frailty and disability) (Palumbo et al. 2014). In transplant ineligible patients, components of GA have been shown to predict survival and treatment tolerance (Palumbo et al. 2015). Although data in older transplant eligible patients are currently lacking, studies are ongoing to evaluate this question.

The lower risks of NRM after a myeloma autograft enable older and less fit patients undergo therapy. Although transplant eligibility will be less strict, a GA may still be informative to capture health information to anticipate toxicities.

Non-Hodgkin Lymphoma

Several studies, including some very large international database studies, have compared the toxicity and efficacy of transplant in older patients with relapsed NHL (indolent, aggressive, and mantle cell) (Jantunen et al. 2008, 2012; Lazarus et al. 2008; Wildes et al. 2008) (Table 5). Older age is variably defined as >55 to >65 years. Although the smaller studies have tended to show no difference in NRM, PFS, or OS, the larger studies have shown worse PFS and OS in older patients.

Evidence from small series of selected patients with lymphoma demonstrates feasibility of autologous transplant in patients over the age of 70. Elstrom et al. published a series of 21 patients aged 69–86 (Elstrom et al. 2012). Nonrelapse mortality at 100 days was 19%. Age $\geq$ 75 was associated with worse PFS and borderline worse OS in a small number of patients. High comorbidity score by HCT-CI predicted worse outcome.

Table 5 Studies evaluating effect of increasing age on autologous transplant outcomes for NHL

	Population	NRM	PFS	OS
Jantunen et al. (2008) DLBCL	N = 463 $\geq$ 60 N = 2149 < 60	Worse (8.7% at 1 year)	Worse (51% at 3 years)	Worse (60% at 3 years)
Lazarus et al. (2008) NHL indolent	N = 173 $\geq$ 55 N = 615 < 55	No effect (7% at 5 years)	Worse (29% at 5 years)	Worse (54% at 5 years)
Lazarus et al. (2008) NHL aggressive	N = 632 $\geq$ 55 N = 1334 < 55	Worse (15% at 5 years)	Worse (19% at 5 years)	Worse (30% at 5 years)
Wildes et al. (2008) NHL	N = 59 > =60 N = 93 < 60	No effect (8.5%)	No effect (median 22 months)	No effect (median 48 months)
Jantunen et al. (2012) MCL	N = 79 $\geq$ 65 N = 633 < 65	No effect (3.8%)	No effect (29% at 5 years)	No effect (61% at 5 years)

NRM nonrelapse mortality, *NRM* nonrelapse mortality, *PFS* progression-free survival, *OS* overall survival, *DLBCL* diffuse large B-cell lymphoma, *NHL* Non-Hodgkin lymphoma, *MCL* mantle-cell lymphoma
Adapted from Artz and Olin (2016)

Andorsky et al. published results on 17 patients ≥70; NRM was 18% at 100 days and 35% at 1 year (Andorsky et al. 2011). Compared to 39 patients aged 65–69, relapse mortality and overall survival were both worse in the older cohort. In this series, a history of falls (which may be a marker of frailty) was associated with worse outcomes. Compared to myeloma autografts, advancing age seems to be a stronger marker for worse outcomes, likely in part to more intensive regimens given for lymphoma relative to melphalan only for myeloma. The prior treatments for lymphoma may also exact a greater toll on patients relative to novel myeloma-based induction regimens.

In determining whether autologous transplant should be performed for a given older patient, consideration should be given to functional status and frailty, although there are not yet strong data to support this in the literature. Higher HCT-CI has a statistically significant but clinically small effect on rates of TRM and OS after autologous HCT (Pasquini et al. 2012). As well, given the number of novel treatments which have been developed for NHL in recent years, including immunotherapy, the relative merits of transplant versus nontransplant approaches should be weighed.

Early-Stage Breast Cancer in Older Adults

38

Kwok-Leung Cheung, Lorenzo Livi, and Etienne Brain

Contents

Abstract

Breast cancer is the most common cancer afflicting women worldwide. Its incidence peaks around 70, while mortality increases greatly after 75 years old. Given the competing risks on mortality with multimorbidities, geriatric assessment is a leitmotiv and is considered as the mandatory and non-opposable strategy to use for personalizing treatment. This is especially true for strategies used in early-stage breast cancer since benefits are expected to come with long follow-up.

Therefore treatment choice needs careful assessment of the benefit/risk balance and guidance according to a general health status assessment, in order to avoid jeopardizing functional status and quality of life.

This chapter will highlight the unmet clinical needs, future opportunities and adjusted strategies for local treatments (surgery and radiotherapy), and systemic treatments (chemotherapy, endocrine therapy, and anti-HER2 treatment) in the older patients with early-stage breast cancer.

Keywords
Adjuvant · Neoadjuvant · Breast cancer · Chemotherapy · Endocrine therapy · Radiotherapy · Surgery · Anti-HER2 therapy

Introduction

Around 40% of breast cancers (BC) occur in women aged 65 and older and 20% in women over 75. Mortality increases greatly after 75 (Biganzoli et al. 2012). This contrasts sharply with the iconic and unfair portrayal of BC in the media and social attitudes. Of note, comorbidities increase in number and severity according to age. They compete with BC prognosis and make necessary to prioritize medical problems and to individualize treatment referring to a geriatric assessment.

A further problem is that older BC patients in trials are fitter than the wider population of older patients, creating important gaps between approvals and applications in routine practice. Indeed the lack of trial guidance for older BC patients has resulted in both overtreatment (given the higher risk of toxicities and competing causes of mortality) and undertreatment (because of age-based restrictions).

As for more advanced and/or metastatic cases, management of early-stage BC in the older person requires specific adjustments and considerations for the different modalities available: surgery, radiotherapy, and systemic treatments.

Surgery

An ancient dictum says, "Good surgeons know how to operate, better ones when to operate, and the best when not to operate." Can we not operate or operate "less" on BC in the older adults in relation to the primary tumor and the axilla? Differing tumor biology according to age, the use of systemic therapy, and mortality due to competing causes of death are the core issues to consider behind this question.

Surgery to the Breast

Over a century ago, George Beatson, a surgeon from Glasgow, first reported the use of endocrine manipulation (using a surgical approach at the time, i.e., oophorectomy) in inducing a complete clinical response on a young woman with inoperable recurrent BC (Beatson 1896). A Cochrane review of 7 small randomized controlled trials comparing surgery with primary endocrine therapy, primarily using tamoxifen for estrogen receptor (ER) unselected tumors, in a total of 1,571 older adults, does not show any significant difference in overall survival (OS) (Hind et al. 2006). A later systematic review of 6 of these trials and also 31 non-randomized studies demonstrates an advantage for surgery over primary endocrine therapy in terms of disease control and a likely survival benefit in older adults with a predicted life expectancy of 5 years or more (Morgan et al. 2014). Patients treated only with aromatase inhibitors (AI) were found to have superior rates of disease control when compared to tamoxifen. Our group was involved in two of these randomized controlled trials, and the long-term results show a significant correlation between the efficacy of primary endocrine therapy and ER status, e.g., the 10-year local failure rate decreased from 80% to 43% from the first trial (ER unselected) to the second one (ER H (histochemical)-score $\geq$ 100 (out of a maximum of 300) required) (Chakrabarti et al. 2011; Johnston et al. 2012). We have also analyzed a consecutive cohort of 1,065 older women with ER (H-score $\geq$ 50)-positive tumors treated by either surgery or primary endocrine

therapy over a 37-year period in a single institution and noted no difference in BC-specific survival rates between both groups when the H-score was ≥250 (Syed et al. 2011). With tamoxifen being used in 69.3% of the patients receiving primary endocrine therapy, the median time to progression was 49 months (4–132 months), which was significantly prolonged with the use of an AI (Syed et al. 2011). All this data suggests that primary endocrine therapy may produce comparable survival outcome to that of surgery in patients with strongly ER+ tumors. Our work along a similar line shows that not just that BC in older adults tend to be ER+, they are more ER rich. In a series of over 3,000 primary BC patients, the peak H-score in all age groups was found to be between 100 and 200 with the exception of those ≥70 years, when it was between 200 and 300 (Cheung et al. 2008). Partitional clustering of a panel of 24 biomarkers measured by immunohistochemistry (IHC) of tissue microarrays constructed from surgical specimens from our institution has also demonstrated differing biology according to age, with a unique subtype, "low ER luminal," showing low ER expression and overexpression of luminal cytokeratins), identified in the older population (Syed et al. 2013). In summary, if we were to consider not operating on an old adult with BC, someone with an ER-rich tumor (approaching an H-score of 300 or equivalent) may be the right person from the biological perspective, as long as systemic endocrine therapy, preferably an AI as opposed to tamoxifen, is being used.

Surgery to the Axilla

Recent pivotal studies have revolutionized the application of the time-honored axillary lymph node dissection (ALND) as surgical treatment to the clinical node-negative axilla. The Z011 trial randomized patients with positive sentinel lymph node biopsy (SLNB) following breast-conserving surgery and receiving postoperative whole breast irradiation and adjuvant endocrine therapy (for ER+ tumors) to proceed to ALND or no further axillary treatment (Giuliano et al. 2011). Omitting ALND did not show an inferior survival. In the AMAROS trial where patients with positive SLNB were randomized to receive either ALND or radiotherapy to the axilla, showing no difference in recurrence or survival, the omission of surgery was associated with a significantly lower incidence of lymphedema (Donker et al. 2014). The use of preoperative ultrasound assessment, a widely practiced standard of care in the UK, coupled with the use of SLNB, means that for those patients undergoing SLNB (implying a negative preoperative axilla on imaging with or without needle cytology or biopsy), the chance of finding a huge tumor burden in the remaining axilla is expected to be even lower than as shown in these trials. As a result, a number of national and international guidelines have changed advocating the omission of axillary treatments, including ALND and even SLNB in selected cases (Coates et al. 2015; Lyman et al. 2014; Association of Breast Surgery Consensus Statement 2015). In contrast to the trials mentioned above in relation to primary endocrine therapy versus surgery to the breast primary, these trials investigating axillary treatments were not specific to the older population. Given the argument in terms of differing biology with a higher chance of ER+ and ER-rich tumors in the older adults, it is not difficult to imagine that the proposed approach to *all* patients as per these changing guidelines should be even more applicable to the older population.

Other Factors to Consider and Future Directions

When compared to their younger counterparts, older adults have shorter life expectancy due to comorbidities or competing causes of death (Yancik et al. 2001). None of the above studies demonstrate any impact on survival with the use of "less" surgery, which however has been shown to be beneficial in terms of local control in the cases of treating the primary tumors (Hind et al. 2006; Morgan et al. 2014; Chakrabarti et al. 2011; Johnston et al. 2012). This effect however may be offset if the life expectancy of the person is

reduced. Our work shows that the median time to progression for primary endocrine therapy using anastrozole was around 5 years as compared to approximately 4 years for tamoxifen, regardless of ER H-score (as long as it was ≥50) (Syed et al. 2014). More potent and novel endocrine agents continue to be developed. Fulvestrant, a selective ER downregulator, has recently been shown in a phase III trial to be significantly more efficacious than anastrozole when used in advanced BC (Robertson et al. 2016). Based on all these factors, primary endocrine therapy with a more potent agent, if used in an older adult with shortened life expectancy due to comorbidities, and a very strongly ER+ tumor, may produce the optimal outcome in terms of local control, survival, and health-related quality of life (HRQoL). The same principles should apply to the selection for axillary surgery. Future research should also aim to personalize treatments (surgery or no or "less" surgery) taking full account of both biological (e.g., biomarkers other than ER, exploiting other techniques such as genomics) and geriatric (e.g., frailty, patient choice) (Hubbard) information into consideration.

Radiotherapy

Radiotherapy in older BC patients follows much less standard guidelines than in younger ones and is omitted in 40% after 75 (Schonberg et al. 2010; Biganzoli et al. 2012).

Radiotherapy Omission

Some authors have investigated the possibility to omit it after breast-conserving surgery in older patients, in ER+ cases with very good prognosis (Hughes et al. 2013). With long follow-up beyond 10 years, they have reported that although radiotherapy decreases local and regional relapse, it does not impact on OS in these patients aged 70 and above. This is in partial agreement with the Oxford overview which has shown an OS benefit of locoregional radiotherapy, observed as early as from 5 years of follow-up, but in the general adult population. Therefore, omitting adjuvant radiotherapy after breast-conserving surgery in older patients with small tumors and very good prognosis has been adopted by important guidelines as the NCCN. However, it remains debated and attitudes vary greatly across countries. The psychological burden of local recurrence should not be neglected, and compliance to endocrine therapy should be closely monitored. When considered, final decision to omit adjuvant radiotherapy should always take into account an estimate of life expectancy.

Innovations

The International Society of Geriatric Oncology (SIOG) recommends tailoring radiotherapy to patients using specific techniques and schedule modalities that will minimize toxicities without reducing effectiveness: position (lateral or prone), volume (partial), once-per-week fractionation, and accelerated partial breast irradiation (PBI) (Kunkler et al. 2014).

Hypofractionated schedules are validated and provide good alternatives to standard fractionation, sparing expensive and burdensome transportations, especially in case of long distance from home (Fast 2011; Kirova et al. 2009).

Potential advantages of accelerated PBI include shorter treatment time, improved cosmesis, and cost reduction compared with standard whole breast radiotherapy (e.g., IMPORT trial (Coles et al. 2017)). Intensity-modulated radiotherapy (IMRT) has the theoretical advantage of a further increase in dose conformity compared with three-dimensional techniques, with increased normal tissue sparing, with potential benefit in older patients (Meattini et al. 2015). This is particularly important since age > 70 years seems to be one of the most significant factor for the occurrence of ischemic heart disease induced by radiotherapy (Darby et al. 2013).

Moreover, according to the BASO-II trial (Blamey et al. 2013), patients treated with either exclusive adjuvant radiotherapy or endocrine therapy show the same low yearly locoregional relapse rate (0.8%). This questions the systematic

use of both strategies in very good prognosis cases, especially for older patients in whom mostly HRQoL drives treatment's choice, making patient's information crucial to avoid compliance issues observed with extended endocrine treatment or burdensome transportations with radiotherapy.

Systemic Treatment

Systemic treatment for early-stage BC must be interpreted in the context of the important effort led to identify subgroups of tumors with different prognosis according to in-depth biology. Since the shift in treatment decision from prognosis to prediction which happened during the first 2000 decade, treatments have evolved toward more personalization combining both aspects (Curigliano et al. 2017). One now considers treatments relying first on several biological features, expression of hormonal receptors [ER and progesterone receptors (PgR)], and HER2, distinguishing roughly three groups: luminal cases (ER+ and/or PgR+), triple-negative tumors (ER-, PgR-, and HER2-), and HER2+ disease (overexpression of HER2 by IHC or amplified by F(C)ISH). The proliferation rate (e.g., Ki67) is used to differentiate further luminal cases that are aggressive from others, knowing that its optimal threshold (around 20–25%) is still a matter of debate.

Based on this evolving strategy, priority systemic treatments match all these categories: endocrine therapy for luminal cases, chemotherapy for triple-negative tumors, and when proliferation is considered as high, anti-HER2 treatments for HER2+ tumors but combined with chemotherapy as a standard since the benefit seems to derive from a high synergism between both classes of compounds.

In the general population, all these "priority" treatment modalities can be combined, either out of principle (e.g., anti-HER2 treatment and chemotherapy) or because of the benefit that can be expected from the different actions (e.g., chemotherapy if more than three lymph nodes involved in addition to endocrine therapy in ER+ and/or PgR+ tumors).

However, in adjuvant setting, treatments are applied blindly postoperatively based on a risk estimate summarizing the delicate trade-off between benefit sought through treatment (correction of a risk of relapse and death) and potential side effects. By essence, the long-term projections of benefit for such strategy aiming at postponing as much and as late as possible – if not cancelling – the risk of relapse collides bluntly with the list of comorbidities and competing risk for mortalities, all increasing in incidence and in severity with aging (Kendal 2008; Piccirillo et al. 2008).

One can look at each systemic treatment modality.

Endocrine Therapy

Given the clear gradual increase of the proportion of luminal cases according to age (Jenkins et al. 2014), most of older patients are beforehand candidates for adjuvant endocrine therapy. The historical debate between AI versus antiestrogen (tamoxifen) is over. Although there is a small additional benefit on disease-free survival (DFS) favoring AI, the true impact on OS is limited to one or two trials, stressing the need to pay attention first and foremost to side effects to ensure good compliance and regular intake. Indeed older patients with bone and joint disease are more at risk of stopping treatment with increased arthralgias and fractures as reported with the use of AIs (Coates et al. 2007). Risk of side effects or poor compliance may be worsened after an ALND or even a SLND, in those with a carpal tunnel syndrome or with severe osteoporosis. On the other hand, decreased functionality with low mobility may expose to a higher risk of thromboembolic events, more frequent with antiestrogen as tamoxifen.

Chemotherapy

Key cytotoxic agents in BC management are more difficult to handle in older patients because of the higher risk of side effects: congestive heart failure with anthracyclines (Swain et al. 2003), peripheral neurotoxicity and taxanes (Biganzoli et al. 2016),

and myelosuppression with most cytotoxic agents requiring a wider use of G-CSF for primary prophylaxis of febrile neutropenia (Biganzoli et al. 2012). Adjuvant chemotherapy can provide similar benefits in older patients than in younger ones, but the risk of toxicity is higher, including fatal events (x10) and should be cautiously monitored (Muss 2005). This is also why selecting cases relevant for such strategy is crucial, especially since so few patients older than 65 have been included in most trials of adjuvant chemotherapy, preventing from drawing any solid conclusion, and breaking the usual implemented misconception of the extrapolation of data obtained in younger patients to older ones.

Chemotherapy is clearly beneficial in patients with ER- disease, with up to 25% mortality (BC-specific and global) reduction and an early effect, at 2–3 years when relapse peaks. Therefore it should be always considered for ER- disease, even in older patients, after careful general evaluation. This has been very well highlighted in retrospective works on large series where benefit vanishes as soon as the ER- population is mixed with the ER+ one (Elkin et al. 2006; Giordano et al. 2006), as well as in prospective trials as the CALGB 49907 where there was a high interaction between ER status and the efficacy of standard chemotherapy (Muss 2009).

Validated regimens are fuddy-duddy and include four cycles of doxorubicin/cyclophosphamide (AC) and the old cyclophosphamide/methotrexate/fluorouracil (CMF) (Muss 2009) or four cycles of docetaxel/cyclophosphamide (TC) (Jones et al. 2009). Sequential schedules (anthracyclines followed by taxanes) have never been rightly investigated after 65 years and usually double the length of chemotherapy period which is highly influential on the risk of serious side effects as identified in the last work led by the late Arti Hurria (Hurria et al. 2018), reflecting the decline of functional reserves with age.

For chemotherapy, the main question mark remains whether selected patients with ER+ disease may derive some additional benefit from chemotherapy without triggering high rates of side effects and jeopardizing the whole therapeutic plan. This explains why so much expectation has been put in multiparametric tests assessing the in-depth biology of the tumor with genome profiling. However, despite large trials with number of patients often exceeding 5,000 each, none has been led consistently with accrual closed to patients aged 65 and above, making the extrapolation of the use of such signatures in older patients from the data obtained in younger ones very theoretical and inadequate. A solution could be to factor part of the age-linked heterogeneity and competing risks in these algorithms. More recent research, as the ASTER 70s randomized phase III, addresses this issue and might help in the future fine-tuning indications of chemotherapy for ER+ BC in older patients (Coussy et al. 2016). Until this happens, adjuvant chemotherapy for ER+ BC patients above 65–70 should be considered only as optional and in a very limited number of cases, endocrine treatment bringing already an important benefit.

Anti-HER2 Treatments

Despite accounting for 40% of BC patients, few older women have been included in pivotal trials: only 16% of patients in the key studies of adjuvant trastuzumab were 60 and above. Trastuzumab, pertuzumab, and neratinib are all approved for (neo) adjuvant therapy.

The benefit of adding trastuzumab to adjuvant chemotherapy is independent of age as shown in most large adjuvant trials like HERA (Cameron et al. 2017). Attempts to use anthracycline-free regimen potentially decreasing the cardiac risk as in the BCIRG 006 with docetaxel and carboplatin (TCH regimen) cannot be considered valid in the older population which was excluded from the trial (Slamon et al. 2015).

Indeed, establishing the standard adjuvant trastuzumab regimen in older patients is difficult since the accompanying chemotherapy remains poorly defined. Data are lacking for sequential chemotherapy, leaving us with the old-fashioned four AC, six CMF, and four TC. The attractive results from a single-arm study led in patients with low-risk HER2+ node-negative BC with weekly paclitaxel x12, and trastuzumab have opened by extrapolation such use for older ones but with a

very low level of evidence and the risk of neuropathy (Tolaney et al. 2017).

Although most trials of short-duration trastuzumab (6 months or 9 weeks vs. 1 year) failed to show the non-inferiority of shorter duration, PERSEPHONE did find that 6 months trastuzumab was non-inferior to 12 months (Earl et al. 2018). Some subgroup analysis suggests also that patients with small node-negative tumors would not derive extra benefit from extending trastuzumab beyond 6 months (Kramar et al. 2014). In these studies showing lower rate of cardiac dysfunction with the shorter-duration arm, shorter duration might be relevant in older patients at increased cardiac risk.

Of note, data from the Surveillance, Epidemiology, and End Results (SEER) registry show that patients >65, especially octogenarians and those with comorbidities, often receive incomplete ($\leq$ 9 months) treatment (Vaz-Luiz et al. 2014), whether related to the chemotherapy partner or to the antibody. Delay or cessation was seen in 15–40% of cases. Thirty percent of patients developed an LVEF decrease $\geq$10% and 3–11% were hospitalized for cardiac events within 1–2 years of follow-up.

As oral formulation for chemotherapy, subcutaneous trastuzumab would help older patients avoid the need to travel to hospital if approved for administration at home.

Although approved for extended treatment after trastuzumab, neratinib, an irreversible TKI of HER1, HER2, and HER4, gives more than 40% of grade 3–4 diarrhea making it unlikely such a strategy will suit the general older population (Chan et al. 2016).

Dual blockade with pertuzumab (or lapatinib) and trastuzumab is another attractive innovative strategy (von Minckwitz et al. 2017). Disappointingly, studies exploring this concept had no greater success than previous ones in enrolling patients >65. Moreover, to the issues of selecting the right chemotherapy partner and controlling the increased risk of side effects, dual blockade adds the difficult selection of older patients according to frailty status for a modest absolute benefit.

Actually the crucial research question remains whether HER2+ BC can be adequately treated by adjuvant anti-HER2 therapy alone, as suggested by the randomized Japanese study (RESPECT) (Sawaki et al. 2018).

Table 1 summarizes some of the key points regarding adjuvant chemotherapy and anti-HER2 treatment in older early-stage BC patients, based on SIOG recommendations (Biganzoli et al. 2012; Brain et al. 2019).

Table 1 Summary of key points on chemotherapy and anti-HER2 treatment in older early-stage BC patients

Chemotherapy	
Indications	Focus on ER- and HER2+ tumors if pT > 5 mm
Regimens	
4 AC (or 6 CMF), 4 TC	Validated
Weekly paclitaxel x 12	Option?
Liposomal doxorubicin	Potential interest (lower cardiac toxicity) but no data
"Sequential" chemotherapy (anthracyclines and taxanes)	No data
Capecitabine or docetaxel weekly	No indication
Primary prophylaxis of febrile neutropenia with G-CSF	From a lower threshold of risk of febrile neutropenia than the standard one used in the adult population (20%)
Trastuzumab	
Indications	No restriction if chemotherapy indicated
Regimens	
4 TC + trastuzumab	Most validated
Weekly paclitaxel x 12 + trastuzumab (Tolaney et al. 2017)	Option
TCH x 6	Very unlikely in older patients since carboplatin AUC 6!
Trastuzumab without chemotherapy	Can be considered, especially for unfit patients (+ endocrine therapy in the case of ER+ tumors)
Duration	1 year Shorter duration (6 months) may be considered in small node-negative tumors or in patients at increased cardiac risk

Neoadjuvant Strategy

The neoadjuvant approach in older patients can be difficult since this strategy generally involves chemotherapy rather than endocrine treatment, possibly jeopardizing subsequent surgery by causing a deterioration of health status. However, as discussed previously in the surgery section, primary endocrine therapy may be a good alternative to upfront surgery. It allows also exploring new treatments and selection processes, enabling investigating strategies omitting aggressive treatments as chemotherapy through multiple blockade of the HER2 and associated pathways such as ER.

Abstract

The management of older adults with breast cancer poses a challenging dilemma to most treating oncologists given the under-representation of older age groups in most pivotal clinical trials. Older patients are at risk of undertreatment, which may be due to physician bias and/or patient preference. There is mounting evidence suggesting that older patients with breast cancer may derive as much benefit from treatment as their younger counterparts. However, generalizing treatment for all older breast cancer patients without further health

assessment poses the risk of over-treatment. Although the efficacy outcomes may be similar across age groups, the tolerance to toxicity may differ, as determined mostly by comorbidities, organ function, and aging heterogeneity. In metastatic breast cancer, the main goal of care is to offer the least toxic treatment that can control symptoms, prolong survival, and preserve the quality of life. Therefore, defining the goals of treatment while carefully assessing the overall health status in addition to risk-benefit ratio is paramount to the treatment decision-making.

Introduction

Breast cancer (BC) is the leading cause of cancer diagnosis and death in women worldwide, and the risk increases with aging. The BC specific incidence and mortality in women ≥70 years are 21% and 31%, respectively (Ferlay et al. 2013). The incidence of de novo metastatic BC (MBC) is approximately 6–10% (American Cancer Society, Inc. 2015) and unknown in those with metastatic recurrence, although estimated to be higher of around 20–30% (O'Shaughnessy 2005). Managing older women with MBC can be challenging, mainly due to limited evidence from lack of representation in clinical trials and aging heterogeneity. Experts' collaboration has recommended guidelines for managing older adults with MBC (Biganzoli et al. 2012; Cardoso et al. 2017). This chapter will focus on specific treatment considerations and options in managing this complex patient group.

Special Treatment Considerations in Older Adults with Metastatic Breast Cancer

As with any metastatic disease, the goal of care in patients with MBC is to optimize the length and quality of life. Treatment decision is based both on patient and tumor characteristics, as well as on previously received therapies (Fig. 1). As the treatment benefit is seen regardless of age group, age alone is not sufficient to determine the type and intensity of treatment (Cardoso et al. 2017). However, it should be kept in mind that age-related physiological changes are expected to affect various organs and functions, as discussed in section (Patho) physiology of Aging

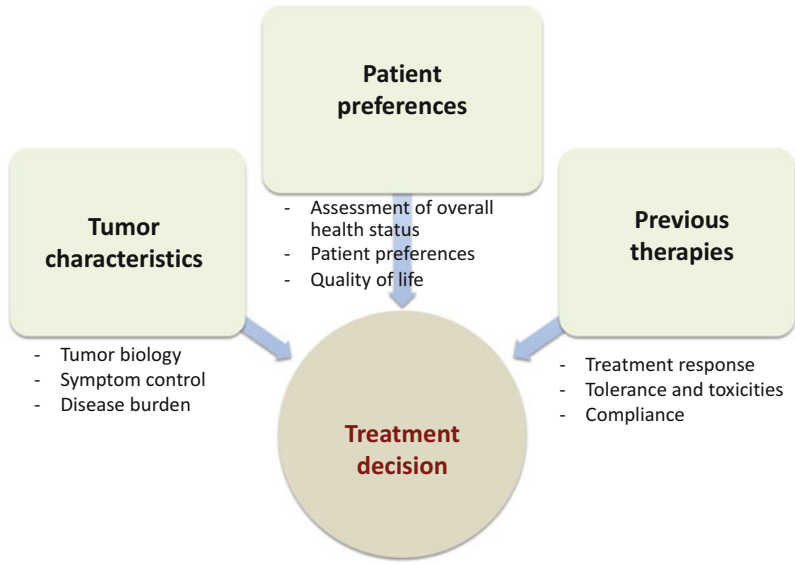

Fig. 1 Treatment considerations for treating older patients with metastatic breast cancer

and Cancer. This can subsequently affect certain pharmacokinetic and pharmacodynamics of numerous anticancer drugs and reduce tolerability of organs/systems to the negative effects of drugs. Understanding the age-related physiological changes and homeostatic reserve in addition to comorbidities is therefore essential.

Several age-related factors can influence the management plan in older adults with MBC. Comorbidities can affect the treatment choice and tolerability; concurrent medications can have important interactions; cognitive and psychological status can impact strategy understanding and consent; adherence to complex treatment regimens and toxicity management, nutrition, and physical function can define tolerance and prognosis; and socioeconomic factors can also influence adherence to treatment. The comprehensive geriatric assessment (CGA) is a multidimensional assessment of the overall health status based on validated geriatric tools that identifies potential health problems on functional, nutritional, emotional, comorbid, and cognitive domains, providing opportunity for interventions, particularly if these are potentially reversible. The Chemotherapy Risk Assessment Scale for High-Age Patients (CRASH) and the Cancer and Aging Research Group (CARG) have both developed an objective scoring system that predicts the risk of chemotherapy toxicity in older patients based on various clinical and laboratory factors (Extermann et al. 2012; Hurria et al. 2011, 2016), which may be useful in assisting with treatment decision-making. CGA has been discussed extensively in section Geriatric Assessment and Management in Oncology.

Systemic Treatment Options and Clinical Evidence

Treatment of Choice for Older Women with Hormone Receptor-Positive Metastatic Breast Cancer

Hormone therapy is the preferred standard option for hormone receptor-positive (HR+) MBC, even in the presence of visceral disease, unless there is a concern or proof of endocrine resistance or visceral crisis, needing a rapid response (Biganzoli et al. 2012; Cardoso et al. 2017). Current endocrine treatment options for older patients are similar with younger postmenopausal patients and must be continued until there is evidence of treatment refractory. Recent data have revealed a significant improvement in the progression-free survival (PFS) when inhibitors to mechanistic target of rapamycin (mTOR) or cyclin-dependent kinases 4 and 6 (CDK 4/6) were added to endocrine therapy, though evidence for overall survival (OS) benefit is still lacking.

The BOLERO-2 study is a phase III, randomized trial comparing exemestane (25 mg/d) plus everolimus (10 mg/d), an mTOR inhibitor, to placebo in 724 postmenopausal women with HR+ MBC recurring or progressing after treatment with nonsteroidal aromatase inhibitors. Depending on the age cutoff of 70, both age groups have shown an improvement in PFS (4.10 months in <70 years and 5.26 months in ≥ 70 years), favoring everolimus combination (hazard ratio, HR 0.44 and 0.45, respectively), and had similar incidences of adverse events (AE), i.e., stomatitis, infection, rash, pneumonitis, and hyperglycemia, although more on-treatment deaths were noted among older patients (7.7% vs. 1.3%) at 18 months of median follow-up (Pritchard et al. 2013). This was attributed to the overall health status that was mainly driven by the comorbidities noted in older patients at baseline. The expanded-access multicenter European trial (BALLET) studied similar patient population as the BOLERO-2 and has reported similar trends in the overall safety of everolimus + exemestane among 2133 women, although the elderly group (26.4%) had a slightly shorter median duration of drug exposure, more frequent dose reductions and interruptions, grade 3/4 adverse events (AE), and treatment-related AE leading to treatment discontinuations and death (Jerusalem et al. 2016). Although recent investigation on everolimus pharmacokinetics suggests no difference among patients aged <70 versus ≥ 70 years and is somewhat reassuring (Willemsen et al. 2016), one cannot make any conclusive statement regarding the utility of dose adjustment strategy,

even if potentially pharmaco-guided. Pharmacokinetics indeed does not investigate functional reserves of drug-targeted organs that are potentially affected by aging and thus cannot be singled out to explain pharmacodynamics as shown for docetaxel, for instance (ten Tije et al. 2005). The new modulators of endocrine resistance present different patterns of toxicity than chemotherapy and deserve similar cautious consideration.

Recently, palbociclib or ribociclib, an oral, small-molecule CDK 4/6 inhibitor, has shown a growth-inhibitory effect in HR+ BC cells by preventing cell-cycle progression from the G1 to S phase (Rocca et al. 2014) and works synergistically with endocrine agents. Subgroup analysis of patients <65 vs. ≥65 years in the PALOMA-1/TRIO-18 trial that assessed the efficacy and safety of palbociclib plus letrozole as first-line treatment for HR+, HER2-negative (HER2-) MBC has shown a significant improvement in PFS and clinical benefit rate (CBR) in both age groups with comparable safety profile at 29.6 months of median follow-up (Finn et al. 2015, 2016). Neutropenia, leukopenia, fatigue, and anemia had similar incidence (>10%) in both age groups receiving combination therapy; nausea was more common in ≥65 and alopecia in <65 age group. Irrespective of age, there was no significant differential incidence of permanent or temporary discontinuations and dose reductions due to AE (Finn et al. 2016). Similarly, palbociclib in combination with fulvestrant has shown a significant PFS improvement at 5.6 months follow-up in 521 women with HR+, HER2- MBC who progressed during prior endocrine therapy, where 24.8% were aged ≥65 years (Turner et al. 2015). Same trends were presented in the pooled analysis of the PFS benefit of palbociclib + endocrine therapy in 872 older patients (25% were ≥65–74, 10% were ≥75 years) without any new safety concerns identified (Rugo et al. 2016). Although patients aged ≥75 developed more myelosuppression, grade ≥3 incidence was similar across all age groups. A phase III trial on ribociclib combined with letrozole for first-line treatment of 668 postmenopausal women (44% aged ≥65 years) with HR+, HER2- recurrent or MBC has also shown increased PFS and a higher rate of myelosuppression (Hortobagyi et al. 2016). Dose interruptions and reductions due to AEs were more common in ribociclib arm. Although the subgroup age analysis on AE has not been reported, similar if not worse trends may be anticipated in older patients, and future investigations need to be explored particularly in the presence of comorbidities, polypharmacy and risk of interactions, and functional impairments. A summary of age comparison on efficacy and safety of novel endocrine treatment options for older adults treated for MBC is reported in Table 1.

Treatment of Choice for Older Women with Hormone Receptor-Negative, Triple-Negative, Hormone Refractory, or Rapidly Progressive Metastatic Breast Cancer

Chemotherapy is the best treatment option for MBC patients with hormone receptor-negative (HR-), hormone-refractory, triple-negative, or rapidly progressive disease (Biganzoli et al. 2012), regardless of age. A 7-year retrospective, single-center analysis of 117 patients aged ≥75 years has shown that chemotherapy administration can be tolerated in this population (Debled et al. 2011). Nevertheless, a significant age-related variation in chemotherapy use has been observed in older patients with MBC (Wan and Jubelirer 2015) highlighting that they are less likely to be offered treatment. Older patients have lesser tolerance to chemotherapy toxicities. A retrospective chart review of 318 patients aged 80+ years initiating chemotherapy (69% with ECOG 0–2; 12% for BC) found a high risk of hospitalization (32%) due to toxicity despite dose delays (31%), reductions (37%), and omission (15%) (Sud et al. 2015). Therefore, it is advocated that single-agent chemotherapy with better safety profile be chosen over combination regimens (Biganzoli et al. 2012). Several chemotherapy regimens have been studied in older women with MBC showing considerable efficacy and safety. The treatment choice will rely on tolerability to toxicities as determined by comorbidities, prior

treatment, dosing schedule, and patient preference. A summary of age comparison on treatment efficacy and safety in older adults treated for MBC using chemotherapy is reported in Table 2.

Capecitabine is a relatively safe and effective oral chemotherapy to use in older women with MBC and has been favored as first-line treatment and as subsequent treatment for those previously treated with anthracyclines and taxanes. In a study of 73 patients aged ≥65 years (median age 73), the dose of 1000 mg/m^2 twice daily was better tolerated than the standard dose of 1250 mg/m^2, particularly in patients with pre-existing renal impairment, with fewer patients needing dose reductions and lower overall incidence of grade 3/4 toxicities reported (Bajetta et al. 2005). The use of a lower-dose capecitabine was supported in a retrospective study on 89 patients aged ≥70 years, even in the first-line setting, confirming that dose reduction, although frequently required in this population, did not affect outcomes (Kotsori et al. 2010).

Vinorelbine has also shown efficacy and safety in MBC without any age-related pharmacokinetic difference (Sorio et al. 1997). Single-agent intravenous vinorelbine had a 35% and 32% objective response rate for first- and second-line treatment, respectively, in a multicenter, nonrandomized, open-label phase II study on 107 women (45% aged ≥65 years) (Weber et al. 1995). The objective efficacy appears to be rather modest when using oral preparation, but this might be biased

AE adverse events, *CBR* clinical benefit rate, *PFS* progression-free survival, *OS* overall survival

by the limited number of patients investigated and the varying drug bioavailabilities. In a phase II trial specifically conducted on 25 women aged ≥65 years, CBR was only 12%, median time to progression was 4.7 months, and fatigue and neutropenia were the most commonly reported severe toxicities (Baweja et al. 2006). Fractionated, metronomic dose regimen (50 mg flat dose 3× a week) has provided a comparable efficacy with good tolerability, posing a valid option among less fit older patients who are unable to tolerate the standard regimen (Addeo et al. 2010).

Therefore both capecitabine and vinorelbine are valid alternative to the two main classes of cytotoxic agents used in BC management, anthracyclines and taxanes (Biganzoli et al. 2015).

Anthracyclines indeed increase risks for cardiac toxicities. The risk is higher with older age, independent of comorbidities and performance status; current or history of cardiac dysfunction, hypertension, diabetes and coronary artery disease; prior treatment with anthracyclines; higher cumulative doses (≥400 mg/m^2); and short duration infusion (Aapro et al. 2011a). The International Society of Geriatric Oncology (SIOG) recommends screening for risk factors, rigorous monitoring of cardiac function and early interventions, and use of specific strategies to alleviate cardiotoxicity in this population (Aapro et al. 2011a). Bi-weekly 20 mg/m^2 of pegylated liposomal doxorubicin has been studied in 32 women ≥70 years with locally advanced or MBC (Basso et al. 2013). Response rate was 33.3% in the 27 evaluable women, median time to progression was 10.3 months, and 9.4% had treatment interruption due to toxicities, regardless of the frailty status (vulnerable vs. fit) based on the multidimensional geriatric assessment (Basso et al. 2013).

Conventional, solvent-based paclitaxel and docetaxel have shown significant efficacy when used in MBC. However, peripheral neuropathy is common, especially when given for an extended period of time, and due to the risk of hypersensitivity reactions, steroid premedication is usually administered, causing potential problems with hyperglycemia or even delirium. Older women aged ≥65 years have derived similar efficacy benefit with paclitaxel as younger women for first- or second-line treatment for MBC (Lichtman et al. 2012). However, older patients were noted to have a higher risk for developing specific hematological and non-hematological AEs, particularly more so among patients receiving it as second-line therapy (Lichtman et al. 2012). Weekly paclitaxel at a dose of 80 mg/m^2 was highly active in 46 older women with MBC (median age 74), having an ORR of 53.7%, but was associated with a 15.2% unacceptable toxicity, including febrile neutropenia, severe allergic reaction, pulmonary embolism, and somewhat troublesome and unusual congestive cardiac failure (Del Mastro et al. 2005). Tolerance to docetaxel, either weekly or three-weekly regimen, may also be difficult especially with fatigue, in addition to neurotoxicity, both potentially impacting the level function. It is certainly not to be given above 75 mg/m^2 in routine practice (Biganzoli et al. 2016), unlike in younger adults where 100 mg/m^2 is approved, although rarely used. Nanometer-sized albumin-bound paclitaxel (nab-paclitaxel) allowed safe drug infusion of higher paclitaxel doses, at shorter infusion time, without needing any premedications (Gradishar et al. 2005) and may be a cost-effective alternative when the cost of managing the toxicity is considered (Biganzoli et al. 2016). Prospective data on the optimal dosing, safety and efficacy of nab-paclitaxel in older patients with MBC is lacking. Post hoc analysis of two studies on different nab-paclitaxel dosing schedules vs. solvent-based taxanes in 114 older patients (≥65 years) with MBC has revealed better tolerability and efficacy of weekly nab-paclitaxel over that of the three-weekly schedule and solvent-based taxanes (Aapro et al. 2011b). Recent multicenter, noninterventional, prospective studies that included older MBC patients who were given nab-paclitaxel in a real-life setting have confirmed its efficacy and safety (Potthoff et al. 2016; Steger et al. 2016). The final results of the recently completed EFFECT trial are awaited, where preliminary results have shown that both doses of 100 and 125 mg/m^2 can be safely administered in this population, though non-hematological toxicities were more prevalent in the higher dose (Mislang et al. 2015).

Age subgroup analysis from 827 heavily pretreated patients who received a non-taxane microtubule inhibitor, eribulin mesylate, given at 1.4 mg/m^2 on days 1 and 8 on a 21-day cycle, revealed no age difference on efficacy outcomes in terms of OS, PFS, overall response rate (ORR), or CBR (Muss et al. 2014). No overall age effect was seen on the incidence of AE including neuropathy, neutropenia, and leukopenia, although patient aged ≥70 had a higher observed grade 3/4 treatment-related asthenia/fatigue and peripheral neuropathy (Muss et al. 2014).

Treatment of Choice for Older Women with HER2-Positive Disease

Patients with HER2+ disease should receive HER2-targeted therapy preferably in combination with chemotherapy or with endocrine therapy or as monotherapy depending on the HR status, disease burden or organ crisis, level of fitness, and patient preference (Biganzoli et al. 2012). Trastuzumab, pertuzumab, trastuzumab emtansine, and lapatinib are four HER2-targeted agents that have been approved for treatment of advanced BC with HER2 amplified disease. Meta-analysis of eight pivotal trials on unselected age groups has confirmed the efficacy benefit of adding HER2-targeted agents to standard therapy, with 22% improvement in OS, 37% improvement in PFS, and 67% increase in ORR (Harris et al. 2011). A prospective, multicenter, observational cohort (registHER) study of 1023 patients (17% aged ≥65 years) described the treatment patterns and clinical outcomes of patients with HER2 + MBC (Kaufman et al. 2012). The study revealed that PFS was higher among patients given trastuzumab as first-line treatment regardless of age; however, a significant OS advantage was only noted for patients aged <65 years (Kaufman et al. 2012). In addition, cardiotoxic events during the 27 months of follow-up were higher in older patients, highlighting the need for careful monitoring in this age group who may already be predisposed to cardiovascular events due to pre-existing cardiovascular comorbidities.

Lapatinib in combination with capecitabine has shown superiority to capecitabine alone in women (median 54 years, range 26–80) with HER2+ advanced diseased who progressed after taxane and trastuzumab therapy (Geyer et al. 2006). Similar efficacy was noted regardless of age, although with higher incidence of grade 3 AE (33% vs. 19%) among patients aged ≥70 years and with longer duration of diarrhea (Crown et al. 2008).

Predefined subgroup PFS analysis of pertuzumab, trastuzumab, and docetaxel (CLEOPATRA) according to age has confirmed the efficacy of adding pertuzumab as first-line treatment in older patients with advanced HER2+ MBC, without increasing the risk of cardiac dysfunction, although diarrhea, fatigue/asthenia, anorexia, vomiting, and dysgeusia were more frequently noted in patients ≥65 years, and more peripheral neuropathy attributed to pertuzumab in older patients (Miles et al. 2013). This regimen, therefore, is the new treatment of choice regardless of age, though best given to selected, fit older patients with minimal to no contravening comorbidities (e.g., underlying neuropathy, cardiac dysfunction).

The EMILIA study is a phase III trial showing improved PFS, OS, ORR, and safety profile of trastuzumab emtansine (T-DM1), an antibody-drug conjugate incorporating the HER2 with a microtubule inhibitory agents (DM1), against lapatinib and capecitabine in patients with HER2+, unresectable, locally advanced, or MBC previously treated with trastuzumab and taxanes (Verma et al. 2012). The benefit among patients aged ≥75 years, however, is less definite, without a confidence interval strong enough to show conclusive benefit even if potentially due to limited numbers included in the study (2.5% of the population). When T-DM1 was compared to a physician's chemotherapy of choice after progression from two or more HER2 agents including trastuzumab and lapatinib (TH3RESA), a significant improvement in PFS was noted at 7.2 months median follow-up, favoring T-DM1 (Krop et al. 2014). The number of patients with serious AEs was lower with T-DM1 (18% vs. 21%) although with more common grade ≥3 thrombocytopenia

compared with more prevalent grade ≥3 neutropenia, febrile neutropenia, and diarrhea in the physician's choice arm (2% vs. 16%, 1% vs. 4%, and <1% vs. 4%, respectively) (Krop et al. 2014). In a pooled safety analysis of 884 patients from 6 studies who were given T-DM1 monotherapy, a numerically higher incidence of grade ≥3 AE was reported in patients aged ≥65 years (52% vs. 44%) (Dieras et al. 2014). The safety and tolerability of T-DM1 was presented in the preliminary results of the KAMILLA study, revealing no age difference in all-grade and grade ≥3 AE associated with T-DM1 (Barrios et al. 2015). A summary of age comparison on treatment efficacy and safety of these trials is reported in Table 3.

Conclusion

Chronological age, by itself, should not preclude access to newer systemic agents, particularly in fit older patients. Although many evidences suggest similar efficacy and safety in many cancer treatments specific to BC regardless of age, it is clearly evident that older patients are predisposed to tolerate their treatment less due to higher susceptibility to toxicities, compounded by the presence of competing comorbidities, compromised organ function, and underlying frailty, to name a few. Hence, older patients warrant explicit monitoring and proactive management of treatment toxicities, which could well match cautious dose escalation strategy especially for vulnerable or frail ones. Despite recent advances in the systemic treatment of MBC, management of older patients is still challenging, given the difficulty of generalizing available treatment regimens to this complex patient group, mostly from underrepresentation in many pivotal clinical trials, variable aging trajectory, and lack of data on managing less-fit or frail patients. Thus, treatment goals and regimens should be personalized taking into account the treatment safety and efficacy but, more crucially, symptom control and burden of disease, the tumor biology and mechanism of resistance, as well as the patient heterogeneity and preference.

Abstract

Prostate cancer is the most common cancer in elderly patients. Localized disease is treated following almost the standard of younger patients. However, the treatment depends on health status evaluation. Only patients in good health status with aggressive prostate cancer will benefit of curative treatment, based on the induced comorbidities. Surgery is often not the best option, based on the increased side effects with increased age, compared to external beam radiotherapy. In nonmetastatic situations, androgen deprivation monotherapy has only a minimal place, while it is the standard of care in metastatic situations. Most patients with castration-resistant disease can receive standard treatment. Early introduction of palliative care is mandatory in order to optimize the outcome. Disease aggressiveness and health status are the two main factors to consider, on top of patient's wishes for final decision-making.

Introduction

In the USA, there were 119.8 per 100,000 men new prostate cancer diagnosed per year with a mortality estimated of 20.1 per 100,000 men per year based on 2010–2014 data (Ries and Krapcho 2014). Approximately 11.6% of men will be diagnosed with prostate cancer (PCa) at some point during their lifetime (Noone et al. 2017). The GLOBOCAN statistics show 1.1 million new worldwide PCa diagnosed in 2012, representing 15% of the diagnosed cancer in men, ranking it as the fifth most dreadful cause of cancer (Noone et al. 2017).

Moreover, the mortality rate is higher among black population (42 per 100,000 in sub-Saharan Africa compared to 8.8 per 100.000 in Asia). According to the *US Surveillance, Epidemiology, and End Results* (SEER) registry (Ries and Krapcho 2014), the median age at diagnosis and at death was, respectively, 66 years and 80 years during the 2009–2013 period (Ries and Krapcho 2014), with 71% of PCa-related deaths occur in men aged >75 years (Ries and Krapcho 2014). The incidence of elderly patient with PCa will increase as the life expectancy increases (US Census Bureau DIS). Almost 70% of cases are diagnosed based on prostate-specific antigen (PSA). In fact, PSA measure combined with digital rectal examination (DRE) has incredibly changed the diagnosis as PCa is actually discovered earlier with lower extension and better prognosis (Catalona et al. 2017). The main problem is the management of senior adults with PCa. Comorbidities are still the major driver of patient's survival, leading to adapted diagnosis and treatment strategies. This highlights the importance of dedicated guidelines for senior adults. The *International Society of Geriatric Oncology (SIOG)* has updated new recommendations for the management of elderly patient with PCa (Griebling 2015), as well as the *National Cancer Center Network* (NCCN) (NCCN 2016).

Clinical Presentation

Elevation of PSA level associated with suspicious DRE usually constitutes the first step for PCa diagnosis. As for younger men, no systematic

screening is recommended in senior adults (Hayes and Barry 2014). Furthermore the PSA-based early diagnosis is highly questionable beyond 75 years of age based on life expectancy. This must be balanced by individual life expectancy. It is currently recommended to offer an early diagnosis only to those men with at least 10–15 years life expectancy. This might represent up to 20% of aged men (Walter and Covinsky 2001). Biopsies are performed based on an abnormal PSA, a suspicious DRE, or clinical symptoms of advanced cancer (Lavallée et al. 2016).

Nonspecific urological problems such as voiding problems with abnormal/suspect DRE, dysuria, and hematuria might suggest the need for further evaluation. A decreased renal function associated with bilateral ureterohydronephrosis might lead to suspicion, as well as symptomatic metastases such as painful bone lesions (usually inflammatory or related to pressure or movements, pathological fractures). On X-ray, suspicious lesions are usually dense ivory-like bone sign. Neurological symptoms especially those suggesting spinal cord compression might also represent unusual warning signal when the disease is unknown.

Diagnosis, Staging, and Prognostic Factors

Diagnosis

Several guidelines on this topic have been published and recently updated such as the European Association of Urology (EAU) (Mottet et al. 2016; Cornford et al. 2016) and the NCCN (2016).

PCa is usually suspected on the basis of DRE and/or abnormal PSA levels. Formal diagnosis is based on pathology following prostate biopsy cores. Sometimes the diagnosis is made after non-oncological procedures such as transurethral resection of the prostate (TURP) or prostatectomy for benign prostatic enlargement (BPE).

PSA level increases with age (Cochetti et al. 2016) and must be performed in a non-inflammatory, noninfectious, and nontraumatized urinary tract (such as catheterization) matter period.

There is no specific serum PSA level (except when above several hundred ng/ml) which can confirm a PCa. An elevated PSA of $\leq$100 ng/mL can be seen in patients with acute prostatitis. PSA is mainly a signal that might lead to biopsy. Even if biopsy might be questionable in rare unequivocal situations (very high PSA, unequivocal DRE, and images of bone metastases), the standard of care is to confirm the diagnostic with histology, if such a diagnostic is useful. The method to be used for prostate biopsy – transrectal or transperineal biopsies – is still a matter of debate. Anti-aggregants (except aspirin) and anticoagulants must be stopped before biopsying. They are usually performed as outpatient procedures under ultrasound guidance, after an antibiotic prophylaxis. When a nodule is palpable, directed biopsies are done. When a curative approach is considered, 10–12 core biopsies must be obtained (Mottet et al. 2016). When palliation is the goal, less extensive sampling is enough. The role of a pre-biopsy multiparametric MRI (mpMRI) is still a matter of debate for the first biopsy round but is mandatory when a second round is considered based of persistent abnormality after a first negative round (Mottet et al. 2016).

Histological data should clarify the following points: the number of cores, presence or absence of cancer, length of cancer on each core, and, most importantly, modified Gleason score (Epstein et al. 2016), as well as the ISUP 2014 Gleason grade (Epstein et al. 2016). The Gleason score consists of the Gleason grade of the dominant component plus the highest grade, irrespective of its extent.

Staging Procedures

Accurate tumor staging is essential for treatment decision. It is based on the TNM staging (AJCC 2017). The clinical local staging is based on DRE and sometimes mpMRI. For extra-prostatic extension, only mpMRI is helpful, even if clearly suboptimal. Locoregional evaluation (i.e., lymph node involvement) is based on CT or MRI. Images are not specific, and suspicion is

only based on nodal size (1 cm in the shorter axis). The standard for nodal evaluation is histology following an extended lymph node dissection. Distant metastases are assessed by bone scan and CT scan or MRI. Bone scan is not disease-specific but only reflects the bone activity. If curative treatment is considered, a complete workup is needed. MRI is far superior to CT scan for local staging, and whole-body MRI is better compared to bone scan to rule out metastases. PET-FDG has no place in PCa management; PET-choline has no place in initial statement (Mottet et al. 2016).

Prognostic Factors

The optimal management of patients with PCa requires accurate assessment of the risk of unfavorable outcome. The most widely used prognostic factors are clinical T stage, pretreatment serum PSA level, and Gleason score on prostate biopsy. These factors are the basis of a stratification tool developed by D'Amico et al. (Pashtan et al. 2014; D'Amico et al. 2003). The low-risk group is defined as T1c–T2a, PSA level <10 ng/mL, and Gleason score ≤ 6. The high-risk group is based on either a T stage $\geq$T2c or a PSA >20 ng/mL or a Gleason score ≥ 8, whereas other patients are classified in the intermediate-risk group. This classification has been widely published and validated (Mottet et al. 2016).

Post-surgery results (pathology status: pT, pN, Gleason score of the specimen, margins) and the treatment result (PSA nadir) are the most predictive factors of survival (Mottet et al. 2016). Post-treatment scores and nomograms are still a matter of debate in terms of real practical clinical interest. They have to be externally validated. In case of prostate cancer recurrence, there is evidence that after radical prostatectomy or radiation therapy, PSA doubling time (PSA-DT) can identify patients at highest risk of distant metastases or death from the disease (D'Amico et al. 2004). The usual threshold is 12 months and the lower the PSA-DT, the worse the outcome.

In metastatic situations, median survival is 42 months in newly diagnosed patients (James et al. 2015), but the population is heterogeneous: survival is influenced by performance status, age, Gleason score, and metastases localization (visceral vs. bone only and bone localization). Survival is also based on the PSA-level 7 months after ADT. A study showed that PSA <4 ng/mL is a good prognostic factor in metastatic situations with a median overall survival around 13 months if PSA >4 ng/ml compared to 75 months if <0.2 ng/ml (Hussain et al. 2006).

In senior adults, on top of specific survival, overall survival is mainly driven by comorbidity. Age itself has almost no impact for non-cancer-specific death in localized PCa treated with RP (Tewari et al. 2004). At 10 years, most men with a Charlson Comorbidity Index (CCI) score >2 had died from competing causes, irrespective of age or tumor aggressiveness. Currently, the Cumulative Illness Score Rating-Geriatrics is the best tool for assessing mortality risk unrelated to PCa (Groome et al. 2011). Evaluation of these factors must be considered before doing anything, starting from requesting a PSA and a DRE in completely asymptomatic men.

Health Status Evaluation in Senior Adults

The working expert group of the SIOG guidelines (Droz et al. 2017) has highlighted the importance of health status evaluation in senior adults with PCa. The gold standard is the comprehensive geriatric assessment (CGA) (Decoster et al. 2015), including evaluation of the possibility for a patient to make decisions about his own treatment (Extermann et al. 2005). The following paragraph is a summary of these proposals.

Evaluation of Health Status

The G8 screening tool (Kenis et al. 2014) is the recommended screening tool, done in less than 5 min, even by a dedicated nurse. A score <14 means the need for a further geriatric evaluation starting with the simplified geriatric evaluation. A decision-making tree (Fig. 1) can help to evaluate health status (Tables 1 and 2).

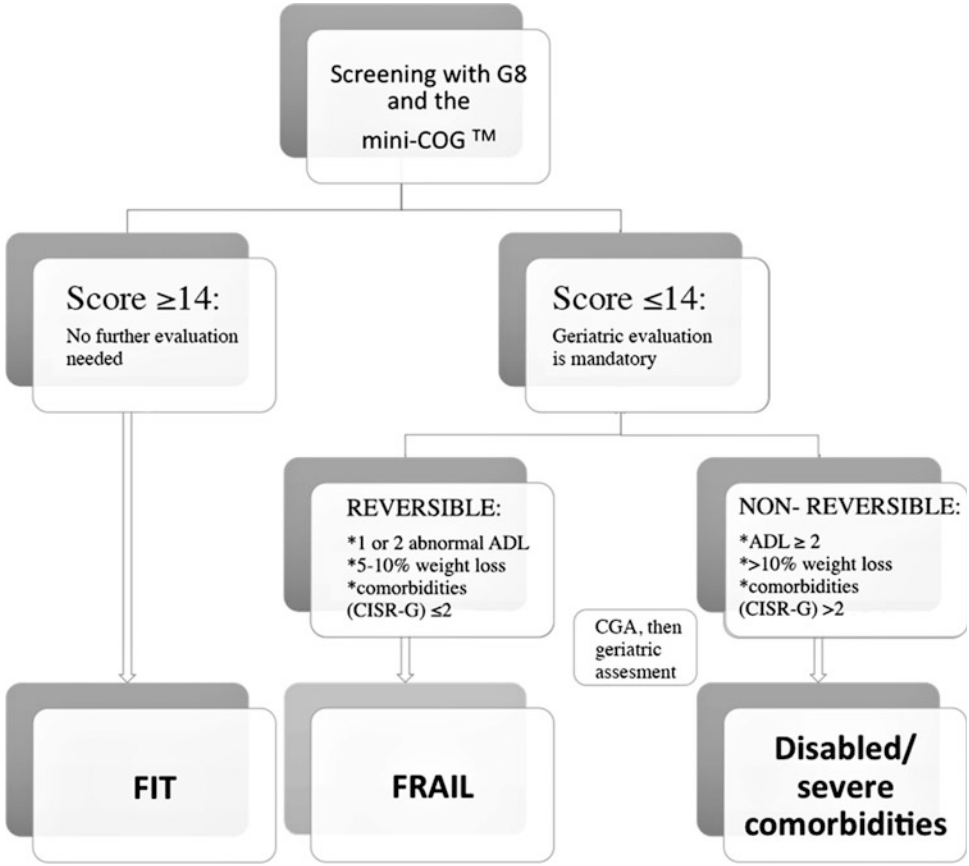

Fig. 1 Decision tree to determine patient health status. *mini-COG™* mini-COG™ cognitive test, *ADL* activities of daily living, *CIRS-G* cumulative illness rating score-geriatrics, *CGA* comprehensive geriatric assessment. (Adapted from Droz 2017)

Cognitive Screening

Patient's capacity to integrate and analyze information is essential to evaluate. The Mini Mental State Examination (MMSE) is a valid questionnaire to screen for cognitive impairment (Isenberg-Grzeda et al. 2016). A score of more than 24 points out of 30 means a normal cognition. A quicker alternative is the Mini-COG test, also possibly done by a dedicated nurse (Borson et al. 2003). Here a full geriatric assessment is needed if the score is $\leq$3 out of 5.

Simplified Geriatric Evaluation

It includes the measure of dependence through the activity of daily living (ADL) (Table 3) as well as the instrumental activity of daily living (IADL) (Table 4) (Lawton and Brody 1969), the analysis of the global comorbidities by the Cumulative Illness Score Rating-Geriatrics tool (CIRS-G) (Table 5) (Parmelee et al. 1995), and the approach of the nutritional status through weight loss during the past 3 months.

Patient Staging and Treatment Strategy After Geriatric Evaluation

The individual life expectancy estimation is based on both age and comorbidity (Heidenreich and Pfister 2016). It is well established that in localized prostate cancer situation, life expectancy should be $\geq$10 years. In metastatic castration-resistant

Table 1 G8 screening tool

Items	Possible responses	Score
(A) Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing, or swallowing difficulties?	Severe decrease in food intake	0
	Moderate decrease in food intake	1
	No decrease in food intake	2
(B) Weight loss during the last 3 months?	Weight loss >3 kg	0
	Does not know	1
	Weight loss between 1 and 3 kg	2
	No weight loss	3
(C) Mobility?	Bed or chair bound	0
	Able to get out of bed/chair but does not go out	1
	Goes out	2
(D) Neuropsychological problems?	Severe dementia or depression	0
	Mild dementia	1
	No psychological problems	2
(E) Body mass index (BMI)? (weight in kilograms)/(height in square meters)	BMI <19	0
	BMI 19 to <21	1
	BMI 21 to <23	2
	BMI ≥23	3
(F) Takes more than three prescription drugs per day?	Yes	0
	No	1
(G) In comparison with other people of the same age, how does the patient consider his/her health status?	Not as good	0
	Does not know	0,5
	As good	1
	Better	2
(H) Age	>85	0
	80–85	1
	<80	2
Total score 0–17	**Cutoff ≤14**	

situations, shorter life expectancy is expected and can be predicted with available electronic tools (University California San Francisco 2016). The Charlson Comorbidity Index (CCI) has been developed and seems to be the most reliable tool to predict non-prostate-cancer-related mortality. It contains 19 categories of comorbidity and predicts the 10-year mortality for a patient who may have a range of comorbid conditions. Each condition is assigned with a score of 1, 2, 3, or 6 depending on the risk of dying associated with this condition. Then, a life expectancy >10 years is the threshold that leads to an active PCa therapy, whereas a life expectancy <10 years favors the use of watchful waiting.

Patients can be directed to one of the four categories according to previous health status based on G8 score >14 (*fit* patient) versus G8 score <14 (included in *vulnerable* or *frail* patient). This will lead the treatment strategy combined with the patient's wishes:

- Fit patient should access standard treatment as the youngest one. They are expected to tolerate the standard treatment, but modalities and the choice of particular must be discussed with the patient.
- Vulnerable patients have reversible comorbidities (CIRS-G grade 2 comorbidities or a single grade 3; one to two reversible deficiencies in ADL and malnutrition). Once reversed with geriatric intervention, they should receive standard treatments.
- Frail patients have irreversible comorbidities that will negatively impact on their life

Table 2 MMSE

Maximum score	Patient's score	Questions
5		"What is the year? Season? Date? Day of the week? Month?"
5		"Where are we now: State? County? Town/city? Hospital? Floor?"
3		The examiner names three unrelated objects clearly and slowly and then asks the patient to name all three of them. The patient's response is used for scoring. The examiner repeats them until the patient learns all of them, if possible. Number of trials
5		"I would like you to count backward from 100 by sevens." (93, 86, 79,72, 65, . . .) Stop after five answers. Alternative: "Spell WORLD backwards." (D-L-R-O-W)
3		"Earlier I told you the names of three things. Can you tell me what those were?"
2		Show the patient two simple objects, such as a wristwatch and a pencil, and ask the patient to name them
1		"Repeat the phrase: 'No ifs, ands, or buts'"
3		"Take the paper in your right hand, fold it in half, and put it on the floor." (The examiner gives the patient a piece of blank paper.)
1		"Please read this and do what it says." (Written instruction is "Close your eyes.")
1		"Make up and write a sentence about anything." (This sentence must contain a noun and a verb.)
1		"Please copy this picture." (The examiner gives the patient a blank piece of paper and asks him/her to draw the symbol below. All ten angles must be present and two must intersect.)
30		Total

Instructions for Administration and Scoring of the MMSE

Orientation (10 points):

• Ask for the date. Then specifically ask for parts omitted (e.g., "Can you also tell me what season it is?"). One point for each correct answer

• Ask in turn, "Can you tell me the name of this hospital (town, county, etc.)?" One point for each correct answer

Registration (3 points):

• Say the names of three unrelated objects clearly and slowly, allowing approximately 1 s for each. After you have said all three, ask the patient to repeat them. The number of objects the patient names correctly upon the first repetition determines the score (0–3). If the patient does not repeat all three objects the first time, continue saying the names until the patient is able to repeat all three items, up to six trials. Record the number of trials it takes for the patient to learn the words. If the patient does not eventually learn all three, recall cannot be meaningfully tested

• After completing this task, tell the patient, "Try to remember the words, as I will ask for them in a little while"

Attention and Calculation (5 points):

• Ask the patient to begin with 100 and count backward by sevens. Stop after five subtractions (93, 86, 79, 72, 65). Score the total number of correct answers

• If the patient cannot or will not perform the subtraction task, ask the patient to spell the word "world" backward. The score is the number of letters in correct order (e.g., dlrow = 5, dlorw = 3)

Recall (3 points):

• Ask the patient if he or she can recall the three words you previously asked him or her to remember. Score the total number of correct answers (0–3)

Language and Praxis (9 points):

• **Naming**: Show the patient a wristwatch and ask the patient what it is. Repeat with a pencil. Score 1 point for each correct naming (0–2)

• **Repetition**: Ask the patient to repeat the sentence after you ("No ifs, ands, or buts."). Allow only one trial. Score 0 or 1

• **Three-Stage Command**: Give the patient a piece of blank paper and say, "Take this paper in your right hand, fold it in half, and put it on the floor." Score 1 point for each part of the command correctly executed

• **Reading**: On a blank piece of paper, print the sentence, "Close your eyes," in letters large enough for the patient to see clearly. Ask the patient to read the sentence and do what it says. Score 1 point only if the patient actually closes his or her eyes. This is not a test of memory, so you may prompt the patient to "do what it says" after the patient reads the sentence

(*continued*)

Table 2 (continued)

Maximum score	Patient's score	Questions
• **Writing**: Give the patient a blank piece of paper, and ask him or her to write a sentence for you. Do not dictate a sentence; it should be written spontaneously. The sentence must contain a subject and a verb and make sense. Correct grammar and punctuation are not necessary		
• **Copying**: Show the patient the picture of two intersecting pentagons, and ask the patient to copy the figure exactly as it is. All ten angles must be present, and two must intersect to score 1 point. Ignore tremor and rotation		
Interpretation of the MMSE		
Method	**Score**	**Interpretation**
Single cutoff	<24	Abnormal
Range	<21	Increased odds of dementia
	>25	Decreased odds of dementia
Education	21	Abnormal for eighth grade education
	<23	Abnormal for high school education
	<24	Abnormal for college education
Severity	24–30	No cognitive impairment
	18–23	Mild cognitive impairment
	0–17	Severe cognitive impairment

Table 3 Activity of daily living (ADL)

Activities point (1 or 0)	Independence (1 item = 1 point)	Dependence (1 item = 0 point)
Bathing	Bathes self completely or needs help in bathing only a single part of the body such as the back, genital area, or disabled extremity	Needs help with bathing more than one part of the body, getting in or out of bathtub or shower. Requires total bathing
Dressing	Gets clothes from closets and drawers and puts on clothes and outer garments complete with fasteners/may have help tying shoes	Needs help with dressing self or needs to be completely dressed
Toileting	Goes to toilet, gets on and off, arranges clothes, and cleans genital area without help	Needs help transferring to the toilet, cleaning self, or using bedpan or commode
Transferring	Moves in and out of bed or chair unassisted. Mechanical transferring aides are acceptable	Needs help in moving from bed to chair or requires a complete transfer
Continence	Exercises complete self-control over urination and defecation	Is partially or totally incontinent of bowel or bladder
Feeding	Gets food from the plate into the mouth without help. Preparation of food may be done by another person	Needs partial or total help with feeding or requires parenteral feeding
Score = 6 (independent)	**Score = 0 (dependent)**	

expectancy. These included patients with more than two deficiencies in ADL, multiple grade 3 comorbidities on CISR-G or any grade 4 comorbidity, or a weight loss >10%. The treatment must be adapted to the symptoms and the disease aggressiveness. Here the quality of life (QoL) is the main priority, and patients will often only be able to receive a suboptimal specific treatment.

- The last category represents terminal illness patient that should only receive palliative treatment. They should only be representing symptomatic patients, as none should have undergone any diagnostic workout if asymptomatic.

If mini-COG ™ score is abnormal, a complete neuropsychological assessment is wishable. Prospective studies are necessary to validate these tools in this specific elderly

prostate cancer population, like G8. Furthermore this classification in four groups must be validated by specific prospective studies.

Treatment of Localized Disease

Introduction

Many men with screening-detected localized PCa will not benefit from definitive treatment, and 45% of them are candidates for deferred management (Mottet et al. 2016). Overall mortality is a balance between specific and non-specific mortality, the latter being linked to comorbidities. In high-risk groups and in some intermediate ones, the disease aggressiveness outweighed comorbidity, even at 10 years. The ProtecT trial (Hamdy et al. 2016) has shown that specific survival at 10 years is equivalent in treated and actively monitored low-/intermediate-risk patients, close to 99%, highlighting the major role of individual life expectancy, especially in senior adults.

Decisions in senior adults must take into account the disease aggressiveness, the risk of dying from another cause, the risks of treatment, and the patient's preferences.

Senior adults have often a concomitant benign prostatic hyperplasia (BPH) associated with their PCa. If bothersome, BPH requires a specific treatment, even sometimes surgery that must be distinguished from the cancer treatment. However BPH might have a major impact in the treatment choice, regarding the various available modalities.

Deferred Treatment (Watchful Waiting, Active Surveillance)

Watchful waiting is a possible option in asymptomatic patients with localized PCa and limited life expectancy since PCa often progresses slowly (Adolfsson 2008). Active surveillance is an option only if the expected life expectancy is long in a subgroup of low-risk situations. It is based on repeated biopsy with the aim to postpone any active treatment as long as not definitively needed. The results of the active monitoring regimen described in the ProtecT trial (Hamdy et al. 2016) for low- and intermediate-risk patients, based on clinical and PSA follow-up with less rebiopsy, really question the exact place of active surveillance in senior adults, or at least in patients with less than 15 years life expectancy. No specific survival difference was observed at 10 years, and the chance that a difference is observed before 15 years is really minimal. Active treatments mostly benefit patients with intermediate- or high-risk disease and the longest expected survival or those with symptoms related to the disease itself.

Radical Prostatectomy

This treatment is the only one that has been associated with survival benefit compared to watchful waiting in a randomized controlled trial (Bill-Axelson et al. 2014). It allows a precise pathological staging. It is however associated with side effects such as incontinence and impotence, leading to a decreased physical health-related quality of life (HRQoL) (Mottet et al. 2016), even if this was recently discussed from the ProtecT trial. These side effects are directly linked to age (Adejoro et al. 2016), especially for incontinence and impotence. The observed results might therefore not be applicable to senior adult patients, as none were included. This increased risk of incontinence must be clearly presented to patients during the initial discussion for treatment choice.

The surgical approach (open, laparoscopic, or robotic) does not seem to have a major impact in the functional outcome (Yaxley et al. 2016), even if suggestions have been made favoring of the robot (Ficarra et al. 2012). Robotic prostatectomies do not reveal any difference in complications and continence between patients above or below 70. Only potency recovery appeared to be better in younger patients (Basto et al. 2014). Surgery will treat at the same time the disease and the voiding troubles, if present and severe.

In high-risk lesions, surgery in a multimodal strategy (i.e., combined with adjuvant and/or salvage modalities) leads to up to

Table 4 Instrumental activity of daily living (IADL)

Item	Instrumental activity	Score
A. Telephone	1. Operates telephone on own initiative, looks up and dials numbers, etc.	1
	2. Dials a few well-known numbers	1
	3. Answers telephone but does not dial	1
	4. Does not use telephone at all	0
B. Shopping	1. Takes care of all shopping needs independently	1
	2. Shops independently for small purchases	0
	3. Needs to be accompanied on any shopping trip	0
	4. Completely unable to shop	0
C. Food preparation	1. Plans, prepares, and serves adequate meals independently	1
	2. Prepares adequate meals if supplied with ingredients	0
	3. Heats and serves prepared meals or prepares meals but does not maintain adequate diet	0
	4. Needs to have meals prepared and served	0
D. Housekeeping	1. Maintains house alone or with occasional assistance (e.g., "heavy work domestic help")	1
	2. Performs light daily tasks such as dishwashing, bed making	1
	3. Performs light daily tasks but cannot maintain acceptable level of cleanliness	1
	4. Needs help with all home maintenance tasks	1
	5. Does not participate in any housekeeping tasks	0
E. Laundry	1. Does personal laundry completely	1
	2. Launders small items, rinses stockings, etc.	1
	3. All laundry must be done by others	0
F. Mode of transportation	1. Travels independently on public transportation or drives own car	1
	2. Arranges own travel via taxi, but does not otherwise use public transportation	1
	3. Travels on public transportation when assisted or accompanied by another	1
	4. Travel limited to taxi or automobile with assistance of another	0
	5. Does not travel at all	0
G. Responsibility for own medications	1. Is responsible for taking medication in correct dosages at correct time	1
	2. Takes responsibility if medication is prepared in advance in separate dosages	0
	3. Is not capable of dispensing own medication	0
H. Ability to handle finances	1. Manages financial matters independently (budgets, writes checks, pays rent and bills, goes to bank), collects and keeps track of income	1
	2. Manages day-to-day purchases but needs help with banking, major purchases, etc.	1
	3. Incapable of handling money	0

Scoring: The patient receives a score of 1 for each item A–H if his or her competence is rated at some minimal level or higher. Add the total points circled for A–H. The total score may range from 0 to 8. A lower score indicates a higher level of dependence

91% cancer-specific survival. Survival can reach 95% with one risk factor (Gleason >7 or T > T2 or PSA >20 ng/ml) and 79% with three risk factors (Joniau et al. 2015). Thirty-day mortality after radical prostatectomy increases with age; it is only 0.66% in men aged 70–79, with risk of death or major complications depending on comorbidities (Alibhai et al. 2005).

External Beam Radiotherapy

External beam radiotherapy (EBRT) combined with androgen deprivation therapy (ADT) is another standard of care for intermediate- or high-risk (localized or locally advanced) PCa. EBRT is associated with the same cancer-specific survival compared to surgery in low/intermediate risk (Hamdy et al. 2016), but a formal comparison

Table 5 Cumulative Illness Rating Scale (CIRS-G)

Rating strategy	
0	None
1	Mild (or past significant problem)
2	Moderate (moderate disability or morbidity, requires first-line therapy)
3	Severe (constant significant disability/uncontrollable chronic problems)
4	Extremely severe (immediate treatment required/end-organ failure/severe impairment in function)
Items	Score (0–4) per item
Heart	
Vascular	
Respiratory	
Eyes, ears, nose, throat, and larynx	
Upper GI	
Lower GI	
Hepatic	
Renal	
Genitourinary	
Musculoskeletal/integument	
Neurological	
Endocrine/metabolic	
Psychiatric illness	

Patients are classified as:
- **Fit** if they have no Grade 3 score
- **Vulnerable**: one or two Grade 3 scores
- **Frail**: >2 Grade 3 or any Grade 4 scores
- **Too sick**: multiple Grade 4 scores

for the high-risk group is still lacking. The treatment-related comorbidities with EBRT are independent of age for dose >72Gy using intensity-modulated or image-guided radiotherapy (Mottet et al. 2016). They are mainly represented by gastrointestinal morbidity and with those associated with ADT. Usually EBRT is combined with ADT in intermediate- and mainly high-risk situations. Duration of ADT is related to the risk category: 6 months for intermediate risk while 18 months to 3 years needed for high risk (Mottet et al. 2016). The initial cardiac status might decrease this duration, especially in intermediate- and high-risk localized disease. ADT has been shown to be associated with increased cardiovascular mortality in patients with a previous history of cardiovascular morbidity in a small cohort (D'Amico et al. 2008), and the practical impact of this finding must be balanced with the added benefit of ADT with high-risk lesions. Shortening the ADT duration to 18 months compared to 36 months might be an option. Moderate hypo-fractionation (20 fractions in 4 weeks) might represent the new standard for EBRT (Mottet et al. 2016), at a cost of a slightly increased bowel toxicity (Motwani and Tendulkar 2016). Brachytherapy is another form of radiotherapy, restricted mainly to low- and also for some low-intermediate-risk patients, with a prostate size <50 g and no or minimal voiding symptoms. It has no specific side effects in senior adults compared to younger ones (Mottet et al. 2016).

Androgen Deprivation Therapy (ADT)

ADT alone is inferior to ADT plus radiotherapy in terms of specific survival and must be considered as a real undertreatment (Mottet et al. 2016). In patient with localized or locally advanced PCa not

suitable or unwilling for a local treatment, immediate ADT should be only used in patients requiring symptom palliation or for those with a PSA level >50 ng/mL or with a PSA doubling time <12 months (Mottet et al. 2016).

Minimally Invasive Therapies

The real place of minimally invasive therapies such as HIFU, cryotherapy, photodynamic therapy, and laser therapy is still highly debatable (Valerio et al. 2017) and should only be considered as experimental (Mottet et al. 2016). In older patients, an increased rate of postoperative genitourinary complications such as incontinence and stricture when compared with the same procedure in younger men has been reported (Adejoro et al. 2016).

Treatment of Advanced Disease

Metastatic Hormone-Naïve Prostate Cancer

ADT is the first-line treatment in hormone-sensitive metastatic PCa. Since 2016 docetaxel associated with ADT is recommended for newly diagnosed metastatic patients fit enough for chemotherapy (James et al. 2015; Sweeney et al. 2015; Vale et al. 2016), leading to a 9% absolute survival benefit (Vale et al. 2016). Risk benefit must be discussed in senior adults (median age in trials <67 years) – as well as for those patients with a low volume disease, as suggested in one trial (Sweeney et al. 2015).

ADT is associated with several side effects that might have a real impact on QoL. ADT increases bone fracture risk, cognitive impairment, diabetes, thromboembolic events, and all-cause mortality in cardiovascular past medical history (Cornford et al. 2016).

These must all be considered and prevented as much as possible. A detailed review is far beyond the scope of this chapter but may be found in various guidelines (Mottet et al. 2016). Increased physical activity seems to be always of major benefit, whatever the considered side effect. Bone problems represent a major issue in senior adults. The SIOG recommends the evaluation of baseline bone mineral density and prevention of osteoporosis by calcium and vitamin D supplement (Droz et al. 2017). Neither monthly zoledronic acid nor denosumab has any place here as none has any impact on survival- or skeletal-related events (Mottet et al. 2016; Droz et al. 2017). They might be used for osteoporosis treatment, with specific dosages and regimen.

Castration-Resistant Prostate Cancer (CRPC)

When PCa becomes castration resistant (requiring a testosterone level checking), ADT must be continued lifelong. Major progresses have been made in metastatic castration-resistant PCa (mCRPC), while M0 situations, induced by the early use of ADT. The median life expectancy in mCRPC is around 30 months, highlighting the importance of QoL preservation. Guidelines regarding the best choice have been published but are clearly limited by the lack of dedicated trials (Cornford et al. 2016).

Endocrine Therapy

Abiraterone is a CYP17 inhibitor. It must be used with 10 mg prednisone daily to suppress the induced mineralocorticoid effect based on the increased ACTH level. It has been associated with an improved survival either before (Ryan et al. 2015) or after (Fizazi et al. 2015) docetaxel in mCRPC. It has an overall good tolerance, even in senior adults. The liver and cardiovascular function must be regularly checked, especially during the 1st months of treatment (Mottet et al. 2016). Enzalutamide is a new androgen receptor antagonist. It increases survival in mCRPC patients before (Beer and Tombal 2014) and after (Scher et al. 2012) docetaxel. Its tolerance is good, with different side effects compared to abiraterone. With both drugs, a 19–37% survival benefit has been observed, depending on the drug, the control arm, and the timing of treatment

regarding chemotherapy. Outside specific side effects and contraindication, no specific guidelines exist on the drug choice.

Chemotherapy

Docetaxel-based chemotherapy is the other standard drug in fit and vulnerable older men. Docetaxel 75 mg/m^2 every 3 weeks plus daily prednisone is the standard regimen for mCRPC (Droz et al. 2017). Overall survival benefit in men older than 75 years old is similar to that in younger patient (Droz et al. 2017) at a cost of more G3/G4 toxicities requiring either dose reduction or the early use of GCSF factors. A 50 mg/m^2 every 2 weeks regimen has been shown to be effective and better tolerated compared to the 75 mg regimen (Kellokumpu-Lehtinen et al. 2013). Following docetaxel treatment, cabazitaxel, another taxane, has been shown to improve survival. This regimen is feasible and as safe in senior adults as in younger ones, provided GCSF and diarrhea prevention are systematically considered (Heidenreich and Pfister 2016; Droz et al. 2016).

The chemotherapy toxicity in senior adults can be evaluated and predicted using two published models based on the geriatric health status, type of chemotherapy, and biological characteristics (Droz et al. 2017). Senior adults must be monitored closely considering the increased toxicity risk and possible regimen adaptation in senior adults (Droz et al. 2017). They should never be denied chemotherapy just based on age.

Radiotherapy, Radiopharmaceuticals, and Bone-Targeted Therapy

Elderly men with mCRPC and localized painful metastasis can benefit from palliative radiotherapy. In patients with painful bone metastases, without visceral metastases, radium-223 has been shown to extend overall survival, delay bone-related events, and improve life quality (Droz et al. 2017).

In mCRPC with bone metastases, zoledronic acid (4 mg IV) or denosumab (120 mg s/c) every 4 weeks is recommended to decrease skeletal-related complications (bone pathological fractures). Vitamin D and calcium supplementation are needed. Before using both drugs, an initial dental check is highly recommended (Mottet et al. 2016), and the duration of treatment should probably be limited to 2 years, considering the risk of devastating jaw necrosis.

Vaccine (Sipuleucel-T)

Not available outside the USA, with very limited data on senior adults.

Choosing the Right Treatment and Sequencing

No available data exist regarding these two points. No upfront comparison between drugs is available, and it is therefore impossible to select a best option in senior adults (Cornford et al. 2016). The selection will mainly be based on specific side effects and previous comorbidities. General rules suggest that it is better to alternate a hormonal treatment and a chemotherapy regimen, except in very selected populations, far beyond the scope of this chapter.

Palliative Care

The patient might benefit from very early introduction of palliative care (Cornford et al. 2016; Droz et al. 2017). This approach reduces treatment side effects, improve patient quality of life, and maximize the efficacy of therapies through the avoidance of dose reductions and treatment discontinuations (Scotté 2012). Major benefits are expected on anxiety and time spent in hospital reduction. Improving the quality of life is essential especially in the elderly.

Conclusion

Half of the patients with newly diagnosed prostate cancer are older than 70 years. Specific recommendations are available with the recently updated

SIOG guidelines (Droz et al. 2017). The key message is that elderly patients should be managed according to their health status and not according to age. They are best treated if a multidisciplinary team is involved, including geriatricians and dedicated nurses, on top of treatment specialists.

Evaluation of health status is essential with validated screening tools (the G8 questionnaire for health status, CISR-G scale for the assessment of comorbid conditions, the ADL for the degree of dependence, the weight loss estimation for nutritional status, the MMSE score for cognitive screening). Approach in the fit elderly should be the same as in younger patients and based on existing international recommendations, while it must be adapted in those with severe uncorrected comorbidities. This attitude is the only one able to reduce the undertreatment of senior adults and improve both the quality and the quantity of life.

Abstract

Bladder cancer (BC) is a disease of the elderly. Considering the increasing aging of the population, BC will become a more important public health challenge to manage in a very close future. However, the current treatment of BC in the elderly remains controversial. The purpose of this article is to review the previous literature to summarize and gather the current

knowledge in order to describe the management and treatment of BC in the elderly, in all its aspects. Original articles in English as well as reviews and editorials were selected based on their clinical relevance. The definition of elderly can differ as it is based on varying chronological ages. However, it is commonly found in most BC literature reviews that the elderly may be affected more severely than the younger people. Even if the management of non-muscle-invasive BC (NMIBC) does not strongly differ from younger patients, the impact of adjuvant intravesical immunotherapy might be inferior. Patients with muscle-invasive BC (MIBC) may benefit from a multidisciplinary geriatric evaluation. Radical cystectomy (RC) remains the curative treatment to BC, and elderly patients should not be withheld a potentially lifesaving intervention only based on chronological age. Bladder-sparing techniques may be a potential replacing treatment approach for unsuitable patients to a major surgical approach. Geriatric assessment could help identify the frail elderly and customize their perioperative care. In conclusion the treatment of BC in the elderly has to be patient-centered and focused on biological age and functional reserves. Age per se should not be the key driver.

Bladder cancer · Elderly · Geriatrics assessment · Treatment

Introduction

Bladder cancer (BC) is the 11th most common cancer worldwide, with higher incidence in more developed regions such as in Europe and North America, where it is the 5th most common cancer (Fitzmaurice et al. 2016). The age-adjusted incidence has been stable to slightly decreasing in the USA and Europe over the past few decades; however, these statistics belie important changes in the total burden of BC especially in elderly patients (Burger et al. 2013; Yazbek-Hanna et al. 2016).

The individual risk of BC, reflected in age stratum-specific incidence rates, increases dramatically over the age of 65, with the highest rates in patients aged 75–84 (Howlader et al. 2013). More men than women are affected by BC, at a ratio of 3:1, extending to 3.6:1 after 80 years of age (http://www.cancerresearchuk.org/health-professional/cancer-statistics/statistics-by-cancer-type/bladder-cancer/incidence#heading-One). Reductions in mortality from cardiovascular disease coupled with aging of the "baby boom" generation have radically changed the demographic structure of the population at risk for BC. For instance, there were 49,000 new cases in the USA in 1990, with a median age at diagnosis of 70 (http://onlinelibrary.wiley.com/doi/10.3322/canjclin.40.1.9/pdf). In 2005, 63,210 individuals were diagnosed at a median age of 72 (http://onlinelibrary.wiley.com/doi/10.3322/canjclin.55.1.10/full), and in 2016, an estimated 76,960 adults will be diagnosed, at a median age of 73 (http://seer.cancer.gov/statfacts/html/urinb.html) – the highest median age at diagnosis of all cancer sites (http://www.cancer.org/acs/groups/content/@research/documents/document/acspc-048074.pdf) (Fig. 1).

Based on US Census and SEER data, it is estimated that the number of cancer survivors in the USA will increase from 15.5 million in 2016 to 26.1 million by 2040, with the proportion of survivors >65 years old rising from 62% to 73% (Bluethmann et al. 2016). 765,950 BC survivors have been estimated in the USA as of January 1, 2016, to which 76,960 cases will be added this year as newly diagnosed BC patient. A tragic growth of the BC in older adults is highly likely to occur in the coming years, considering the constantly increasing number of cases over the past two decades and the continuous aging of the population forecasted over the next decades.

In the elderly patients, there is an impact of complex comorbidity from multiple chronic conditions, and more than half of them have moderate to severe comorbidity burden (by Charlson index – Fig. 2), substantially exceeding that of age-matched patients without cancer (Bluethmann et al. 2016). These estimates of the prevalent comorbidities in the population of older adults with BC are likely conservative, given common conditions not included in the Charlson (e.g., hypertension, arthritis, atrial fibrillation,

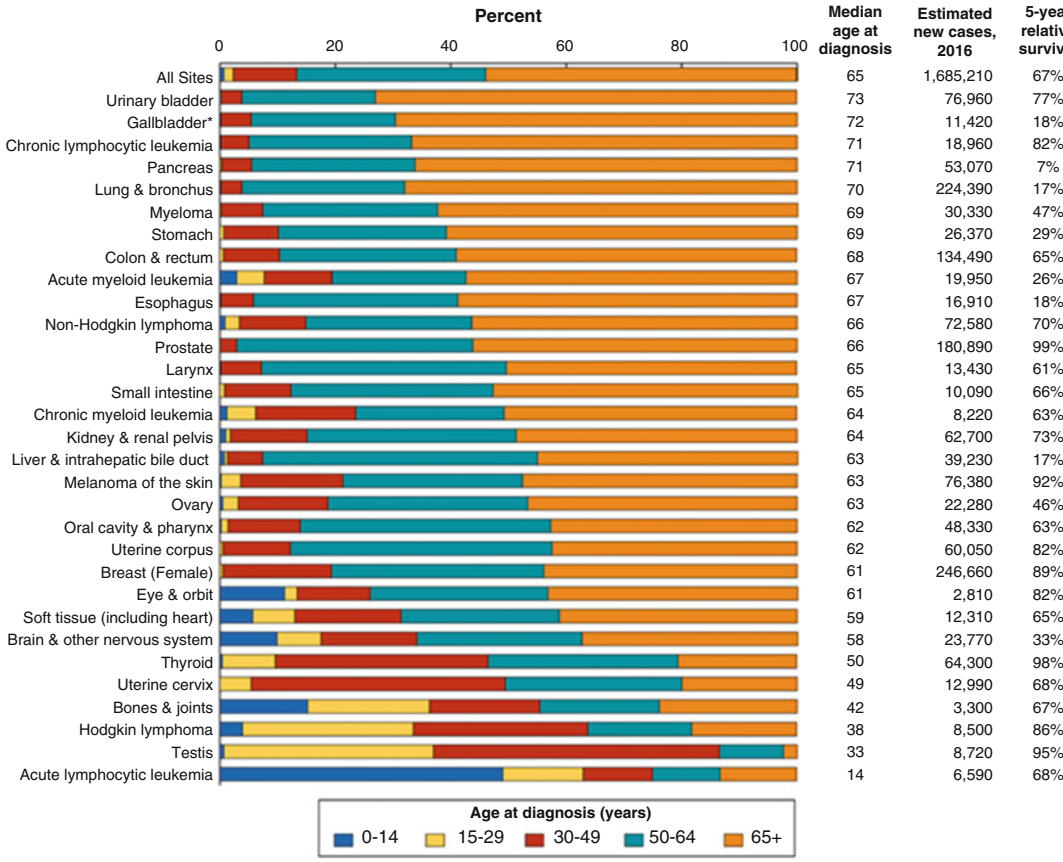

Fig. 1 Age distribution (%), median age at diagnosis, 5-year relative survival, and estimated number of cases by cancer type (http://www.cancer.org/acs/groups/content/@research/documents/document/acspc-048074.pdf)

chronic ischemic coronary artery disease, thromboembolic disease. . .). Moreover, elderly patients have other geriatric syndromes, including frailty, functional dependence, and cognitive impairment, underreported in large observational datasets. These factors present both competing risks for mortality and specific vulnerabilities for toxicity or complications of guideline-recommended treatment protocols.

Even though older patients are highly affected by cancer, the amount of studies toward this population stay minor (Levit et al. 2013) as highlighted in the US cooperative group clinical trials finding, with patients over 65 years of age representing only 56% of patients enrolled in BC trials, at a time when approximately 75% of patients in the population were in this age group (Hutchins et al. 1999).

Clinical Presentation

Macroscopic, asymptomatic hematuria is the most frequent although nonspecific sign of BC. Irritative voiding symptoms such as urgency, frequency, and nocturia can be caused by BC.

Score	Condition
1	Myocardial infarction (history, not ECG changes only)
	Congestive heart failure
	Peripheral vascular disease (includes aortic aneurysm ≥ 6 cm)
	Cerebrovascular disease: CVA with mild or no residua or TIA
	Dementia
	Chronic pulmonary disease
	Connective tissue disease
	Peptic ulcer disease
	Mild liver disease (without portal hypertension, includes chronic hepatitis)
	Diabetes without end-organ damage (excludes diet-controlled alone)
2	Hemiplegia
	Moderate or severe renal disease
	Diabetes with end-organ damage (retinopathy, neuropathy, nephropathy, or brittle diabetes)
	Tumor without metastases (exclude if >5 y from diagnosis)
	Leukemia (acute or chronic)
	Lymphoma
3	Moderate or severe liver disease
6	Metastatic Solid tumor
	AIDS (not just HIV positive)

NOTE. For each decade > 40 years of age, a score of 1 is added to the above score.
Abbreviations: ECG, electrocardiogram; CVA, cerebrovascular accident; TIA, transient ischemic attack; AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

Fig. 2 Charlson comorbidity index scoring system (Bluethmann et al. 2016)

Gross hematuria from tumor growth results in frequent emergency department visits, catheterizations, surgical intervention to prevent bleeding and relieve clot burden, as well as hospitalizations for continuous bladder irrigation. A significant anemia may also be caused by a large bleeding tumor, possibly requesting blood transfusions. Local pelvic symptoms as well as lower extremity pain from nodal and nerve involvement (Bellmunt et al. 2014) or upper tract obstruction may suggest a muscle-invasive situation, as well as symptomatic metastases.

Etiology and Risk Factors, Pathology, Natural History, and Tumor Biology

Etiology and Risk Factors

BC has been induced by tobacco smoking for 65% of all cases of BC in the male and 30% in the female population. Non-smokers have two to four times lower relative risk (RR) of developing BC compared to smokers. Aromatic amines including amphetamines, and specifically benzidines and derivatives, are likely to be involved in tobacco smoking as well as in the occupational environment (i.e., industrial manufacturing of chemicals, hair dyes, rubber, and metal). In Middle East, schistosomiasis has been a major risk factor, leading to a slightly different histological lesion.

Pathology

BC is also known as urothelial carcinoma, 90% of cases being transitional cell carcinoma (TCC). Among all the TCCs, 90% are observed in the urinary bladder, 8% in the renal pelvis or calyx, and the remaining 2% within the ureter. More rarely, the urothelial lining of the urethra can also be a site of disease. This TCC can be associated with metaplasia (adenocarcinoma or squamous cell) but are still considered as TCC. The remaining 10% of BC cases correspond to the pure adenocarcinoma, squamous cell carcinoma (mainly schistosomiasis induced), and small cell carcinoma, with a different prognosis and often a different treatment strategy.

A disease limited to the mucosa or submucosal layer through the lamina propria represents about 75% of cases and is referred to as non-muscle-

invasive BC (NMIBC) (Siegel et al. 2016; Aldousari and Kassouf 2010). Infiltration into the muscular wall or beyond is referred to as muscle-invasive BC (MIBC) situation. NMIBC shows an intrinsic tendency toward recurrence in about 50–80% of cases. Progression to MIBC can be observed in up to 50% of cases, chiefly depending on grade and stage of initial lesions.

While MIBC is always high grade, NMIBC is likely to represent two distinct diseases: low-risk or low-grade papillary malignancy that rarely invades or metastases but may recur. High-risk diseases are less common, with high-grade lesions invading the submucosa (about 15–25% of cases), with a high tendency to recurrence and invasion, possibly leading to metastases and ultimately death.

In general, cancer-specific survival ranges from 70% to 85% at 10 years in high-grade NMIBC and is even higher for low-grade disease (Palou et al. 2012).

Peculiar features are shown by carcinoma in situ (CIS) or Tis and consist of a high-grade flat, intraepithelial lesion. Macroscopically, its recognition is inconstant, but when visible, it is discernible by reddish velvety spots. CIS can be found in association with established high-grade NMIBC or MIBC. Although the natural origin of the presence of CIS is not entirely known, it may have a substantially negative influence on prognosis.

Patients and clinicians are provided numbers of clinical decision support tools to help them estimate the risks of NMIBC recurrence and progression, according to the patients' clinical and pathologic characteristics. The European Organization for Research and Treatment of Cancer (EORTC) has provided a risk calculator, which is a scoring system that combines data from seven clinical trials of NMIBC to predict recurrence and progression (Sylvester et al. 2006).

Diagnosis, Staging, and Prognostic

Diagnosis: Imaging, Cystoscopy, and Urinary Cytopathology

The diagnosis of BC is based on histology. But endoscopy is the main imaging process allowing to characterize the lesions: number, location, size, aspects of the lesions, and the base. This endoscopy can be optimized with fluorescence (especially for CIS detection) that will decrease the rate of missed lesions. This endoscopy is always the first step of a transurethral bladder resection but can represent an independent procedure when the diagnosis of bladder lesion is questionable.

A bladder sonography is only helpful if positive, but false positivity exists as well (clots, stones). It allows checking the potential impact of the tumor on the upper urinary tract with an upper tract dilatation. The general staging is obtained through an abdomen and pelvic computed tomography (CT) scans with contrast medium. Real bladder wall infiltration on CT scan is neither very sensitive nor specific, with underestimation and overestimation of up to 50%. MRI might be an alternative with at least the same definition (Witjes et al. 2016).

Urine cytopathology (UC) is mandatory and particularly helpful in the diagnosis of lesions which are not detectable at cystoscopy (CIS), as tumors of the urothelium exfoliate cells in the urine. Only positive findings are relevant.

Staging

The 2002 TNM classification approved by the Union Internationale Contre le Cancer (UICC) was updated in 2009 (7th version) and then in December 2016 when the TNM 8th edition was published (Figs. 3 and 4) (Brierley et al. 2016).

Stage and grade are significant prognostic factors for recurrence, progression, and survival and, therefore, are critical for the appropriate treatment and management of MIBC (Epstein et al. 1998).

Additional descriptors include lymphatic vessel invasion (L) and venous invasion (V).

Accurate pathological diagnosis, grading, and staging of BC represent the cornerstone for treatment strategy.

Prognosis of BC

Tumor recurrence and progression are the clinically relevant events associated with the diagnosis of NMIBC. Generally, high-grade NMIBC

T - Primary tumour			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Ta	Non-invasive papillary carcinoma		
Tis	Carcinoma *in situ*: 'flat tumor'		
T1	Tumor invades subepithelial connective tissue		
	Tumor invades muscle		
T2		T2a	Tumor invades superficial muscle (inner half)
		T2b	Tumor invades deep muscle (outer half)
T3	Tumor invades perivesical tissue		
		T3a	Microscopically
		T3b	Macroscopically (extravesical mass)
T4	Tumor invades any of the following: prostate, uterus, vagina, pelvic wall, abdominal wall		
		T4a	Tumor invades prostate, uterus or vagina
		T4b	Tumor invades pelvic wall or abdominal wall
N - Lymph nodes			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastasis in a single lymph node in the true pelvis (hypogastric, obturator, external iliac, or presacral)		
N2	Metastasis in multiple lymph nodes in the true pelvis (hypogastric, obturator, external iliac, or presacral)		
N3	Metastasis in common iliac lymph node(s)		
M - Distant metastasis			
MX	Distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis		
		M1a	positive nodes in the retroperitoneal
		M1b	visceral metastases

Fig. 3 TNM classification of urinary BC

1973 WHO grading
Urothelial papilloma
Grade 1: well differentiated
Grade 2: moderately differentiated
Grade 3: poorly differentiated
2004 WHO grading system [papillary lesions]
Urothelial papilloma (completely benign lesion)
Papillary urothelial neoplasm of low malignant potential (PUNLMP)
Low-grade (LG) papillary urothelial carcinoma
High-grade (HG) papillary urothelial carcinoma

Fig. 4 Histopathologic grading (G) of urinary BC/WHO grading in 1973 and in 2004

including CIS tends to behave aggressively, whereas low-grade pTa and pT1 tumors have a good prognosis with a very low lethal potential. About 66% of patients have tumor recurrences and new occurrences during follow-up depending on several factors such as stage, grade, number, and size of initial lesions. A reliable and strong prognostic factor for outcome is the presence of recurrence at the first 3-month cystoscopy. Progression, defined by developing muscle invasion from initial NMIBC, differs depending on stage, grade, number, and size of initial lesion(s) from approximately 4% for low-grade Ta tumors to 50% for high-grade T1 tumors. The risk of progression is highly increased when there is an associated CIS.

The 5-year survival after radical cystectomy (RC) for MIBC is generally unsatisfactory. It varies from 40% to 60% for stage pT2 N0 M0 to around 15% for stage pT4. With surgery alone, the median survival for pN+ patients may vary from 6 to 24 months.

Patients who do not consider a treatment for a diagnosed BC have to concede the potential threats on their QoL and survival. However the natural history of untreated BC is poorly documented.

Geriatric Assessments (GA)

GA is used to detect earlier unrecognized conditions that can influence treatment tolerance, efficacy, and surgical outcomes. Recognizing areas of vulnerability may assist for specific correction and in decision-making.

Comorbid conditions and impairments of activities of daily living are experienced by many older patients with BC and may lead to a higher competing risk of non-cancer mortality (Fung et al. 2014; Messing et al. 2009; Noon et al. 2013). The negative effect of age on overall and BC-specific survival may be explained by an increase disease aggressiveness with age or by an undertreatment of senior adults compared to their younger counterparts (Messing et al. 2009; Noon et al. 2013; Nielsen et al. 2007). To increase BC outcomes, decision-making process must be improved including HRQoL into the treatment choice but also specific interventions, such as exercise or GA (Karvinen et al. 2007; Wildes et al. 2013).

The elderly patients with MIBC are defied for taking a decision about various treatment interventions. Clinical trials that establish the safety and efficacy of cancer treatment (surgery and chemotherapy) include patients who are on average 10 years younger than those with the disease in the general community and include patients without significant health status issues (i.e., minimal comorbidity and good performance status). Thus, there is not many data regarding the safety and efficacy of standard treatment regimens in older patients, especially those who are aged $\geq$75 years and have other health status issues (Hutchins et al. 1999). Many of those patients, especially those with a smoking history, are much more likely to have underlying health issues that can increase complications and reduce the efficacy of cancer interventions. "Fit" older patients should have treatment as needed for their MIBC, regardless of their age, whereas those with significant health issues leading to a shortened life expectancy may not benefit from aggressive modalities and may be more vulnerable to harms from treatment. Medical concomitant disease impacts the feasibility and tolerability of cystectomy and perioperative chemotherapy (Goossens-Laan et al. 2014) and may increase the risk of mortality from surgery or chemotherapy toxicity. Comorbidities, functional impairments or mobility disability, and geriatric syndromes (including cognitive impairment) provide clinically useful, reasonably accurate estimates of individual life expectancy (Walter and Covinsky 2001). The independent effects of health status considerations such as functional impairments, mobility disability, and geriatric syndromes have not been well studied in patients with BC, while all those elements have been independently associated with a higher risk of surgical complications, morbidity, and mortality from

chemotherapy in other cancers (Mohile et al. 2012; Koroukian et al. 2010). Thus, sarcopenia, as measured by decreased lumbar skeletal muscle thickness, was independently associated with all-cause mortality (hazard ratio 1.93; $P = 0.004$) on multivariable analysis in over 200 patients who were to undergo cystectomy (Psutka et al. 2014).

Both patient-reported outcomes and objective tests of functional are included in GA tools. Their importance has been highlighted in several guidelines, such as the EAU (Witjes et al. 2016). It encompasses measurements of functional status, cognitive status, comorbidities, self-assessed health status, mobility, nutritional status, psychological status, and social circumstances (Mohile et al. 2012; Pal et al. 2010). GA has been applied in oncological clinical practice and trials (Hurria et al. 2005, 2010). Higher geriatric depression score, cognitive impairment, and decreased functional status independently predicted worse 30-day and 90-day major complication rates after surgery (OR, 4.02, 95% CI 1.24–13.09) and increased likelihood of discharge to a facility (OR 3.16, 95% CI 1.99–13.02) (Balducci and Extermann 2000a; Gill et al. 2003; Hewitt et al. 2015). Frailty was also associated with longer postoperative hospitalization and greater mortality at 30 and 90 days (OR 4.0, 95% CI 1.1–15.2 and OR 3.0, 95% CI 1.3–7.4, respectively) (Hewitt et al. 2015).

GA can detect patients with highest risk for serious toxicities from chemotherapy (Hurria et al. 2011). A predictive risk stratification tool was developed for the incidence of chemotherapy toxicity. It was shown to be superior to the Karnofsky Performance Status, the existing standard use by oncologists for assessment of fitness. GA can help identify patients with cognitive impairment, which has implications for consent to any form of treatment and increases risk from therapies such as surgery and chemotherapy (Ketelaars et al. 2013).

With the intention to classify elderly patients with BC for any treatments, information from the GA can categorize patients into three groups that correlate with life expectancy (Mohile et al. 2009). Patients who are "fit" have no significant functional impairments and/or comorbidities. Those ones should be treated as the younger ones. Patients classified as "frail" demonstrate dependence in basic functional tasks, significantly impaired mobility and significant comorbidities (Balducci and Extermann 2000a). They are at highest risk for toxicities from cancer treatment, and adapted treatment strategy must be considered: less toxic, with an acceptable benefit/risk balance, but maybe suboptimal in terms of cancer control. In the third group, patients have concomitant mild functional or cognitive issues, well-controlled and non-life-threatening comorbid conditions, and/or depression. They are considered as vulnerable leading to a more complex decision. Targeted interventions must be proposed with the aim of getting better outcomes from cancer-directed therapy. For example, "prehabilitation" to improve physical functioning may improve the likelihood of tolerating treatment for patients with mobility disorders (Gill et al. 2003).

Treatments

Treatment of BC

Most senior adults will benefit from a multidisciplinary evaluation, including the geriatrician. Supportive care should be considered early, especially in senior adults considering the aggressiveness of the disease and related treatments, especially in MIBC. Standard definitive treatment raises a multitude of concerns including treatment toxicity or competing risk from morbidity in elderly patients with BC and is therefore less likely to be applied to them (Nielsen et al. 2007; Karvinen et al. 2007; Wildes et al. 2013). If left untreated, disease progression leading to severe bothersome symptoms impacting the QoL may arise. This is a special situation in MIBC where the active treatments are often difficult to conduct in senior adults with comorbidities where preserving the QoL might be considered as a more important objective compared to specific survival. Therefore decision-making among this population must reach a balance between treatment risks and

potential side effects according to the natural history of untreated BC within the context of individual patient's goals and preferences.

Calculating the risks of recurrence and progression might prove to be valuable when advising senior adults with NMIBC. Although these NMIBC are rarely lethal in the mid-term, their recurrence and progression might significantly impact the QoL and must be balanced with the surgical and anesthetic risks that goes along with repeated transurethral resection of bladder tumor (TURBT) for recurrences or toxicities and complications associated with adjuvant intravesical instillations sometimes needed. Shared decision-making for surveillance schedules and treatments between patients and providers is therefore mandatory.

The decrease specific survival in senior adults compared to younger ones might be partly based of lower rates of standard-of-care treatment (Goossens-Laan et al. 2014; Hollenbeck et al. 2004; Prout et al. 2005). In addition, poorer oncologic outcomes such as upstaged disease and worse cancer-specific mortality may be more prevalent among older adults (Nielsen et al. 2007).

Treatment of NMIBC

Non-muscle-invasive BC (NMIBC) represents 70% of all diagnosed cases of BC (Burger et al. 2013; Ferlay et al. 2015; Babjuk et al. 2017). The high recurrence rates of NMIBC with up to 80% can be managed via transurethral resection (TURBT) and intravesical treatments (e.g., BCG or chemotherapeutic agents) should the situation require it. Even though surgical procedures and the anesthesia may pose a significant risk for some highly morbid elderly, they are neither especially intrusive nor disruptive and generally well tolerated. The high risk associated with some morbid cases with multiple comorbidities might be handled through follow-up or fulguration under local anesthesia, especially in low volume and low-risk disease (Shariat et al. 2009; Hofbauer et al. 2014).

With NMIBC being a heterogeneous disease, it can be classified according to EORTC nomograms in the risk of recurrence and progression (Cambier et al. 2016). It was shown that tumor size (Cho et al. 2009), stage (Cho et al. 2009), grade (Cho et al. 2009; Shi et al. 2008), and multiplicity (Cho et al. 2009) are increasing with age, while surgical retreatments (Noon et al. 2013), frequency of installation therapies, and response to intravesical treatments (Joudi et al. 2006; Kohjimoto et al. 2010) are decreasing. As a result these factors lead to increased recurrence (Cho et al. 2009; Shi et al. 2008), decreased progression-free survival (Cho et al. 2009; Thomas et al. 2012), and increased specific mortality (Noon et al. 2013; Thomas et al. 2012) in the elderly (Hofbauer et al. 2014).

Transurethral Resection of Bladder Tumor (TURBT)

Transurethral resection of bladder tumor (TURBT) plays a key role as it is the only modality for accurate diagnosis, grading, and staging. The superficial part/s of the lesion/s as well as the underlying muscular wall are sampled and sent separately to the pathologist as "endoluminal" portion and a full-thickness sample of the detrusor muscle underlying the tumor.

TURBT also constitutes the standard treatment for NMIBC if all visible lesions are completely eradicated. This can be optimized using fluorescence (Babjuk et al. 2017). Although local control of the disease is achieved in less than one-third of the patients, morbidity and mortality after TURBT are low, and 5-year survival is high.

Laser treatment and fulguration are considered palliative treatments.

Intravesical Therapies

Intravesical treatments are recommended for intermediate- and high-risk lesions (Babjuk et al. 2017). For intermediate- and high-risk tumors, BCG is advised as standard of care, while in the case of intermediate-risk tumors, introduction of a chemotherapeutic drug is an option.

There is not much systemic absorption of the intravesical agents; hence they do not produce significant systemic effects to which elderly might be more vulnerable (Shariat et al. 2010).

Age above 69 years has been considered as an independent risk factor for BCG side effects (Heiner and Terris 2008). This was later challenged with a further analysis from the EORTC GU trial 30911. Although it suggests that elderly may have stopped treatment earlier, there was no association of age and toxicity leading to discontinuation of treatment in patients with NMIBC (Oddens et al. 2016).

The long-term prognosis in intermediate- and high-risk NMIBC patients treated with BCG that are >70 years old is rather poor, although BCG is more effective than epirubicin independent of patient age (Oddens et al. 2014). This condition might be explained by changes in the immune response among the elderly (Solana et al. 2006), while adjuvant BCG improves overall and cancer-specific survival in patients with NMIBC (Spencer et al. 2013). Storage and voiding problems might impair the feasibility of intravesical therapies. These problems have to be considered and evaluated. Additionally symptomatic side effects of an intravesical therapy might lead to a discontinuation or delay of treatment.

Alternative treatment strategies have been investigated recently or are currently under investigation, especially for patients with intermediate- and high-risk tumors or for those with BCG failure (Kamat et al. 2015; Lightfoot et al. 2011).

Treatment of MIBC

Surgical Treatment

Radical Cystectomy (RC)

The standard treatment for MIBC as well as for the recurrent NMIBC stages CIS, pTis, or pTis G3 is radical cystectomy (RC). RC includes the ablation of the bladder with the prostate and seminal vesicles in the male patient and the bladder, uterus, ovaries, and a portion of the anterior vaginal wall in the female patient. A bilateral pelvic lymphadenectomy is mandatory.

Generally speaking the 5-year recurrence-free survival rate in patients undergoing radical cystectomy for BC ranges between 58% and 68%, and 5-year cancer-specific survival ranges between 62% and 66% (Shariat et al. 2006; Nuhn et al. 2012; Stein et al. 2001).

It is standard of care to use a neoadjuvant cisplatin-based chemotherapy (Witjes et al. 2016). However most senior adult patients are not fit enough to receive it. Therefore upfront RC is often considered. Eligibility criteria for chemotherapy are discussed in the next paragraph (metastatic situations).

The increased average age of the population has led to an increased diagnosis of muscle-infiltrative BC especially among the elderly. The analysis of the SEER database found that RC is only performed in 21% of patients with MIBC and at an age over 65 years (Gore et al. 2010). Similar results were found in the US National Cancer Database, with cystectomy rates of 55%, 45%, and 21% in patients <70 years, 70–79 years, or >79 years, respectively. About half of the patients >80 years did not receive any treatment (Fedeli et al. 2011). Because of refinements in patient selection in the elderly and in perioperative management, RC is considered also in senior adults.

Urinary diversion encompasses several possibilities ranging from the simple ureterocutaneostomy and ureteroileostomy (also referred to as an ileal conduit) to more sophisticated forms of urinary diversion consisting in continent reservoirs obtained from intestinal segments. These reservoirs are referred to as orthotopic neobladders implanted at the anatomical site of the native bladder. An alternative can be the implementation of a continent catheterizable reservoir at a different site, most frequently the lower right abdomen, and those reservoirs are referred to as heterotopic reservoirs. Indications for a specific urinary diversion should be based on the features of both the tumor and the host. However, most cohorts suggest that an ileal conduit might most often be the most acceptable urinary diversion in senior adults, based on poor functional outcome with ileal neobladder.

The Eighth Annual BC Think Tank sponsored by the BC Advocacy Network reported and pointed out that interventions to enhance quality of life (QoL) for BC patients is an urgent, unmet need and should be a research priority (Apolo et al. 2015).

Many HRQoL questionnaire instruments are used to assess broad cancer treatment side effects, including the European Organization for Research and Treatment of Cancer Quality of Life Questionnaire version 3.0 QLQ-C30 (EORTC QLQ-C30) and Functional Assessment of Cancer Therapy-General (Botteman et al. 2003; Parkinson and Konety 2004).

The majority of the HRQoL research in BC is concentrated on the effect of RC and urinary diversions on HRQoL of patients with MIBC, whereas HRQoL of patients with non-MIBC have hardly been studied (Singer et al. 2013; Mohamed et al. 2012). Eventually, limited study size and poor response rates (30.38–51%) have weakened the numbers of studies of HRQoL (Karvinen et al. 2007; Gilbert et al. 2007).

One study compared prospective modifications in HRQoL among 1,432 patients aged more than 65 years diagnosed with cancer through 9 cancer sites during 2 years with changes in HRQoL in a similar time frame among a set of matched control subjects without cancers (Reeve et al. 2009). The mean physical component score (PCS) of BC patients ($n = 89$) decreased significantly by 4.3 points (95% confidence interval [CI] −2.5, −6.1) over 2 years, whereas the decrease in the mean mental component score (MCS) was not statistically significant. A cross-sectional study of 1,476 BC patients (aged ≥65 years) compared HRQoL among those before and after BC diagnosis. Significant differences in mean PCS and MCS scores between the pre-BC and post-BC diagnosis groups were observed (Fung et al. 2014). In patients with NMIBC, the differences in the PCS (−1.9; $P < 0.01$) and MCS (−1.4, $P = 0.01$) scores were statistically significant but not clinically meaningful (less than 5 points (Norman et al. 2003)). In contrast, there was a statistically and clinically significant difference in the PCS score (−5.3; $P < 0.01$) for patients with MIBC, whereas the difference in the MCS score was not statistically significant (−2.7, $P = 0.07$).

Among patients with MIBC, decreases in HRQoL develop after RC with urinary tract reconstruction (i.e., ileal conduit, continent cutaneous diversion, or orthotropic neobladder), especially in the sexual and urinary area (Botteman et al. 2003; Roaldsen et al. 2014). Besides many studies comparing several forms of urinary diversion after RC, none has proven to achieve a formal superiority in regard to HRQoL (Mohamed et al. 2012; Roaldsen et al. 2014). There are advantages and drawbacks of each procedure; thus, it is important to give patients adequate information about each surgical approach to allow for an individual choice (Roaldsen et al. 2014). Decreased body image and self-consciousness and decreases in travel and activity levels are frequently experienced by patients with ileal conduits, whereas those with continent diversions report urinary symptoms related to use of a catheter (Botteman et al. 2003; Roaldsen et al. 2014). Among patients who underwent construction of orthotropic neobladders, nighttime leakage can negatively impact HRQoL (Botteman et al. 2003). In addition, acute and long-term adverse effects related to systemic chemotherapy and radiotherapy for treatment of MIBC may also affect HRQoL (Efstathiou et al. 2009; von der Maase et al. 2000).

Complications of RC and urinary diversion are reported in the range of 15–35%, mainly influenced by general patients' status and the complexity of the diversion.

RC is a major procedure. Perioperative morbidity and mortality are increased, and continence rates after orthotopic urinary diversion are impaired in elderly patients undergoing radical cystectomy. Complications are frequent in this population, particularly when an extended postoperative period (90 days instead of 30 days) is considered (Froehner et al. 2009). Although age alone does not preclude radical cystectomy for muscle-invasive or recurrent bladder cancer or for certain types of urinary diversion, careful surveillance is required, even after the first 30 days after surgery. Excellent perioperative management may contribute to the prevention of morbidity and mortality of radical cystectomy. Data on perioperative morbidity of cystectomy in elderly is controversial. While some studies show significant differences others do not, this discrepancy exists most likely due to a non-standardized record of perioperative complications or patient

selection. Mortalities are reported between 0% and 11% (Froehner et al. 2009).

Surgical Alternatives to Radical Cystectomy

Bladder-preserving techniques might represent an alternative for elderly patients diagnosed with MIBC who are unfit for RC or who decline major surgery.

Often unimodal treatments will result in a worse outcome with reduced cause-specific survival (CSS) and reduced rates of local tumor control and should not be used in a curative approach. None of those treatments have proven to be equally effective as cystectomy in prospective trials.

For some well-selected elderly patients, a bladder-sparing approach might be beneficial. This might result in a good functional outcome as well as a higher QoL and a very acceptable survival.

Radical TURBT Only

Large cystectomy series show pT0 rates in up to 18.9% of patients (Stein et al. 2001; Hautmann et al. 2012). These patients might be suitable for a TURBT and bladder-preserving approaches even if a 20% nodal involvement in organ-confined pT2 tumors is observed (Stein et al. 2001). Furthermore up to 22% of patients may have missed lesions with TURBT alone in MIBC (Herr 1999). Two prospective cohorts of very selected patients have shown 10 years specific survival of 79.5% and 76%. The first one was based on deep negative tumor bed biopsy (Solsona et al. 2010), while the second requested a formal deep negative reTURBT (Herr 2001). None accepted CIS. Therefore a radical aggressive TURBT alone is an option for very selected cases. Nevertheless, about 33% of the patients will show local recurrence with muscle-invasive disease.

Partial Cystectomy +/− Lymphadenectomy

For patient suitable for an open-surgical approach, a partial cystectomy combined with a pelvic lymphadenectomy might be a reasonable option for very selected cases, leading to 5-year relapse-free survival rates from 39% to 67% (Kassouf et al. 2006), 10-year metastasis-free survival of 66%, and cancer-specific survival rates of 63%. These results are in line with those observed with RC with 61% and 58%, respectively (Knoedler et al. 2012). They have been conformed in a SEER database including NMIBC and MIBC (Capitanio et al. 2009). However they must be restricted to selected patients with a single lesion up to 3 cm, located in the mobile part of the bladder, without concomitant CIS or hydronephrosis.

Nonsurgical Treatments/Organ-Sparing Treatments

Radio-Chemotherapy

Nonsurgical organ-sparing treatments have been investigated with the reason to keep up the native bladder in muscle-intrusive BC.

Chemotherapy (CT) is utilized at decreased amounts as radio sensitizer, after TURBT, in relationship with external irradiation. Five-year survival in the same range as observed after RC has been obtained, with a bladder remaining in place in around 40% of patients.

Radio-chemotherapy is considered as a treatment choice for patients with contraindications for surgery and as a viable option in some surgical candidates. 65 Gy are standard for the radiotherapy.

Mak et al. performed a pooled analysis of long-term outcomes in patients with MIBC enrolled across studies which evaluated bladder-preserving combined-modality therapy (CMT) for MIBC, reserving cystectomy for salvage treatment. Six multicenter, prospective RTOG bladder-preserving CMT protocols were analyzed. For similarly staged MIBC, a long-term disease-specific survival (DSS) comparable to immediate cystectomy studies was observed. A total of 468 patients (median age, 66 years) with clinical stage between T2 and T4a N0 were included. All protocols included chemotherapy with cisplatin (several dosages and several schedules), requesting a good renal function. Thirty-six percent of the patients were older than 70 years. Given the low incidence of late recurrences with long-term follow-up, CMT can be considered as an alternative to radical cystectomy, especially in

elderly patients not well suited for surgery (Mak et al. 2014). The best results are observed in patients with single T2 lesion and complete TURBT, no hydronephrosis, no CIS, no tumor invasion into stroma of the prostate, and with well-functioning bladder. A large cohort of CMT without cisplatin has been published and might represent a real alternative for those unfit for RC and having an impaired renal function (James et al. 2012). A formal systematic review has just been published highlighting the urgent need for specific trials dealing with senior adults and MIBC (Fonteyne et al. 2018).

Metastatic Bladder Cancer/Palliative Treatments

Cystectomy with urinary diversion has almost no place and should only be performed in locally advanced disease if there is no other option for relieve of symptoms (Witjes et al. 2016). In a palliative setting, TURBT or radiotherapy alone should be used to control symptomatic bleeding, pain, and urinary check.

In metastatic situation, chemotherapy is the gold standard, provided it is feasible. The standard first-line for fit patients is based on a cisplatin combination: either with methotrexate, vinblastine, and adriamycin (MVAC regimen) or gemcitabine (GC regimen). They prolong survival to up to 14.8 and 13.8 months, respectively, compared to monotherapy and older combinations. According to Bajorin, three poor prognostic factors exist when a cisplatin-based regimen is used: Karnofsky PS of $\leq$80% and presence of visceral metastases and anemia (Bajorin et al. 1999). When no poor risk factor exists, the median survival is close to 36 months, 20 months with 1 factor, and only 12 months with 2 or more.

Senior adults have some important specific characteristics to be considered. They have a decreased bone marrow reserve, leading to a frequent use of primary GCSF prophylaxis and/or reduced primary dose or adapted schedule. These patients are underrepresented in clinical trials (Hutchins et al. 1999; Crome et al. 2011). Senior adults may have neuropathies with dose cumulative (platinum, taxanes) associated risk. They might worsen in 30% even after treatment discontinuation. Most importantly up to 50% of patients are ineligible for cisplatin (Dash et al. 2006; Balducci and Extermann 2000b). Galsky made in 2011 an update of the EORTC definition of "fit" and "unfit" for cisplatin: "fit" is GFR $\geq$ 60 ml/min and PS 0-1, while "unfit" represents a GFR <60 ml/min and/or PS $\geq$2 (Galsky et al. 2011; De Santis et al. 2011).

The first randomized phase II/III trial in this setting compared methotrexate/carboplatin/vinblastine (M-CAVI) and carboplatin/gemcitabine (GCa) in patients unfit for cisplatin (De Santis et al. 2011). OS was not statistically significantly different between GCa (9.3 months) and M-CAVI (8.1 months) HR 0.94 (0.72–1.22). However less adverse effects were observed with GC (9.3%) compared to M-CAVI (21.2%). Finally it was shown that if PS 2 and GFR <60 (Bajorin poor prognosis group), the median OS was only 5.5 months (20% had only 1 cycle), suggesting that the best supportive care might be the best option in this group.

Vinflunine based chemotherapy might represent an alternative, based on a phase II trial (De Santis et al. 2014).

The second-line treatment chemotherapy is a challenge. Multiple small phase II trials use mainly single agents with high variability of response and heterogeneity of population. Gemcitabine seems active but is already used in first-line. Cisplatin can be rechallenged but only if the relapse is after 6–12 months, provided the patient is fit enough to receive it (Witjes et al. 2016).

The main drug for second-line treatment is vinflunine. In the critical stage III trial, it was compared with best supportive care (Bellmunt et al. 2013). Vinflunine was associated with a 2-month survival benefit (6.9 vs. 4.6 months) however not statistically significant ($p = 0.287$), and this drug is not considered worldwide as a standard regimen. Furthermore, based on decreased vinflunine clearance in patients above 80 years of age, the regimen should be adapted to age. Many different medications have been tried yet the outcomes are very frustrating with low reaction rates and short survival (Sonpavde et al. 2010).

New Drugs

The scene of treatment for urothelial carcinomas is evolving. New immunotherapy medicines with immune checkpoint inhibitors are assessed and appeared to be fascinating in cutting-edge urothelial carcinomas. As second-line treatment following platinum salt, two large phase II trials observed much better responses compared to standard second-line regimen. This was confirmed in a phase III trial comparing pembrolizumab to chemotherapy, with a HR for survival of 0.7 (0.59–0.91) (Bellmunt et al. 2017). This new class of compounds must be specifically tested in senior adults, even if there is apparently no difference in relapse-free survival based on age, from a meta-analysis of various CTLA-4 or PD-1 inhibitors (Nishijima et al. 2016). Elderly patients need to be formally analyzed and included in clinical trials.

Follow-Up

NMIBC

Patients with pTa, pT1, and low-grade tumors ought to get urinary cytology and cystoscopy three to four times each year for the initial 2 years and at 6-month intervals for the accompanying 3 years. Patients with high-grade lesions or CIS should be followed at 3-month intervals for the initial 3 years and at 6-month intervals from that point, based on the EAU guidelines which are of low grade (grade C) (Babjuk et al. 2017). No specific recommendation is available for senior adults.

MIBC

After Optimal Treatment

As the EAU guidelines advocate, an appropriate schedule for disease monitoring should be based on natural timing of recurrence, probability and site of recurrence, functional monitoring after urinary diversion, and possible treatment of recurrence. The follow-up after RC should monitor the urethra, pelvis, and additionally upper urinary urothelium, liver, lungs, and skeletal apparatus, as well as retroperitoneal nodes. It is not standardized and mainly based on expert opinion. It needs to be adjusted to patients' status. Patients after curative treatment, with a significant life expectancy, have to follow up in view of suggestion by the distinctive rules, e.g., EAU rules on MIBC (Witjes et al. 2016). Outside the clinic, biology and repeated CT scan represent the basis of this follow-up. Patients with bladder-preserving approaches with curative intent must be followed using the same parameters but also including cystoscopy and urinary cytology to monitor intravesical recurrence.

The functional complications after RC should be followed. They are related to the used bowel segment. They specifically include vitamin B12 deficiency, renal function, urinary infections, as well as chronic metabolic acidosis potentially associated with an increased long-term bone loss (Gupta et al. 2014). Specific complications such as ureterointestinal anastomosis, stoma complications in patients with ileal conduit, neobladder continence problems, and emptying dysfunction must also be considered. Particular attention should be paid to assess the quality of life.

Palliative Treatment

In non-curative or metastatic BC, HRQoL is reduced. There is limited literature describing HRQoL in BC patients receiving palliative care, but there are reports of bladder-related symptoms relieved by palliative surgery, RT, and/or chemotherapy. Palliative care must be considered as a priority and are optimized within a multidisciplinary team including a geriatrician team. Supportive measures have to be implemented as early as possible.

localized disease are as high as 50%. There are a number of issues unique to the older adult with RCC which needs to be taken into account before assigning the appropriate treatment to them. Although new drugs approved for mRCC were assessed without age limitation and included patients over 65 years, no prospective trials dedicated to older RCC patients are available. All the phase III mRCC trials conducted thus far showed no differences in efficacy and toxicity in younger patients compared to older patients (>65 years old). A similar scenario is also observed in the setting of the treatment of localized RCC in the elderly. This textbook chapter aims to highlight the unique issues afflicting the elderly with both localized and metastatic RCC and comprehensively review the key treatment modalities that are currently used in their management.

Geriatric · Older generation · Kidney cancer · Renal cell carcinoma · Guidelines

Introduction

Renal cell carcinoma (RCC) is the 16th most common cancer and 17th most lethal cancer in the world (Global Burden of Disease Cancer Collaboration et al. 2015). It afflicts over 290,000 people all over the world. RCC is a disease in which malignant cells are found in the lining of tubules in the kidney. RCC accounts for approximately 3% of adult malignancies and can exist in both sporadic and hereditary forms. Sporadic form of RCC is usually seen in older patients, whereas the hereditary cases are usually seen in the young. The hereditary form is mostly caused by a mutation in the Von Hippel Lindau (VHL) gene. The clinical presentation of RCC is usually described with the classic symptoms such as hematuria, flank pain, and fever. However with the advances in imaging modalities, more kidney tumors are now being detected incidentally. RCC is usually unilateral. Bilateral RCC comprises of only 2–4% of the cases. It is a clinically and pathologically heterogeneous disease, with clear cell renal cell carcinoma (CCRCC) being the dominant subtype accounting for over 75% of all RCCs. Other subtypes include papillary RCC (type I and type II), chromophobe RCC, hereditary cancer syndromes, multilocular cystic RCC, collecting duct carcinoma, medullary carcinoma, mucinous tubular and spindle cell carcinoma, neuroblastoma-associated RCC, Xp11.2 translocation-*TFE3* carcinoma, hereditary leiomyomatosis and RCC syndrome-associated RCC, succinate dehydrogenase-deficient RCC, tubulocystic RCC, acquired cystic disease-associated RCC, clear cell papillary RCC, and unclassified lesion (Moch et al. 2016). In general the treatment of RCC is divided into groups, namely, clear cell RCC and non-clear cell RCC.

Renal Cell Carcinoma in the Older Adults

RCC is predominantly a disease afflicting the elderly with a median age of diagnosis of 64 years. About one third of all RCC patients are metastatic at diagnosis, while recurrence rates of those treated for localized disease are as high as 50% (Bellmunt et al. 2009). Older adults are usually underrepresented in clinical trials, and the majority of data for both the localized and metastatic RCC setting arises from subgroup analyses. Although new drugs approved for mRCC were assessed without age limitation and included patients over 65 years, no prospective trials dedicated to older mRCC patients are available. All the phase III mRCC trials conducted thus far showed no differences in efficacy and toxicity in younger patients compared to older patients (>65 years old). A systematic review published by International Society of Geriatric Oncology (SIOG) Task Force in 2009 has also suggested that the survival benefits seen in patients aged 65 years and above were similar to those in younger patients and that the frequency and severity of major toxicities was not more in the older patients (Bellmunt et al. 2009). Another point to note

is that older patients included in pivotal studies typically have more robust general health than unselected older patients and fewer of the comorbidities that complicate management. It is hence important to use the information from the various sources of clinical research to incorporate into best practice approaches in the treatment of the older RCC patient taking into account issues unique to this group of patients.

Unique Issues Affecting Older Adults with RCC

Physiology of Aging and Treatment Implications

There is a decline in physiologic function as a person grows old. These physiologic changes can affect the pharmacokinetics and pharmacodynamics of various therapies used in the treatment of RCC. A decrease in liver mass and blood flow lead to a decline in liver function. Cytochrome P450 microsomal enzyme system has been reported to decline with the increase in age and may substantially impact on drug metabolism, given that the most of the targeted agents for mRCC are metabolized via that system (Wauthier et al. 2007). In the aging kidney, blood flow decreases and glomeruli are lost and replaced by fat and fibrotic tissue. The aging kidney coupled with the presence of renal cell carcinoma both lead to lower glomerular filtration rate which affects the pharmacokinetics of targeted therapies in mRCC. However some studies have shown that mRCC targeted therapy like sunitinib is efficacious with an acceptable toxicity profile in patients with impaired kidney function as well (Kim et al. 2014), hence still making it a viable option for older mRCC patients.

With the recent emergence of immune checkpoint inhibitors in mRCC, it can be assumed that age-related changes of the immune system (immunosenescence) might also affect the efficacy and toxicity of immunotherapy in elderly patients. It is known that the expression of immune checkpoints on T cells increases with age, hence making this potentially an important target with immune-oncology drugs (Hurez et al. 2017).

Decision-Making and Treatment Goals

Older patients differ from their younger counterparts when it comes to cancer treatment decision-making processes. They are different as they are less likely to trade off current quality of life for a prolonged overall survival compared to their younger counterparts (Yellen et al. 1994). Maintaining quality of life is often the primary goal of therapy in treating older cancer patients. As such tolerability of treatment-related side effects in older RCC patients as mentioned above plays a key role in the decision-making process. A recent systematic review found that one of the key reasons for declining cancer treatment in the older adults is the fear of side effects (Puts et al. 2015). It is then very important to address the specific concerns and treatment goals an older RCC patient may have in order to enable them to make the best informed decision possible.

Treatment Compliance

Compliance to treatment is also another issue to consider in treating older RCC patients. Treatment for mRCC predominantly involves oral therapies (in the first line, e.g., only bevacizumab and interferon are exceptions to this). This presents several advantages such as no complications related to intravenous access. However oral administration also comes with its own problems in the elderly, specifically with the issue of drug compliance. Older patients may be less compliant to oral medication compared to younger ones due to reasons like polypharmacy, cognitive decline (memory related), and general physical decline (eyesight, physical strength) (Biganzoli et al. 2015) . Poor compliance can lead to decreased drug efficacy and increased toxicities if the patient persists in taking medication during rest periods (with sunitinib, e.g., which has a 2-week rest

period after 4 weeks of treatment). As these drugs are taken at home with follow-ups only at certain intervals, there could also be issues with drug continuation and compliance. In order to increase compliance and ensure that the older mRCC patient is aware and is able to seek help for treatment-related toxicities, it would be very important to also ascertain the social support the patient has. If the social support is poor, and there is no community-based home visit help, prescription of these oral targeted therapies may not be appropriate in certain groups of older patients. In this instance and in circumstances where there are issues pertaining to compliance to oral therapies, an intravenous option like bevacizumab and interferon should be considered as an alternative option.

The Role of Geriatric Assessment (GA) in Older RCC Patients

In view of the multiple physical, psychological, and social issues that affect older RCC patients described above, it is important to ensure the appropriate tool is used in their assessment. This is where the role of a cancer-based GA comes in as the most appropriate tool to predict functional age of these older RCC patients (Kanesvaran et al. 2011). For example, should an mRCC patient have polypharmacy due to their multiple comorbidities, drug interactions become a major concern. For patients on vascular endothelial growth factor (VEGF) tyrosine kinase inhibitors (TKI), proton pump inhibitors used concurrently can inhibit the absorption of the TKI leading to lower serum concentration levels and lower efficacy. In terms of nutritional status, a malnourished patient with mRCC planned to be treated with targeted therapy is at higher risk of dying compared to a well-nourished patient (Gu et al. 2015). Hence it is important for the treating oncologist to work in a multidisciplinary setting to ensure that older RCC patients who are found to have GA deficits are optimized. This will ensure they are fit for surgery in a case of localized RCC and fit for systemic therapies in a case of mRCC.

Localized Renal Cell Carcinoma in Older Adults

Surgical Resection

In a fit older patient with localized RCC, there are a number of treatment options available. These options vary depending on the size and site of the tumor. For solitary RCC that is 4 cm or larger, the treatment of choice would be a radical nephrectomy (RN), with removal of the entire kidney and tumor en bloc. This can be done safely laparoscopically with a recent study showing reduced morbidity in terms of genitourinary complication rate and blood loss in older RCC patients (Becker et al. 2014). With the rising use of imaging in the investigation of various symptoms in elderly patients, there has been an increase in the detection of small renal masses (<4 cm), of which a substantial number are RCCs (Sun et al. 2011). In these patients, nephron-sparing surgeries, or partial nephrectomy, are the treatment of choice for localized small RCC based on their location. In certain locations, partial nephrectomy (PN) may not be possible leading to RN instead. As mentioned in the paragraph above, there are numerous physiologic factors inherent in the older adults that may complicate the surgical procedure. Hence a key element in the management of an older RCC patient planned for surgery would be optimal preoperative assessment (Chow et al. 2012).

Adjuvant Systemic Therapies

After surgical resection of the RCC, there is currently some data to support the role of adjuvant therapy. Two recently published phase 3 randomized controlled trials (RCTs) – the ASSURE trial (Haas et al. 2016) and the S-TRAC trial (Ravaud et al. 2016) – have tested sunitinib and sorafenib (in ASSURE only) as an adjuvant treatment for high-risk, resected RCC with contrasting results. In the S-TRAC trial, sunitinib increased median disease-free survival in patients with clear cell RCC who were at very high risk of recurrence, but at the time of data cutoff, data were not mature

enough to evaluate overall survival (Ravaud et al. 2016). In contrast, in the ASSURE trial, adjuvant sunitinib and sorafenib have been reported to provide no additional survival benefit compared to placebo and caused an increase in treatment-related toxicities (Haas et al. 2016). A meta-analysis done in 2016 on the combined benefit-risk profile of adjuvant sunitinib for RCC failed to demonstrate survival benefit and confirmed increased toxicities with the use of sunitinib in the adjuvant setting (Gyawali and Ando 2017). The median age of the patients in the ASSURE trial was reported as 56 years for the sunitinib arm (range, 49–64) and 55 years for the sorafenib arm (range, 48–63 years); whereas for the S-TRAC trial, the median age of the patients for the sunitinib arm is 57 years (range, 25–83 years). This makes the data to some extent valid for older RCC patients as well in view of the fact that subsets of patients were over 65 years of age. However an area of concern here with regard to the use of adjuvant sunitinib in older mRCC patients would be its use for a prolonged period of 1 year, in which the toxicities of the treatment may be overwhelming. Another factor to take into consideration in the older adult would be competing comorbidities that may impact their life expectancy and hence nullify the benefit of adjuvant therapy. Hence these patients (who may have a shortened projected life expectancy) should be on an active surveillance protocol although there is currently no consensus on the exact frequency of imaging in the various guidelines (Williamson et al. 2016). Presently, there are no standardized guidelines for surveillance regimens and thresholds for implementation of delayed treatment.

Ablation Therapies

Ablative therapies have been developed for the treatment of small renal tumors as an alternative to nephron-sparing surgery, with the goal of reducing operative morbidity. The common methods of ablative therapy are radiofrequency ablation (RFA) and cryoablation. A systematic review comparing cryoablation versus partial nephrectomy reported higher rates of tumor progression with cryoablation, but both had similar low rates of distant metastases of less than 2% (Klatte et al. 2011), hence making it a suitable option for the frail elderly patient. Frail older patients with a shortened life expectancy with a solitary renal mass may not have many treatment options available to them. For large tumors (>=4 cm), these patients may not be fit for any form of surgery and will be treated expectantly for symptom control with palliative care.

Active Surveillance

Another feasible option for the frail older RCC patient would be active surveillance of their small RCC (Borghesi et al. 2015) due to the slow growth of small renal masses. Active surveillance has emerged as an alternative to surgical or medical intervention for small renal masses, especially for select patients with poor renal function and high operative risk or the elderly with comorbid disease.

Metastatic Renal Cell Carcinoma in the Older Adult

Clear Cell mRCC

Role of Cytoreductive Nephrectomy

There were two randomized control trials conducted more than a decade ago, in the cytokine era, which found a survival benefit for mRCC patients who had undergone cytoreductive nephrectomies (CN). In the study done by the SWOG group, the median age of patients undergoing CN was 58.8 years, although the oldest patient in the study was 87 years of age (Flanigan et al. 2001). In the European study done at about the same time, the median age of the patients was 61 years and the oldest patient enrolled was 76 years of age (Mickisch et al. 2001). More than age of the patients, it was the disease burden, site of disease (lung better prognosis), and performance status of the patients that stood out as key determinants of the success of CN. This further highlights the benefit of doing GA in this group of patients before selection for CN.

The role of cytoreductive nephrectomy had also been studied specifically in older mRCC patients, and there was no significant difference between the older and younger group of patients in terms of median overall survival (Kader et al. 2007). However that study also showed that the perioperative mortality of patients older than 75 years of age was significantly higher than that seen in younger patients. This was not surprising as similar surgical outcomes were seen with elderly cancer patients having other tumor types as well. Much of this increased risk can be attributed to the lower physiologic reserve of older RCC patients.

However in the targeted therapy era, we currently only have retrospective data that suggest that certain groups of mRCC patients may continue to benefit from CN. In the largest of these retrospective studies, the international metastatic RCC database consortium (IMDC) had relatively younger patients with a median age of 59.3 years (range 52.7–67.4 years) (Heng et al. 2014). Hence while waiting for prospective data on the benefit of CN in mRCC patients, current data seem to suggest that older mRCC patients when selected appropriately with adequate presurgical assessment and/or GA may be suitable for CN.

Systemic Therapies

Since 2005, a number of targeted therapies have been developed that has revolutionized the way we treat older mRCC patients. Apart from high-dose interleukin-2 which has shown efficacy in a small group of younger patients, there is no data to support cytokine use in the elderly (Fyfe et al. 1996). These mRCC patients should first be stratified into the appropriate prognostic risk group as defined by either the Memorial Sloan Kettering Cancer Center (MSKCC) or the International Metastatic Renal Cell Carcinoma Database (IMDC) criteria (Heng et al. 2009). Table 1 shows the various phase 3 clinical trials that have led to the approval of the targeted therapies for use in the different settings in the

Table 1 Summary of phase III trials for approved agents which had older mRCC patients enrolled in them

Line of treatment	Phase 3 trial	Patient population	Median age (years)	Age of oldest patient (years)	Median PFS (months)	Median OS (months)
1st	Sunitinib (Motzer et al. 2007)	Clear cell mRCC; no previous systemic therapy	62	87	11	26.4
1st	Bevacizumab + IFN-α (Rini et al. 2010)	Clear cell mRCC; no previous systemic therapy	61	82	8.5	18.3
1st	Pazopanib (Sternberg et al. 2010)	Advanced RCC/mRCC; with or without prior cytokine-based systemic therapy	59	85	9.2	22.9
1st (poor risk)	Temsirolimus (Hudes et al. 2007)	Poor prognosis mRCC; no prior systemic therapy	58	81	3.8	10.9
2nd	Nivolumab (Motzer et al. 2015)	Clear cell advanced RCC/mRCC; received one or two previous regimens of antiangiogenic therapy	62	88	4.6	25.0
2nd	Cabozantinib (Choueiri et al. 2015)	Clear cell advanced RCC/mRCC; received at least one VEGFR-targeting tyrosine kinase inhibitor	63	86	7.4	–
2nd	Everolimus (Motzer et al. 2008)	Clear cell mRCC; prior VEGFR TKI therapy	61	85	4	14.8
2nd	Axitinib (Rini et al. 2011)	Advanced RCC/mRCC; prior VEGFR TKI, cytokine-based systemic therapy	61	82	8.3	20.1

treatment of mRCC. Data for the older adults can be extrapolated from these phase III studies as about one third of the patients enrolled in them were over 65 years of age (Bellmunt et al. 2009). A key piece of data from these studies is that there is no upper limit to the age of the patients enrolled, with the oldest patients in these randomized trial well over 80 years in age (Table 1). The randomized trials of sunitinib and sorafenib reported no difference in survival benefit between subset of patients aged 65 years and younger and the older patients. The bevacizumab and interferon study showed that there was no statistically significant difference among older patients that received study treatment versus that receiving standard arm treatment, implying little benefit for the elderly. For MSKCC poor-risk patients, temsirolimus, which is the drug of choice, has not been shown to increase survival in patients over 65 years of age who were given temsirolimus compared to interferon which was unlike the finding seen in the younger age group which benefited from temsirolimus treatment (Hudes et al. 2007).

A recent study comparing patient preference between sunitinib and pazopanib reported that a majority of mRCC patients prefer pazopanib due to its better toxicity profile and quality of life (QOL) (Escudier et al. 2014). In a study which found pazopanib to be non-inferior to sunitinib in the first-line treatment of mRCC patients, there was a nonsignificant trend favoring the use of sunitinib in patients older than 65 years of age (Motzer et al. 2013). Although this was not an older adult specific study, the lower toxicities and better QOL assessment make it a suitable choice for them.

In the second-line setting, there are a number of drugs approved for use in the treatment of mRCC patients (Table 1). Recently reported studies in the second line indicate that treatment with nivolumab, a programmed death 1 (PD-1) checkpoint inhibitor, or cabozantinib, a multikinase inhibitor, may be suitable options for older mRCC patients after it was found to have superior efficacy and better tolerability when compared with everolimus (Motzer et al. 2015; Choueiri et al. 2015). The median age reported in the nivolumab trial was 62 years for both the nivolumab and everolimus groups (range, 23–88 years and 18–86 years, respectively) (Motzer et al. 2015). For the cabozantinib trial, the median age was 63 years for the cabozantinib group (range, 32–86 years) and 62 for the everolimus group (range, 31–84 years) (Choueiri et al. 2015). Axitinib, a second-generation inhibitor of VEGF receptors, is also approved as the second-line treatment of mRCC patients after the pivotal trial comparing its efficacy against sorafenib (Rini et al. 2011). Seven hundred twenty-three patients were included in the trial, and the median age was 61 years for both arms (range, 20–82 for axitinib group and 22–80 for sorafenib group) (Rini et al. 2011). Based on those age ranges, it is fair to say that both these drugs can be used in selected older mRCC patients in the second line.

Although these drugs have shown that it is reasonably well tolerated in the younger population in which it was tested on, it is important to note that older patients have a multitude of other issues (as described above) that need to be taken into account before they are treated. The potential toxicity with cytotoxic systemic therapy can pose special concerns in older patients; thus, it is important to put in extra care with prophylactic treatment, patient education, and monitoring of response, toxicity, and quality of life. Table 2 describes some of the common toxicities to look out for in older mRCC patients on systemic therapies.

There is still a lack of high-quality evidence to guide therapy choices in third-line setting of mRCC. A retrospective analysis conducted by a large collaborative consortium, the IMDC, has analyzed 1012 patients receiving third-line targeted therapy and reported that third-line therapy use in favorable- and intermediate-risk patients was associated with the greatest overall survival. The age distribution of the patient population was however not reported in the paper (Wells et al. 2017).

Active Surveillance

For older mRCC patients who are frail or choose not to have treatment initially, active surveillance

Table 2 Therapies and special consideration in older patients with mRCC

Line of treatment	Drug	Safety data	Data source	Specific considerations in older adults
1st	Sunitinib (Motzer et al. 2007)	Available	Elderly specific data	Monitor for GI toxicity, HFS, HTN, fatigue; first-line dose modification may be appropriate
1st	Bevacizumab + IFN-α (Rini et al. 2010)	Available	Elderly specific data	Monitor for HTN; screen for vascular risk factors
1st	Pazopanib (Sternberg et al. 2010)	Available; favorable toxicity profile in elderly patients (PISCES)	Pivotal trial	Monitor for GI toxicity, HTN, anorexia
1st (poor risk)	Temsirolimus (Hudes et al. 2007)	Available	Pivotal trial	Monitor for rash, fluid retention, hyperlipidemia, hyperglycemia
2nd	Nivolumab (Motzer et al. 2015)	Limited	Pivotal trial	Monitor for fatigue, nausea, pruritus, diarrhea
2nd	Cabozantinib (Choueiri et al. 2015)	Limited	Pivotal trial	Monitor for HTN, diarrhea, fatigue
2nd	Everolimus (Motzer et al. 2008)	Available	Elderly specific data	Monitor for stomatitis, rash, fatigue
2nd	Axitinib (Rini et al. 2011)	Available	Pivotal trial	Monitor for HTN, diarrhea, fatigue
2nd	Sorafenib (Escudier et al. 2007)	Available	Elderly specific data	Monitor for skin toxicity, diarrhea, fatigue, and rare serious AEs (HTN, cardiac ischemia)

in this group of patients may be a feasible option as well based on a recent multicenter phase 2 study (Rini et al. 2016).

Non-clear Cell RCC

Much of the data for non-clear cell RCC patients have been derived from subset analyses from large clinical trials that had both ccRCC and non-ccRCC patients. The earliest data from a phase III trial came from the temsirolimus study in poor-risk mRCC patients. There were a number of patients in that study who were older than 65 years; however, in the subset analyses, the hazard ratio for PFS did not show a clear benefit for this group of patients. Recently however there was a phase 2 study which looked at the various types of metastatic non-ccRCC, and their responses to the targeted therapies (ASPEN). In this study, the median age was 59 years for the sunitinib arm (range, 24–100 years) and 44 years for the everolimus arm (range, 29–90 years) (Armstrong et al. 2016). The study outcome showed that sunitinib significantly increased progression-free survival compared with everolimus in metastatic non-clear cell RCC. Overall survival, however, was not different between the two treatment groups, although there were differences in treatment effect between the various histologic subtypes and prognostic risk groups. Based on a subset of older patients enrolled into this study, the results may be extrapolated for use in this group of patients as well.

Guidelines

Currently, the only available treatment guideline for the treatment of metastatic RCC in older patients is based on the systematic review developed in 2009 by a SIOG task force (Bellmunt et al. 2009).

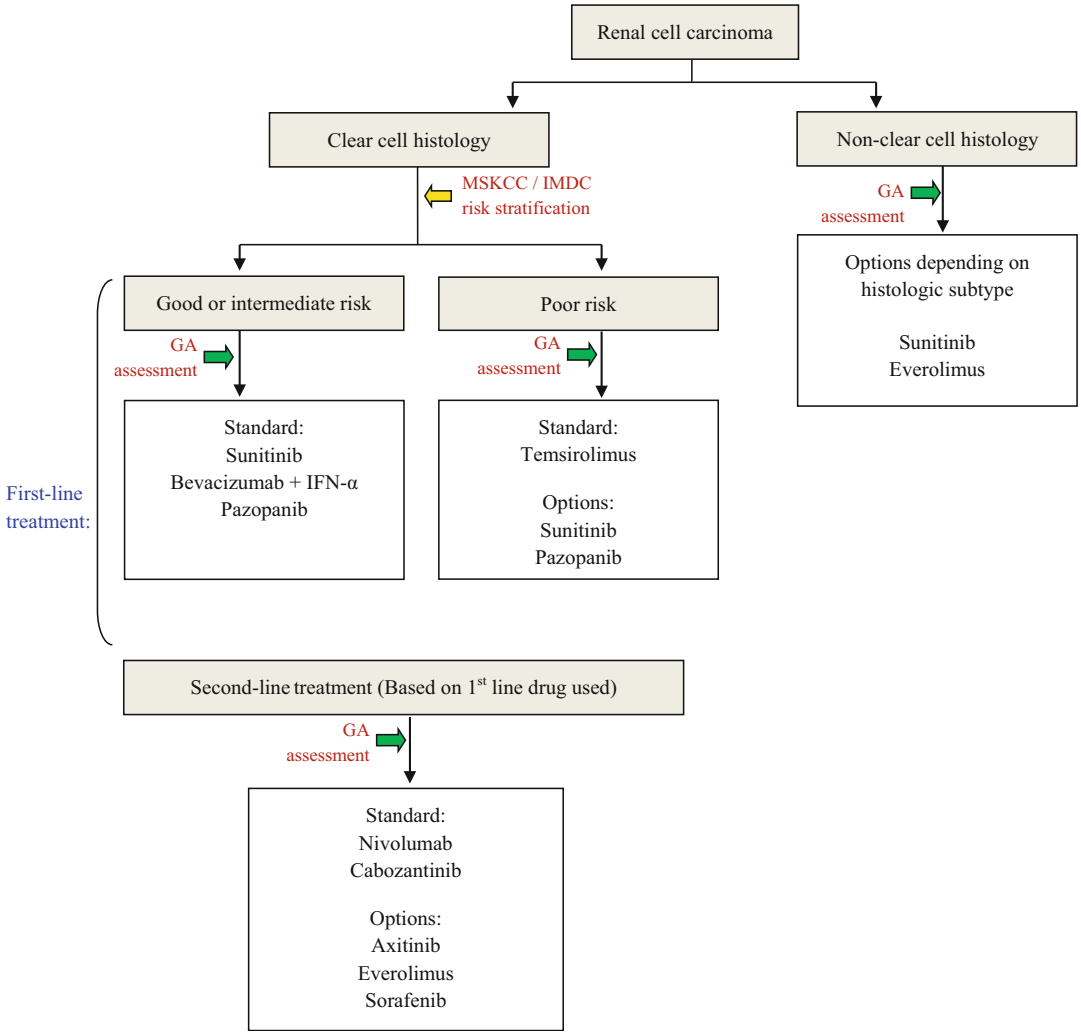

Fig. 1 Algorithm for systemic treatment in mRCC in older adults

SIOG has formed another mRCC task force to work on an update to the 2009 guidelines, which should be ready by the end of 2017. Figure 1 shows a suggested treatment algorithm for elderly mRCC patients incorporating the use of GA prior to treatment selection and the drugs with some data on older mRCC patients.

Summary

Although there is a dearth of data from older adult specific prospective clinical trials in the treatment of RCC, there are ample retrospective and subset analyses of trial data to assist us in choosing the most appropriate treatment for this vulnerable group of patients. Fit older patients with RCC should be offered surgery (RN or PN depending on the size and location of the lesion). Frail older patients with localized RCC may be offered local ablative therapy or active surveillance. In mRCC depending on their risk stratification, they should receive targeted therapies just like the younger counterparts. If they are frail, they can still be offered targeted therapies depending on their degree of frailty, concurrent medication use, and predicted life expectancy. Active surveillance is another option to consider in these mRCC patients

as well. The key factor in determining treatment choice would be a thorough assessment with a GA. All older RCC patients should have a GA done (including a discussion on treatment goals) and have their case discussed in a multidisciplinary tumor board before deciding on the most appropriate treatment for them.

Colorectal Cancer in Older Adults: Systemic Treatments

43

Thomas Aparicio

Contents

Abstract

Colorectal cancers are common in elderly patients. However, cancer screening is poorly used after 75. Elderly patients form a heterogeneous population with specific characteristics. Standards of care cannot therefore be transposed from young to elderly patients. Tumor resection is frequently performed, but adjuvant chemotherapy is rarely prescribed as there are no clearly established standards of care. In a metastatic setting, recent phase III studies have demonstrated that doublet frontline chemotherapy provided no survival benefit. Moreover, several studies have established the benefit of bevacizumab in association with chemotherapy. There is a lack of evidence for the efficacy of anti-epidermal growth factor antibodies in elderly patients. Geriatric assessments could help to select the adequate treatment strategy for individual patients. Geriatric oncology is now the challenge we have to face, and more specific trials are needed.

Introduction

Colorectal cancer (CRC) is one of the most frequent cancers. Currently, in Europe and the USA, the median age of CRC diagnosis is 70 years (Ferlay et al. 2013; Siegel et al. 2016). The specific questions about age arise mainly after 75 years. Given the ageing of the population, the proportion of patients with CRC aged over 75 years will increase even further in the coming years. Unfortunately the majority of organized mass screening programs for CRC are restricted to the population aged 50–74 years. The efficacy of CRC screening with fecal occult blood test (FOBT) has never been prospectively evaluated in elderly subjects (Quarini and Gosney 2009). Elderly patients form a specific population due to comorbidities, disability, and organ-specific physiological changes that have impaired their enrolment in clinical trials and thus the transposition of current guidelines established in younger patients (Frerot et al. 2015; Sorbye et al. 2009; Yee et al. 2003). The therapeutic strategy for CRC after 75 is often difficult to establish because of the lack of specific data for elderly patients. Recently, the International Society of Geriatric Oncology published recommendations for the treatment of CRC in elderly patients (Papamichael et al. 2015). Nevertheless, many issues remain unsolved (Aparicio et al. 2016c).

Geriatric Evaluation in Colorectal Cancer

Very few studies have assessed geriatric evaluation specifically in CRC. A comprehensive geriatric assessment (CGA) is recommended before CRC treatment decisions by the SIOG (Papamichael et al. 2015). However, the CGA is time consuming. Several screening tools are therefore used to identify frail elderly patients with cancer who are most likely to benefit from the CGA (Hamaker et al. 2012). Among these tools, the Geriatric 8 screening tool (G-8) may be the most sensitive to select patients for CGA (Bellera et al. 2012). In a recent study, significant differences were noted in the ability of G-8 to accurately detect frailty according to tumor site. In colorectal cancer, the G-8 screening tool identified frail elderly patients with high sensitivity (90%) but low specificity (23%) (Liuu et al. 2014). Relevant screening tools to assess frailty and predict morbidity must be adapted to the cancer stage, the primary site, and the treatment toxicities.

Predicting the toxicity of chemotherapy in elderly patient is an important challenge. A predictive score based on a cohort of elderly patients with several cancer types has been proposed. Age, gastrointestinal or genitourinary cancer, standard chemotherapy dosing, polychemotherapy, anemia, low creatinine clearance, hearing disability, falls, autonomy impairment, walking disability, and decreased social activities have been identified as predictors for toxicities (Hurria et al. 2011). Another score identified diastolic blood pressure, independent activity of daily living (IADL), ECOG performance status, mini mental health status (MMS), mini nutritional assessment (MNA), lactate dehydrogenase (LDH) level, and chemotherapy regimen as predictive factors for toxicity (Extermann et al. 2012). Nevertheless, these factors and others remain to be validated in the specific situation of adjuvant or metastatic settings in CRC.

In elderly patients, special attention must be paid to malnutrition that is still not sufficiently screened for and not sufficiently managed, although it is a major prognostic factor for all cancers especially for elderly patients (Soubeyran et al. 2012). Some geriatric syndromes, such as cognitive impairment and depressed mood, are independently associated with malnutrition in digestive cancers (Paillaud et al. 2014).

Adjuvant Chemotherapy After R0 Resected Colon Cancer

Stage III

Postoperative adjuvant chemotherapy combining fluoropyrimidine and oxaliplatin is the standard therapy after R0 resection of a colon cancer (Andre et al. 2004; Haller et al. 2011). Single-

center or registry studies indicate that adjuvant chemotherapy after resection of stage III colon cancer is less prescribed after 75 years than in younger counterpart (Aparicio et al. 2009; Faivre-Finn et al. 2002). Although this rate has increased more recently, a large proportion of elderly patients do not receive adjuvant chemotherapy (van den Broek et al. 2013) especially after 80 years (Bouvier et al. 2005; Lievre et al. 2014). The reasons of the absence of prescription of chemotherapy were usually poorly documented (Mahoney et al. 2000). Nevertheless, the increase rate of adjuvant chemotherapy in elderly in the last decade suggests that gastroenterologist, oncologist, and surgeon have taken in consideration the specificity of elderly patients.

Post hoc analysis of seven prospective phase III trials that enrolled patients after resection of a stage II or III colon tumor suggested a prognostic improvement with 5FU chemotherapy in patients over 70 years similar to that in younger patients (Table 1). However, only 15% of the patients enrolled were over 70 years and 0.7% over 80. This suggests that elderly patients were highly selected, and thus no conclusions can be drawn for patients over 80 years. With the exception of leukopenia, side effects were no more frequent in older patients (Sargent et al. 2001). The question about the benefit of fluoropyrimidine-based adjuvant chemotherapy in very elderly, unselected patients is still an issue.

The recommended adjuvant treatment for stage III cancer is a combination of fluoropyrimidine and oxaliplatin (Andre et al. 2004). However, this association has not demonstrated its effectiveness in elderly patients. An analysis of randomized trials comparing fluoropyrimidine adjuvant chemotherapy with or without oxaliplatin revealed no significant improvement in disease-free survival after age 70 (HR = 0.91 (95% CI, 0.75–1.11) after resection of stage III cancer (McCleary et al. 2013) and no overall survival (OS) advantage (Table 1). This lack of benefit with oxaliplatin in elderly patients was again observed in a subgroup analysis of the MOSAIC trial (Tournigand et al. 2012). Moreover, a registry study revealed that the combination of capecitabine and oxaliplatin did not confer a survival advantage compared to capecitabine alone (van Erning et al. 2017). A decrease in dose intensity is frequently observed in elderly patients treated by oxaliplatin and may explain the decrease of efficacy of this treatment (Laurent et al. 2018). Nevertheless, oxaliplatin could be beneficial in some selected elderly patients. Altogether, there are still two concerns: First, does fluoropyrimidine-based adjuvant chemotherapy procure any benefit in unfit elderly patients? Second, does oxaliplatin-based adjuvant chemotherapy procure any benefit for fit elderly patients? A prospective trial (PRODIGE 34 – ADAGE) is ongoing to evaluate the benefit of adjuvant chemotherapy in elderly patients (Aparicio et al. 2016a).

Stage II

The benefit of adjuvant chemotherapy is controversial for stage II tumors. The QUASAR study highlighted a 2.8% improvement in 5-year OS in patients receiving 5FU adjuvant chemotherapy

Table 1 Results of post hoc analysis of pooled clinical trials of adjuvant chemotherapy after colon cancer resection in subgroup of patient >70 years. (Adapted from Aparicio et al. (2016c))

	Patient number (%[a])	Adjuvant treatment arm	Disease-free survival HR (95% CI)	Overall survival [HR (95% CI)]
Sargent et al. (2001)	506 (15%)	Surgery alone	0.68 (0.60–0.76), $p < 0.001$	0.76 (0.68–0.85), $p < 0.001$
Stage II and III		5FU		
McCleary et al. (2013)	1119 (21%)	5FU	0.94 (0.78–1.13), NS	1.04 (0.85–1.27), NS
Stage II and III	–	5FU + oxaliplatin	0.91 (0.74–1.11), NS	–
Only stage III				

[a]Percentage of patients over 70 in the whole study population

after resection of stage II colon cancer. However, there was no advantage but even a trend for a deleterious effect for OS in the subgroup of patients over 70 years treated with adjuvant chemotherapy (Quasar Collaborative Group et al. 2007). The decision to give chemotherapy after stage II resection was based on the presence of pejorative factors such as T4 stage, tumor vascular invasion, high tumor grade, and occlusion at diagnosis, even though the benefit of adjuvant chemotherapy in high-risk stage II colon cancer patients is not clearly demonstrated (O'Connor et al. 2011).

Recently, some biological tumor characteristics have been recognized as prognostic factors. The deficient DNA mismatch repair phenotype (dMMR) has been demonstrated as a good prognostic factor (Ribic et al. 2003). In a post hoc analysis of five prospective trials comparing 5FU-based adjuvant chemotherapy to surgery alone, the patients with dMMR tumors did not benefit from adjuvant chemotherapy. Moreover, a reduced OS was associated with adjuvant chemotherapy in patients with dMMR stage II tumors (Sargent et al. 2010).

In elderly patients, MMR dysfunction is most often due to senescence-related hypermethylation of the *hMLH1* gene promoter. In the elderly, *hMLH1* epigenetic silencing is mostly associated with the *BRAF* gene V600E somatic mutation (Aparicio et al. 2014). Moreover, the frequency of the dMMR tumor phenotype increased with age, reaching 22% in patients over 75 years and 36% in patients over 85 years, and is associated with an excellent prognosis for stage II colon cancer (Aparicio et al. 2013b). In both studies, the frequency of the dMMR phenotype was higher in women than in men. The high rate of dMMR tumors in elderly patients was confirmed in another study, which reported 35% of dMMR tumors in patients over 80 years (Lievre et al. 2014). As the dMMR phenotype was associated with a lack of efficacy of 5FU adjuvant chemotherapy (Sargent et al. 2010), this tumor characteristic should be considered for adjuvant chemotherapy decisions, especially in elderly women.

In conclusion, adjuvant chemotherapy decisions remain unclear and should be decided in multidisciplinary meeting taking into account the geriatric assessment, tumor stage, and tumor phenotype. The best chemotherapy regimen remains an issue. Given the excellent prognosis of stage II tumors with dMMR and the lack of efficacy of 5FU adjuvant chemotherapy in this case, adjuvant chemotherapy is not recommended in these patients.

Specificities for Rectal Cancer

A meta-analysis of rectal cancer studies suggested that advanced chronological age should not, by itself, exclude patients from curative rectal surgery or from other surgical options that are available for younger patients. Although overall survival is lower in elderly patients than in younger patients, cancer-specific survival does not decrease with age (Manceau et al. 2012).

The functional results, after surgery, are impacted by neo-adjuvant treatment. Radiotherapy is less frequently used in elderly patients than in younger counterpart (Aparicio et al. 2009; Olsson et al. 2011). Some concerns have been raised about the benefit of neo-adjuvant radiotherapy in elderly patients (Jung et al. 2009). Nevertheless, preoperative radiotherapy improved local control in elderly patients compared with no preoperative radiotherapy (Martijn and Vulto 2007). Several preoperative radiotherapy schedules are used: short-course radiotherapy of 5 × 5 Gy in 1 week and long-course radiotherapy of 45–50 Gy in 5 weeks with or without oral or infusional fluoropyrimidine. Short-course radiotherapy is an attractive schedule for elderly patients, but when surgery is performed 1 week after the end of radiotherapy, tumor down-staging or downsizing could not be achieved. Moreover, compliance and toxicity for long-course radiochemotherapy is a concern in elderly patients. Other strategies should also be explored in the elderly, such as intensity-modulated radiotherapy to reduce toxicity, high-dose rate intraluminal brachytherapy, or *contact* X-ray therapy for T1 or T2 tumors. Moreover, a watch and wait strategy with the aim to avoid surgery among patients with complete tumor response after neo-adjuvant

radiochemotherapy is attractive in elderly patients (Maas et al. 2011).

Palliative Chemotherapy in Metastatic Patients

The current management of metastatic CRC (mCRC) involves various active chemotherapy agents, either in combination or as single agents: fluorouracil plus leucovorin (5-FU/LV), capecitabine, irinotecan, oxaliplatin, and recently trifluridine-tipiracil. In addition to these chemotherapy drugs, six biologic agents have been developed (bevacizumab, cetuximab, panitumumab, ziv-aflibercept, ramucirumab, and regorafenib) which also improve survival outcomes for mCRC patients.

Evaluation of Chemotherapy for Treatment of mCRC in Elderly Patients

A meta-analysis of 22 trials evaluating 5FU monotherapy for mCRC, which enrolled 3825 patients, among whom 629 (16%) were over 70 years, revealed comparable tumor response rates, progression-free survival (PFS), and OS in patients under 70 years and over 70 years (Folprecht et al. 2004). A meta-analysis of four randomized trials comparing 5FU monotherapy with doublet chemotherapy of 5FU + irinotecan suggested that the benefit of irinotecan for PFS and OS was preserved in patients over 70 years. Nevertheless, regarding the subgroup of patients over 75, they represented only 6.9% of the randomized patients, and in this subgroup, irinotecan provided no significant improvement in PFS or OS. Neutropenia 33% vs 40% ($p < 0.05$) and stomatitis 5% vs 10% ($p < 0.05$) were more frequent after 70 years (Folprecht et al. 2008). A post hoc analysis of randomized trials comparing doublet with oxaliplatin versus 5FU alone in first-line and second-line treatment suggested that the benefit of oxaliplatin was also preserved in patients over 70 (Goldberg et al. 2006). In a retrospective series of selected fit elderly patients over 75, irinotecan or oxaliplatin combined with fluorouracil chemotherapy was manageable, but a dose reduction was done in 35% of the cure (Aparicio et al. 2003). A prospective phase II study evaluated the FOLFIRI regimen in patients over 70 year and concluded that the treatment was well tolerated and effective in selected elderly patients (Francois et al. 2008).

However, the results of two randomized trials specifically for elderly patients did not confirm these preliminary data (Table 2). The FOCUS 2, phase III study comparing frontline 5FU monotherapy, capecitabine monotherapy, 5FU + oxaliplatin, and capecitabine + oxaliplatin in elderly or frail patients with mCRC did not demonstrate a significant gain of PFS or OS with doublet compared with fluoropyrimidine alone. Moreover, there was more toxicity with capecitabine than with infusion 5FU (Seymour et al. 2011). The FFCD 2001–2002 phase III study assessed the efficacy of and tolerance to doublet 5FU + irinotecan vs 5FU alone in the first-line treatment of mCRC in patients over 75 years. Once again, neither PFS nor OS were improved by doublet treatment, but toxicity was increased (Aparicio et al. 2016b) (Table 2). Surprisingly, in the latter study, chemotherapy with 2 days of a 5FU bolus regimen was more efficient than those with only 1 day of a 5FU bolus regimen. Nevertheless, in both studies, response rates were significantly improved with doublet chemotherapy. Moreover, a compilation of published data of all of the above studies specific to elderly patients or to the elderly subgroup of trial patients with no age limit suggested that doublet chemotherapy prolonged PFS (HR = 0.82; [95% CI, 0.72–0.93]) but had no effect for OS (Landre et al. 2015).

All these observations underline the need to conduct specific studies in elderly patients to avoid inappropriate conclusions for the general population due to patient selection. The choice of the appropriate chemotherapy regimen for the patient is the main challenge in a metastatic setting. A CGA could help in this choice. An ancillary study of the FFCD 2001–2002 study revealed that cognitive and functional impairments were predictive of severe toxicity or unexpected

Table 2 Results of randomized clinical trials dedicate for elderly patients comparing different first-line therapy in metastatic colorectal cancer. (Adapted from Aparicio et al. (2016c))

	Patient's number	Treatment arm	Progression-free survival HR (95% CI)	Overall survival HR (95% CI)
Seymour et al. (2011)	459	Fluoropyrimidine monotherapy vs	4.5 vs 5.8 months	10.1 vs 10.7 months
		Oxaliplatin doublet	0.84 (0.69–1.02), $p = 0.073$	0.99 (0.82–1.19), $p = 0.916$
Aparicio et al. (2016b)	282	5FU monotherapy vs	5.2 vs 7.3 months	14.2 vs 13.3 months
		Irinotecan doublet	0.84 (0.66–1.07), $p = 0.157$	0.96 (0.75–1.24), $p = 0.750$
Cunningham et al. (2013)	280	Capecitabine vs	5.1 vs 9.1 months	16.8 vs 20.7 months
		Capecitabine + bevacizumab	0.53 (0.41–0.69), $p < 0.0001$	0.79 (0.57–1.09), $p = 0.18$
Price et al. (2012)	69	Capecitabine vs	–	–
		Capecitabine + bevacizumab	0.53 (0.32–0.86), $p < 0.001$	0.80 (0.47–1.36), $p = 0.48$
Aparicio et al. (2018)	102	LV5FU2 or FOLFOX or FOLFIRI vs	7.8 vs 9.7 months	19.8 vs 21.7 months
		Idem + bevacizumab	0.78 (0.53–1.17)	0.73 (0.48–1.11)

hospitalization (Aparicio et al. 2013a). Moreover, in the FFCD 2001–2002 trial, normal IADL was independently associated with better OS. In this study, an exploratory analysis suggests a PFS improvement in patients treated with doublet chemotherapy compared to 5FU monotherapy in the following subgroups of patients: <80 years, unresected primary tumor, leukocytes >11,000/mm^3, and carcinoembryonic antigen >2 N (Aparicio et al. 2017). More studies evaluating geriatric parameters are needed to develop an accurate predictive tool. Nevertheless, though fluoropyrimidine monotherapy appears to be the best option in the first line, a doublet should be discussed by the multidisciplinary team in cases of symptomatic tumor or the potential use of metastases resection.

Evaluation of Targeted Therapy for the Treatment of mCRC in Elderly Patients

Several targeted therapies have demonstrated activity in the treatment of mCRC. Regarding antiangiogenic pathway inhibition, most of the data for elderly patients were obtained with bevacizumab (anti-VEGF monoclonal antibody). Concerns have raise about cardiovascular tolerance of antiangiogenic therapy in elderly patients. US data from SEER-Medicare and French data from national insurance revealed that patients over 75 and patients with preexisting cerebrovascular disease were less likely to receive bevacizumab in first line (Doat et al. 2014; Shankaran et al. 2013). In the SEER-Medicare study, bevacizumab receipt was not associated with an increased risk of first adverse event compared with chemotherapy alone (Shankaran et al. 2013). An observational cohort in 2953 patients, which enrolled 363 (12%) patients older than 75 years treated with bevacizumab in combination with chemotherapy for mCRC, revealed that OS decreased according to age: 28 months <65 years vs 19.5 months >75 years. Severe thromboembolic events are more frequent in elderly patients (1.5% vs 4%) (Kozloff et al. 2009). A pooled analysis of four randomized trials that assessed bevacizumab in combination with chemotherapy in the first-line or second-line treatment for mCRC showed that, in the subgroup of patients ≥70 years, median PFS (6.4 months vs 9.2 months, $p < 0.0001$) and OS (14.1 vs 17.4 months; $p = 0.005$) were improved in

patients receiving bevacizumab (Cassidy et al. 2010). In this pooled analysis, only 24% of the patients were over 70 years; this suggests that elderly patients were highly selected. A subgroup analysis of a randomized phase III study comparing capecitabine with capecitabine + bevacizumab showed a significant PFS improvement in patients over 75, no significant additional toxicity, and similar quality of life (Price et al. 2012).

A prospective randomized phase III trial specifically for patients over 70 years compared first-line treatment of mCRC with capecitabine alone or in association with bevacizumab. The tumor response rate was significantly improved by the addition of bevacizumab (10% vs 19%, $p = 0.04$), and the median PFS was significantly increased from 5.1 to 9.1 months in favor of the bevacizumab arm (HR = 0.53, 95% CI, 0.41–0.69, $p < 0.0001$). OS was not significantly improved by bevacizumab (16.8 vs 20.7 months; HR = 0.79, 95% CI 0.57–1.09, $p = 0.18$), but the study was not designed to assess OS as the main endpoint. Grade 3 venous thromboembolic and arterial thromboembolic events occurred more frequently in patients treated with bevacizumab 4.4% vs 8.2% and 0.7% vs 3.7%, respectively (Cunningham et al. 2013). Another randomized phase II study enrolled patients over 75 years and compared 5FU monotherapy or doublet with or without bevacizumab. The primary endpoint, assessed 4 months after randomization, was a composite endpoint based on efficacy (tumor control, stable disease, or objective tumor response and the absence of a decrease in the Spitzer QoL index) and safety (absence of severe cardiovascular toxicities and unexpected hospitalization). This was the first study in the mCRC setting to assess such a combined endpoint, which evaluated the tumor, quality of life, and safety. The efficacy criteria were met in 58% of the patients in the chemotherapy-alone arm and in 50% of the bevacizumab + chemotherapy arm. The safety criteria were met in 71% of the patients in the chemotherapy-alone arm and 61% in the bevacizumab + chemotherapy arm. A normal IADL score and previous cardiovascular disease were predictive factors for the composite criteria. There is a trend in favor of bevacizumab arm for PFS (7.8 vs 9.7 months, HR 0.78, 95% CI 0.53–1.17) and OS (19.8 vs 21.7 months, HR 0.73, 95% CI, 0.48–1.11) (Aparicio et al. 2018a). Even though both studies revealed a trend in favor of improving OS with bevacizumab treatment, the difference was not statistically significant. Multivariate analysis revealed that a high baseline Köhne score (Köhne et al. 2002) was associated with a short PFS and that a low baseline Spitzer QoL index (Spitzer et al. 1981), albumin $\leq$35 g/L, CA 19.9 > 2LN, and high Köhne score were significantly associated with a short OS (Aparicio et al. 2018b). Interestingly, exploratory subgroup analyses suggested that bevacizumab significantly prolonged PFS in patients with impaired nutritional status and impaired ADL. Thus bevacizumab treatment should not be denied for patients with this kind of frailty characteristics. Further studies should be performed to assess patient subgroups who show a clear OS benefit with bevacizumab.

Concerning EGF receptor inhibitors, there are very few available data for elderly patients (Rosati et al. 2016). Cetuximab is a recombinant chimeric monoclonal antibody, and panitumumab is a recombinant, fully humanized that competitively inhibits the binding of EGF and other ligands on EGF receptor. The efficacy of anti-EGF receptor monoclonal antibody is restricted to the patient with a tumor without *RAS* mutation. The available data concerning the efficacy and safety of cetuximab or panitumumab in older patients with mCRC are derived from retrospective studies, pooled analyses, and small prospective trials. In a retrospective series of 54 patients older than 70 years treated with cetuximab + irinotecan, a response rate of 41% and a 4.21-month PFS in the non-mutated *KRAS* patients subgroup were reported (Fornaro et al. 2011). In 39% of cases, a decrease in the dose of irinotecan was necessary due to treatment-induced diarrhea. A large multicenter retrospective study suggested that the efficacy and safety profile of a combination of irinotecan and cetuximab in irinotecan pretreated patients aged >65 was similar to that in pretreated patients aged 18–65 years (Jehn et al. 2014). Nevertheless, the threshold of 65 years used in this

study resulted in a median age of 70 years in the elderly group, which made it impossible to draw conclusions for patients aged over 75. In a post hoc pooled analysis of the CRYSTAL and OPUS trials, which compared chemotherapy alone with chemotherapy + cetuximab, the age interaction test was not significant for the tumor response rate, PFS or OS. Nevertheless, cetuximab demonstrated no significant PFS improvement in the subgroup of patients over 70 but a higher toxicity rate especially for neutropenia and diarrhea (Folprecht et al. 2010). Analysis of subgroups of elderly patients treated in a trial that compared panitumumab monotherapy with best supportive care revealed no significant difference for toxicity or efficacy compared with younger patients (Van Cutsem et al. 2007). Nevertheless, another subgroup analysis of patients over 75 from a large phase III study that have compared FOLFOX + panitumumab to FOLFOX alone demonstrated that the favorable effects of the treatment combination were not seen in patients with poor PS or patients older than 75 years of age (Douillard et al. 2014). Several phase II studies dedicated to patients over 70 years suggested that in selected patients, cetuximab alone (Sastre et al. 2011) or in combination with capecitabine (Sastre et al. 2012) or panitumumab alone (Sastre et al. 2015) was effective. To date there are no prospective randomized trials exploring anti-EGFR antibody in the elderly mCRC population.

Regorafenib is an oral tyrosine kinase inhibitor that inhibits several receptors involved in angiogenesis, oncogenesis, and the tumor microenvironment. Data concerning regorafenib in elderly are still very scarce. A post hoc analysis of the CORRECT study evaluated treatment with regorafenib in patients aged 65 years compared with younger patients (Van Cutsem et al. 2013). The hazard ratio for overall survival (regorafenib/placebo) was 0.72 (95% CI, 0.56–0.91) in patients less than 65 years and 0.86 (95% CI, 0.61–1.19) in patients aged over 65 years ($p = 0.405$ interaction test). The median proportion of the planned dose really taken was 83.3% before 65 and 78.6% after 65. Most of the patients had side effects in relation to the treatment (<65, 93.8%; ≥65 years, 91.7%). The rate of grade ≥3 adverse effects related to regorafenib was 52% in patients <65 years, 57% in patients aged 65–74, and 66% in patients >75 years. Hypertension was more frequent in this last group than in younger patients.

No data are available regarding elderly patients over 75 for the treatment recently registered for mCRC.

In conclusion, choice of palliative chemotherapy in elderly patients remains controversial. Although doublet chemotherapy and targeted therapy did not demonstrate significant improvements in OS, an effort should be made to assess subgroups of patients who will benefit from these treatments. The benefit of chemotherapy should not focus on survival alone but must also consider patient autonomy and quality of life.

Abstract

This chapter centers on what surgeons, patients, and hospital administrations want and need to know about surgical care for colorectal cancer in the older patients. From all angles, it is clear that older patients are unique and their colorectal cancer care should be individualized and approached in a multidisciplinary fashion. Evaluation of patient fitness to undergo surgery should be undertaken in the elective and emergent settings. If patients are deemed fit for treatment, they should be offered the appropriate treatment, regardless of their age. This includes proceeding with surgery and/or chemotherapy and utilizing minimally invasive techniques, when appropriate. In addition, quality of life should be a priority in the care of older patients and patient reported outcomes should be assessed and reported.

Keywords

Rectal cancer · Older patients · Outcomes · Quality of life · Tailored surgery

Introduction

Patients, surgeons, and institutions view colorectal care of the older patients through different lenses. However, the goals of care should be to enhance the patient's quality of life and treat the malignancy while maintaining the patient's quality of life. The patient's decision after multidisciplinary discussion as well as determination of their fitness to undergo treatment should be given priority in choosing a treatment modality. Treatment modalities should not be chosen solely based on the older patient's age.

What Do Surgeons Want To Know?

Role of Screening Tools in a Busy Surgical Practice

Every colorectal surgeon needs a fast and reliable preoperative evaluation of patients, especially when they are coming from both the elective and emergent settings. Several systems have been proposed and validated to evaluate patients in order to stratify operative risk and highlight possible areas amenable for prehabilitation. As reported in a previous chapter (Principles of Cancer Surgery in Older Adults), the overall message is that, regardless for the system of choice, it is essential to systematically assess older cancer patients to determine whether the patient is fit for surgery, which surgical plan is appropriate, and which adjustments may be needed before the procedure. As a rule of thumb, it is mandatory, regardless of the preferred system, to obtain information about three main domains: cognitive status (including history of delirium), independence/living situation, and sarcopenia, gait ability, and nutrition (Audisio et al. 2008; Fong et al. 2009; Huisman et al. 2014; Hempenius et al. 2015; Mohri et al. 2013).

Among the numerous and available tests, two deserve special attention since they seem to be well suited for common situations faced by a colorectal surgeon: the short amount of time available in a busy clinic and the need for quick decision in the emergency setting. These two instruments are the "Timed Up and Go" (TUG) test and the Triage Risk Screening Tool (TRST) in its Flemish version (fTRST).

The TUG is a tool that has been designed with the purpose of identifying frail older patients by quantifying their functional mobility and has been shown to be easy to administer and directly correlate with functional status (Podsiadlo and

Richardson 1991). The test is carried out by asking the patient to sit in a chair and when the timer goes off, the patient stands up and walks for 3 m, makes a 180° turns, and comes back to the chair. At the moment the patient is back in the chair, the final time is recorded. If a patient needs a walking device or a cane, this can be used during the test. The TUG has extensively been studied in community-dwelling older patients (Bischoff et al. 2003; Davis et al. 2011; Kim et al. 2010), and it was found to predict the risk of early death in oncogeriatric patients receiving chemotherapy (Soubeyran et al. 2012). The TUG was also investigated in cohorts of surgical patients and predicts long-term functional outcomes in patients undergoing hip surgery (Laflamme et al. 2012). In patients undergoing major cardiovascular or abdominal surgery, the TUG successfully predicted prolonged institutionalization and postoperative delirium (Brouquet et al. 2010; Robinson et al. 2011). In a prospective study among patients, >75 years old undergoing major elective abdominal surgery, multivariable analysis of the predictive value of a high TUG (>20 s) for postoperative delirium showed a hazard ratio of 4.8. A total of 47.6% of patients with a high TUG suffered from postoperative delirium, compared to only 18.5% of patients with a normal TUG (Brouquet et al. 2010). Robinson et al. found a 13 times higher risk of discharge to an institutional care facility, i.e., nursing home or rehabilitation center, for geriatric surgical patients with a high TUG (>15.0 s) (Robinson et al. 2011).

Data on the predictive value of the TUG in the oncogeriatric surgical population were recently published as part of the PRE-OP study (Huisman et al. 2014, 2015). In total, 362 patients were assessed in this study and the median age was 76 years. The majority of patients underwent major surgery ($n = 223$; 68.0%) and the most prevalent conditions were colorectal cancer and breast cancer. The study results showed that the TUG is a more useful screening tool than American Society of Anesthesiology (ASA) score or the more time-consuming Comprehensive Geriatric Assessment (CGA) in identifying those patients at higher risk of adverse outcome. This was also emphasized by the ability of TUG to predict the need for extended care postoperatively, as shown by the prolonged length of stay (LOS) and the increased number of specialists involved in the care of patients with an elevated TUG. The TUG seems to give an assessment of cognitive elementary abilities to follow simple orders, basic functional mobility, coordination and muscle strength in older patients which are reliable proxies for sarcopenia, considered as the ultimate predictor (Wagner et al. 2016).

An increasing number of older patients are seeking urgent surgical care because of unplanned emergent conditions (Desserud et al. 2016). Decision-making in the emergency setting is complex since a number of variables must be considered in order to tailor the surgical treatment. These include each patient's specific characteristics, the nature of the disease, and patient's wishes versus the pressing need to act proficiently in a short period of time (Launay-Savary et al. 2015). Frailty, not chronological age, is the most important risk factor associated with poor surgical outcomes even in the emergency setting (Farhat et al. 2012; Subramanian et al. 2010). It has been established that every older patient with cancer should undergo a specific geriatric assessment before every treatment (Extermann et al. 2005). Unfortunately, this is not always applicable in the busy emergency setting. To date, no concise frailty screening tool is available for emergency general surgery older patients. A recent cohort study describing the use of six short screening tools, (Vulnerable Elders Survey VES-13, fTRST, G8, Groningen Frailty Index (GFI), Rockwood/Balducci score) validated on oncogeriatric setting, has been reported with the aim to assess frailty before an emergent surgical procedure (Kenig et al. 2015). The authors concluded that the screening tools were adequate to investigate frailty also in the emergency setting. However, these screening tools were created for cancer patients, requiring an accurate knowledge of the patient's past medical history, which is not always available. A blood test is sometimes needed and they are still too time-consuming to be used routinely in the emergency room. Among the group of oncogeriatric-specific validated frailty screening

tools, there is a short, five-item questionnaire, which is very easy to perform: the fTRST (Kenis et al. 2006). The original TRST, designed in 2001 in the Emergency Department (ED), was a risk-stratification tool used to identify older patients at risk of recurrent trips to the ED, hospitalization, and nursing home admission (Mion et al. 2001; Meldon et al. 2003). The Flemish version fTRST is shorter and based only on five domains: presence of cognitive decline (2 points), living alone or no help from partner/family available (1 point), reduced mobility or falls in the past 6 months (1 point), hospitalized in the past 3 months (1 point), and polypharmacy (≥5 different medications) (1 point). A recent published recommendations update by the International Society of Surgical Oncology (SIOG) reported that the fTRST is an accurate instrument to identify oncogeriatric patients in need of a comprehensive geriatric assessment (Decoster et al. 2015) but no cutoff has been established in order to identify patients at higher risk for major complications after emergency general surgery. Recently, Zattoni et al. presented at the SIOG annual meeting the initial results of a prospective study including >70-year-old patients undergoing emergency, non-trauma surgery (Zattoni 2016). All patients underwent multimodal preoperative frailty assessment with fTRST, Charlson Age-Comorbidity Index (CACI), ASA score, and the Activity Daily Living (ADL) test. They prospectively enrolled 110 consecutive patients operated on under general anesthesia for emergency abdominal surgery. The vast majority of cases were related to small or large bowel primary diseases and the median age was 81. The postoperative 30-day mortality was 20.2% but the majority of death events (56%) occurred during the first postoperative week. Fourteen were recorded after major surgery (87.5%). A fTRST score ≥2 showed good sensitivity (93.7%) and specificity (41.3%) in detecting postoperative mortality (OR 10.5; 95% CI 1.31–84.8; $p = 0.027$). Logistic regression analysis showed a significant correlation between 30-day mortality and fTRST≥2, ASA≥4, while patients' age was not statistically relevant. Of the 63 patients who survived surgery, 17% developed severe functional loss. Scoring 2 or 3 at fTRST was highly related to functional deterioration. A regression model showed a significant correlation between a fTRST score ≥2 and the need for postoperative intensive care unit (ICU) admission, prolonged LOS, and need for long-term institutionalization.

Role of the Standard of Care in Older Fit Patients

Laparoscopy

The goals of minimally invasive surgery (MIS) are to obtain the same disease-related and functional outcomes as an open operation while decreasing the surgical stress and consequently the associated morbidity and mortality. Early studies showed that laparoscopy promoted improvements in return of bowel function, earlier oral intake, decreased opioid analgesia requirements, and decreased length of hospital stay, while improving cosmesis and patient satisfaction (Dunker et al. 1998).

Another goal of MIS is promotion of functional recovery. Return to active life, return to independent living or bowel/urinary control are particularly important in older patients, and reaching these goals often means the difference between an operation's success and failure (Frasson et al. 2008). Frasson et al. focused on functional recovery after laparoscopic surgery, analyzing a series of 535 patients with colorectal disease randomly assigned to laparoscopic ($n = 268$) or open ($n = 267$) resection. Within the two groups, the outcome of young patients was compared with those in patients ≥70 years. The authors demonstrated that laparoscopy reduced morbidity and LOS when compared to an open operation in the older patients group but less so in the young group (Frasson et al. 2008). In addition, laparoscopy in the older patients promotes a higher rate of postoperative independence at discharge and faster postoperative recovery. Stocchi et al. also demonstrated that independent status on admission (assessed in 37 patients undergoing laparoscopic-assisted colectomy and 38 undergoing open colectomy) was more frequently maintained at

discharge in those undergoing laparoscopic-assisted colectomy (95% vs. 76%, respectively, $p = 0.025$) (Stocchi et al. 2000).

Recently, Li Y et al. "settled" the debate of laparoscopic surgery versus open surgery in octogenarians by publishing a meta-analysis of 11 comparative studies pooling 1,066 laparoscopic and 1,034 open colorectal resections. The results demonstrated that laparoscopy is safe and carries a lower risk of infectious complications (both pulmonary and at the surgical site), shorter LOS, and a reduced incidence of postoperative ileus while maintaining the same cardiovascular risk as compared to open surgery. The authors concluded that laparoscopy is safe and feasible in the older patients population and has the additional benefit of faster return to productive lives (Li et al. 2016).

Given the expansion of robotic surgery in colorectal surgery, several authors examined the role of robotic surgery in the older patients' population. Ceccarelli et al. compared patients undergoing robotic surgery for a variety of indications including colorectal diseases in three age groups: $\leq$64, 65–79, and $\geq$80. They showed an increased conversion rate in the 65–79-year-old group, but no differences in morbidity or mortality between groups (Ceccarelli et al. 2017). The authors concluded that robotic surgery can be safe in properly selected older patients.

MIS is safe and feasible in properly selected older patients, and, in fact, is associated with faster functional recovery. Operative approach should be determined by the surgeon's expertise as well as the patient's cancer location and comorbidities.

Enhanced Recovery

Enhanced recovery or fast-track programs include some degree of preoperative patient education, selective use or no bowel preparation, no perioperative starvation (use of carbohydrate-loaded liquids), no use or early removal of the nasogastric tube and urinary catheter, tailored anesthesia and postoperative analgesia, and early mobilization with minimal fluid infusion. "Fast-track protocol" has been often used as a synonym of the enhanced recovery after surgery (ERAS) protocol, but the two entities are not the same. The ERAS protocol, promoted through the ERAS® society, refers to a well-designed but necessarily strict list of items that need to be entirely fulfilled in order to obtain the desired effect (Gustafsson et al. 2011). But adherence to the long list of tasks is not easy to achieve and, as demonstrated by several studies and surveys, despite increasing awareness of the importance of structured perioperative management, the implementation of this complex protocol has been slow (Segelman and Nygren 2014). Therefore, a patient-centered fast-track approach is likely more efficacious in the older population than a rigid set of ERAS protocols especially because the older population may not be able to follow a complex set of instructions and have great variability in the preoperative functional status. In addition, some of the items reported in the ERAS protocol such as the use of epidural anesthesia have been questioned, especially with the use of laparoscopy (Halabi et al. 2014), and the combination of antibiotics and mechanical bowel preparation has been reported to lower postoperative infections (Chen et al. 2016).

The literature suggests that older patients have an advantage in functional recovery if enrolled in a fast-track program. Baek et al. analyzed a group of 337 patients (87 over 70 years of age and 250 under 70 years of age) who underwent laparoscopic colorectal surgery with a perioperative fast-track program. No significant difference between age groups was observed for return of flatus, stool passage, progression of diet, complication rate (26% in the older patients vs. 32% in the young patients) or LOS (12 days for each group). There was no impact as well of comorbidities (70% in the older patients vs. 44.7% in the younger patients) and ASA score. Of note, the authors observed a rate of cardiopulmonary complications lower than expected, which they attributed to the use of a low-pressure pneumoperitoneum (8 mmHg). The only significant difference observed between the two groups was in the number of emergency room visits or readmissions (11.7% vs. 4% total, in older vs. younger patients) (Baek et al. 2013). Pawa et al. achieved similar global conclusions, with a median

LOS of 6 days in 558 patients <80 vs. 8 days in 130 patients ≥80 year ($P = 0.363$). There were no significant differences in 30-day readmission rates (8.6% in the whole population) (Pawa et al. 2012).

A second goal of fast-track protocols is to reduce stressors and to decrease the inflammatory response following surgery. Pursuing this aim, a recent systematic review by Watt et al. examined the impact on the magnitude of the systemic inflammatory response (SIR) for each ERAS component following colorectal surgery through objective markers such as C-reactive protein (CRP) and interleukin-6 (IL-6). The review analyzed 19 studies including 1898 patients. With the exception of laparoscopic surgery, it did not show any effect of individual components of ERAS protocols to reduce the stress response following colorectal surgery (Watt et al. 2015).

Based on the current evidence, we conclude that older patients may more often benefit from laparoscopic surgery with a tailored patient-specific pre- and postoperative program than they would with a strict list of prescriptions as in ERAS. Early and progressive reintroduction of an oral diet, ambulation and physical therapy, early removal of drains and catheters, minimization of opioid analgesia, and individualized/limited fluid management are the components most likely to improve functional outcomes and recovery in older patients. In addition, preoperative and postoperative counseling and ongoing communication with the patient and his/her family is most effective in engaging the patient and meeting goals of recovery.

Adjuvant Chemotherapy in Older Patients with Stage III Colorectal Cancer

The benefit of adjuvant chemotherapy in Stage III colon cancer has been demonstrated and has become the standard of care in the adult population (National Comprehensive Cancer Network, Colon Cancer 2017). However, questions arise about whether older patients should be offered the same treatment as young patients. Bergquist et al. evaluated 8141 patients aged 80–89 who underwent surgery for Stage III colon cancer with curative intent. Fifty-seven percent of patients had surgery alone and 43% received postoperative chemotherapy. Patients who did receive chemotherapy were statistically significantly shown to be younger (82 years vs. 84 years), healthier (73% vs. 70% without comorbidities), and more likely to have advanced N2 disease (40% vs. 32%). In patients who received chemotherapy, the overall survival was prolonged (median 42.7 vs. 61.7 months; $p<0.001$). Of note, in 1315 patients deemed fit for chemotherapy who declined it, the overall survival was worse than in those who received chemotherapy (median 42 vs. 61 months; $p<0.001$). Multivariable analysis showed that surgery alone and refusal of chemotherapy were independently associated with increased mortality hazard (HR 1.83, HR1.45; $p < 0.001$) (Bergquist et al. 2016). Ko et al. analyzed 810 patients, 423 <70 years and 387 ≥70 years. The median age at diagnosis for the entire cohort was 69 years. Older patients had significantly more comorbidities than young patients (34% vs. 19% with ≥3 comorbidities; $p<0.001$). Young patients were more likely to undergo adjuvant chemotherapy (91% vs. 57%; $p<0.001$), more often with combination than monotherapy (74% vs. 32%; $p<0.001$). In comparison to younger patients who did not receive adjuvant chemotherapy in <10% of cases, older patients did not receive chemotherapy in 43% of cases because of age (45%), comorbidities (36%), or minimal benefit perceived by the medical oncologist (2%). In addition, advanced age was cited as the main reason to receive only monotherapy. However, multivariate analysis did not reveal any significant correlation between advanced age and worse outcome when using adjuvant chemotherapy. Treatment with either combination or monotherapy had same impact on cancer-specific survival in both age groups (Ko et al. 2016).

Chemotherapy in older patients with Stage III colon cancer should not be withheld based on age alone. Therapy should be tailored in a patient-centered multidisciplinary strategy to attempt a balance between improved survival and quality of life.

Undertreatment Versus Customized-Conservative Treatment in Older Patients with Rectal Cancer

Older patients' rectal cancer management is frequently influenced by many factors, leading to undertreatment and poorer outcome. This was first demonstrated by Chang et al. (2007) in a group of 21,390 patients identified from the Surveillance, Epidemiology, and End Results (SEER) database (1991–2002). The authors showed that rectal-cancer-specific survival rates decreased with increasing age. More recently, EUROCARE-5 study (2014) showed a global increase in survival for rectal cancer from 1999–2001 to 2005–2007 (52.1% vs. 57.6%) (De Angelis et al. 2014). Unfortunately, this did not apply to the older segment of the population. In UK, the National Cancer Intelligence Network reported the high rate of under treatment in surgery for older cancer patients (National Cancer Intelligence Network 2010). This is highlighted for colorectal cancer patients in who resection rate falls from 68% in the group of 64–74 years to 40% after 80 years, as do the use of multimodal treatments and radical resection in contrast of local excision.

Standard treatment for rectal cancer includes surgical resection with total mesorectal excision (TME) for early stage tumors (T1 N0 M0; T2 N0 M0). Locally advanced tumors (T3/4, N+) are treated with neoadjuvant chemoradiation followed by TME (National Comprehensive Cancer Network, Rectal Cancer 2017). However, a more tailored approach is appropriate in older patients to optimize workup and treatment. When judged as fit, they should follow standard of care as in younger adults with radical surgery and/or chemoradiotherapy. In those with comorbidities or refusing surgery, adjusted strategy should be discussed with the patient and the family.

The role for local resection in older patients is debated. A proctectomy indeed can yield high risk of poor functional outcome in the postoperative period in addition to the risk of definitive stoma (Kim et al. 2002; Paun et al. 2010). Age is the first item to consider according to the predictive nomogram for Low Anterior Resection Syndrome (LARS) (Pelicancancer.org 2017). In this light, local excision gives better functional results and decreases postoperative morbidity and mortality, especially for vulnerable or frail patients. There was also a renewal of interest for local excision with the launch of user-friendly and soft platforms. Since 1992, standardized transanal Endoscopic Microsurgery (TEM) has shown advantage over transanal excision with traditional instruments for which the surgeon often needs to combine operator' and speleologist' skills (Buess et al. 1985). Despite clear superiority (Christoforidis et al. 2009), the technique is spreading slowly in the surgical community because of the steep learning curve and the small number of eligible cases. There was a recent renewed interest for transanal endoscopic surgery after its first uses 30 years ago, due to increased knowledge on natural history of rectal cancer, increasing number of patients candidates for an organ-sparing approach, and development of easy to use soft platforms allowing Transanal Micro-Surgery techniques.

Several studies have tried to confirm the tailored approach. Several have selection biases, with poor experience and local excision being limited to patients with early stage or poor general conditions. More recently, the multicenter ACOSOG Z6041 trial evaluated organ preservation for T2 N0 distal rectal tumors treated with neoadjuvant chemoradiation and local excision (Garcia-Aguilar et al. 2015). High toxicity rates were encountered when oxaliplatin was included in the chemotherapy composition. However, long-term results were impressive with 3-year overall survival of 94.8% and a very low (4%) local recurrence rates. Return to normal bowel function and good quality of life were reported 1 year after surgery. Given the low (3%) lymph node positivity in ypT0-1, important data were published by Creavin et al. (2017) regarding standard local excision with TEM or Transanal Minimally Invasive Surgery (TAMIS) platform in patients having downstaged their tumor to cT0-1following neoadjuvant chemoradiation. Of note, node-positivity around 20% and 33% in

ypT2 and ypT3 tumors (Martin et al. 2012; Smith et al. 2010; Smith et al. 2012) makes TME mandatory for tumors ≥ypT2. In Creavin et al. experience, of 362 patients with rectal cancer, 60 (16.5%) had an organ-preserving strategy (10 with "watch and wait" and 50 by transanal excision). Fifteen patients were referred for salvage TME postlocal excision because of final pathological reports. There was no significant difference in overall survival or disease-free survival rate between radical surgery and organ preservation strategy (85.6% vs. 93.3%, $P = 0.414$, and 78.3% vs. 80%, $P = 0.846$, respectively). Tumor regrowth occurred in 4 out of 45 (8.9%) patients who had organ preservation. Despite the high interest for these results, a recent systematic review by Smith et al. (2017) warned against use of organ sparing techniques after chemoradiation, based on scattered residual tumor cells among radiation-induced fibrosis precluding the ability to reliably classify residual disease. Moreover, three studies have shown the difficulty to spot or identify these occult and scattered foci within the bowel wall (Hayden et al. 2012; Mandard et al. 1994; Perez et al. 2014). Of note, the systematic review by Garcia-Aguilar et al. (2015) describe at 3 years, only three local recurrences (4.0%) with disease-free and overall survival rates of 86.9% and 95.7%. With an 84-month median follow-up, Lezoche et al. (2008) report only two local recurrences (5.7%) and no difference in survival between local excision versus radical surgery incorporating TME (94%). Similarly but with only 17-month median follow-up, Verseveld et al. (2015) report four local recurrences (9%) in patients treated with conservative strategy while deemed fit for surgery including cT3. Although well-designed studies with standardization are still needed before adopting local excision as standard of care after neoadjuvant chemoradiation strategy, we consider this is a highly valuable option to discuss in some older patients unfit for major procedures or refusing surgery and loss of function.

In addition to organ preserving surgical strategies, there is new emphasis on "watch and wait" proposals after clinical complete response under neoadjuvant chemoradiation. Angelita Habr-Gama and her group investigated the possibility to skip surgery in patients developing a complete clinical response after chemoradiotherapy, showing similar 5-year disease-free and overall survival as compared with standard surgery (Habr-Gama et al. 2004). They extended these investigations to more advanced stages (cT2-4, cN1-2 low rectal) (Habr-Gama et al. 2013). Of 70 patients, 35 patients (51%) did not require any surgery and were in complete remission after 56 months of median follow-up. Although not conducted in an old population (mean age 60.2 ± 12.9), this strategy might be interesting for senior adults unfit-for-surgery. This was further evaluated by McLean Smith et al. (2015), using three age groups: 60 years with mild comorbidities, 80 years with minor comorbidities, and 80 years with significant comorbidities (Charlson score >3). Patients with a complete clinical response after chemoradiotherapy were followed by a watch-and-wait protocol or offered radical surgery (TME). Overall survival was similar in 60-year-old patients for both strategies, but in patients 80 years of age or those with significant comorbidities, watch and wait provided a 10.1% advantage over surgery, with no difference in disease-free survival or quality-adjusted life years. This suggests that watch and wait after a complete clinical response is a valid option in older patients limiting surgery-induced morbidity. Of note, same hypothesis has been explored at the Memorial Sloan Kettering Cancer Center group and a prospective study is ongoing.

Data from the international Watch and Wait database (IWWD) on behalf of the EUropean REgistry of Cancer CAre (EURECCA) have been presented in Krakow at the last meeting of the European Society of Surgical Oncology. The rate of local relapse was 29% at 3 years, 64% of patients recurring within 12 months. Local recurrence was very heterogeneous with only 60% of patients receiving a proper surveillance with the standard of care pelvic Magnetic Resonance Imaging (MRI). This calls for more controlled research before adopting such strategy in routine. However, they represent an important challenge for older patients to limit invasive

surgery and protect independence and quality of life.

Contact X-ray brachytherapy (CXB) is a last attractive strategy to mention. CXB is based on using 50 kVp Xrays with a short focus to skin distance (FSD). This noninvasive organ preserving technique was launched by Papillon (1975) in the 60s for T1 N0 rectal adenocarcinoma. Between 1980 and 2001, CXB has been used in several French centers in three different settings: adjuvant treatment after local excision for T1/N0 lesions in the case of high-risk pathological features (Gerard et al. 2000); for T2 and early T3 N0 tumors, mainly in older patients or frail patients, in combination with external beam radiotherapy to treat both the primary tumor and perirectal subclinical lymph nodes (Gerard et al. 2002; Papillon 1990); and treatment of distal locally advanced T3 N0-2 tumors when an abdominoperineal resection (APR) was indicated in order to increase the chances of a sphincter preserving procedure.

Frin et al. (2017) published their 12-years, 112-patients experience of using CXB with the above indications. In the first scenario, CXB was performed in case of T1 N0 (tumor <3 cm) treated after initial local excision if tumor fragmentation, vascular invasion, tumor budding, poor differentiation, R1 resection, or submucosal infiltration level of sm2 (according to the Kikuchi classification) was detected. At 5 years, the local recurrence rate was estimated at 4%. The overall 5-year survival rate was 94% with organ preservation in 26 of 27 patients (96%). In the case of T2 or early T3 (<4 cm) N0 tumors, a combination of CXB and CRT was proposed to achieve organ preservation as an option to avoid a standard TME surgery. A cCR was achieved in 43 patients (96%) with a small residual ulceration present at 1–6 months after treatment in 15 of them. Ulcerations were painless and healed spontaneously but two patients underwent an elective local excision (ypT0 and ypT1 R0 with few residual cells). The 5-year cumulative rate of local recurrence was 11%. The 5-year cumulative rate of distant metastases was 17%. The cancer-specific survival was 87% at 3 years and 76% at 5 years. To treat a distal locally advanced T3 N0-2 with the goal of avoiding an APR, the authors recommended CXB combined with CRT in order to shrink the tumor and increase the chance of a sphincter-saving surgery. A cCR was achieved at the end of irradiation in 15 patients (37%). An APR was performed in seven patients (18%) and 31 (82%) underwent a sphincter-saving surgery. Eight cases of ypT0 (21%) and 17 cases (44%) of ypT1, 2, and 3 with only few residual cells (Dworak TRG3) were observed. The overall survival rate was 84% at 3 years and 72% at 5 years.

The treatment of older patients with rectal cancer is evolving, but one cannot stress enough the importance of patient-centered multidisciplinary care to optimize oncologic, function, and quality-of-life outcomes in individual patients. When considering alternative treatment strategies, it is important to appreciate how some treatments, which are considered the standard of care for the general population (level 1 evidence), might not apply to senior cancer patients. As an example, TME has been established and validated on the general population of rectal cancer patients. However, considerable evidence has been gathered to prove the opposite is true for older rectal cancer patients, where the increased operative mortality and morbidity exceeds the survival advantage (Rutten et al. 2008). In short, when considering either alternative or standard treatment pathways, patient selection seems again to be the key step in order to offer feasible solutions without under treating our older patients (Ugolini et al. 2014).

What Do Patients Want to Know?

The Role of Patient-Reported Outcome Measures

Effectiveness of any oncologic treatment has been historically measured by several indicators in order to define patient survival after (or hopefully because of) the treatment. Overall survival (OS), disease-free survival (DFS), or progression-free survival (PFS) 5 years from the diagnosis have long been considered the best indicators to define the ability of a given treatment to stop or prevent cancer progression. Several

of the most important studies in colorectal cancer surgery treatment have used that indicator to suggest superiority of one treatment over another (Bonjer et al. 2015; Sauer et al. 2004). Unfortunately, 5-year DFS has only a limited value for 80-year-old patients undergoing colorectal surgery for an obstructing malignancy. The only "historically-used" outcome that has been shown to be of interest in this group of patients is mortality or OS. Progress in the care of older patients affected by cancer has been slow and halting, partly because measurement of outcomes that matter to patients, aside from survival, remain limited.

Even with higher rate among older cancer patients, death is a rare event. Many physicians, surgeons in particular, have the tendency of stop measuring mortality 1–3 months after surgery and so these data fall under the radar. Mortality is also a rare occurrence right after elective colorectal surgery, and it fails to differentiate excellent from merely competent providers. In one of the most innovative papers about this topic, Porter et al. have summarized the reason why the scientific community should undertake a more challenging (but also more efficacious, in the long run) outcome-measuring system: the patient-reported outcome measure (PROM) (Porter et al. 2016). Authors defined four reasons why PROM studies are critical in the modern health care system that must be centered on outcomes that matter to patients. First, hospital administrations and health-care-management specialists have often reduced the "quality" of care to detecting the system's compliance with evidence-based practice guidelines rather than as improvement in pure patients' outcomes. Secondly, what generally matters to patients are outcomes that encompass the whole cycle of care, more than a single phase of the process (e.g., surgery, chemotherapy, etc.). This includes the global health status achieved during and after the care. Data such as functional status and quality of life are rarely reported at the end of the process. Patient's time, the burden of having a complication, and the suffering involved in getting the care are usually not considered when discussing/deciding about the overall benefits of a treatment strategy and frequently the amount of time those benefits will last is ignored (e.g., time until recurrence). Third, efforts at outcomes measurement have been overwhelmingly focused on disease-related status (e.g., survival and other outcomes that are readily captured by laboratory or radiological tests), while functional status is often left out, even though improving functional status is why patients seek care. These omissions reflect clinicians' inclination to focus on readily accessible data, as well as the fact that many outcome measures developed to date have emerged from controlled clinical trials, which often have a single primary clinical end point. It should be acknowledged that focusing on functional results is extremely demanding, as shown, for example, by the limited amount of good-quality data about urinary and sexual dysfunction after rectal resections. The challenge is complex because function is sometimes subjective and because patient perspectives are altered depending on a number of variables that may or may not reflect the level of the care delivered. Lastly, progress on outcomes measurement has been slowed dramatically by the lack of standardization of recording and stratification.

The role of providers, payers, patient-advocacy groups, and regulators is crucial to create a process to agree on a minimum sufficient set of outcomes for each important medical condition. From this perspective, the role of The International Consortium for Health Outcomes Measurement (ICHOM) has been crucial (ichom.org 2017). This international group of about 300 specialists focused on the most frequent medical conditions that, together with patient representatives, have defined the minimum standard outcome sets and risk factors using a structured process. ICHOM has approved or is in the final stages of approval of more than 20 sets covering about 45% of disease burden in the USA and other high-income countries, with many more to come. The international nature of the effort has allowed participants to see that patients with a given condition have the same or similar needs everywhere. ICHOM working groups understood that their role is not to devise new outcome measures but to agree on which

well-validated ones, including patient-reported measures, everyone should use. These standards are putting providers, payers, patients, and information technology vendors on a common path for tracking what needs to be tracked and making implementation of outcome measurement easier and more efficient. Aiming for the same targets, the GOSAFE (Geriatric Oncology Surgical Assessment and Functional rEcovery after Surgery) study has been recently launched by the European Society of Surgical Oncology in collaboration with the International Society of Geriatric Oncology (@GOSAFEstudy). The GO SAFE study is a prospective international collaborative high-quality registry aiming to gain knowledge about postoperative outcomes in older cancer patients with a particular emphasis on QoL and FR. The target is to obtain meaningful data to assist clinicians in tailoring the care to avoid under/overtreatment and providing robust data to identify new strategies to improve functional outcomes in older cancer patients. The same way Porter et al. (2016) concluded their manuscript we also predict that "*a time will soon come when it will be hard to believe that measurement of outcomes that mattered to patients was rare in 2016 – and organizations that measured them each did it in their own way.*"

What Do Hospital Administrations Want to Know?

Costs and Perception of Surgical Oncology Versus Medical Oncology

In September 2012, the Royal College of Physicians released its annual report on "Hospitals on the edge? – the time for action" (rcplondon.ac.uk 2017). The College realized that the reality of care in the UK hospitals has changed considerably over the last 10 years. Data showed an increasing number of patients seeking care in the NHS are older and frail, and around 25% of inpatients have a diagnosis of dementia. Nearly two-thirds (65%) of people admitted to hospital are over 65 years old and they occupy more than 51,000 acute-care beds at any one time, accounting for 70% of bed days (Cornwell et al. 2012; Imison et al. 2012; Hospital Episode Statistics 2017). People over 85 years old account for 25% of bed days, increased from 22% over the past 10 years. This equates to more than five bed days per annum, compared to only one-fifth of a bed day each year for those under 65. People over 85 years tend to spend around 8 days longer in hospital than those under 65 years, 11 days compared to 3. This becomes a larger burden for health care sustainability if we consider the cost related to cancer care, on top of hospitals beds' occupancy. The US Department of health, through the Agency for Healthcare Research and Quality (AHRQ) and the Medical Expenditure Panel Survey (MEPS), reported that cancer care is the first source of expenditures with $25,000 per person (trauma-related disorders is second with about $20,000/person) (meps.ahrq.gov 2017). It has been also unfortunately showed that costs increase proportionally when cancer is associated with comorbidities, which is quite a common condition in older patients. The HealthCore 2002–2005 claims data set reported that total cost rises from $31,000 for "healthy"-cancer patients to $46,000 in the presence of one comorbidity and is reported to increase dramatically up to about $65,000 per patient in cases where 3+ comorbidities are documented. While the increase in cost is understandable given the fact that more complicated conditions require higher expenses to be treated/managed, it must be noted that there is currently a disproportion of funds allocation for cancer treatment modalities. This is particularly relevant if we consider that of hypothetical 5 Euros for cancer treatment, 3.5 Euros are used for the chemotherapy drugs, and 1.5 Euros for the rest of the cancer care (including surgery and radiation therapy).

The misbalance between these two sides of cancer care has been recently reported by a powerful editorial in *Cancerworld*, the journal reporting opinion leaders' thoughts on medical and surgical oncology across Europe. Wagstaff (2016) reported first a widely cited analysis of cancer research stories published between 1998 and 2006 on the BBC website, chosen by the

researchers as "an ideal surrogate... for overall media impact," finding that stories about cancer drugs dominated, accounting for around 20% of all coverage (Lewison et al. 2008). Stories about research on any other modality of treatment were so few and far between that they didn't even get a mention in the report. Other major research topics, in order of frequency, were stories on lifestyle, genetics, food and drink, and work-related risk factors. It's surprising how surgery has not given any attention, given the fact that the vast majority of the most common solid tumors (e.g., breast and colorectal) are mainly cured with surgery. The same article described a peculiar reason to explain why medical management grabs so much more attention than surgery by reporting an interesting paper published in the Journal of the European Molecular Biology Organization. Sullivan et al. (2010) indeed brought together a body of evidence to show that we are all hard-wired, through evolution, to seek medication when we are not feeling well, and that we share this trait with much of the animal world. Significantly, it linked this trait to the placebo effect, the real biological effect (hence the evolutionary benefit) that has been demonstrated to arise simply from our seemingly irrational belief in the efficacy of an ingested medicine. Irrational or not, it's a common misunderstanding that efforts in cancer research and basic science should have their main focus on ridding a patient of the need for surgery while almost nobody realizes that research should be focused on improving the quality of surgery since the majority of are cured by surgery and only around 5% or 6% by medical oncology.

While considering the disproportion of collective awareness and funds allocated for medical vs. surgical care, everyone who carries responsibilities for any hospital administration should explore the Memorial Sloan Kettering Cancer Center colorectal cancer nomogram (mskcc.org/nomograms 2017) to determine the predicted impact of adjuvant chemotherapy in the group of patients that is currently receiving it: older patients 70 year and older (Weiser et al. 2008). For example, per the nomogram, for a 70-year-old male with T3, N1 colon cancer with lymphovascular invasion and perineural invasion, the 5 year disease-free survival only increases minimally from 48% to 51% with the addition of chemotherapy while the 10 year disease-free survival increases from 36% to 39% (mskcc.org/nomograms 2017). This nomogram can help counsel patients further about the risks and benefits of undergoing adjuvant chemotherapy based on their characteristics and the characteristics of the tumor.

What Is the Value of Health Care: Outcomes That Matter to Patients/Cost per Patient Ratio

"Achieving high value for patients must become the overarching goal of health care delivery, with value defined as the health outcomes achieved per dollar spent" (Porter and Teisberg 2006). This simple but powerful statement by a Harvard Business School group of authors is the key message of this chapter. "If value improves, patients, payers, providers, and suppliers can all benefit while the economic sustainability of the health care system increases," they continued. Unfortunately, value in health care remains largely unmeasured and misunderstood. The process carries intrinsic complexity (increased by the single patient's complexity as for older patients cancer patients) but also because providers tend to measure only what they can directly control in a particular intervention and what is easily measured, rather than what matters for patients. For example, current clinical-outcomes-measure strategies often cover either a miniscule part of a process (e.g., intraoperative blood loss, too narrow to be relevant to patients who are managed in a multidisciplinary fashion) or outcomes of a whole hospital, such as infection rates (too broad to be relevant to individual patients). Rigorous, disciplined measurement and improvement of the awareness of the true meaning of clinical "value," instead is the best way to drive progress of the healthcare system. Since value is defined as outcomes relative to costs, it incorporates efficiency. Cost reduction without regard to the outcomes achieved is dangerous and self-defeating, leading

to false "savings" and potentially limiting effective care (Porter 2010).

In order to identify the proper unit for measuring value, administrations should encompass all services or activities that jointly determine success in meeting a set of patient needs. Examining the rectal cancer case, for example, true value for patients cannot be achieved without measuring the cumulative efforts that produce a high standard of care. The system starts with preoperative staging/imaging (underlining the key role of dedicated MRI specialist), to the multidisciplinary management by radiation and medical oncologists, to the pivotal role of dedicated rectal-cancer surgeons and their teams, and moving forward, the crucial value of specialized pathologists able to define tumor regression grade and circumferential margin status in order to guide the need for further treatments. Altogether, the system generates value for the single patient but if one step of the ladder is analyzed independently you may obtain a misleading perception.

Porter (2010) identified two key elements that should drive the measurement of outcomes that matter to patients. First, "the value comes from the sum of combined efforts from health care providers over the full cycle of care." The benefits of any one intervention for the ultimate outcome will depend on the effectiveness of other interventions throughout the care cycle. This is not just the definition of a "care cycle" but should be the spirit that characterizes every true multidisciplinary system considered devoted to cancer care. Second, "value for patients is often revealed only over time and is manifested in longer-term outcomes such as sustainable recovery, need for ongoing interventions, or occurrences of treatment-induced illnesses" (Institute of Medicine 2006). The only way to accurately measure value, then, is to track patient outcomes and costs longitudinally.

This approach is diametrically opposed to the one often used by hospital administrations that tends to dissect the process in microscopic segments (e.g., cost of laparoscopic energy devices in the operating room) in order to apparently govern the system expenses. Unfortunately, this way of approaching the problem doesn't allow managers to capture either the economic value (the use of laparoscopic energy devices may or may not reduce surgery time and may or may not reduce postoperative complications/length of stay) or the patients' true benefit (faster recovery after surgery using "expensive" laparoscopic devices) of a given surgical practice. Outcome measurement should include the health circumstances most relevant to patients addressing a period long enough to comprehend the ultimate results of care.

Today, health care organizations measure and accumulate costs around departments, physician specialties, discrete service areas, and line items such as drugs and supplies as a reflection of the organization and financing of care. Costs, like outcomes, should instead be measured around the patient. Measuring the total costs over a patient's entire care cycle and weighing them against outcomes will enable truly structural cost reduction, through steps such as reallocation of spending among types of services, elimination of non–value-adding services, better use of capacity, shortening of cycle time, provision of services in the appropriate settings, and so on (Porter 2008).

Outcome measurement should then include sufficient measurement of risk factors or initial conditions to allow for risk adjustment as in the case of older cancer patients. Measuring, reporting, and comparing outcomes are perhaps the most important steps toward rapidly improving outcomes and making good choices about reducing costs. The role of clinicians in this process is to show hospital administrations that good, patient-centered clinical practice is effective because it produces outcomes that matter to patients and it's ultimately able to control expenses because it can prioritize what is essential and reduce what is of little value for oncologic patients.

There is probably no better way than reporting the Royal College of Physicians 2012 annual report (rcplondon.ac.uk 2017) to summarize a practical vision of what it means to promote the true value for health care among professionals and administrations. As the College highlights, this virtuous process should be implemented through three simple steps:

1. Rebuild awareness that patients' dignity is the center of our profession
2. Redesign services to improve patients' care
3. Reconsider the way medical education is delivered and physicians are trained in the modern era

> We must promote dignity and patient-centered care. We must make sure patients are at the heart of service design and clinical practice. Hospitals must be a safe place in which all patients are treated with dignity and respect, including those with dementia. All health professionals have a duty to ensure patient needs are met, working together as a team to deliver the best possible care [. . .].
>
> We must redesign services. We must make difficult decisions about the design of services where this will improve patient care. In some areas, this will require service reconfiguration. Decisions about service redesign must be clinically led and clinicians must be prepared to challenge the way services – including their own service – are organized. [. . .] We must change the way we organize hospital care. We must reorganize hospital care so that patients have access to efficient, high-quality, expert care regardless of their age or day of the week. [. . .] We must consider whether the way we educate, train and deploy physicians ensures the right balance of general and specialist skills to deliver expert, holistic care for current and future patients. It is vital that all medical professionals have the skills and knowledge they need to care for older patients with complex conditions, frailty and dementia. (rcplondon.ac.uk 2017)

Conclusions

Cancer care in the older patients should be patient-focused, multidisciplinary, and take into account patient, surgeon, and institution factors. In striving for patient-centered outcomes rather than surgeon- or institution-driven outcomes, patients stand to gain quality of life, and the chance to meet their goals of care.

Summary

Colorectal cancer care cannot be dictated by chronological age alone. Regardless of the system of choice, it is essential to systematically assess older cancer patients to determine whether the patient is fit for surgery, which surgical plan is appropriate, and which adjustments may be needed before the procedure. Main domains that should be accessed before colorectal surgery are: cognitive status (including history of delirium), independence/living situation, sarcopenia, gait ability, and nutrition. Minimally invasive colorectal surgery is safe and feasible in properly selected older patients, and, in fact, is associated with faster functional recovery. Perioperative enhanced recovery protocols can be safely adopted and are beneficial in senior adults with colorectal cancer undergoing surgery. Rectal cancer management is changing; in addition to organ preserving surgical strategies, there is new emphasis on "watch and wait" protocols after clinical complete response following neoadjuvant chemoradiation. Both strategies could be of tremendous benefit for older rectal cancer patients especially in vulnerable or frail individuals. In order to better understand the value of different treatment strategies, data such as functional status and quality of life should be routinely reported at the end of the process. Achieving high value for patients must become the overarching goal of health care delivery, with value defined as the health outcomes achieved per dollar spent. Costs, like outcomes, should be measured around the patient. Measuring the total costs over a patient's entire care cycle and weighing them against outcomes will enable truly structural cost reduction in colorectal cancer care.

Abstract

Liver, pancreatic, and gastric cancers are aggressive and common malignancies and their incidence is increased in the elderly. Treatment requires a multidisciplinary approach involving multiple specialties including gastroenterology, surgery, radiation oncology, interventional radiology, and medical oncology. Appropriate management is limited by inherent biases among clinicians and the fact that very few clinical trials enroll elderly patients. It is well documented across multiple malignancies that elderly patients often receive substandard care, are denied potentially curative surgery, and are less likely to be treated with standard of care chemo- and radiation-therapies. However, it is clear that chronological age should not be used as the sole determinant when formulating a treatment strategy. Various tools included within a Comprehensive Geriatric Assessment are available and can aid in the decision-making process, when considering the best treatment for patients with advanced age.

Mounting data support the argument that elderly patients derive somewhat similar benefit from treatment compared with younger patients. Surgical complications and toxicities with chemotherapy may be higher in elderly population because of associated comorbidities, diminished functional status, and altered pharmacokinetic profiles. Increased clinical trial accrual of elderly patients is needed and can help provide data to guide management of these complex patients. In the following chapter, we evaluate the multidisciplinary management of liver, pancreatic, and gastric cancer in the elderly with a focus on evidence-based, patient-centered treatment strategies.

Keywords

Hepatocellular carcinoma · Cholangiocarcinoma · Colorectal liver metastases · Pancreatic adenocarcinoma · Gastric cancer

Introduction and Background

Tumors of the liver, pancreas, and stomach are common in elderly patients and are associated with high morbidity and mortality. Healthcare providers frequently struggle with how to best manage the elderly, often resulting in substandard care. Most of the available data support a more aggressive treatment approach that puts less emphasis on chronologic age and more on patient function, comorbidities, and quality of life. It is clear that a multidisciplinary treatment approach is necessary, especially in the very elderly patient with multiple comorbidities, advanced local or systemic disease, and/or a complex social situation. It is crucial that patients are given the opportunity to voice their goals and values so that an appropriate treatment plan is formulated. Many elderly patients will require transitional care placement after a complex operation, and in some cases, they may experience increased complications rates. Similarly, aggressive chemotherapy regimens might not be well

Table 1 Selected studies of liver resection in young versus elderly patients for mixed indications

Reference	Number of patients by age	Perioperative mortality (%)	Perioperative complications (%)	5-year survival (%)	Comments
Cescon et al. 2003	≥70 y ($n = 23$) <70 y ($n = 99$)	0 2	39.1 32.3	64.2 53.9	Survival is 3-year. No significant differences
Menon et al. 2006 (Cescon et al. 2003)	≥70 y (N = 127) <70 y ($n = 390$)	7.9 5.4	31 33	–	No significant differences
Shirabe et al. 2009	≥ 80 y ($n = 43$) < 80 y ($n = 307$)	0 0.3	26 22	–	No significant differences
Reddy et al. 2011	≥75 y ($n = 423$) 65–74 y ($n = 2261$) 50–64 y ($n = 1703$) ≤50 y ($n = 883$)	≥50 y 7.7 <50 y 1.5	- -	- -	Analysis based on age as continuous variable. Each 1-year and 10-year increase in age associated with 1.036 and 1.426 odds ratio of mortality
Schiergens et al. 2016	18–90 y ($n = 763$) examined age as continuous variable	4/7	43	–	Age had no effect on long-term survival within the first 3 years of surgery

tolerated. Patients must be thoroughly counseled regarding the risks and benefits of various approaches so that they can make the most informed decision possible. Whenever possible, we recommend treatment at high-volume centers. Several tools are available to assist clinicians with the management of elderly patients, including the Comprehensive Geriatric Assessment (CGA), which can help streamline care and guide clinicians in the management for these complex patients.

Liver Malignancies

In contrast to most malignancies, the incidence of liver cancer is increasing at a staggering rate of 3–4% per year, with an associated nearly 3% increase in mortality (Siegel et al. 2017). The burden of this increase is realized disproportionately by the elderly. The MacArthur Foundation predicts the number of patients older than 65 will triple by 2050 (Olshansky et al. 2009). Accordingly, physicians are treating a rapidly increasing number of geriatric patients with hepatobiliary cancers. Significant disparities have been documented in the geriatric population, with many patients receiving substandard cancer care based on their age. In some, but not all cases, additional comorbidities present in the elderly will determine overall survival. However, life expectancy is often underestimated by health care professionals when assessing elderly patients with comorbidities (Wirth and Sieber 2012). This may lead to unacceptable denial of appropriate medical and surgical therapy.

Liver Resection and Special Considerations

Liver resection remains the best option for patients with potentially curable primary and metastatic liver tumors. Traditionally, advanced age was considered a contraindication to major hepatic resection. Many elderly patients present with poor cardiopulmonary, renal, and hepatic reserve, often in the setting of poor nutritional status and significant physical and mental frailty. However, there is increasing worldwide experience to support hepatic resection in appropriately selected elderly patients with primary and secondary liver tumors. Over time, it has become quite clear that major hepatic resection is safe and feasible in elderly patients, and chronologic age alone should not determine surgical candidacy (Table 1).

Technical aspects of surgery, including liver ultrasound, surgical devices for parenchymal transection, and improved anesthetic care, have been refined over recent decades and have led to low mortality rates, typically less than 3% in well-selected patients, and when performed at high-volume institutions. Increased experience with portal vein embolization and ablative strategies has opened doors for patients with increasing burdens of disease, who would otherwise be considered unresectable. A multidisciplinary approach with coordination of care between the surgeon, oncologist, primary care physician or geriatrician, anesthesiologist, and often interventional radiologist is crucial for successful management of these patients.

The feasibility of hepatic resection is largely determined by the size and underlying function of the future liver remnant – the liver parenchyma to remain after surgery. Postoperative liver failure is a rare but often fatal complication, with highly variable rates depending on the series (Aldrighetti et al. 2006; Menon et al. 2006). Physiologic changes within the aging liver may account for an increased incidence of postoperative hepatic failure demonstrated in some series. Hepatic blood flow is decreased in the elderly, and average liver size decreases from 2.5% total body mass to 1.5% total body mass in the octogenarian. The number of hepatocytes appears to decrease, with a concomitant hypertrophy of those that remain. Under normal circumstances, liver function is not noticeably impaired, although clotting factors and other liver proteins may be produced in lower numbers. In the setting of hepatic stress such as surgery or hepatotoxic chemotherapy, these effects may become more apparent (Aalami et al. 2003). The effects of chronic liver injury over the course of a lifetime are also a concern, especially given increasing prevalence of obesity and diabetes in the aging population. Animal studies have also reported decreased capacity for liver regeneration in older animals (Schapiro et al. 1982). However, most human series suggest little difference in the rate of hepatic regeneration following resection in old and young patients when compared using pre- and postoperative volumetric analysis (Kit Wan Chiu and Fong 2011). Liver regeneration is certainly impaired in patients with diabetes, nonalcoholic fatty liver disease, and cirrhosis, and resection should be undertaken in these patients with extreme caution.

Comorbidities and frailty associated with elderly populations can make the decision when to operate difficult. First and foremost, it is crucial that those caring for the patient have an understanding of the patients overall values and healthcare goals, especially as they relate to expected and possible treatment outcomes. Some patients will value quality of life over all else, while others may have very specific future events, such as a grandchild's wedding or graduation, that they aim to attend. Many elderly patients that undergo major hepatic resection will require placement in a transitional care facility for an uncertain amount of time after discharge from the hospital. This must be clear to the patient preoperatively. Similarly, clinicians tend to focus on perioperative mortality and discrete complications such as liver failure, sepsis, and bleeding, but the higher than average risk of postoperative functional and cognitive decline should also be addressed explicitly as they are often considered even more important by the elderly, and have a significant effect on both quality of life and survival (Hofman et al. 2015). As with other surgical procedures, preoperative evaluation should include a multidisciplinary evaluation to assess fitness for surgery. Comprehensive assessments with tools such as the preoperative assessment of cancer in the elderly (PACE – a comprehensive geriatric assessment model) examine general health, specific and relevant to the geriatric population, through a series of validated scales and tests with the goal of identifying modifiable risk factors and predicting postoperative morbidity and mortality (Kim et al. 2013a; Pope et al. 2006). Although liver specific assessment tools are not currently available, the use of this and other similar screening tools can help identify patients at high risk of adverse events, and most importantly, guide providers regarding specific deficits that can be optimized before, during, or after surgery.

Recent analysis of the American College of Surgeons (ACS) National Surgical Quality Improvement Program (NSQIP) database demonstrated

increased mortality in elderly patients across all gastrointestinal oncologic operations, with these findings most pronounced after hepatectomy. In this study, 30-day mortality increased from 3.6% in patients younger than 65 years, to 5.7% in patients 65–74 and 7.9% in patients 75–84 years old. Patients older than 85 years of age had a five-fold increase in mortality when compared with patients less than 65 years old (Yeo et al. 2016). Similar results were published in a multi-institutional analysis of patients undergoing major liver resection at Duke University and the University of Pittsburgh from 2002 to 2009. In this study, a 1.5% mortality rate was reported in patients below the age of 50, versus 7.7% in patients over age 50 (Reddy et al. 2011). Similarly, a population-level study evaluating outcomes after hepatectomy in patients with colorectal liver metastasis also found that older patients were significantly more likely to require post-acute care needs following discharge; 18.3% of those $\geq$75 years old patients required postdischarge care at another institution (i.e., rehab, skilled nursing facilities, among others) as compared to only 2.1% of those <65 years old (p <0.001) (Orcutt et al. 2012). The difference in these outcomes is not driven by age alone and should not be interpreted as a reason to withhold surgery for geriatric patients. Instead, they underscore the importance of proper patient selection as well as an opportunity to improve upon and streamline current guidelines for perioperative care in the elderly, with a special focus on the quality of recovery. Specific perioperative system interventions such as enhanced recovery after surgery (ERAS) protocols, geared at improving the quality and experience of surgery during the whole perioperative period, can have a meaningful impact for the elderly and should be considered as a model to optimize care for this population.

Hepatocellular Carcinoma

Hepatocellular carcinoma (HCC) is the second most common cause of cancer-related death in men and the sixth most common in women worldwide. It differs from other liver tumors by the increased prevalence of chronic liver disease and associated cirrhosis. Malignant transformation often occurs in the setting of chronic hepatic inflammation and injury, with the peak age of HCC incidence being variable worldwide. This is explained by variability in etiologic factors, including viral hepatitis, alcoholic cirrhosis, and nonalcoholic steatohepatitis (NASH) in different parts of the world. Specifically, patients in the developing world are more likely to develop hepatitis B virus (HBV) related HCC and present at an earlier age. In western countries, HCC is more likely related to hepatitis C virus (HCV), alcoholic cirrhosis, and nonalcoholic steatohepatitis (NASH), and median age at presentation is over 60 years (McGlynn and London 2005). Furthermore, as treatment options for HBV and HVC become increasingly available, it is postulated that the peak incidence of HCC will be even further delayed.

Diagnosis

In the majority of patients, HCC causes no additional symptoms besides those associated with chronic liver disease. As the tumor grows, patients may develop pain, distention, weight loss, fatigue, and anorexia. Hepatic decompensation in a previously well-compensated cirrhotic may be the first sign of malignancy. Depending on tumor location, the patient may present with invasion or obstruction of the biliary tree, portal vein, hepatic artery, or inferior vena cava. Extrahepatic spread is rare, with only about 5–15% of patient with metastases at presentation. The most common sites are lung, intra-abdominal lymph nodes, bone, and adrenals (Uka et al. 2007).

Workup consists of thorough history and physical exam with focus on the presence and extent of chronic liver disease. Laboratory studies including CBC, coagulation studies, hepatitis serologies, AFP, and CEA are needed. Cross-sectional imaging with multidetector row CT or MRI with liver protocols is helpful in distinguishing HCC from other benign or malignant tumors of the liver. Furthermore, it is necessary to determine the extent of intrahepatic tumor burden and assess local resectability. It is important to note that perihepatic adenopathy

should not be assumed to represent extrahepatic spread since many cirrhotics harbor benign nodal enlargement, particularly in the setting of viral infections.

The best strategy for early diagnosis of HCC in high-risk patients is close follow-up with ultrasound at 6-month intervals. Unfortunately, most patients at high-risk, particularly elderly patients, do not undergo recommended screening (Davila et al. 2010). Yan et al. recently published a large series using the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) population based cancer registry from 2003 to 2011; patients age 70 years or older presented with more advanced disease, were less likely to fall within Milan criteria at diagnosis, were less likely to receive any HCC treatment, and had significantly worse long-term survival (Yan et al. 2017). There is a perception, often incorrect, that elderly patients may not benefit from treatment and may suffer undue harm from complications and toxicity. However, there is clear evidence to suggest that treatments for HCC in elderly patients are as effective as in younger patients and that when appropriate treatment is provided, outcome is predicted by cancer stage, not age (Mirici-Cappa et al. 2010).

Resection

Based on different US and international guidelines, it is agreed that resection should be first line of treatment for patients with limited liver tumors (e.g., solitary lesions) and well-preserved liver function (Heimbach et al. 2018). The significance of chronic liver disease in patients with HCC cannot be overstated, and the surgeon must be experienced in the simultaneous management of chronic liver disease and HCC. Perioperative mortality after liver resection in cirrhotic patients is expected to be 2–10% and may be slightly higher in the elderly. That said, several reports indicate that elderly patients with HCC present with less cirrhosis than their younger counterparts, possibly because patients with cirrhosis die at a younger age (Nakamuta et al. 2005). Multifocal HCC also appears to be less common in the elderly. Proper patient selection is paramount and a thorough understanding of the patients overall fitness, hepatic reserve, and the presence of portal hypertension must be obtained.

Multiple contemporary studies have examined outcomes following surgical resection for elderly patients with HCC and reported that age is not an independent determinant of prognosis (Table 2). These studies are generally limited by small sample sizes and all are

Table 2 Selected studies of liver resection in young versus elderly patients with hepatocellular carcinoma

Reference	Number of patients by age	Perioperative mortality (%)	Perioperative complications (%)	5-year survival (%)	Comments
Kondo et al. 2008	≥70 y ($n = 109$) <70 y ($n = 210$)	3.7 2.9	41.3 43.8	- -	No significant differences

retrospective in nature. Furthermore, most of these studies were conducted in Asian populations and should be applied to Western patients with caution. Despite these limitations, they do provide mounting support for the safety and efficacy of liver resection for HCC in the well-selected elderly population. Unfortunately, analysis of patient-centered and transitional outcomes, such as need for prolonged inpatient rehabilitation, is seldom included.

Transplant

Unfortunately, only 5–15% of patients with HCC present with adequate liver reserve to tolerate curative resection (Bismuth et al. 1999). Liver transplant is the treatment of choice in patients with advanced cirrhosis and HCC but is often not considered for patients older than 65–70 years old. Some studies have demonstrated equivalent outcomes with respect to perioperative and long-term morbidity, mortality, and rejection in elderly patients, while others have raised concerns (Nishikawa et al. 2013). The concern regarding substandard outcomes in the elderly and the limited number of organs available are both important considerations that have led to a limited role of liver transplantation for those over 70 years old. Further, it is clear that elderly patients with associated comorbidities are not candidates for transplant. Despite this, there is an increasing trend at high volume centers to evaluate the elderly using the same selection criteria as is used for younger patients (Taner et al. 2012), and for well-selected elderly patients this may be a treatment option to be evaluated on a case-by-case basis.

Ablation

Experience with potentially curative ablative strategies, including radiofrequency (RFA) and microwave ablation (MWA), has greatly expanded in recent years. Ethanol ablation and cryoablation, which were once commonly employed, have fallen out of favor given increased efficacy and efficiency of RFA and MWA. Tumor ablation can be performed percutaneously, typically by an interventional radiologist, or during an open or laparoscopic surgical procedure. Tumor ablation is an excellent option for elderly patients with medical comorbidities and/or cirrhosis that would render them poor candidates for resection. In fact, in contrast to resection, technical aspects of RFA are enhanced by a cirrhotic parenchyma because of the "oven effect," whereby the stiff cirrhotic liver traps the heat generated by ablation within the tumor. RFA is currently considered the standard of care for small unresectable HCC (Bruix et al. 2011), and there are randomized data to support equivalence between RFA and resection for small tumors, typically <3 cm (Huang et al. 2010; Chen et al. 2006; Lü et al. 2006). Ablative strategies are typically used for up to three lesions of small size and can also be employed in combination with resection or embolization.

Hepatic Arterial Embolization

Transarterial embolization, with or without chemotherapy, capitalizes on the fact that the blood supply for HCC is preferentially derived from the hepatic artery rather than the portal vein. It is a viable option for intermediate size or multifocal HCC that is deemed unresectable but is without vascular invasion or extrahepatic spread in patients with relatively preserved hepatic function. A recent meta-analysis demonstrated similar 5-year survival in elderly and nonelderly patients treated with transarterial chemoembolization (TACE) suggesting this is a safe and effective treatment modality (Hung and Guy 2015). Complications were similar and included liver failure, abscess, peptic ulcers, and renal impairment. Radioembolization with Yttrium-90 (Y-90) labeled glass (TheraSphere) or resin (SIR-Spheres) has also gained traction as a liver-directed therapy and an alternative to TACE. A recent series from Italy reported radioembolization is as well tolerated and effective for elderly patients as it is for older patients with HCC (Golfieri et al. 2013). Complication rates may also be less compared with TACE in certain circumstances, including portal vein thrombosis (Tsai et al. 2010).

Systemic Therapy – Sorafenib

The SHARP trial demonstrated a modest survival benefit in patient with advanced HCC

(unresectable or metastatic) treated with sorafenib (Llovet et al. 2008), a multitargeted tyrosine kinase inhibitor. The use of sorafenib in the elderly has been evaluated largely by way of retrospective data. No significant differences in overall survival, tumor response, and frequency, and severity of drug-related adverse events have been identified in the elderly, including very elderly patients age >80 years (Jo et al. 2014). Cytotoxic chemotherapy is not typically recommended for patients with HCC and use has largely been limited by hepatic reserve, the presence of cirrhosis, and possibly the fact that HCC is relatively chemo-refractory. Neoadjuvant and adjuvant systemic therapies, including sorafenib, have not proven beneficial in patients treated with resection or ablation and are not generally recommended outside of a clinical trial.

Cholangiocarcinoma

After HCC, cholangiocarcinoma is the second most common primary hepatic malignancy and accounts for about 3% of GI malignancies. The incidence is nearly two-fold higher in the elderly (Khan et al. 2008). Resection is the treatment of choice for patients with non-metastatic intrahepatic cholangiocarcinoma with reported 5-year survival of 30–35% with R0 resections (de Jong et al. 2011). In patients with unresectable/metastatic disease, or those that undergo R1 resection, there are essentially no survivors at 5 years. Data from a recent large retrospective multinational cohort (Vitale et al. 2016), which is the only study to specifically examine management of intrahepatic cholangiocarcinoma in the elderly, found that older patients were more likely to suffer severe postoperative complications after resection and were less likely to be treated with adjuvant systemic therapy. However, there was no difference in disease free or overall survival. Once again, disease characteristics and not age were predictive of long-term outcomes. For patients with unresectable/metastatic disease, the preferred systemic chemotherapy is with combination gemcitabine and cisplatin based on the ABC-02 trial (Valle et al. 2010). The role of systemic therapy in the neoadjuvant or adjuvant setting is not well defined. Transarterial therapy, in particular radioembolization, for patients with intrahepatic cholangiocarcinoma is of significant benefit and may be an alternative to the more toxic systemic therapy, for patients with unresectable, not-metastatic disease. Its favorable toxicity profile may be a more reasonable alternative for elderly frail patients specifically.

Colorectal Liver Metastasis

An estimated 30–50% of patients with colorectal liver cancer either present with or develop liver metastases at some point during their course. Optimal care of elderly patients with colorectal cancer liver metastases (CRC LM) is complex and requires a multidisciplinary team approach. Although the majority of patients diagnosed with CRC LM are 65–85 years old, elderly patients are underrepresented in clinical trials and population-based studies. Furthermore, improvement in outcomes has lagged when compared with younger populations. Cancer specific survival is significantly worse in the elderly, and this is at least partially driven by treatment (Anaya et al. 2011). There is mounting evidence to support that appropriately selected elderly patients with CRC LM benefit from standard of care treatment and, when treated aggressively, have long-term outcomes similar to younger populations (Leporrier et al. 2006). Unfortunately, age remains an independent predictor that a patient will be treated symptomatically, and not with the intent of improving survival (Kopetz et al. 2009).

Resection

Surgery remains the only curative option for patients with colorectal cancer liver metastases (CRC LM), and approximately 10–20% of patients present with surgically resectable disease (Simmonds et al. 2006). After 5 years, at least 30% of patients that undergo metastasectomy are alive, with approximately two-thirds of them without evidence of disease versus less than 5% of

Table 3 Selected studies of liver resection in young versus elderly patients with colorectal Cancer liver metastases

Reference	Number of patients by age	Perioperative mortality (%)	Perioperative complications (%)	5-year survival (%)	Comments
Brunken et al. 1998	>70 y ($n = 25$) <70 y ($n = 141$)	4 2	28 26	47 36	No significant differences

patients treated with best supportive care and 5-FU based chemotherapy (Manfredi et al. 2006; Mazzoni et al. 2007). A 2012 report by Orcutt et al. used the United States National Inpatient Sample to evaluate short-term outcomes in elderly patients that underwent resection for CRC LM and reported a 1.3% mortality rate in patients younger than 65, 2.2% in patients 65–74, and 3.3% in patients 75 and older. This study also highlighted the significantly increased need for placement in transitional care facilities in elderly patients undergoing liver resection (Orcutt et al. 2012).

It is not surprising that several studies have demonstrated slightly increased perioperative mortality in elderly patients that undergo hepatectomy for CRC LM (Table 3). Despite this finding, perioperative mortality is still low and within acceptable ranges and we believe that liver resection should still be the treatment of choice for appropriately selected patients. A number of prediction tools have been reported to guide treatment options in the elderly. Mazzoni et al. formulated a clinical risk score to predict overall survival in elderly patients with CRC LM treated with liver resection. The authors concluded that a clinical risk score of 3 or more should be a contraindication to surgery and advised RFA or TACE depending on the clinical scenario (Table 4) (Mazzoni et al. 2007). Although tools such as this can potentially help in decision-making, this model still warrants external validation.

Table 4 Clinical risk score to predict overall survival in elderly patients with CRC LM treated with liver resection. (Mazzoni et al. 2007)

Risk Factor	Points
Node-positive primary tumor 1	1
Disease-free interval <12 months 1	1
Number of metastases >1 1	1
Tumor size >5 cm 1	1
Preoperative CEA >100 ng/mL 1	1
Score	*Predicted median overall survival (months)*
0–2	30–46
3–4	20–23
5	12

Although for the most part indications for liver resection should not be based on age alone, there are specific circumstances with extensive resections in which older patients, even those fit and with limited comorbidities, may not do as well. Specifically, major operations such as the Associating Liver Partition and Portal Vein Ligation for Staged Hepatectomy (ALPSS) though most applicable for patients with CRCLM have been shown to have significantly higher mortality rates in older patients and as such, it is generally considered contraindicated for this population (Oldhafer et al. 2016). Additional data are needed in the elderly with respect to combined resection of liver metastases and the primary tumor, though this has been shown to be safe in the general patient population with low-moderate volume disease.

Chemotherapy

The available data suggest similar cytotoxic efficacy of chemotherapy in young and old patients, with variably increased toxicity in the elderly. The optimal approach in patients with resectable CRC LM remains somewhat unclear, especially for the elderly. Perioperative chemotherapy is the current approach for most patients outside of a clinical trial. A phase III EORTC trial in which perioperative FOLFOX (3 months before and 3 months after surgery) administration led to a 7.3% improvement in progression free survival at 3-years, but no difference at 5-years. There was no difference in overall survival at 5 years, but the study was not powered to detect this endpoint. Perioperative morbidity increased from 16% to 25% in patients treated with chemotherapy (Nordlinger et al. 2013). Current NCCN guidelines recommend 6 months of an active systemic regimen administered perioperatively in patients with resectable disease (Benson et al. 2017). 5-Fluorouracil/leucovorin alone or 20% dose-reduced FOLFOX are reasonable approaches in elderly patients with poor reserve that may not be able to tolerate full dose oxaliplatin (Sanoff and Goldberg 2013). A recent Italian multicenter analysis demonstrated a treatment benefit in patients over 80 years old with metastatic CRC (not limited to liver), reporting a 2-year overall survival of 34.8% in patients treated with chemotherapy versus 17.6% in those not treated (Grande et al. 2016). The optimal timing of chemotherapy for patients with CRC LM remains a topic of debate.

In patients that are poor candidates for, or decide against resection with or without systemic therapy, additional alternatives include tumor ablation and hepatic arterial directed therapy.

Neoadjuvant Therapy

Neoadjuvant chemotherapy is sometimes appealing, especially in high-risk patients with synchronous or large volume metastases as an in vivo test of tumor biology and the patient's response to treatment. In addition it allows for early treatment of any micrometastatic foci of disease and ensures that patients actually receive systemic treatment. However, chemotherapy-induced hepatotoxicity with steatosis and noncirrhotic portal hypertension have been associated with increased

postoperative complications and limit the utility of upfront systemic treatment in patients with clearly resectable disease (Zorzi et al. 2007). This is even more relevant in elderly patients that may already have compromised hepatic function. Finally, complications related to chemotherapy sometimes worsen an already borderline patient's performance status, such that surgery is no longer an option.

Conversion Therapy

Conversion therapy is administered with the goal of converting a patient with borderline or unresectable disease into a surgical candidate. The optimal regimen has not been determined. Both FOLFOX and FOLFIRI have been demonstrated to achieve resectability in 12.5–40% of patients (Ychou et al. 2013). The addition of bevacizumab, a vascular endothelial growth factor (VEGF) inhibitor, should be decided on a case by case basis and is only appropriate for the most fit elderly patients with borderline/unresectable CRC LM, but modest improvement in tumor control needs to be weighed against treatment toxicities including stroke and arterial thromboembolic events, and bowel perforation. If used in the neoadjuvant setting, it should be held at least 4–8 weeks prior to resection to minimize effects on wound healing and perioperative complications (Gruenberger et al. 2008). In exceptionally fit elderly patients with wild-type KRAS and BRAF tumors, the EGFR inhibitors cetuximab or panitumumab plus FOLFIRI may be considered if curative resection seems possible. In all cases, patients should be re-scanned at least every 2 months and duration of systemic treatment should be limited if the patient becomes a surgical candidate.

Adjuvant Therapy

Although no clear survival advantage has been demonstrated compared with observation alone in patients that undergo R0 resection, the standard of care is to administer systemic therapy for a period of 6 months. If no therapy was administered in the neoadjuvant setting, it is administered postoperatively. Given the lack of conclusive evidence in elderly patients with resected disease, it is important to consider the patients' health-related goals and performance status so that an informed decision can be made. FOLFOX or XELOX are the preferred regimens, as there is no evidence to support the use of irinotecan, cetuximab, or bevacizumab in patients with no evidence of disease after resection of primary colorectal cancer with metastases to the liver.

Pancreatic Cancer

Pancreatic ductal adenocarcinoma accounts for 90% of the tumors in the pancreas. Pancreatic adenocarcinoma is the fourth most common cause of cancer deaths in the United States with estimated 43,090 deaths and 53,670 new cases in 2016 (Siegel et al. 2017). It is expected that pancreatic cancer will become the most common cause of cancer-related death in the next decade (Rahib et al. 2014). The median age at diagnosis is 72 years for pancreatic cancer and is the highest of all cancers (Olson and Kurtz 2013). The strongest risk factor for pancreatic cancer is age. The risk for pancreatic cancer increases from only 73.4 per 100,000 in those aged 50–54 years to 104 per 100,000 for those aged 75–79 years. There are gender-specific differences as well with men having higher risk than women (13.5 vs. 10.8 per 100, 000) (Olson and Kurtz 2013). In terms of race, the incidence rate is highest among African Americans followed by whites, Hispanics, and Asians. Because of age distribution in United States among different races, the majority of patients with pancreatic cancer are whites.

Despite the fact that pancreatic cancer is a disease predominantly of older patients, there are limited data available on how to treat older patients. Most of the data are derived from small retrospective series. Even though the median age of diagnosis of pancreatic cancer is 72 years, the median age of patients enrolled in clinical trials is almost a decade younger. Further, some trials have excluded very elderly patients from enrolling in the clinical trials (Conroy et al. 2011). Similar bias is observed in surgical resection of pancreatic cancers where older patients are less

likely to undergo curative surgery. One study comparing the pathologic features of pancreatic cancer in elderly *and* younger patients did not find any differences in the grade, location, or incidence of the local spread, although elderly patients developed fewer hematogenous metastases (Kamisawa et al. 1998). Some reports have suggested that older patients present more diploid tumors or with p53 mutations, which are associated with a worse prognosis (Sato et al. 1997).

Both genetic and epidemiologic risk factors are associated with development of pancreatic cancer. Cigarette smoking remains the strongest environmental risk factor with almost a two-fold increased risk among current smokers compared to nonsmokers (Lynch et al. 2009; Iodice et al. 2008). Other environmental risk factors associated with pancreatic cancers include diabetes, obesity, pancreatitis, heavy alcohol use, and allergies (Calle et al. 2003; Ben et al. 2011; Olson 2012; Lucenteforte et al. 2012; Turner et al. 2006). A family history of pancreatic cancer is observed in 5–10% of patients with pancreatic cancers. Mutations in BRCA gene, especially BRCA2 and PALB2, are associated with increased risk of pancreatic cancers. Other known associated genetic conditions include hereditary nonpolyposis colon cancer (Lynch Syndrome), familial atypical multiple mole melanoma syndrome (FAMMM), Peutz–Jeghers syndrome, familial adenomatous polyposis, and hereditary pancreatitis (Olson and Kurtz 2013).

Staging

Accurate staging is required for patients with pancreatic cancer for selecting appropriate treatment strategies. Staging work-up includes measurement of tumor markers (CA19–9 and CEA), endoscopic ultrasound, and cross-sectional imaging (CT or MRI). In addition, laparoscopy and/or positron emission tomography (PET) scan may help detect metastases in additional patients initially considered to have early stage disease and thus prevent futile pancreatic resection.

There are two types of staging system typically used for prognosis and treatment: TNM staging by American Joint Committee on Cancer (AJCC) and clinical classification system based on imaging studies (Edge et al. 2009). TNM staging is based on tumor size, involvement of blood vessels and lymph nodes, and presence of metastatic disease. More frequently, the clinical classification system is utilized for making treatment recommendations. The clinical classification system divides the patients into following four groups: Resectable, Borderline resectable (Table 5), Locally advanced, and Metastatic disease. The classification of nonmetastatic pancreatic cancer into different groups is based on degree of involvement of blood vessels and the definitions are not uniform (Mahipal et al. 2015). Moreover, individual institutions may utilize their own criteria for determining resectability. At the time of staging, approximately 50–55% of the patients present with metastatic disease, 20% with

Table 5 Common definitions of borderline resectable pancreatic cancer

Blood vessel	NCCN (Tempero et al. 2014)	AHPBA/Consensus (Vauthey and Dixon 2009)	MD Anderson (Katz et al. 2008)
Celiac axis	Distortion of narrowing of the vessel wall, and/or reconstructible occlusion	Uninvolved	Short segment occlusion/ reconstructible
Superior mesenteric artery	Tumor-vessel interface $\geq$180 degrees of the circumference of the vessel wall	Abutment	Abutment
Hepatic artery	Reconstructible short segment interface between tumor and vessel	Abutment or short segment encasement	Abutment or short segment encasement
Superior mesenteric vein/portal vein	Distortion or narrowing of the vessel wall, and/or reconstructible occlusion	Abutment, impingement, encasement of the SMV/PV or short segment occlusion	Short segment occlusion/ reconstructible

resectable disease, and 20–25% with locally advanced stage (Stathis and Moore 2010).

Surgical Resection in Elderly Patients

Pancreatic cancer is an aggressive malignancy associated with poor prognosis. Despite recent advances for the treatment of pancreatic cancer, the 5-year survival rate remains approximately 6% (Siegel et al. 2016). Surgical resection with negative microscopic margins remains the only curative option. Even among patients who undergo potentially curative resection, the 5-year survival is only 20%. With the improvements in modern surgical techniques and adjuvant chemotherapeutic regimens, the median survival in clinical trials has increased to 28 months. Notably, the perioperative morbidity and mortality has substantially decreased, especially at high volume centers, making surgical resections feasible for higher proportion of patients. It is of utmost importance to select patients for surgical resection after appropriate staging, as there is no survival benefit of surgery for patients with metastatic disease.

Typically, upfront surgical resection is recommended for patients with resectable pancreatic cancer and neoadjuvant therapy for patients with borderline and locally advanced disease. At some centers, neoadjuvant therapy is routinely delivered even for patients with resectable disease. The probability of effective down-staging followed by surgical resection with negative margins is much lower for patients with locally advanced disease compared with resectable disease.

Prior to 1990, pancreaticoduodenectomy (PD) for pancreatic cancer was rarely performed in patients older than 70 years of age because of high mortality and morbidity rates (Gudjonsson 1987). Overall, the mortality after pancreatic resection was as high as 20% on average prior to 1984. In recent series, the mortality rate is less than 4% on average (Gudjonsson 2016). More importantly, both mortality and postoperative complications have significantly decreased at high volume centers (Scurtu et al. 2006). This has led to feasibility of potentially curable surgical resection for pancreatic cancer among older patients. Multiple studies have demonstrated that PD can be performed safely in patients older than 70 years of age (Scurtu et al. 2006; DiCarlo et al. 1998; Vickers et al. 1996). Some studies have demonstrated safety even in patients older than 80 years of age (Teague et al. 2015).

Older patients have similar postoperative mortality after PD as younger patients (Sohn et al. 1998; Makary et al. 2006). Some studies have demonstrated that elderly patients may have higher operative risks after PD. Some intraoperative factors like blood loss, transfusion requirements, and operative length seems to be similar across different age groups (Sohn et al. 1998). Elderly patients may have a more complicated postoperative period with some studies showing longer postoperative stay (Scurtu et al. 2006; Sohn et al. 1998). Some complications like delayed gastric emptying seems to be more common in patients >80 years of age (Finlayson et al. 2007). The proportion of patients being discharged to nursing home after the surgical resection was higher in older patients with 10.6% in the age group 60–65 years and 36.7% with ages ≥80 years were unable to be discharged home (Finlayson et al. 2007).

Surgical resection has demonstrated to increase the survival in patients with pancreatic cancer regardless of age. However, elderly patients are much less likely to undergo surgical resection than younger patients. In a population-based study, patients ≥85 years of age are 94% less likely than patients <70 years of age to undergo pancreatic resection (Riall et al. 2011). Since the benefit of surgery does not necessarily diminish with age, older patients with resectable pancreatic cancer should be considered for surgical resection. There are some tools available to assess elderly patients. Elderly patients should undergo comprehensive geriatric assessment (CGA). CGA is a multidimensional, interdisciplinary diagnostic process that focuses on the determination of medical, psychosocial, and functional capabilities in older people to develop an integrated treatment plan. CGA has been shown to improve overall survival, quality of

life, and physical functioning in the nononcologic geriatric population. Several recent reports have strongly suggested that different components of comprehensive geriatric assessment can be useful in oncology to predict early death, functional decline, toxicity, and overall survival (Puts et al. 2014; Hurria et al. 2011). As part of geriatric assessment functional status, comorbidities, cognition, mental health status and support, fatigue, and polypharmacy are assessed (Higuera et al. 2016). The Charlson age comorbidity index (CACI) is another tool that assesses the comorbidity in standardized fashion to predict the postoperative mortality of patients undergoing surgery. CACI is a statistically validated tool that assigns different weights to patient's comorbidities and can be adjusted for age of the patients. In a study of 379 patients with pancreatic cancer undergoing surgery, high CACI score of more than 4 was associated with significant poor survival (Asano et al. 2017). With the help of these validated tools, patients can be better selected for pancreatic resection and age alone should not be used as a discriminating factor to exclude patients from potentially curative surgery.

Chemotherapy in Elderly Patients

Metastatic Disease

Until few years ago, single agent gemcitabine had remained the mainstay treatment of patients with pancreatic cancer. This was based on a phase III multicenter randomized trial which assigned patients to either treatment with gemcitabine at a dose of 1000 mg/m2 for 7 weeks followed by 1 week of rest and then weekly for 3 weeks on and 1 week off or 5-fluorouracil (5-FU) 600 mg/m^2 given weekly on the same schedule (Burris et al. 1997). The median survival was 5.6 months in gemcitabine arm as compared to 4.4 months in 5-FU arm. There were no specific concerns about using single agent gemcitabine in elderly patients. Multiple randomized trials evaluating combination gemcitabine with a novel agent failed to demonstrate any significant clinical benefit. Combination of gemcitabine and erlotinib provided modest benefit with median survival of 6.2 months in the combination arm compared to 5.9 months with single agent gemcitabine (Moore et al. 2007). Erlotinib containing arm had higher incidence of rash, diarrhea, stomatitis, and infection. Gemcitabine and erlotinib has fallen out of favor in the clinical practice.

More recently, the combination of gemcitabine and nab-paclitaxel (albumin bound paclitaxel) was compared to gemcitabine in a large randomized phase III trial of 861 patients (Von Hoff et al. 2013). This study was conducted in both USA and Europe. The median age was 63 years (Range: 27–88 years). Patients with Karnofsky performance score (KPS) of 70 or higher were included in this trial. The median survival in the combination arm of gemcitabine and nab-paclitaxel was significantly higher than single agent gemcitabine arm (8.7 versus 6.6 months ($P < 0.001$). Gemcitabine plus nab-paclitaxel was associated with increase rates of neutropenia, leukopenia, fatigue, peripheral neuropathy, and diarrhea. Higher proportion of patients experienced grade 3 or higher treatment-related, treatment-emergent adverse events in the nab-paclitaxel plus gemcitabine arm (77%) than in the gemcitabine-alone arm (51%). Forty two percent of the patients were $\geq$65 years of age and significant survival benefit was observed in this subgroup as well (Goldstein et al. 2015). However, the median survival was shorter in both arms in older patients compared to younger patients. In the subgroup analysis, patients with KPS score of 70–80 also derived significant benefit with combination treatment. Overall, patients with better performance status had better survival.

In a randomized phase 3 trial conducted in Europe, single agent gemcitabine was compared to combination chemotherapy of 5-fluorouracil, leucovorin, oxaliplatin, and irinotecan (FOLFIRINOX) (Conroy et al. 2011). Only patients with Eastern Cooperative Oncology Group (ECOG) performance status score of 0 or 1 were included in this trial to select for patients who can better tolerate this intensive chemotherapy. Patients >75 years of age were excluded from this trial, thus limiting the generalization of these results to very elderly patients. The median age in this trial was 61 years, almost a decade

lower than the median age of pancreatic cancer patients in actual practice. The median survival was 11.1 months in the FOLFIRINOX group compared to 6.8 months in gemcitabine group (P <0.0001). Higher objective responses were seen in the FOLFIRINOX group (31.6% versus 9.4%). Incidences of grade 3 or 4 neutropenia (45.7% versus 21%), febrile neutropenia (5.4% versus 1.2%), thrombocytopenia (9.1% versus 3.6%), diarrhea (11.4% versus 1.2%), and sensory neuropathy (9% versus 0%) were significantly higher in the FOLFIRINOX group, whereas the incidence of grade 3 or 4 elevated alanine aminotransferase levels was significantly higher in the gemcitabine group. The quality of life at 6 months was better for patients receiving FOLFIRINOX likely due to better control of tumor growth. At 6 months, 31% of the patients in the FOLFIRINOX group had a definitive decrease in the scores on the Global Health Status and Quality of Life scale versus 66% in the gemcitabine group (hazard ratio, 0.47; 95% CI, 0.30 to 0.70; P <0.001). Thus, FOLFIRINOX therapy resulted in almost doubling of median survival at the expense of increase toxicities. However, this trial excluded older patients and patients with marginal performance status. Thus, it is not clear if FOLFIRINOX chemotherapy would provide benefit for elderly patients. Different dose modifications have been proposed to reduce the toxicity profile of FOLFIRINOX while maintaining the efficacy of the regimen. 5-Fluorouracil bolus is commonly omitted. Prophylactic G-CSF can be added as well. In a retrospective series from Memorial-Sloan Kettering Cancer Center, all patients were dose reduced to 80% of the standard dose from the beginning without compromising efficacy (Lowery et al. 2012). Other modifications include reducing the dose of irinotecan only and omitting bolus 5-fluorouracil (Conroy et al. 2013). The outcomes of these modifications of FOLFIRINOX chemotherapy in elderly patients with pancreatic cancer remain unclear. We typically do not use age as a cutoff for administering FOLFIRINOX. However, it is preferred in patients with excellent performance status with limited comorbidities, in the palliative setting. Gemcitabine and nab-paclitaxel combination was evaluated in more representative population of pancreatic cancer with significant proportion of older patients in the clinical trial. Single agent gemcitabine is reserved for patients with borderline performance status.

Adjuvant Treatment

Adjuvant chemotherapy after surgical resection for pancreatic cancer has been demonstrated to improve survival. In the CONKO-001 trial, a phase III multicenter randomized trial, efficacy, and toxicity of gemcitabine was evaluated as an adjuvant treatment (Oettle et al. 2013). The disease-free survival (DFS) was significantly prolonged in the gemcitabine group compared to observation group (13.4 vs. 6.7 months, P <0.001). The long-term survivors were almost doubled with 5-year survival of 20.7% in the treatment group compared to 10.4% in the observation group. Median age was 62 years with 62% of the patients were more than 65 years of age. Patients older than 65 years had slightly lower survival than younger patients, but older patients also derived similar benefit from adjuvant chemotherapy. In a large randomized trial of 1088 patients, The European Study Group for Pancreatic Cancer (ESPAC)-3 trial, 5-fluorouracil was compared to gemcitabine as an adjuvant therapy after pancreatic resection (Neoptolemos et al. 2010). No significant differences in overall survival were reported. In this study, age was not found to be of prognostic significance again, suggesting that elderly patients should not be excluded from receiving adjuvant therapy.

More recently, addition of capecitabine to gemcitabine as an adjuvant therapy was evaluated in ESPAC-4 trial. Seven hundred and twenty two patients were randomized to receive gemcitabine plus capecitabine combination or single agent gemcitabine. The median survival was 28 months in the combination group compared to 25.5 months in the gemcitabine arm. The combination arm has higher incidences of grade 3 or 4 diarrhea, infection, neutropenia, and hand-foot syndrome. The median age was 65 years. As with previous trials, age was not significantly associated with prognosis or

treatment benefit. Thus, gemcitabine plus capecitabine combination has now become standard of care treatment, but the combination treatment does have additional toxicities.

Despite the survival benefit reported with chemotherapy, adjuvant treatment is underutilized in elderly patients. Several large retrospective series have demonstrated that adjuvant therapy is less frequently administered to older patients. In a retrospective study using Surveillance, Epidemiology, and End Results (SEER)-linked Medicare data of patients >65 years of age, only 11% of the patients underwent resection and adjuvant chemotherapy (Parmar et al. 2014). The median age was 77 years in this study. Among patients who underwent resection, over half of the patients did not receive any adjuvant therapy. Younger patients were much more likely to receive chemotherapy. In another study, only 30% of the patients older than 70 years of age received adjuvant chemotherapy compared to 52% of the patients younger than 70 years (Nagrial et al. 2014). Older patients who received chemotherapy had much better survival with median survival of 21.8 months compared to 13.1 months for those who did not receive chemotherapy. Interestingly, among patients who received chemotherapy, the mean numbers of cycles administered were similar across different age groups suggesting that older patients are equally likely to complete treatment. Moreover, there is a perception that elderly patients are likely to die from non-cancer related deaths and thus may derive only limited benefit from adjuvant treatment. However, the predominant cause of deaths in both younger and older age group was pancreatic cancer and there were no significant differences between the two groups. Adjuvant therapy is the only actionable variable associated with improved survival in elderly resected pancreatic cancer patients.

Based on the above data, elderly patients should be considered for receiving adjuvant therapy. Current standard of care adjuvant therapies would include combination of gemcitabine plus capecitabine or single agent gemcitabine. Fluoropyrimidine-based chemotherapy is rarely administered in adjuvant setting in clinical practice. The role of chemoradiation therapy remains controversial. Age should not be used as a single determinant for excluding patients from receiving adjuvant therapy.

Neoadjuvant Treatment

Patients with borderline resectable and locally advanced pancreatic cancer have vascular involvement that limits the feasibility of upfront margin-negative resection **(**Table 5**)**. The definitions for these stages are not uniform and continue to evolve (Mahipal et al. 2015). With better imaging tools, patients can be more accurately staged into these subgroups. Technically, patients with locally advanced pancreatic cancer are surgically unresectable. However, with recent advancements in neoadjuvant therapy, higher response rates are observed and small proportion of patients with locally advanced disease are able to undergo surgical resection.

Patients with borderline resectable pancreatic cancer receive neoadjuvant therapy that could involve chemotherapy, radiation therapy, or combination of both. There is no standard of care for the type of neoadjuvant therapy in this patient population. The treatment regimens are usually reported from a single institution experience and are largely retrospective in nature. Only few small prospective trials have been reported and elderly patients were underrepresented in these studies (Landry et al. 2010; Kim et al. 2013b). After neoadjuvant therapy, depending on the case series, approximately 50% of the patients are able to undergo resection (Mahipal et al. 2015). There are only few reports regarding surgical resection for patients with locally advanced pancreatic cancer. Higher response rates are observed with regimens like FOLFIRINOX which has increased the likelihood of possible resection with negative margins (Hackert et al. 2016). At some centers, neoadjuvant treatment is recommended even for patients with resectable pancreatic cancer.

Only a few studies have evaluated the role of neoadjuvant therapy in elderly patients. Miura et al. reported the outcomes of neoadjuvant therapy in resectable and borderline resectable pancreatic cancer patients with ages ≥75 years (Miura et al. 2015). Similar rates of completion

of neoadjuvant therapy were observed in older and younger patients (67% vs. 73%). Older patients did have higher CACI score than younger patients. Among patients who completed neoadjuvant therapy, there were no statistically significant differences in survival. Postoperatively, older patients had a similar median duration of hospital stay compared with younger patients; however, older patients were more likely to be discharged to a skilled nursing or rehabilitation center. Older patients who completed neoadjuvant therapy experienced a survival benefit compared with those who did not complete all intended therapy. The reasons for noncompletion of neoadjuvant therapy were different in two age groups. In older patients, comorbidities and worsening performance status were most common reasons while development of metastatic disease was the predominant cause of early termination of therapy.

Neoadjuvant therapy not only helps in downstaging the tumors but also helps in excluding patients from surgical resection who will rapidly progress or soon develop metastatic disease. This approach is particularly appealing for elderly patients. The relative toxicities of neoadjuvant therapy may accentuate underlying medical comorbidities and provide for a more accurate assessment of both performance status and physiologic reserve. Further, some patients are unable to receive adjuvant therapy due to postoperative complications. Thus, for elderly patients with localized pancreatic cancer, neoadjuvant treatment can be a preferred approach.

Elderly Patients and Clinical Trials

Despite the fact that cancer disproportionately affects the elderly, most participants of clinical cancer trials are relatively young. This misrepresentation greatly affects the oncology treatment of the elderly population. It is difficult to generalize the results of pancreatic cancer trials to elderly population if there is only small proportion of elderly patients enrolled. The barriers for enrollment of patients in the trial could include patient related factors including logistics issue, lack of autonomy, and complex pharmacologic and pharmacodynamic changes; physician-related barriers including perception, cultural issue, and lack of evidence; and trial-related barriers including strict inclusion criteria and lack of proper methods for evaluating functional status (Denson and Mahipal 2014). Some of these issues can be tackled by developing geriatric focused trials, improving communication, educating clinical trialists, and using tools like CGA for functional assessment.

Age should not be the sole determinant for developing treatment plan for patients with pancreatic cancer. Pancreatic cancer is an aggressive malignancy and requires multidisciplinary approach for therapy. Clinical stage, functional status, comorbidities, and toxicities of the therapy need to be taken into account for choosing the best treatment option. Participation in the clinical trials should be encouraged especially for elderly patients. Geriatric assessment can help in decision-making process for older patients.

Gastric Cancer

Gastric cancer will have accounted for an estimated 26,370 cases and 10,730 deaths in 2016, with significantly higher incidence and mortality found in men compared to women (Siegel et al. 2016). The 5-year overall survival rate has improved significantly over the last 40 years, almost doubling during that time, but remains low at around 30%. Gastric cancer in elderly patients occurs with clinical and pathological characteristics distinct from those found in younger patients.

Gastric cancer is much more prevalent in older populations, with the highest incidence in patients who are $\geq$80 years. The disease is relatively uncommon in patients younger than 40, while the incidence increases with age after 40 years (Herszenyi and Tulassay 2010). Elderly patients also present with more advanced disease based on TNM stage compared to younger patients (Liang et al. 2013; Lim et al. 2013). In terms of pathological characteristics, gastric cancer in elderly

patients is more common in the lower third of the stomach; additionally, well and moderately differentiated adenocarcinoma are more common in this patient population compared to younger patients (Lim et al. 2013). In a meta-analysis including evaluation of nine retrospective clinical studies, Kong et al. found a lower male-to-female ratio in elderly patients compared to younger ones, more metastases in the peritoneum, and more diffuse type gastric cancer, but less vascular invasion (Kong et al. 2012).

Elderly patients also present with a higher number of co-morbidities compared to younger patients (Lim et al. 2013), which warrants concern regarding their ability to tolerate treatments associated with high toxicity and morbidity.

Surgery

The only potentially curative treatment for gastric cancer is resection (Saif et al. 2010; Jackson et al. 2009). However, there is concern among many providers that elderly patients, who usually present with more co-morbidities, are unable to tolerate invasive surgery without significant morbidity and mortality (Saif et al. 2010). Several studies have sought to investigate complications and outcomes in elderly populations to determine the safety and efficacy of surgical resection. Much debate has focused on the extent of resection, in particular with regards to the degree of lymph node removal (Randle et al. 2016). Standardized limited lymphadenectomy (D1) and standardized extended lymphadenectomy (D2) are the most common lymph node dissections accompanying gastrectomy **(**Table 6**).** In a D1 lymphadenectomy, the portion of the stomach invaded by tumor is removed including the greater and lesser omentum, while the spleen and pancreas are left intact unless involved by the cancer (Hartgrink et al. 2004). A D2 lymphadenectomy entails removal of the omental bursa with the front leaf of the transverse mesocolon, with the vascular pedicles of the stomach cleared (Hartgrink et al. 2004). N1 lymph nodes are classified as the perigastric lymph node stations along the lesser and greater curvature while N2 lymph nodes are those along the left gastric artery, common hepatic artery, celiac artery, and splenic artery (Hartgrink et al. 2004).

The Dutch D1D2 randomized trial prospectively evaluated outcomes in 711 patients younger than 85 years who received D2 lymphadenectomy vs. D1 lymphadenectomy for gastric adenocarcinoma (Songun et al. 2010). In their 15-year follow-up, they reported significantly lower gastric-cancer-related death (37% vs. 48%) as well as lower local recurrence (12% vs. 22%) and regional recurrence (13% vs. 19%) in the group that received D2 lymphadenectomy (Songun et al. 2010). However, D2 lymphadenectomy was also associated with significantly higher complication rate (43% vs. 25%; $p < 0.0001$), greater operative mortality (10% vs. 4%; $p = 0.004$), and higher reoperation (18% vs. 8%; $p = 0.00016$) – data that may indicate concern for extended lymphadenectomy for elderly patients, in whom complications are more poorly tolerated (Songun et al. 2010).

Since then, a number of other investigators have studied D2 resections, demonstrating both its safety and efficacy (Rausei et al. 2016; An et al. 2011). For example, a multi-institutional study comparing outcomes after D1 and D2 lymphadenectomy in 461 patients with gastric cancer found similar morbidity between both resections ($P = 0.85$), but lower mortality

Table 6 Limited vs. extended lymphadenectomy characteristics

Lymphadenectomy type	Extent of resection	Assigned lymph node stations
D1 limited lymphadenectomy	Portion of stomach invaded by tumor including the greater and lesser omentum; spleen and pancreas only if involved	Perigastric lymph node stations along lesser and greater curvature of stomach
D2 extended lymphadenectomy	D1 + anterior leaf of transverse mesocolon with vascular pedicles of stomach cleared	D1 + lymph nodes along left gastric, common hepatic, celiac, and splenic arteries

associated with D2 lymph node dissection (0.9% vs. 1.3%, $P = 0.004$) (Randle et al. 2016). Moreover, patients who underwent D2 lymphadenectomy also experienced significantly higher median overall survival for stages I–III, even after adjustment for other confounders (HR 1.5, 95%CI 1.1–2.0, $P = 0.008$) (Randle et al. 2016). Data from these studies and more have resulted in D2 lymphadenectomy – including some technical modifications – becoming standard treatment for patients undergoing resection for gastric cancer (Rausei et al. 2016; An et al. 2011).

Extent of Resection in the Elderly

Although gastrectomy with D2 lymphadenectomy is standard for resectable gastric cancer, there is concern regarding its safety in the older population (Rausei et al. 2016; An et al. 2011), which often results in elderly patients receiving D1 lymphadenectomy instead. Many studies have examined the safety and efficacy of extended lymphadenectomy specifically in the context of elderly populations with gastric cancer, with mixed results.

Emir et al. reported retrospective outcomes in 53 gastric cancer patients older than 70 years who received either D1 or D2 lymphadenectomy ($n = 28$, 52% and $n = 25$, 48%, respectively) with gastrectomy (Emir et al. 2014). The authors found significantly higher blood loss, transfusion requirement, and length of operation in patients who underwent D2 lymph node dissection compared to those who underwent D1. Other investigators have found no difference in complications from gastrectomy with D2 lymphadenectomy between elderly and younger patients, suggesting that extended lymph node dissection may be safely performed in elderly patients. Jeong et al. prospectively evaluated 383 patients with gastric cancer who underwent a gastrectomy with D2 lymphadenectomy, comparing postoperative complications and hospital courses between patients less than 70 years ($n = 282$) with patients 70 years or grater ($n = 101$) (Jeong et al. 2010). Despite having higher preoperative comorbidity rates and American Society of Anesthesiologist scores, there were no statistically significant differences in surgical complication rates or medical complication rates between elderly and non-elderly patients (18.8% vs. 17.4%, P = 0.746; 5.0% vs. 1.8%, P = 0.137).

In addition to evaluating complication rates based on extent of lymphadenectomy, investigators have also sought to evaluate whether the survival benefit associated with D2 lymphadenectomy is also present in elderly patients. Rausei et al. compared complications and outcomes in 1322 elderly and/or highly co-morbid gastric cancer patients who received D2 to those who received D1 lymphadenectomy (Rausei et al. 2016). They found similar overall postoperative morbidity rates (33.2% in D1 and 29.9% in D2). However, in elderly patients with a high number of co-morbidities, D2 lymphadenectomy resulted in higher postoperative morbidity (39.6%). In regards to survival outcomes, D2-lymph node dissection was associated with significantly increased disease-specific survival at 5 years in elderly patients, while this survival benefit was not found with regards to 5-year overall survival. However, in elderly patients with positive lymph nodes, D2-lymphadenectomy improved both 5-year overall survival and 5-year disease specific survival (29.7% vs. 21.2% in D1, p = 0.008 and 47.5% vs. 30.6% in D1, $p = 0.001$, respectively). When elderly patients with both positive lymph nodes and high co-morbidities were evaluated, the survival advantage was found only with regards to disease-specific survival.

Similarly, when comparing surgical and survival outcomes in 104 patients with gastric cancer aged 80+ years to 1,089 < 80 years, Takeshita et al. found gastrectomy with limited lymph node remove to be more common in the elderly group – however, it did not significantly impact disease-specific survival (Takeshita et al. 2013). Yoshikawa similarly evaluated limited lymphadenectomy in elderly patients with gastric cancer, stratifying patients into those 80 years or older ($n = 44$), those 70–80 ($n = 139$), and those less than 70 ($n = 219$) (Yoshikawa et al. 2016). While there was no significant difference in surgical complications between groups, limited lymphadenectomy was significantly higher in

the oldest group. Despite receiving limited lymphadenectomy at a higher rate, patients in this age group did not experience a significantly different cancer-specific survival than in patients that achieved an R0 resection, suggesting the extended procedure may be unnecessary in elderly patients.

When putting these data together, and despite some conflicting results, the extent of surgery should be geared to providing the results with the best cancer outcomes, in well-selected elderly patients. Having said that, and based on the specific patient's treatment goals and overall risk of surgery, we believe that a more limited surgery (D1 lymphadenectomy) will provide appropriate resection of the tumor with less risk of complications/mortality and a similar oncologic result. A multidisciplinary team discussion including the surgeon, medical and radiation oncologists, and a geriatrician, together with the patient, will serve as the most appropriate and comprehensive way to examine the different treatment options considering patient-, geriatric-, and tumor-related factors.

Perioperative Therapy

The current standard of care for advanced gastric cancer follows one of two courses: either perioperative chemotherapy or upfront gastrectomy followed by adjuvant chemotherapy and concurrent chemoradiation. The treatment carries high morbidity and the efficacy and tolerability in elderly has not been established in a randomized trial.

Saif et al. performed a comprehensive literature review on gastric cancer in the elderly and found similar rates of toxicity and outcome benefits between elderly patients and nonelderly patients who meet the inclusion criteria for clinical trials; however, patients enrolled in clinical trials have a better performance status and may not be applicable to the general population (Saif et al. 2010). Jin et al. found a survival benefit to adjuvant chemotherapy in their retrospective evaluation of 360 elderly gastric cancer patients (aged 65+) who underwent D2 gastrectomy, 34.7% of whom additionally received adjuvant fluoropyrimidine-based chemotherapy (Jin et al. 2013). The authors reported a significant overall survival benefit to adjuvant chemotherapy (HR 0.60, 95%CI 0.42–0.83, P = 0.003). However, stage-stratified analysis showed that this trend was specific to patients with stage III cancer (HR 0.67, 95%CI 0.47–0.97, P = 0.033) only. Additionally, chemotherapy with platinum showed no significant increase in survival compared to chemotherapy without platinum (HR 0.84, 95%CI 0.49–1.45, P = 0.530). In a similar study, Jo et al. examined adjuvant chemotherapy in patients 70 years or older who underwent D2 gastrectomy for stage II or III gastric cancer, and found median relapse-free survival to be significantly higher in patients who received adjuvant chemotherapy compared to those who did not (20.4 vs. 35.5 months, P = 0.030) (Jo et al. 2015). Given that systemic treatment is often withheld from elderly patients due to fear of the associated toxicity and doubt as to its survival benefits, these data suggest that old age should not necessarily prohibit the administration of chemotherapy and that there are clear benefits to a multimodal approach in well-selected patients.

There are a number of retrospective studies evaluating the safety of chemotherapy for resectable gastric cancer, with conflicting results. In general, when considering preoperative chemotherapy for the elderly, one must ensure this will not result in a high degree of toxicity that may preclude the ability to proceed with surgery. On the other hand, planning for an adjuvant approach may also be limited by postoperative complications and delayed surgical recovery. In this context, careful multidimensional evaluation with comprehensive geriatric tools may guide the decision of initiating perioperative chemotherapy, but understanding that based on specific treatment goals, a surgery-alone approach may prove to be appropriate for some patients in whom resection of the primary tumor may provide enough benefits and be aligned with the treatment goals of the individual patient.

Adjuvant Radiation Therapy

The benefit of adjuvant combined chemotherapy and radiation therapy has been shown in

patients who undergo gastrectomy with extended lymphadenectomy for gastric cancer. However, the question as to whether the same benefit persists in an elderly patient population is less clear (Snyder et al. 2012).

Strauss et al. evaluated the impact of combined chemoradiation with 5-Fluororacil following gastrectomy for gastric cancer on survival in patients aged 65 or older (Strauss et al. 2010). They found a lower mortality rate in patients who received adjuvant chemoradiation compared to those who underwent gastrectomy alone (hazard ratio, 0.83; 95% confidence interval, 0.71–0.98) in the 1,476 patients who were between 65 and 85 years old and survived more than 4 months. However, with age stratification, adjuvant therapy resulted in no survival advantage for IB cancer, a trend toward decreased mortality for stage II and significantly decreased mortality for stages III and IV (M0). Eighty to eighty five years was the only age category that the trend toward improved survival did not persist.

Liu et al. examined cancer-specific (CSS) survival in elderly patients aged 75 and older with locally advanced gastric cancer; they compared CSS between four different groups separated by treatment modality (adjuvant radiation, radiation alone, surgical resection alone, and no radiation or surgical resection) (K-t et al. 2017). The highest rates of CSS at 5-years were found in the adjuvant radiation group (43.8%) and the surgical resection alone group (28.5%), while 5-year CSS in the radiation alone group was only 14.9% and 1.4% in the no-radiation or surgery group (univariate log-rank test [$P < 0.001$] and multivariate Cox regression [$P < 0.001$].). Additionally, every age group (75–79 years, 80–84 years, and 85+ years) showed significantly improved survival with adjuvant radiation (all $P < 0.001$).

These results are in contrast to those found by Hoffman et al., who examined the impact of adjuvant chemoradiation on survival in 1023 elderly patients aged 65 years and older who underwent resection for non-metastatic gastric cancer, 30% of whom additionally received adjuvant concurrent chemoradiation (Hoffman et al. 2012). The receipt of adjuvant chemoradiation was significantly associated with nodal involvement ($P < 0.0001$), recent diagnosis ($P = 0.0284$), and young age ($P < 0.0001$). The authors found that there was no significant survival benefit associated with adjuvant therapy ($P = 0.3453$), suggesting that elderly patients may be safely spared the toxicity associated with adjuvant chemoradiation. More data – especially from prospective studies – are required to determine whether adjuvant radiation or chemoradiation confers any survival benefit in elderly patients with gastrectomy.

Metastatic Gastric Cancer in the Elderly

Metastatic gastric cancer also warrants evaluation of treatment options in an elderly patient population, which usually presents with more advanced disease and may not tolerate treatment as well as younger patients. Moreover, elderly patients are under-represented in metastatic gastric cancer trials. There is evidence to suggest that overall survival in patients with metastatic gastric cancer decreases with increasing age. In a study of 13,840 patients with metastatic gastric cancer, patients 44 years old or younger had an overall survival rate double of patients who were 75 years or older (6 vs. 3 months) ($P < 0.001$) (Yang et al. 2011). A number of randomized trials have evaluated the efficacy of different chemotherapeutic regimens in elderly patients with metastatic gastric cancer.

Park et al. compared S-1 with capecitabine as first-line chemotherapy in 107 elderly patients with metastatic gastric cancer in a phase II randomized trial (Park et al. 2013). The authors reported higher rates of tearing (51.9% vs. 28.3%; $P = 0.017$) and vomiting (40.4% vs. 17.0%; $P = 0.010$) in the group that received S-1 ($N = 53$) vs. capecitabine ($N = 54$), while HFS was less frequent in the S-1 group (25.0% vs. 58.5%; $P = 0.001$). There were no significant differences in overall survival between the two groups or median time to progression. The overall response rate though was higher in the group that received S-1 (28.6%; 95% CI, 15.9–41.3%). Both treatments were fairly well tolerated, with a 3.8% incidence of Grade 3/4 neutropenia in each group.

A phase II study was undertaken to assess the efficacy and tolerability of modified FOLFOX

chemotherapy in 43 elderly patients aged 70 and older, who had metastatic gastric cancer (Catalano et al. 2013). The authors found the treatment to be active, resulting in a 34.9% overall response rate with 12 patients exhibiting partial responses and 3 patients complete response. Moreover, treatment was well tolerated, with grade 3 neutropenia occurring in only 9.3% of patients ($n = 4$), vomiting in 4.6% ($n = 2$), fatigue in 7% ($n = 3$), peripheral neuropathy in 2.3% ($n = 1$) and grade 2 peripheral neuropathy in 11.6% ($n = 5$). These data suggest that the modified FOLFOX regimen used in this study is a potentially appropriate treatment modality for elderly patients with metastatic gastric cancer.

Turkeli et al. also retrospectively examined the safety and effectiveness of chemotherapy as a first-line treatment in elderly patients aged 70 years and older ($n = 89$), who had metastatic gastric cancer and received at least two cycles of chemotherapy (Türkeli et al. 2016). The authors reported a 7-month (95% CI: 5.2–8.9) median overall survival and a 5 months (95% CI: 3.7–6.3) median progression free survival in their patient population, in which 43% of the patients had controlled disease and 56.2% of patients experienced progression.

Aldemir similarly studied first-line chemotherapy in 305 elderly metastatic gastric cancer patients between 17 centers, finding it to be both safe and efficacious, reporting partial response in 26.2% and stable disease in 16.7% of the patients (Aldemir et al. 2016). The most common chemotherapy related grade 3–4 hematologic toxicity was neutropenia (22%). The number of drugs in the regimens was positively correlated with both response rates of treatment and with grade 3–4 neutropenia rates ($p = 0.004$, $p < 0.001$; respectively). Engin et al. also found docetaxel, cisplatin, and fluorouracil combination to be both tolerable and effective in patients older than 70 with metastatic gastric cancer with good performance status (Hüseyin Engin 2013).

More prospective studies are necessary to determine which particular regimen is most efficacious and tolerated with the lowest toxicity in elderly patients with metastatic gastric cancer; however, with these data it is clear that there is an oncologic benefit of systemic chemotherapy for elderly patients with metastatic gastric cancer and that overall toxicity appears to be not prohibitive.

Conclusion

As the population continues to age, a substantial increase in the number of elderly patients with primary tumors of the liver, pancreas and stomach, and secondary tumors (metastasis) to the liver is expected. At present, treatment disparities are driven in part by inaccurate perceptions of providers regarding the risks and benefits of standard of care treatment. Elderly patients often receive substandard cancer care, may not be referred to appropriate specialists, and as a result have worse outcomes. However, the available data support the safety and efficacy of aggressive and multimodal treatment of properly selected elderly patients. Whenever possible, referral to high-volume centers has been shown to improve outcomes. Furthermore, assessment of transitional outcomes upon hospital discharge and quality of life will aid clinicians in managing these complex patients. Areas for future improvement should focus on multidisciplinary and multidimensional assessment of the geriatric patient, and a more thorough and robust decision-making process, in which patient treatment goals are heavily considered and guide the different treatment alternatives when also weighing standard measures of health, tumor biology, and geriatric conditions.

Abstract

As older patients are very rarely included in clinical trials, and without any dedicated clinical trials in curative or palliative setting, there are at now no standards of treatment for elderly head and neck cancer (HNC) patients. Treatments recommended for younger patients are therefore adapted to older in the daily practice. Combinations of systemic treatments (chemotherapy or cetuximab) with radiotherapy are usually only proposed to "fit" elderly patients, without any support of evidence-based medicine.

Systemic treatment is therefore essentially discussed for recurrent and/or metastatic HNC patients. The choice between a monotherapy and a platinum-cetuximab combination is based on the *performance status*, which is not suitable and/or sufficient for elderly patients. The main difficulty is therefore to evaluate their ability to receive a systemic treatment and the evaluation of functional age using geriatric assessment is recommended. However, access to comprehensive geriatric assessment is limited in many centers, and the choice of the type of treatment is often not based on objective and reproducible criteria. As a result, vulnerable elderly HNC patients may be overtreated with a risk of increased toxicity and fit patients proposed for suboptimal treatment with a risk of failure of tumor control. Therefore, it is necessary to develop and evaluate customized treatments, based on a simple and reproducible geriatric assessment to guide practitioners to conduct the most suitable therapy. It is therefore crucial to enroll patients in dedicated therapeutics trials for elderly HNC, such as the ELAN studies, exploring new approaches such as promising immunotherapies.

This review focuses on squamous cell HNC patients.

Elderly · Head and neck · Cancer · Systemic treatment · Checkpoint inhibitors

Introduction

In the Western countries, head and neck cancers (HNC) correspond to about 5% of cancers. Approximately, 30% of patients with HNC are aged 70 years and over, and 10% are over 80 years old (Huang et al. 2011). This population has certain specificities compared to the young population: proportion of women increased, less history of alcohol consumption, low proportion of cancers of the larynx/hypopharynx, and predominance of cancers of the oral cavity. The management of HNC in elderly patients is complex due to tumor-related symptoms and the high toxicity of standard treatments. Palliative treatments are difficult to manage in this population because of the highly symptomatic character of the evolution or the tumor recurrence (pain, dysphagia, dyspnea), which leads to a major alteration of the quality of life. It is therefore necessary to propose to elderly patients a treatment sufficiently optimized to control the tumor while avoiding the loss of autonomy. In this population with frequent comorbidities, the main challenges for physicians are therefore to cope with the benefit/risk ratio of treatments and with the tumor-related symptoms (Mountzios 2015; Sarris et al. 2014).

As only few older patients are included in clinical trials (Lewis et al. 2003; Le Saux et al. 2016), and without any results of dedicated clinical trials in curative or palliative setting, there are no standards of treatment for HNC elderly patients to date. As most of the elderly patients enrolled in randomized trials are fit and that the main data are extracted from the subgroup analyses, the results of these studies are applicable to a small proportion of elderly HNC patients (Le Saux et al. 2016).

Treatments recommended for younger HNC patients are therefore adapted to older patients in the daily practice. Radiotherapy (RT) often indicated due to inoperability factors, induces acute toxicities, whose frequency increases with age. Combinations of systemic treatments (chemotherapy (CT) or cetuximab) with RT are usually only proposed to "fit" elderly patients, without any support of evidence-based medicine. Induction therapy delivering standard docetaxel-cisplatin-5FU regimen (TPF), which is mainly used for larynx preservation, is not recommended for older patients due to its toxicity, and alternatives have not yet been validated.

A systemic treatment is therefore essentially discussed for recurrent and/or metastatic (R/M) HNC patients. The choice between a monotherapy and a platinum-cetuximab combination is based on the *performance status* (PS) for HNC patients (Gregoire et al. 2010), which is not suitable and/or sufficient for elderly patients. The main difficulty is therefore to evaluate their ability to receive a systemic treatment (Wedding et al. 2007), and the evaluation of functional age using geriatric assessment is recommended (Wildiers et al. 2014). However, the access to a comprehensive geriatric assessment (CGA) is limited in many centers, and the choice of treatment is often not based on the objective and reproducible criteria. As a result, vulnerable elderly HNC patients may be over-treated with a risk of increased toxicity and fit patients may be proposed for a suboptimal treatment with the risk of failure of tumor control. Therefore, it is necessary to develop and evaluate customized treatments, based on a simple and reproducible geriatric assessment to guide practitioners to conduct the most suitable therapy. It is therefore crucial to enroll patients in dedicated trials for elderly HNC, such as the ELAN studies (Guigay et al. 2014).

This review focuses on head and neck squamous cell cancer (HNSCC) patients.

Systemic Treatment in Curative Intent

In a curative intent, radiotherapy is delivered for patients with inoperable locally advanced HNC or for patients with early-stage cancers not suitable for surgery. In elderly patients, compliance to standard radiotherapy is poor, for two main reasons:

- The acute toxicity with acute functional mucosal reaction is increasing with age: 8% of grade 4 are usually observed in patients under 50 years old, while it is 31% in elderly patients (Pignon et al. 1996). Therefore, in frail patients, these adverse events may become a major concern, conducting to a rapid functional deterioration and a dependence.
- The number of daily transportations in a standard fractionation may imply about 35 daily travels over 7 weeks. Thus, the standard fractionation could be difficult to deliver and the treatment interruption due to fatigue is frequent in elderly patients.

Therefore, physicians have to adapt the radiotherapy schedule for elderly patients, in order to limit potential adverse events, with the risk of under-treating. The Intensity Modulated Radiation Therapy (IMRT) is recommended with adapted schedules of radiotherapy (Grenman et al. 2010).

Retrospective series reported that the radiotherapy schedule delivered to elderly patients with HNC complies with institution's guidelines in less than 50% of cases, emphasizing the need to assess the outcome of personalized/adapted treatment in geriatric patients (Italiano et al. 2008; Lusinchi et al. 1990; Ortholan et al. 2009). The major issue lies in the adaptation that should be done and, then, what could be the individual benefit/risk ratio of this tailored therapeutic decision. To date, there is a need for prospective trials evaluating the efficacy and safety of adapted radiotherapy regimens vs. standard radiotherapy in elderly patients, as the ongoing randomized phase III ELAN-RT trial (NCT01864850) which is comparing hypofractionated split course schedule and standard RT (Guigay et al. 2014). Hypofractionated split course schedules may represent a good compromise between a biologically effective dose and an acceptable tolerance in elderly patients (Hansen et al. 1997).

Systemic Treatments for Locally Advanced (LA) HNC Patients

Concomitant chemoradiotherapy (CCRT) or radiotherapy combined with cetuximab is now a standard for locally advanced HNC, despite an increased toxicity compared to RT alone (Bonner et al. 2006; Pfister et al. 2015; Pignon et al. 2009). However, according to the available data, this intensification seems to benefit only patients less than 65 years old (Bonner et al. 2010; Pignon et al. 2009) (Fig. 1).

A decreasing efficacy of CCRT with an increased incidence of noncancer-related deaths has been reported with increasing age. The acute and late radiation toxicities seem not to be increased with age, and there would be no changes in the radio or chemo-responsiveness with age (Grenman et al. 2010). Among agents combined with RT, cisplatin delivered at a dose of 100 mg/m^2 every 3 weeks is the standard one, which is not suitable for unfit patients.

Anti-epidermal growth factor receptor (anti-EGFR) antibody cetuximab combined with radiotherapy also produced a significant locoregional and survival benefit in moderately advanced HNC (Bonner et al. 2006), but an analysis of 5-year survival data did not show a benefit for elderly patients enrolled in this single randomized study (Bonner et al. 2010).

Therefore, the standard treatment remains adapted RT alone for LA HNSCC elderly patients. Immunotherapy with anti-PD(L)1 is currently tested in combination with RT. As an example, GORTEC trials including elderly patients until 80 years old are ongoing: PembroRad trial is comparing RT-pembrolizumab and RT-cetuximab for locally advanced HNSCC (NCT02707588), and REACH trial (NCT02999087) is comparing RT-avelumab-cetuximab and RT-cetuximab in a cohort of patients not eligible for cisplatin. However, the benefit of immune checkpoint blockers on outcomes of LA HNSCC patients remains unknown.

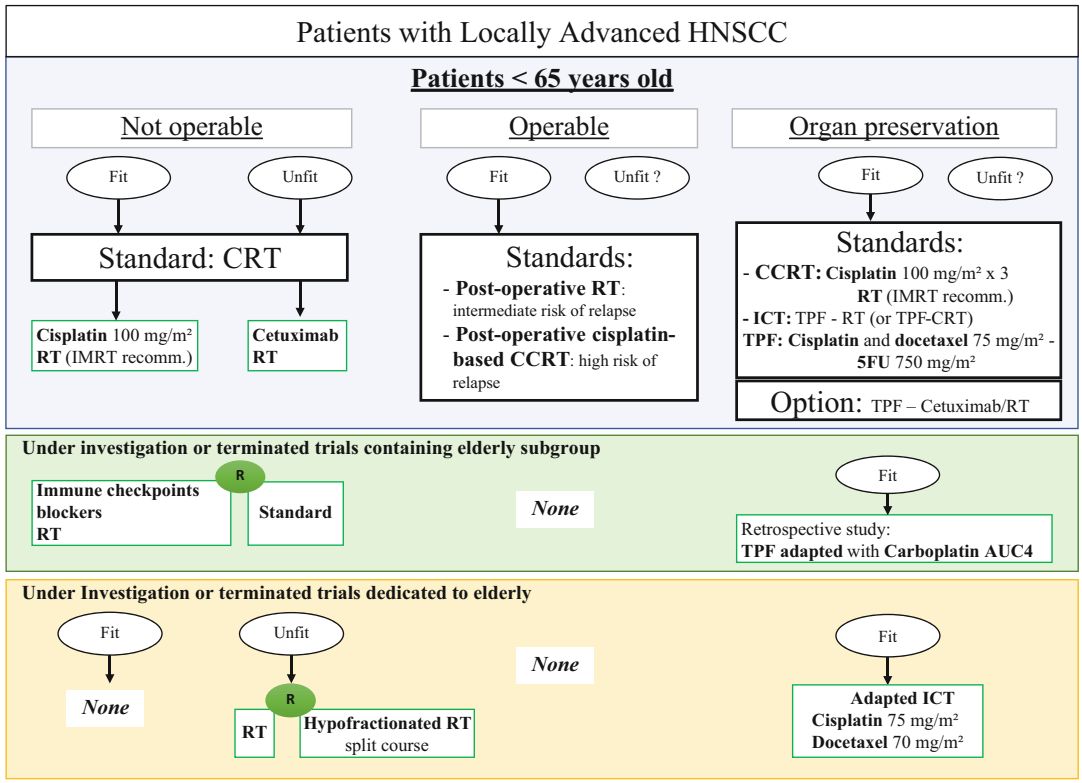

Fig. 1 Treatments of patients with locally advanced HNSCC

Postoperative Radio(Chemo)Therapy

Patients with operable locally advanced HNSCC, for which the surgical piece identifies either microscopically involved surgical margins (R1) or extra-capsular extension (ECE) in positive lymph nodes, are associated with poor prognosis. These "high-risk-for-relapse" patients benefit from the adjunction of cisplatin-based postoperative CCRT (Bernier et al. 2004; Cooper et al. 2004), but this benefit has not been demonstrated for patients at intermediate risk for relapse (Bernier et al. 2005). The role of cetuximab or other targeted therapy has not been validated in postoperative setting.

However, for elderly patients at "high risk for relapse," even evaluated as "fit," cisplatin-based CCRT is not recommended, and the standard treatment for these patients is still postoperative radiotherapy alone. According to the poor outcome of this patients (45% and 55% of 2-year estimates of disease-free survival and overall survival (OS), respectively), there is an urgent need for finding a suitable concomitant treatment to be tested in a dedicated trial (immunotherapy or other).

Induction Chemotherapy

CCRT remains the standard in locally advanced disease (Forastiere et al. 2003), but induction chemotherapy (ICT) is commonly used for larynx preservation. The standard docetaxel-cisplatin-5FU (TPF) regimen with granulocyte colony stimulating factor (GCSF) support (Pointreau et al. 2009) is not recommended for older patients due to renal and hematological toxicities (Ilie et al. 2012). The last GORTEC 2007–02 trial which compared ICT with TPF regimen and CCRT enrolled only fit patients less than 70 years old: 7% of deaths were observed, mainly related to the toxicity of the treatment (Geoffrois et al. 2016).

Alternatives to this combination have not been validated. A phase II study (44 patients) showed that a careful selection of patients over 65 years of age could allow delivering ICT with cisplatin and docetaxel (Choi et al. 2007): the overall response rate was 88%, and hematological toxicity with grade 3–4 neutropenia was 75%. The replacement of cisplatin with carboplatin may be effective, according to a single institution's retrospective analysis (Saada et al. 2012), but no prospective data currently exists to recommend it. Other combinations with cetuximab or new agents such as anti-PD(L)1 need to be explored.

Before administering an ICT, the main point is to discuss in multidisciplinary staff, the real benefit and risk of this treatment compared to CCRT, RT alone, or total laryngectomy.

Supportive Care

The dental and nutritional status of elderly patients should be systematically evaluated before starting any treatment, since rapid deterioration may occur early when delivering CCRT. Dietetic advices and oral nutritional supplements are mandatory, with a regular follow-up of oral intake during treatment. A nutrition by endoscopic gastrostomy or nasogastric feeding tube before treatment should be discussed according to weight loss and swallowing difficulties, especially if mucositis is expected. An ongoing French randomized controlled study (Brugel et al. 2014) is recruiting patients with the main objective to assess the impact of the CGA and the geriatric follow-up on the OS and the functional and nutritional status of elderly patients with HNSCC (NCT02025062). Another randomized Danish study is currently enrolling elderly patients (>70 years old) to assess the impact of an oncogeriatric intervention and follow-up at home (NCT02837679).

The management of skin toxicities related to cetuximab delivered during RT is mandatory (Russi et al. 2015).

Systemic Treatment in Palliative Intent: Recurrent and/or Metastatic (R/M) HNC Patients

There is also no standard palliative treatment for the specific population of elderly patients with R/M SCCHN, and tolerance remains the main

challenge. The main difficulty is therefore to evaluate the ability of elderly HNC patients to receive a systemic treatment (Sacco and Cohen 2015) (Fig. 2).

First-Line Therapy

Fit Elderly HNC Patients

No prospective study on first-line chemotherapy has been conducted in the elderly R/M HNC population. A retrospective analysis has been conducted on 53 fit elderly patients enrolled in two phase III ECOG trials including 399 HNSCC patients (Argiris et al. 2004). ECOG 1393 compared cisplatin-paclitaxel regimen at two dose levels, and ECOG 1395 compared cisplatin-5FU with cisplatin-paclitaxel regimen. Comparing the median OS of older and younger patients, OS did not statistically differ (5.3 vs. 8.0 months, $p = 0.17$), but chemotherapy-related toxicities were increased in elderly HNC patients, namely, nephrotoxicity, diarrhea, thrombocytopenia, and toxic deaths (13% vs. 8%, not significant). The authors recommended not to use cisplatin in elderly HNC patients and emphasized the need to conduct prospective elderly specific studies to better define therapeutic choices.

Cetuximab in combination with platinum-based chemotherapy has been tested in phase III

ECOG 5397 trial including 117 R/M HNSCC patients. Patients were randomized to receive as first-line treatment either cisplatin (100 mg/m^2 every 4 weeks) plus placebo or cisplatin plus cetuximab. For the whole population, the addition of cetuximab to cisplatin improved the overall response rate from 10% to 26% ($p = 0.03$), but did not significantly improve

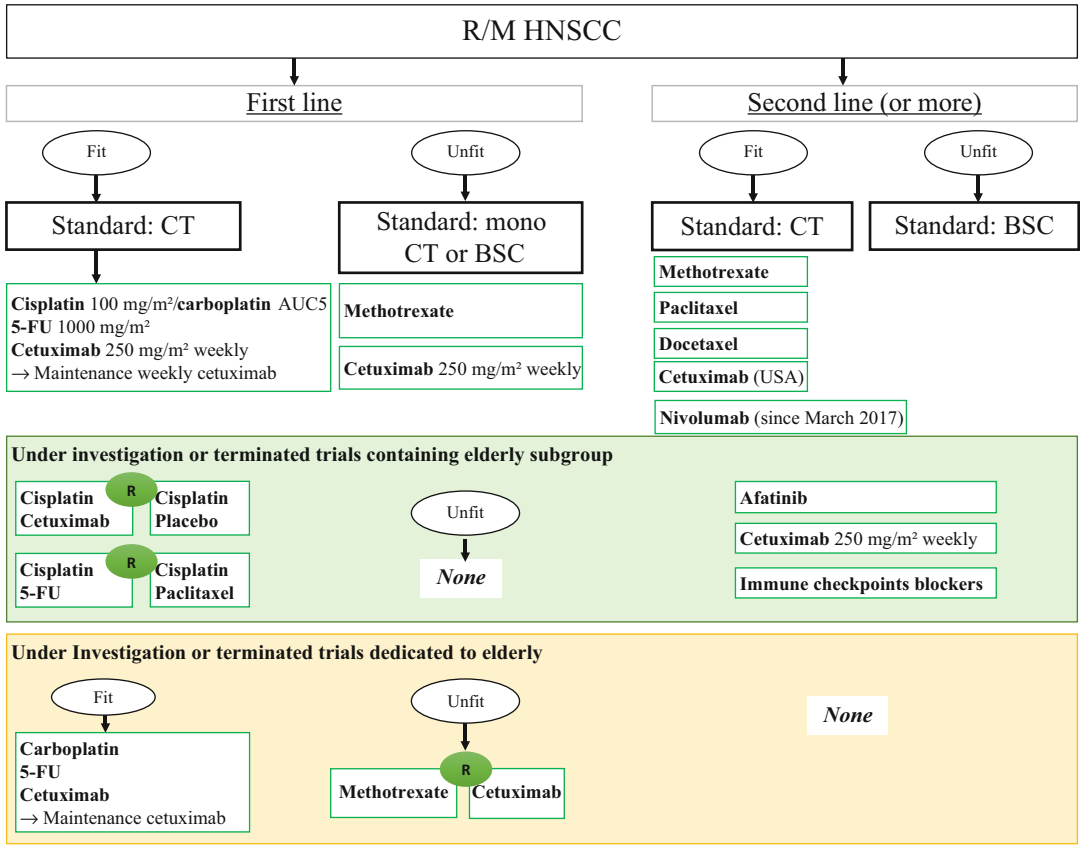

Fig. 2 Treatments of patients with recurrent and/or metastatic HNSCC

either progression-free survival (PFS) or OS. Age group (<55 years, 55–69 years, or ≥ 70 years) was not predictor of PFS or OS ($p > 0.20$). Safety was not analyzed according to age (Burtness et al. 2005).

Cetuximab and platinum-based chemotherapy combination has become a standard of care in first-line treatment of fit patients with R/M HNSCC since the publication in 2008 of the results of the randomized EXTREME study, showing that adding weekly cetuximab to every 3-week regimen combining cisplatin (100 mg/m^2) or carboplatin (AUC 5) and 5FU (1000 mg/m^2 during 96 h in continuous infusion) increased ORR, PFS, and OS (Vermorken et al. 2008). However, the number of elderly patients enrolled in the "EXTREME study" was low (77 patients aged 65 or older), and analysis of results showed a reduced clinical benefit in this subgroup of patients. Objective response rates, median OS, PFS, and time to progression (TTP) are presented in Table 1.

Usually, most of older patients receive carboplatin instead of cisplatin in the first-line R/M setting compared with younger patients (Clement et al. 2016). A prospective phase II trial is currently ongoing to evaluate the efficacy and safety of carboplatin (AUC 5)-5FU (1000 mg/m^2 during 96 h in continuous infusion)-cetuximab (500 mg/m^2 every 2 weeks) combination in fit elderly patients (Guigay et al. 2014).

Delivering chemotherapy combination in elderly HNC patients needs the use of GCSF and erythropoietin to maintain the dose intensity and reduce the hematological toxicity (Wedding et al. 2007; Bokemeyer et al. 2004).

There are, at now, no available data about the efficacy of immune checkpoints blockers in first-line therapy for R/M HNSCC. Trials testing monotherapy or combinations including older patients are ongoing, and results are eagerly awaited.

Unfit Elderly HNC Patients

In frail patients with R/M HNSCC, for which polychemotherapy tolerability is anticipated to be poor, monotherapy is usually recommended. All trials with conventional chemotherapy have failed to demonstrate any advantage over methotrexate (MTX) alone in terms of OS or PFS. Weekly methotrexate may be considered as the accepted standard treatment (proof level I, A). Cetuximab alone has a favorable toxicity profile with activity that is comparable to methotrexate alone, and is thus considered as an option (Gregoire et al. 2010).

Since there is no comparison between taxanes and methotrexate as monotherapy, it is difficult to state whether taxanes are useful in this context, as toxicity of docetaxel is increased in elderly patients (Minami et al. 2004).

However, the objective response rate (ORR) demonstrated with MTX remains usually low: less than 5% (Specenier and Vermorken 2009). Data about the tolerance of MTX in elderly HNSCC patients are missing. In previous published trials, analysis of tolerance of MTX at doses used in HNSCC did not separate the elderly

Table 1 Results of trials including recurrent and/or metastatic HNSCC elderly patients

*Argiris et al. patient subgroups were < 70 and ≥ 70

from the rest of the population enrolled. However, some data are provided by the experience based on the treatment of other diseases. As an example, MTX is used in elderly patients with CNS lymphoma. Despite higher doses (either 1.5 g/m^2 to 3.5 g/m^2 every 3 weeks based on renal function) than those used in HNSCC (40 mg/m^2 weekly), toxicity is considered as manageable in elderly patients (Welch et al. 2012; Zhu et al. 2009). Despite their advanced age, most patients in these studies tolerated therapy well. No one developed nephrotoxicity higher than a grade 2, and there were only two MTX dosage reductions for a transient rise in creatinine. In contrast, myelotoxicity was more common in this elderly population, a finding consistent with previous work in geriatric oncology that demonstrated an inverse association between aging and bone marrow reserve (Hurria et al. 2011). In a second study in CNS lymphoma, grade 3 or 4 toxicities in patients 70 or more years of age were uncommon (9.7% of patients). Only 4 of 31 patients (12.9%) discontinued MTX because of toxicity (Zhu et al. 2009).

Among molecular targeted therapies developed in HNC, cetuximab as monotherapy was approved in the USA in the second-line treatment after failure of a platinum-based chemotherapy, showing a 13% ORR and a median time to progression of 80 days (Vermorken et al. 2007). A recent study conducted by Maubec E. showed that, as first-line monotherapy in elderly patients with unresectable skin squamous cell carcinoma, weekly cetuximab alone was manageable and effective with prolonged responses (Maubec et al. 2011). This phase II multicenter study enrolled 36 patients with a median age of 79 years (23 pts. > 70y). Disease control rate was 69% (32% ORR). Tolerance was considered good by the authors with no cetuximab-related deaths. Grade 1 to 2 rash acneiform occurred in 78% of patients and was associated with prolonged PFS. There were three treatment-related serious adverse events: two grade 4 infusion reactions and one grade 3 cetuximab-related grade 3 interstitial pneumopathy.

As part of a combination regimen with maintenance treatment, cetuximab is usually delivered every week. Tabernero et al. conducted pharmacokinetic studies of cetuximab in patients with metastatic colorectal cancer. Cetuximab doses from 400 to 700 mg/m^2 q2w were well tolerated, and the maximum tolerated dose was not reached. Pharmacokinetic analysis demonstrated that trough plasma concentration levels for the 500 mg/m^2 q2w, 600 mg/m^2 q2W and weekly 250 mg/m^2 regimens were comparable (Tabernero et al. 2010). Based on this work and similar studies (Martin-Martorell et al. 2008; Pfeiffer et al. 2008), cetuximab 500 mg/m^2 q2w was identified as the most convenient and feasible dose in the colorectal cancer patient population. Recent trials conducted in HNSCC (Fury et al. 2011; Guigay et al. 2015, 2016) have shown that cetuximab as monotherapy every 2 weeks (500 mg/m^2) was manageable without the increase of toxicity. The central finding of these studies is that cetuximab 500 mg/m^2 q2W was well tolerated as palliative monotherapy for patients with R/M HNSCC and demonstrated comparable efficacy (11% confirmed partial response rate) as conventional dosing of cetuximab in this population. The most common cetuximab-related AEs (all grades) among treated subjects were rash, fatigue, and hypomagnesemia. Although there are no randomized trials, it seems that there are no differences in terms of efficacy (Fury et al. 2011; Guigay et al. 2015, 2016). This schedule is now widely used to decrease the frequency of infusions, especially for frail patients and long-term maintenance. For elderly patients with R/M HNSCC, cetuximab 500 mg/m^2 q2w monotherapy is an acceptable alternative regimen to conventional weekly cetuximab dosing.

In summary, the only effective drugs recommended in monotherapy in HNC are methotrexate and cetuximab. A randomized phase III study comparing these two drugs (weekly MTX and cetuximab q2w) in first-line treatment in unfit elderly patient with R/M HNSCC is currently ongoing (Guigay et al. 2014). To date, the other anti-EGFR drugs gefitinib and zalutumumab have failed to demonstrate any advantage over methotrexate (Stewart et al. 2009).

To resume, it seems reasonable, after a careful evaluation of the frailty of the elderly HNSCC patient, to propose a platinum-based combination to fit elderly patients and a monotherapy or only best supportive care (BSC) to unfit elderly patients (Peyrade et al. 2013; Sacco and Cohen 2015).

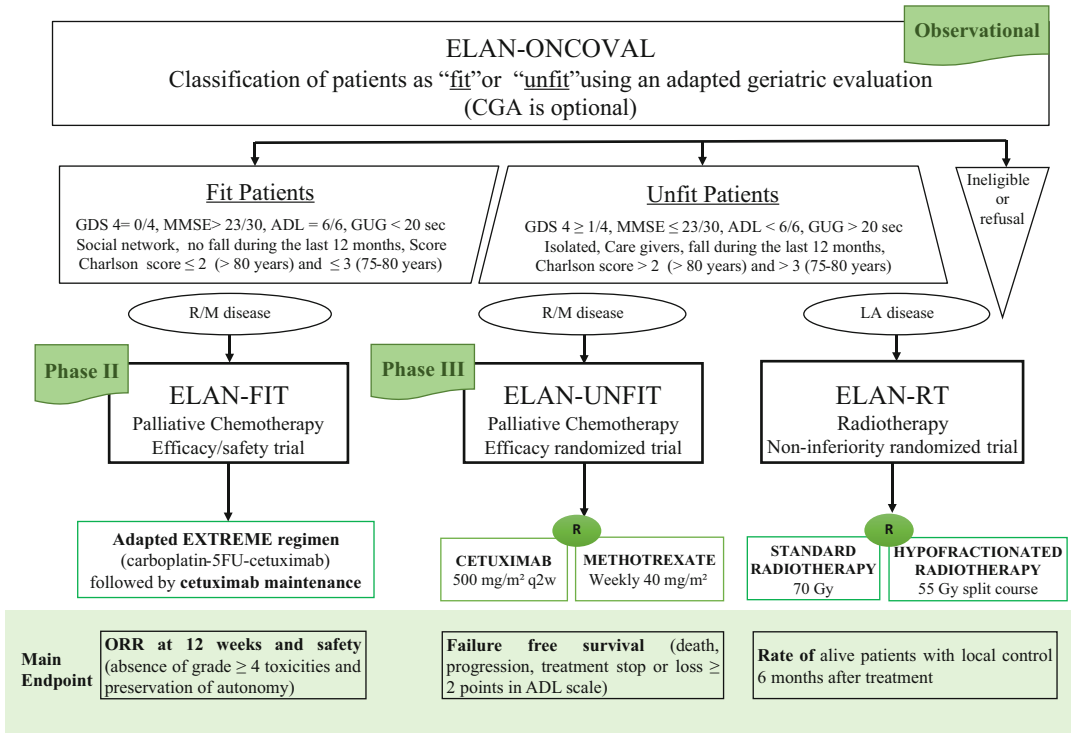

Fig. 3 ELAN studies

ELAN studies are ongoing (Fig. 3), in which elderly R/M HNSCC patients are firstly classified as fit or unfit based on an adapted geriatric evaluation (ELAN-ONCOVAL), before proposing a first-line therapy. Elderly fit patients are then proposed to be enrolled in the phase II ELAN-FIT trial evaluating the clinical benefit of cetuximab/carboplatin/5FU (NCT01884623) and elderly unfit patients in a randomized phase III trial comparing cetuximab with methotrexate monotherapy (NCT01864772) (Guigay et al. 2014). Relationships between HPV status and results of treatment have not been studied in elderly HNSCC patients. ELAN is also investigating this.

Second-Line and More Systemic Treatment

R/M HNSCC patients progressing on/after first-line platinum therapy have a dismal prognosis and treatment options are limited. Second-line treatment for R/M HNSCC based on chemotherapy (methotrexate or taxanes) has a limited efficacy, with only a low ORR and short survival (Gregoire et al. 2010; Pfister et al. 2015). Elderly HNSCC patients often do not receive these therapies due to the high risk of toxicities, and the treatment is usually resumed to BSC.

New agents should provide changes in the management of platinum-refractory HNSCC patients. Cetuximab is only approved in the United States for second-line R/M HNSCC. There are no published dedicated studies evaluating cetuximab in older R/M HNSCC patients. However, the subgroup analyses in a phase II study on cetuximab administered in patients after failure of a platinum-based therapy, reported similar efficacy outcomes in patients aged <65 or ≥ 65 years, but safety was not analyzed according to age (Vermorken et al. 2007). Please refer to Table 1.

Afatinib is an oral, irreversible, anti-EGFR agent which binds to human EGFR 1, 2, and 4 and inhibits signaling from all ErbB family

members. In the phase III LUX-Head and Neck 1 (LHN1) trial, comparing afatinib and MTX, afatinib significantly improved PFS and patient-reported outcomes in platinum-refractory R/M HNSCC patients (Machiels et al. 2015). Among 483 patients enrolled, 128 were aged ≥65 years (83 afatinib; 45 methotrexate), and 25% were aged ≥75 years categorizing the majority as "young old." Similar PFS benefit with afatinib versus methotrexate was observed in older (median 2.8 vs. 2.3 months, HR = 0.68 [95% CI 0.45–1.03], P = 0.061) and younger patients (2.6 vs. 1.6 months, HR = 0.79 [0.62–1.01], P = 0.052) (Table 1). It was associated with a trend toward improvement in OS, ORR, and some disease-related symptoms (Clement et al. 2016). The subgroup of patients aged ≥70 years were too small for meaningful analyses. Toxicities, mainly rash/acne and diarrhea, were similar between age group, and no unexpected safety findings or afatinib-related deaths occurred in older patients. However, as patients with PS ≥2 and/or significant comorbidities were excluded, older patients enrolled in this trial are considered to be fit (Clement et al. 2016).

Recently, immune checkpoint blockers (e.g., anti-CTLA4, anti-PD-1, anti-PD-L1) demonstrated promises in various cancer types including HNSCC. Recent prospective nonrandomized KEYNOTE trials showed promising efficacy of pembrolizumab in heavily pretreated R/M HNSCC patients, with prolonged survival (36% patients living at 1 year) (Seiwert et al. 2016). Notably, the administration of nivolumab (anti-PD-1) to R/M HNSCC patients refractory to platinum-based chemotherapy led to better overall survival and patient-reported outcomes compared to investigator choice (IC) treatment (methotrexate, docetaxel, or cetuximab) in the randomized CHECKMATE 141 trial (Ferris et al. 2016). That is the first randomized trial showing an improvement in OS of platinum-refractory R/M HNSCC patients, and nivolumab has obtained a FDA and European Medicines Agency (EMA) approval in this setting. At baseline, 68 pts. (28.3%) in the nivolumab arm and 45 pts. (37.2%) in the IC arm were ≥ 65 years old. Only a few patients aged >75 years were enrolled in this trial. Baseline characteristics and relative nivolumab dose intensity were generally similar across age groups. OS and tumor response benefits with nivolumab vs. IC were maintained regardless of age. The 30-month OS rates of 11.2% (<65 years) and 13.0% (≥65 years) with nivolumab were more than tripled vs. corresponding IC rates of 1.4% and 3.3%, respectively. As in the overall population, the nivolumab arm had a lower rate of treatment-related adverse events (TRAEs) vs. ICo (Saba et al. 2018). Ongoing trials with other immune checkpoint blockers will provide more information, and these first encouraging data need to be confirmed, keeping in mind that hyper-progressions during immunotherapy may occur in R/M HNSCC (Saada-Bouzid et al. 2017) and that events have been described more frequently in elderly patients (Champiat et al. 2017).

Conclusion

The optimal treatment paradigm in curative or palliative setting for elderly patients with HNSCC has not been well defined, presumably mainly because of the exclusion of these patients (based on age) from clinical trials. Confounding variables such as medical comorbidities, poor performance status, limited social support, functional status, and frailty are also involved in this fact. As a result, without any dedicated clinical trials, there are at now no standards of treatment for HNC elderly patients.

Therefore, the inclusion of elderly HNSCC patients in clinical trials including an adapted geriatric assessment should be routinely offered and encouraged. More dedicated trials for this population are also needed, in addition to the ongoing ELAN program, exploring new systemic treatments such as immunotherapy.

Ovarian Cancer in the Older Woman

47

Mohammad Hissourou III and William P. Tew

Contents

Abstract

Ovarian cancer is the seventh most common cancer in women worldwide and accounts for nearly 4% of all new cases of cancer in women. Almost half of all ovarian cancer patients are over the age of 65 at diagnosis, and over 70% of deaths from ovarian cancer are occurring in this same age group. As the population ages, the number of older women with ovarian cancer is increasing. Compared to younger women, older women with ovarian cancer receive less surgery and chemotherapy, develop worse toxicity, and have poorer outcomes. They are also significantly underrepresented in clinical trials, and thus application of standard treatment regimens can be challenging. Performance status alone has been shown to be an inadequate tool to predict toxicity of older patients from chemotherapy. The use of formal geriatric assessment tools is a

promising direction for stratifying older patients on trials. Elderly- specific trials and adjustments to the eligibility criteria of current frontline trials may allow greater participation of older women. Modified treatment regimens and interventions to decrease morbidities in the vulnerable older population should be useful.

Ovarian cancer · Geriatric oncology · Geriatric assessment · Neoadjuvant chemotherapy

Introduction

Cancer is recognized as a disease of older adults, with over 50% of new cases being diagnosed after age 65 and over 70% of deaths from cancer occurring in this same age group (Oberaigner et al. 2012; Edwards et al. 2002). Ovarian cancer is the seventh most common cancer in women worldwide and accounts for nearly 4% of all new cases of cancer in women (Yancik and Ries 2004). It is also the eighth most common cause of cancer death in the world.

Almost 50% of ovarian cancer is diagnosed in women over the age of 65 (Oberaigner et al. 2012). This ratio is expected to increase in the coming decades as our population ages and life expectancy improves. Outcomes steadily worsen as the age of the patient rises. One European report showed age-standardized relative survival rates at 1 year of 57% for women aged 65–69 years, 45% for those aged 70–74 years, and 33% for those aged 80–84 years (Vercelli et al. 2000).

There have been various theories put forward to account for the decreased survival in older women, including (1) more aggressive cancer with advanced age, including higher grade and more advanced stage; (2) inherent resistance to chemotherapy of cancers occurring in older women; (3) individual patient factors such as multiple concurrent medical problems, polypharmacy, functional dependence, cognitive impairment, depression, frailty, poor nutrition, and limited social support leading to greater toxicity with therapy; and (4) physician and healthcare biases toward the elderly which lead to inadequate surgery, suboptimal chemotherapy, and poor enrollment in clinical trials (Tew et al. 2014).

To improve the outcomes of our older women with ovarian cancer, we will need to better understand biologic differences between tumors of younger and older patients and develop better decision aids to discriminate those patients who will and will not tolerate standard cytoreductive surgery and chemotherapy. Our trials and reports cannot focus exclusively on the healthiest subsection of older women. We may need to modify chemotherapy dosing, scheduling, and timing (neoadjuvant or postoperative) to reduce toxicity in the more vulnerable patients. Finally, there is a need to develop interventions to improve the ability of vulnerable older women to undergo surgery and receive chemotherapy.

Geriatric Assessment

Background

Geriatric assessment (GA) provides clinicians with information about a patient's functional status (i.e., ability to live independently at home and in the community), comorbid medical conditions, cognition, psychological status, social functioning support, and nutritional status. In the cancer setting, several studies have demonstrated the predictive value of GA for estimating the risk of severe toxicity from chemotherapy and surgery (Hurria et al. 2011a, b; Kanesvaran et al. 2011).

Presurgery Assessment

A validated instrument for assessment of the older adult patient with cancer does not yet exist. However, there are several assessments under study for breast and other solid tumors, which may be applicable to women with ovarian cancer. For example, the preoperative assessment of cancer in the elderly (PACE) tool was developed to combine elements of the comprehensive geriatric assessment with surgical risk assessment tools. The authors found no significant association of age

with postoperative complications. IADL, moderate to severely elevated scores on the Brief Fatigue Inventory (BFI), and abnormal performance status (PS) were most predictive of 30-day morbidity. Lower scores for activities of daily living (ADL; basic activities such as eating, bathing, dressing), instrumental activities of daily living (IADL; more complex activities such as managing finances and shopping), and worse performance status (PS) were associated with extended hospital stay (Participants et al. 2008; Pope et al. 2006).

The NRG Oncology Cooperative Group recently completed a GA study in older women undergoing cytoreductive laparotomy surgery for newly diagnosed ovarian cancer (NRG-CC002), both as primary and interval surgery after neoadjuvant chemotherapy. The study uses a modification of the PACE tool to determine the benefit of a GA in predicting postsurgical complications. Preliminary results were presented at the SIOG meeting in 2016. Due to a study population with almost 20% patients with benign disease at the time of surgery, the tool was not predictive of postoperative complication.

Prechemotherapy Assessment

A short screening test to assess toxicity risk for older vulnerable women with ovarian cancer undergoing chemotherapy is needed. The Cancer and Aging Research Group (CARG) Geriatric Assessment (GA) and Toxicity Score is an example. CARG-GA predicted grade 3–5 chemotherapy toxicity far better than performance status (Hurria et al. 2011b). The CARG study did include a small proportion of women with ovarian cancer (50 patients, 10%), and a retrospective subgroup analysis showed that grades 3–5 toxicity occurred in 19 patients (37%). Abnormal CA125 was associated with assistance with IADL, low PS, chemotherapy toxicity, and dose reductions (Won et al. 2013).

The French Groupe d'Investigateurs Nationaux pour l'Etude des Cancers Ovariens (GINECO) has developed a "Geriatric Vulnerability Score (GVS)" from a series of up-front trials in older women with ovarian cancer. This includes low albumin (<35 g/L), low ADL score (<6), low IADL score (<25), lymphopenia (<1 G/L), and a high Hospital Anxiety and Depression Score (HADS) (>14) (Falandry et al. 2013). With a cutoff score of 3, two groups of patients were identified. Compared with patients with a GVS score of 3 or higher, a lower score was associated with significantly worse overall survival (11.5 versus 21.7 months; hazard ratio [HR] 2.94), lower rate of completion of chemotherapy (65 versus 82%; odds ratio [OR] 0.41; $p = 0.04$), and higher incidence of severe adverse events (53 versus 29%; OR 2.8; $p = 0.009$), including unplanned hospitalization (53 versus 30%; OR 2.6, $p = 0.002$).

While the use of GVS score appeared helpful in selecting those at greatest risk, prospective validation studies are needed before it can be routinely utilized in clinic. The GINECO and NRG groups have developed multiple studies incorporating a GA, and these studies are currently being performed and/or results are pending.

Chemotherapy

Background

Older women are less likely to be offered standard or, for that matter, any chemotherapy. A SEER-Medicare analysis showed that among women aged 65 years or older diagnosed with ovarian cancer between the years of 2001 and 2005, 29% received no chemotherapy, 25% received only a partial course of chemotherapy, and just 47% completed their planned chemotherapy course. Those aged older than 80 years were twice as likely to not complete chemotherapy, and those with two or more comorbidities were 83% more likely to not complete chemotherapy. The authors suggested that these results show that chemotherapy may be underused in elderly women, but high-level retrospective analyses cannot determine if the "underuse" of chemotherapy might, in fact, have been medically appropriate. That first-line chemotherapy improves survival in older women with ovarian cancer and has been

shown in observational studies. Unfortunately, only half of this population received platinum-based chemotherapy. A Surveillance, Epidemiology, and End Results (SEER) review, including almost 8000 women older than 65 years with stage III or IV epithelial ovarian cancer, suggested that while patients who underwent surgery only had similar survival compared with patients who received no treatment (22 versus 17 months), patients receiving chemotherapy as the sole treatment for their disease had a better overall survival (14.4 months) (Fairfield et al. 2011). Those who received debulking surgery and optimal chemotherapy (six cycles within an appropriate timeframe) had the best overall survival (39 months), an association that was maintained after multivariate analysis controlling for demographics, cancer type, and comorbidities.

Older patients are more vulnerable to certain chemotherapy toxicities. The most common toxicities of platinum-taxane regimens, the usual first-line therapy for ovarian cancer, are cytopenias and neuropathy. This was highlighted in a large retrospective analysis of outcomes and toxicities seen in the 620 patients aged 70 years and older enrolled on GOG182, a phase III trial studying triplet-chemotherapy regimens for patients with newly diagnosed ovarian cancer (Tew et al. 2010). Older women enrolled on such a trial are likely to be healthier than the average older woman with ovarian cancer, but older patients still had poorer performance status, lower completion rates of all eight chemotherapy cycles, and increased toxicities, particularly grade 3+ neutropenia and grade 2+ neuropathy (36% vs 20% for younger women on the standard carboplatin/paclitaxel arm). Although the difference in median time to disease progression was only 1 month, older women had significantly shorter median overall survival (OS) (37 vs. 45 months, $p < 0.001$).

A number of prospective ovarian cancer trials have enrolled exclusively older women or have analyzed their older subjects separately. Modified regimens studied or being studied in vulnerable populations include increased use of growth factor, single-agent carboplatin chemotherapy, and weekly low-dose chemotherapy.

Chemotherapy: First Line

European Studies: The GINECO has performed a series of frontline chemotherapy trials for patients aged $\geq$70 years with advanced ovarian cancer and used them to develop a decision aid for identifying which patients will not tolerate aggressive chemotherapy (GVS, described above) (Falandry et al. 2013; Tredan et al. 2007; Freyer et al. 2005). The trials used carboplatin/cyclophosphamide, paclitaxel/cyclophosphamide, and single-agent carboplatin. Rates of completion of six cycles of chemotherapy were 75.6%, 68.1%, and 74%, for the three trials, respectively. Overall survival for each of the trials was 21.6 months/25.9 months/17.4 months. The GVS score is being used in the ongoing EWOC (Elderly Women in Ovarian Cancer) trial that randomizes newly diagnosed ovarian cancer patients with a GVS of three or higher to treatment with single-agent carboplatin AUC 5–6, every 3-week carboplatin AUC 5–6 plus every 3-week paclitaxel 175 mg/m^2, and carboplatin AUC 2 plus paclitaxel 60 mg/m^2 both administered weekly for 3 weeks on an every 4-week schedule.

Weekly dosing of chemotherapy is particularly of interest. Carboplatin and paclitaxel were explored in the phase II Multicentre Italian Trial in Ovarian cancer (MITO-5) study, which included 26 vulnerable patients aged $\geq$70 years old with stage IC to IV. In this study, the response rate was 38.5%, and median overall survival was 32.0 months. Toxicity was low, with 23 patients (89%) treated without experiencing serious adverse events. While not specific to older adult women, these data were confirmed in a phase III Multicentre Italian Trial in Ovarian cancer (MITO-7) study subsequently compared carboplatin (AUC 6) with paclitaxel (175 mg/m^2) every 3 weeks to a weekly carboplatin (AUC 2) and weekly paclitaxel (60 mg/m^2) regimen given over 18 weeks in over 800 women with newly diagnosed ovarian cancer at any age (median 59 and 60 years, respectively) and any stage (over 80% with stage III to IV disease). Compared with the women in the every-3-week arm, there was no difference in progression-free survival (PFS) with weekly dosing (median, 17.3

versus 18.3 months, HR 0.96, $p = 0.066$). However, weekly dosing was associated with better quality of life scores (evaluated standardized questionnaires) and lower toxicities, including grade 2 or worse neuropathy and serious (grade 3–4) hematologic toxicity. These data suggest that weekly doing of carboplatin and paclitaxel may be a more reasonable option for older patients, especially those deemed to be at higher risk for treatment-related toxicities, for whatever reason (Pignata et al. 2014).

The GINECO also collected peripheral blood lymphocytes from the patients treated on trial with single-agent carboplatin. Telomere length was estimated using standard terminal restriction fragment analysis. Patients who had a shorter than median telomere length had shorter survival and a higher risk of severe adverse events with chemotherapy (Falandry et al. 2012). There is considerable interest in whether "aging biomarkers" such as leucocyte telomere length, p16INK4a expression in T lymphocytes, or inflammatory cytokine expression might predict toxicities of therapy and supplement clinical measures of function. The European Organization for Research and Treatment of Cancer (EORTC) Elderly Task Force has initiated an aging biomarkers program to test this hypothesis (Pallis et al. 2014).

US Studies: Von Gruenigen and her colleagues conducted an elderly-specific trial of women 70 years and older with newly diagnosed ovarian cancer receiving first-line platinum-based chemotherapy (GOG273) (Von Gruenigen et al. 2017). Patients and their physicians selected from two different regimens: (Arm 1) every 3-week carboplatin AUC 5, paclitaxel 135 mg/m^2, and pegfilgrastim support or (Arm 2) every 3 week single-agent carboplatin AUC 5. Patients could be enrolled either after cytoreductive surgery or prior to any surgical intervention. One hundred fifty-two women enrolled into Arm 1 and 60 into Arm 2. Women on Arm 2 (single-agent carboplatin) were older, had lower performance status, had lower IADL scores, and were more likely to receive chemotherapy prior to surgery and less likely to complete all four cycles without dose reduction or a more than 7-day delay. However, in general, overall completion of four cycles of chemotherapy was high (Arm 1: 92% and Arm 2: 75%). After adjusting for age and PS, baseline IADL was independently associated with the choice of regimen ($p = 0.035$). The baseline IADL score was not found to be associated with completion of four cycles of chemotherapy without dose reduction or delays ($p = 0.21$) but was associated with completion of four cycles of chemotherapy regardless of dose reduction and delay ($p = 0.008$) and toxicity, with the odds ratio (OR) of grade 3+ toxicity decreasing 17% (OR: 0.83; 95% CI: 0.72–0.96; $p = 0.013$) for each additional activity in which the patient was independent. After adjustment for chemotherapy regimen, IADL was also associated with overall survival ($p = 0.019$) for patients receiving CP. This study highlights the importance of IADL scores in pretreatment assessment.

After Arm 1 and 2 completed enrollment, Tew and colleagues explored the widely used dose-dense paclitaxel regimen. Patients were treated with carboplatin (AUC5) every 3 weeks and dose-reduced weekly paclitaxel (60 mg/m^2) on an every 3-week cycle; this arm was designed to test the hypothesis that the geriatric assessment score can predict toxicity to chemotherapy. Enrollment is complete; final results are being prepared for manuscript.

Neoadjuvant Chemotherapy (NACT)

NACT is the delivery of chemotherapy prior to cytoreduction surgery (CRS). NACT use is gaining popularity in both the USA and Europe, particularly for older and frail patients, because it is associated with less surgical toxicity. In an analysis of Medicare patients with stage II–IV ovarian cancer who survived at least 6 months from diagnosis, the use of NACT had increased from 19.7% in 1991 to 31.8% in 2007 and is likely higher now (Wright et al. 2014). Randomized trial data suggest that outcomes with NACT and primary surgery are similar overall, though different subgroups may benefit from different approaches. A prospective randomized study of NACT from the EORTC (Vergote et al. 2010) randomly assigned 632 patients with newly diagnosed

stage IIIC or IV epithelial ovarian cancer to either primary CRS followed by six cycles of platinum-based chemotherapy or three cycles of platinum-based NACT followed by an interval CRS followed by an additional three cycles of platinum-based chemotherapy. The median age was 62 years (25–86) in the primary surgery group and 63 years (33–81) in the NACT group. Survival outcomes in the two arms were similar with a median overall survival of 29 months in the primary surgery group and 30 months in those assigned to NACT. Surgical complications were higher in the primary surgery group, with postoperative death in 2.5% vs 0.7% and infection in 8.1% and 1.7% of participants. Similar results were seen in a preliminary report from the MRC CHORUS trial, which involved an identical randomization and showed 12-month survival rates of 70% for primary surgery and 76% for NACT (Kehoe et al. 2013). Exploratory subgroup analyses of the EORTC trial did not show differences in benefit by age: 5-year survival rates of patients over the age of 69 ($n = 166$) were 20% with primary surgery and 18% with NACT (van Meurs et al. 2013). Interestingly, patients with stage IV tumors and large tumor volume appeared to do better with NACT, while patients with low-tumor burden appeared to do better with primary surgery.

Intraperitoneal Chemotherapy

Intraperitoneal (IP) chemotherapy has shown a survival benefit in multiple randomized trials of patients with optimally cytoreduced ovarian cancer (Markman et al. 2001; Armstrong et al. 2006; Alberts et al. 1996). Only a small fraction of the women enrolled on these trials were over the age of 70 years. All of the randomized trials used cisplatin, which has more nephrotoxicity and ototoxicity than carboplatin. Although some reports have suggested that healthy older patients can tolerate IP chemotherapy (Tew et al. 2009), one small report on women over age 75 treated with aggressive surgery followed by hyperthermic intraperitoneal chemotherapy found a 78% morbidity rate (Cascales-Campos et al. 2014). A SEER-Medicare analysis reported that only 3.5% of ovarian cancer patients in the Medicare population received IP chemotherapy between 2005 and 2009; they did not have an increase in use of acute care services (Fairfield et al. 2014).

Chemotherapy for Recurrent Disease

Older patients with platinum-sensitive disease would seem to be a relatively favorable group; they must have both responded to and survived primary chemotherapy. However the SOCRATES retrospective review of women with platinum-sensitive disease treated in Italy from 2000 to 2002 found that greater age at recurrence was independently associated with worse survival. Despite similar recurrence-free interval, performance status, and number of disease sites, women over 70 years had a median overall survival of only 23.6 months from recurrence versus 30.7 months for younger women. Older women also had less secondary surgery, more frequent single-agent chemotherapy, and lower response rates to chemotherapy (67.2% vs 46.5%) (Pignata et al. 2009).

For patients with platinum-sensitive disease in general, randomized trials show a PFS advantage to a doublet combination with carboplatin and either paclitaxel, gemcitabine (Pfisterer et al. 2006), or liposomal doxorubicin (Pujade-Lauraine et al. 2010) versus treatment with carboplatin alone, and platinum-based doublet therapy is therefore standard. However, an overall survival benefit has been seen only on the ICON-4 trial with the addition of paclitaxel, and a substantial number of patients on that trial had not received paclitaxel in frontline therapy, so single-agent carboplatin remains a viable option for frailer patients (Parmar et al. 2003). Choice of regimen is often based on the toxicity profile, and in older patients, gemcitabine can produce higher rates of cytopenias and paclitaxel higher rates of neuropathy. A subset analysis of patients aged 70 years and older treated on the CALYPSO trial (carboplatin/paclitaxel (CP) versus carboplatin/liposomal doxorubicin (CD)) showed that elderly patients completed the planned six cycles at the

same rate as younger patients (79% for CP and 82% for CD) and had similar rates of hematologic toxicity. Grade 2 or greater peripheral neuropathy was greater among older patients treated with paclitaxel (36% vs 24% for younger patients), and interestingly, carboplatin hypersensitivity reactions were significantly less common in older women (Kurtz et al. 2011).

For platinum-resistant disease, chemotherapy is typically given as single agent, and responses range from 10% to 25% with a median duration from 4 to 8 months. Common options include liposomal doxorubicin, topotecan, gemcitabine, weekly paclitaxel, and vinorelbine (Tew and Lichtman 2008). Gronlund and colleagues described their experience with topotecan (1 mg/m^2 over 5 days) in 57 elderly patients and found no significant differences in toxicity profile or response between an older (>65 years) or younger (<65 years) cohort (Gronlund et al. 2002). Liposomal doxorubicin and gemcitabine are reasonable choices for older patients with platinum-resistant disease, given their relatively good toxicity profiles. However, since these chemotherapy options only offer a low chance of disease palliation, it may be reasonable to focus on better supportive measures, rather than more chemotherapy, in the setting of platinum-resistant disease. Disease progression on two consecutive lines of therapy has been recommended as a guide to stop therapy (Griffiths et al. 2011). In one study, there was a significant cost difference with no appreciable improvement in survival between ovarian cancer patients treated aggressively with chemotherapy versus those enrolled in hospice at the final months of their life. The authors suggest that earlier hospice enrollment is beneficial, particularly in older frail patients (Lewin et al. 2005).

Targeted Agents

The targeted agents currently of most relevance to the treatment of ovarian cancer are the Poly (ADP-ribose) polymerase (PARP) inhibitors and antiangiogenic agents, particularly bevacizumab and the antiangiogenic tyrosine kinase inhibitors.

PARP inhibitors are oral agents and have been approved for women with recurrent ovarian cancer with a BRCA somatic or germline mutation, as well as in the second remission setting as maintenance therapy for all women regardless of BRCA status. There are no elderly-specific data on PARP inhibitors, but they appear generally to be well tolerated. Toxicities of olaparib, for example, have generally included low grade fatigue, cytopenias, GI symptoms, and rash (Kaye et al. 2012). While BRCA-linked hereditary ovarian cancers, particularly BRCA1-associated cancers, tend to occur at a younger age than non-hereditary/sporadic ovarian cancer, the mean age at time of ovarian cancer diagnosis for mutation carriers ranges significantly (BRCA 1: 54 years (31–79), BRCA2: 62 years (44–77), and sporadic 63 years (25–87)) (Boyd et al. 2000). Genetic counseling and consideration of PARP inhibitor therapy are appropriate regardless of age.

Antiangiogenic agents require more caution in the older population. While the effect of bevacizumab on survival outcomes appears to be similar in older and younger patients with ovarian cancer (Burger et al. 2011), a variety of toxicities are increased in the older population. Of particular concern are vascular events. The package insert for bevacizumab as of September 2014 notes that in an exploratory pooled analysis of 1745 patients treated in five randomized controlled studies, the rate of arterial thromboembolic events in bevacizumab-treated patients was 8.5% for those aged 65 years and older versus 2.9% for those younger than 65 years of age (Insert AP 2014). Patients with a history of prior stroke or TIA should not receive bevacizumab, and close attention must be paid to blood pressure control. Mohile et al. conducted a prospective analysis of toxicity older patients receiving bevacizumab in combination with chemotherapy for colon cancer or NSCLC. The addition of bevacizumab increased toxicity, particularly grade 3 hypertension, but no geriatric assessment variables were found to be associated with increased toxicity (Mohile et al. 2013).

Anti-VEGF tyrosine kinase inhibitors are of increasing interest in ovarian cancer with recent preliminary reports of increased progression-free survival in the AGO-OVAR16 randomized trial of pazopanib (Du Bois et al. 2013) and increased

progression-free survival in two trials using cediranib (Ledermann et al. 2013; Liu et al. 2014). While the toxicities of cediranib on these trials appeared manageable, they were substantial, including fatigue, diarrhea, and hypertension.

Class toxic effects of the anti-VEGF oral tyrosine kinase inhibitors (TKIs) appear worse in older patients. Data on older patients with other tumor types treated with sorafenib and sunitinib variably suggest higher incidences of dose reductions, neutropenia, fatigue, and gastrointestinal symptoms (Wong et al. 2011; Gonsalves and Ganti 2011). Age over 65 years predicted increased toxicity on one trial of carboplatin/paclitaxel/cediranib in lung cancer patients (Goss et al. 2010). Cediranib appears to have even greater effects on blood pressure than some of the older anti-VEGF TKIs. A phase II study of cediranib in ovarian cancer reported that women aged 65 or older had a higher average increase in systolic blood pressure by day 3 than younger women (15.9 vs 7.0 mmHg). Caution and close attention to blood pressure management will be needed in older women as this agent is more widely tested/used in ovarian cancer.

Surgery

In an analysis of over 12,000 patients, ovarian cancer patients over the age of 80 years were found to be less likely to receive surgery and less likely to have an optimal cytoreduction. They were also less likely to be treated by oncologists (Hightower et al. 1994). A report by Fairfield et al. showed that there is regional variation in ovarian cancer mortality in the Medicare population and that access to cancer-directed surgery explains some of this variation. Hospital referral region (HRR), assigned by zip code, was a significant predictor of cancer-directed surgery in a SEER-Medicare data analysis of patients with ovarian cancer, with surgery rates ranging from 53% to 88%. HRR was also a significant predictor of all-cause mortality but was no longer significant when cancer-directed surgery was added to the model (Fairfield et al. 2010). This lends support to the idea that surgery may be "underused" in older women and that this contributes to some of the poor outcomes seen in this population.

However, there is clearly substantial toxicity associated with aggressive primary surgical cytoreduction in older patients. A SEER-Medicare analysis showed that of women aged 65 and older with stage III or IV ovarian cancer who had primary cytoreductive surgery, those admitted electively ($n = 4517$) had a 30-day mortality of 5.6%, while those admitted emergently had a 30-day mortality of 20.1%. Those aged 75 and older with either stage IV disease or stage III disease and a comorbidity core of one or more had a 30-day mortality of 12.7% even when admitted electively (Thrall et al. 2011). There is also concern that toxicities of surgery may prevent older women from receiving chemotherapy. One retrospective report on 85 patients over the age of 80 undergoing cytoreductive surgery (mostly primary) showed that 13% died prior to discharge and 20% died within 60 days of surgery. Thirteen percent never received adjuvant therapy, and of those treated, 43% completed less than three cycles of therapy (Moore et al. 2008).

These and other data on the increased toxicity of primary cytoreductive surgery in the elderly have led to the increased use of NACT and interval cytoreductive surgery in older patients (see above). Although randomized trial data discussed above have suggested that survival with NACT and primary chemotherapy is similar, there are likely patients in whom primary surgery produces better outcomes. While older patients present with more poor prognostic disease, a subset can be cytoreduced to no residual disease. AGO found that rates of no residual disease after primary surgery of patients on a clinical trial were 45.1% in patients less than 50 years of age, 25.7% in patients 50–65 years, and 24.5% in patients over the age of 65 (Wimberger et al. 2006). Among patients over the age of 65, surgical outcomes generally continue to appear progressively worse with increasing age. In a series of 280 consecutive patients $\geq$65 years of age treated with primary surgery at the Mayo clinic, rates of residual disease over 1 cm were 43% in women aged 80 years or older versus 25% in women aged 65–69. Three-month mortality was 25% in women 80 years old

or older versus 4% in women aged 65–69 years (Langstraat et al. 2011).

The ability to assess who is fit enough to undergo aggressive CRS followed by chemotherapy and who should be offered an alternative pathway such as neoadjuvant chemotherapy (NACT) and interval cytoreductive surgery or primary chemotherapy alone is an unmet need. Aletti identified a high-risk group of women who do not appear to benefit from primary surgery. Risk features included stage IV disease, high initial tumor distribution, poor performance status (ASA score >= 3), poor nutritional status (albumin <3.0 g/dL), and older age (>= 75 years) (Aletti et al. 2011). Although each patient plan must be individualized, at this time, these criteria are reasonable to use as guidelines for a NACT approach. There are ongoing efforts, as described above, to develop more formalized tools to assess preoperative risk for older patients; most of them are not tested in the setting of aggressive primary cytoreduction surgery for ovarian cancer. The Gynecologic Oncology Group (GOG) will shortly begin accrual to a Preoperative GA Study (ELD1301) to determine whether a score calculated from a modified GA can predict postsurgical complications in women with ovarian cancer undergoing primary cytoreductive surgery. This score is also being tested for its value in predicting chemotherapy complications, and it would be ideal if a simple tool could be used in both presurgical and prechemotherapy settings.

Conclusion/Future Directions

In order to improve the benefit and tolerability of cancer treatment, we must develop new geriatric-specific trials and better geriatric assessment tools and encourage enrollment of older patients onto clinical trials. Age is a strong predictor of survival in ovarian cancer and often influences the treatment plan. Elderly patients, broadly defined as older than age 65 year of age, may be inappropriately not offered participation in clinical research or provided with substandard chemotherapy or surgical options. Since first-line platinum-based chemotherapy with cytoreductive surgery is a potentially curative treatment plan, all standard treatment options should be explored (intravenous, neoadjuvant, and/or intraperitoneal chemotherapy). In the future, a better understanding of the biology of aging and of tumors in older women and interventions designed to decrease the toxicity of treatment in older women will be needed. At this time, we must balance the specific needs of the older patient and be aware of the increased risk of side effects. The oncologist should clearly define the goals (palliative versus curative) and specific risks of treatment to patients and their families. As the field of geriatric oncology evolves and prospective trials tailored to older woman with ovarian cancer are developed, specific guidelines will ultimately assist in these difficult decisions.

Lung Cancer in Older Adults: Local Treatment

48

Drew Moghanaki, Carlos E. Bravo Iñiguez, and Michael T. Jaklitsch

Contents

Abstract

Lung cancer is a malignancy that primarily affects the elderly. It is commonly diagnosed in patients with comorbidities who may have concerns about complications from aggressive therapies. This chapter is written for the non-oncologist to provide guidance on how best to approach elderly patients with lung cancer. An emphasis is made regarding the value of a multi-disciplinary team-based approach, given the evidence continues to evolve for an optimal approach in many clinical situations. It describes the advantages of minimally invasive thoracic surgery that have been reported in randomized clinical trials. It also summarizes the serendipitous outcomes following stereotactic radiotherapy for early stage disease that currently calls into question the time-honored belief that surgery provides the only hope for cure. A section is dedicated to the evaluation of treatment paradigms for patients with locally advanced lung cancer which has led to lower

doses and smaller fields of radiotherapy than ever before. Finally, an update is provided regarding management options for localized small-cell lung cancer.

Introduction

Lung cancer predominantly affects the elderly and is responsible for more deaths than the next five most common cancers combined. The median age at diagnosis is 70 years, and therefore many patients present with comorbidities that introduce management challenges. Elderly patients and their providers are frequently concerned about the risks of treatment and at times may prefer observation even when a tumor is localized (Wang et al. 2012). Such an approach is not widely endorsed in the oncologic community as it often leads to rapid declines in quality of life since most elderly patients live long enough to die from uncontrolled lung cancer (Haque et al. 2018; McGarry et al. 2002).

Fortunately, significant developments in lung cancer therapies now offer treatments that are well-tolerated, even in an elderly population. There have been significant advances in thoracic surgery that have improved its safety for patients who have historically been at a high risk of perioperative complications (Armstrong et al. 2016). There have also been milestone developments in radiotherapy that call into question the time-honored belief that surgery offers the only hope for cure (Chang et al. 2015; Moghanaki and Chang 2016). Each of these life-prolonging therapies has become safer, is more available, and often offers a more favorable option than observation.

This chapter is therefore written to guide non-oncologists who are considering the referral of an elderly lung cancer patient with localized disease for surgery or radiotherapy. It emphasizes the value and importance of tissue diagnosis, of accurate staging, and of a multidisciplinary approach to management. It also provides a contemporary update of outcomes with surgery or radiotherapy, as well as the ongoing controversies.

Surgery for Early Stage Lung Cancer

The importance of an accurate diagnosis and staging workup: It is well-accepted that the suitability of any lung cancer therapy depends upon accurate diagnosis and staging. While CT and PET scans offer useful information to identify the extent of disease, they are insufficient to confirm that a given lung mass is actually a lung cancer. For this reason, lung cancer specialists uniformly endorse obtaining a tissue diagnosis whenever feasible. This offers an opportunity for histologic review to confirm malignancy, to assess the possibility of a malignancy that is not of bronchial or lung origin (e.g., metastasis, sarcoma, or lymphoma), and, when it is in fact lung cancer, to distinguish whether it is a non-small cell or small cell histology.

The least invasive strategies to confirm a pathological diagnosis include sputum cytology, bronchoscopy, and lavage. When unsuccessful, efforts should progress to moderately invasive techniques such as CT-guided needle biopsy, endobronchial ultrasound-guided needle biopsy (EBUS), esophageal ultrasound-guided needle biopsy (EUS), and navigational bronchoscopy. At times, more invasive techniques are needed and may include either a thoracoscopic-guided needle biopsy or excisional biopsy.

Once a cancer diagnosis has been confirmed, accurate staging is required to guide discussions of therapy. “Early stage disease” refers to smaller tumors that have not yet spread to regional lymph nodes that are commonly treated with surgical resection or locally ablative therapies. “Locally advanced” disease refers to scenarios where the disease has spread to the regional lymph nodes in the hilum or mediastinum that are more difficult to cure, even with combinations of chemotherapy, radiotherapy, and surgery. Finally, “metastatic” (stage IV) disease has spread to other organs and is no longer curable with currently available systemic therapies. Clearly then, therapies designed for localized disease will not be successful in the setting of locally advanced or metastatic disease, and every effort should be made to accurately stage the disease in each patient. For elderly patients confirmed to have only localized disease,

there are now several safe and effective options that can produce long-term disease-free survival with minimal risk.

The importance of surgeon expertise. Surgical resection of early stage lung cancer has been historically considered the most effective treatment for patients with early stage disease. It is frequently available, although in the USA only 25% of these procedures are performed by board-certified cardiothoracic surgeons who focus their practice on thoracic surgery (Farjah et al. 2009; Howington et al. 2013). Approximately 30% are performed by general surgeons and 45% by board-certified cardiothoracic surgeons who instead focus their practice on cardiac surgery. A surgeon's limited expertise in thoracic surgery is not trivial, is associated with less understanding of oncologic principles, and is associated with higher rates of postoperative mortality (Howington et al. 2013). Studies have shown that complications, and length of hospitalization, are reduced when thoracic or cardiothoracic surgeons vs general surgeons perform the operation (Schipper et al. 2009; Goodney et al. 2005). A recent meta-analysis reported perioperative mortality, comparing cardiothoracic or general surgeons to thoracic surgeons with specialization in lung cancer management. Respectively, the odds ratios were 0.78 (95% CI, 0.7–0.88; $P \leq 0.0001$) and 0.82 (95% CI, 0.69–0.96; $P < 0.016$) (von Meyenfeldt et al. 2012). It was notable that the improved outcomes with increased surgical expertise persist when considering that more specialized thoracic surgeons often manage sicker patients with more comorbidities (Ferraris et al. 2012). While this information should naturally give pause to any referring clinician, it should also serve as a reminder to consider the surgeon's judgment in selecting patients for resection. Both prospective and retrospective trials have demonstrated that surgical mortality rates can be as low as 0–1% with carefully selected patients (National Lung Screening Trial Research T et al. 2011; Cerfolio et al. 2016). However, when improperly selected, 30-day mortality rates can reach as high as 29%, as reported in a 2016 European study that evaluated the outcomes of over 47,000 patients (Brunelli et al. 2017).

The importance of institutional expertise. There is overwhelming evidence that lung cancer surgery outcomes are superior at high-volume centers of excellence. While historically available only at leading academic institutions, high-quality care may now be found in select community medical centers that have sufficient resources dedicated to a thoracic oncology program, in which thoracic surgeons work collaboratively via excellent lines of communication with pulmonologists, radiation oncologists, and medical oncologists each specializing in lung cancer. They are typically engaged in continuous peer-review and are well-staffed to address the continuum of care that includes patient navigation to reduce a delay to complete an evaluation for treatment, social work, and nutritional services when needed. Although the assessment of patients for thoracic surgery is conceptually straightforward, it frequently requires multiple tests and appointments for which timely coordination and efficient navigation through laboratory, pulmonary, and cardiac evaluations are beneficial. High-quality programs also typically have advanced perioperative services in anesthesia, intensive care, and respiratory therapy which can be equally important to surgical skill. This is particularly important given that large studies ($n > 70{,}000$) have demonstrated the 30-day mortality rate in patients $\geq$75 years with comorbidities can be more than four times that of patients <75 years without comorbidities (5.3% v 1.3%, $p < 0.01$) (Husain et al. 2015).

The advantages of minimally invasive surgery. Over the past several decades, technological advances such as video-assisted thoracic surgery (VATS) have been introduced as a minimally invasive approach for lung cancer. Prospective randomized trials have now measured a variety of meaningful clinical advantages with VATS when compared to a conventional open thoracotomy. This includes reduced operative time and perioperative blood loss (Bendixen et al. 2016), reduced frequency of postoperative air leaks (Kirby et al. 1995), shorter duration of epidural anesthesia and hospital stay (Bendixen et al. 2016), less postoperative pain (Bendixen et al. 2016; Long et al. 2007a, b), lower acute-phase cytokine concentrations associated with surgical

stress (Craig et al. 2001), and improvements in quality of life (Bendixen et al. 2016; Long et al. 2007a, b). Additionally, retrospective case-matched studies have found that VATS is associated with a reduced chest tube duration, reduced length of stay, reduced postoperative complications, lower rates of grade 3 complications and of pain at 3 weeks, earlier return to full preoperative activities, and a lower rate of perioperative mortality (Cattaneo et al. 2008; Demmy and Curtis 1999). These improvements have not yet been aligned with improvements in long-term survival, even considering a randomized trial specifically designed to evaluate this endpoint (Sugi et al. 2000). However, such data offer meaningful insights into the clinical gains that can be afforded by VATS for patients who present with a high risk of perioperative complications.

Concerns about surgery in any elderly patient. Despite advances in surgical care, elderly patients often harbor comorbidities that can complicate the postoperative recovery period given a limited physiological capacity to heal. This can occur even among those who are found by evidence-based risk stratification tools to be a more ideal candidate for a lung resection (Samson et al. 2016). Many of these tools underestimate the importance of impaired vision and hearing, urinary incontinence, falls, depression, poor baseline nutrition, and cognitive disorders such as dementia and delirium (Rao et al. 2016). As such, the recovery period is occasionally prolonged, can take up to months, and may even require transfer to a skilled nursing facility. In an analysis of 1007 surgically treated lung cancer patients in the CanCORS database (Cancer Care Outcomes Research and Surveillance Consortium), it was found that the risk of nursing home placement 1 year after surgery precipitously increased from 2% for patients younger than 74 years of age to 11% for patients over the age of 80 years (Billmeier et al. 2013). In addition to the continued care of patients even after they return home, protracted convalescence is often associated with financial burden and affects both patients and family. Fortunately, meaningful advances in lung cancer research have introduced nonsurgical options that offer alternative treatment strategies that may be equally effective. As described below, one of these is stereotactic radiotherapy, which should at least be presented for discussion as a treatment option to all elderly patients with localized non-small cell lung cancer.

Stereotactic Radiotherapy for Early Stage Lung Cancer

Technological advances in radiotherapy (RT). For much of the past century, lung cancer radiotherapy has been reserved for those who are medically inoperable. Its purported futility was originally declared by Graham and Singer in 1933 in their initial report of the first successful surgical resection of a lung tumor (Graham and Singer 1933). This idea became engrained in 1963 when a small randomized trial of 58 patients at the Hammersmith Hospital demonstrated the superiority of surgery versus conventional radiotherapy (Morrison et al. 1963). While this study predated computed tomography and utilized lower, palliative doses of RT that targeted "the opaque area of the lung" seen on X-rays, its results were highly influential and engrained the belief that surgical resection offered the only hope for cure. It supported lectures and publications in the literature that declared RT was "worse than useless" (Shorvon 1947). Furthermore, it impeded efforts to evaluate radiotherapy's role as an alternative to surgery for the next half-century (Timmermann 2007). As a consequence, the majority of reports in the literature that have evaluated the outcomes of radiation therapy for early stage lung cancer remained widely unfavorable, given its use was largely limited for the treatment of "surgical rejects" (Timmermann 2007).

Technological milestones in the 1990s facilitated the safe delivery of high doses of radiotherapy to moving lung tumors with a new form of treatment known as stereotactic body radiation therapy (SBRT) – also known as stereotactic ablative radiotherapy (SABR) (Blomgren et al. 1995). Improved accuracy facilitated the escalation of radiation doses to levels previously considered unsafe. With dose escalation and more accurate targeting, with only three outpatient treatments,

tumor control rates exceeding 90% were soon reported in several series (McGarry et al. 2005; Timmerman et al. 2003, 2010, 2014; Baumann et al. 2009; Fakiris et al. 2009; Hof et al. 2007; Onishi et al. 2007; Senthi et al. 2012; Guckenberger et al. 2013). Of equal interest, prospective trials have documented a 0% risk of treatment-related mortality at 5 years (Timmerman et al. 2014). In a milestone prospective single-arm trial, toxicities such as dyspnea requiring steroids, or self-limited hemoptysis, were identified after SBRT, actuarially, in 16% at 5 years. However, each case occurred within 3 years (Timmerman et al. 2010, 2014). Over time, more careful selection of patients receiving SBRT helped avoid the occurrence of any severe esophagitis. Promising outcomes were eventually reproduced in multiple centers around the world via both prospective and retrospective analyses (Baumann et al. 2009; Timmerman et al. 2010, 2014; Fakiris et al. 2009; Hof et al. 2007; Onishi et al. 2007; Senthi et al. 2012). The published results eventually contributed to the widespread acceptance of SBRT as the preferred form of radiotherapy for patients with early stage lung cancer (Howington et al. 2013), and the utilization of SBRT subsequently increased around the world (Corso et al. 2017).

The importance of technological expertise. Similar to high-quality thoracic surgery programs, centers of excellence for SBRT are not yet available everywhere. They are identified not only by the skill and knowledge of the radiation oncologist but also when appropriate technology is available with an advanced medical physics team whose expertise is essential to the safe delivery of SBRT. That is because the treatment of moving targets in the lung with high doses of SBRT is not straightforward and requires appropriate software, as well as standardized operating procedures with detailed quality assurance programs (Solberg et al. 2012). This is particularly important for tumors close to critical structures such as the spinal cord, trachea, or proximal bronchi. As discovered in the early days of lung SBRT, severe complications such as fatal hemoptysis can occur with tumors close to critical structures near the mediastinum. Thus, radiation therapy teams must be cognizant of patient selection criteria and updated recommendations that presently facilitate the safe delivery of SBRT to patients who have early, potentially curable lung cancer (Chang et al. 2014; Senan 2012).

The occasional conundrum of post-SBRT surveillance imaging. The evaluation of tumor control after SBRT is often straightforward, but not always. Serial chest CT scans every 6 months following treatment are advised, reserving positron emission tomography (PET) only for a strong suspicion of relapse or metastasis. The CT scan images commonly demonstrate diffuse radiographic changes near the initial tumor location. At times, they can be difficult to interpret, particularly for radiologists unfamiliar with the effects of high-dose radiotherapy. When uncertainties emerge, providers may develop "scanxiety" and order more frequent posttreatment imaging studies (Paul et al. 2016). A failure to appreciate post-SBRT patterns of fibrosis can lead to unnecessary invasive procedures that have included biopsies or even salvage lobectomies for benign fibrotic changes (Neri et al. 2010; Taira et al. 2014).

Proper radiographic evaluations should therefore investigate whether radiographic densities resemble a "disc-like" pattern that mimics the beam arrangement of most lung SBRT prescriptions. As illustrated in Fig. 1, these changes often appear much larger on axial slices and are better visualized on coronal and sagittal reconstructed images. Evaluations that merely consider enlarging opacities at the primary site have a specificity for recurrence of only 67% (Huang and Palma 2015). Characteristics more specific for relapse include sequential enlargement (100%), linear margin disappearance (100%), loss of air bronchogram (96%), cranio-caudal growth of $\geq$5mm and $\geq$20% (83%), enlargement after 12 months (83%), or a bulging margin (83%) (Huang and Palma 2015).

Salvage surgery for relapse. There is evidence to support the idea that long-term survival may not be compromised in patients who develop a local relapse after upfront SBRT for early stage lung cancer. Building upon the results of multiple randomized clinical trials of organ preservation for malignancies of the larynx, breast, anus,

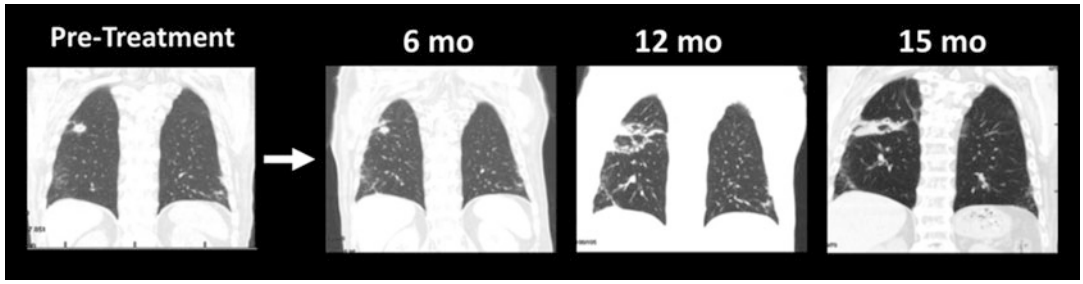

Fig. 1 The delivery of SBRT occasionally leads to substantial fibrotic changes that evolve in a disc-like pattern, mimicking the pattern of treatment beams. These changes are less concerning when viewed on sagittal, as pictured here, or coronal projections, to facilitate more accurate evaluation of cranial-caudal growth, which is highly specific for tumor progression (Huang and Palma 2015). They are best followed with shorter interval scans, with FDG-PET/CT imaging reserved for only when there is a strong suspicion for tumor progression

bladder, and extremities, there are many tumors that today are managed with upfront radiotherapy or chemoradiotherapy, with reservation of a salvage oncologic resection only for the minority who develop local-only progression (Timmerman et al. 2014). This approach has now been found to be safe in early stage lung cancer, as thoracic surgeons have found minimal to no adhesions in the thorax following SBRT to small tumors during salvage resections, even with a minimally invasive technique (Verstegen et al. 2016). This has now permitted the emergence of a new clinical scenario in the management of early stage lung cancer (Bradley 2010). Appreciating that SBRT has historically been used to treat medically inoperable patients and that the long-term survival equivalence of upfront SBRT as compared to pulmonary resection has yet to be validated, increasing numbers of operable patients are now opting for upfront SBRT while reserving salvage lung cancer surgery if relapse occurs (Timmerman et al. 2013; Senthi 2014). Such a paradigm can help many patients avoid the need for general anesthesia.

Deciding Between Surgery and Radiotherapy

Shifting referral patterns. The favorable outcomes with SBRT have created a conundrum following widespread enthusiasm for its use as an alternative to lung cancer surgery (Corso et al. 2017). This is even though its long-term efficacy compared to surgery remains a vital question. Although it has yet to be endorsed by evidence-based guidelines for patients who are operable, SBRT for lung cancer is an FDA-approved treatment that has been increasingly prescribed in healthier populations (Haque et al. 2018). This shift has facilitated the evaluation of SBRT for patients harboring less comorbidities. While it's unclear if any operable patient has compromised their survival by preferring upfront SBRT, the growing body of experience has provided a more accurate evaluation of its long-term comparative effectiveness as an alternative to surgery. As summarized in Table 1, a growing body of literature with over 1000 patients now suggests that SBRT survival rates are equivalent, or superior, to resection. While these data are encouraging, it's critical to appreciate that they do not derive from level 1 evidence, at times include patients without biopsy-confirmation of malignancy, and include limited survival data beyond median follow-up periods of about 3 years.

The equipoise to open randomized trials. In order to better understand the value of SBRT as a primary treatment option in operable patients, a total of eight prospective randomized trials have been launched since 2008, directly comparing SBRT and surgery with a primary endpoint predominantly being overall survival. Unfortunately, enrollment has been difficult given the challenges of equipoise. The first group of studies all closed prematurely due to poor accrual

Table 1 Summary of overall survival rates in operable patients with stage I NSCLC who refused surgery and were treated with SBRT instead

Survival after SBRT in operable patients with stage I NSCLC

(NCT00687986, NCT00840749, NCT01336894, and NCT01622621). A new generation of trials has since opened with innovative recruitment strategies that shed light on provider biases, a factor widely believed to have limited accrual in the first set of trials (NCT02629458, NCT01753414, NCT02468024, and NCT02984761) (Berman et al. 2016). This includes the VALOR trial which is sponsored by the Veterans Affairs Cooperative Studies Program and is the largest phase III trial ever attempted for this study population (Veterans Affairs Lung Cancer Surgery or Stereotactic Radiotherapy (VALOR) n.d.). With a primary endpoint of overall survival beyond 5 years, it aims to randomize 670 low-risk operable patients between an anatomic pulmonary resection (lobectomy or anatomic segmentectomy) and SBRT. The final results of each of these studies are greatly anticipated by many individuals in the lung cancer community.

The conundrum of retrospective studies. In lieu of randomized evidence, multiple comparative effectiveness research studies have compared outcomes following SBRT or surgery. The results have been mixed, revealing either an association of higher survival with surgery (Zhang et al. 2014), no difference between either treatment (Shirvani et al. 2014), or improved survival with SBRT (Chang et al. 2015). While insightful, each of these studies is best viewed as hypothesis generating with each facing the limitations of selection bias that is inherent whenever comparing overall survival between operable and inoperable cohorts. The imbalance in baseline life expectancy has been difficult to adjust for, not only because of incomplete data that often omits pulmonary function test values (e.g., in analyses using the National Cancer Database) but also because of the ongoing preference of surgeons and many radiation oncologists for reserving SBRT for patients with short life expectancy using factors that simply cannot be measured by health service researchers and data scientists. Furthermore, some of the comparative studies have included patients who received SBRT without tissue confirmation of lung cancer, and only a few have compared survival beyond 3 years.

It is incorrect to compare overall survival outcomes in carefully selected surgical patients to SBRT results in surgically unfit patients. In fact, when one compares surgically fit patients treated with SBRT with surgically fit patients treated with surgery, there are comparable results (Crabtree et al. 2014). For example, a propensity-matched comparison based on age, tumor size, comorbidity score, pulmonary function test, and location of tumor produced 56 matched pairs in an analysis by the thoracic surgeons at Washington University in St Louis. The 3-year overall survival was 52% for SBRT and 68% for surgery ($P = 0.05$). Yet, at 3 years the local recurrence-free survival was 90% versus 92% for SBRT and surgery.

The importance of shared decision-making. The lung cancer community typically benchmarks the success of its therapies to overall survival. As a result, many intellectual debates about the merits of surgery and SBRT focus on this endpoint. However, it is known that elderly patients are commonly less interested in treatments that offer

"survival at any cost." Instead, they frequently prefer clinical management strategies that prioritize quality, over quantity of life. This was best demonstrated in a 1978 landmark study of lung cancer patients that was published in the *New England Journal of Medicine* and titled "Fallacy of the Five-Year Survival in Lung Cancer" (McNeil et al. 1978). It revealed that when patients were offered either lung cancer surgery or radiotherapy, they often preferred the less invasive approach even when it was made clear that there would be an increased probability of long-term survival with surgical resection. It's important to note that if repeated today, this study might yield different findings. This is not only because the outcomes with surgery or radiotherapy have significantly improved since the 1970s but, as mentioned above, because the practice of reserving surgery for salvage was not commonly accepted at that time.

The dilemma of incomplete nodal staging. The omission of surgery in the upfront setting has raised concern that it might miss a critical opportunity for more accurate and earlier nodal upstaging in approximately 10–15% of patients who have a negative preoperative workup of the hilar and mediastinal lymph nodes (Pignon et al. 2008; Douillard et al. 2006). It's argued that patients who harbor occult nodal disease, detected only upon surgical staging, might therefore miss out on the 5% survival benefit at 5 years with postoperative chemotherapy that's been demonstrated in randomized clinical trials for patients with node-positive lung cancer (Pignon et al. 2008; Douillard et al. 2006). However, as many elderly patients are unable to tolerate postoperative chemotherapy, clinical models estimate that only 1 in 200 patients might benefit from a paradigm of operating on all patients to achieve more accurate nodal staging (Louie et al. 2015). That is because out of every 200 thoracotomies for stage I NSCLC, approximately 30 (15%) will be upstaged, of which only 20 (10%) will likely receive a course of adjuvant chemotherapy. These estimates are based on the NATCH randomized phase III trial where only two-third of node-positive patients received adjuvant chemotherapy after their thoracotomy (Felip et al. 2010). Among the 20 patients from this cohort who may eventually receive postoperative chemotherapy, a 5% survival benefit would translate into a single additional patient being alive at 5 years in this cohort of 200 patients. This benefit of a 0.5% survival gain at 5 years would naturally disappear if the perioperative mortality rate exceeded 0.5%. Meanwhile, by avoiding upfront surgery, more normal lung tissue can be preserved which may be important in the event that additional treatment(s) are needed when there is relapse or a secondary new lung cancer, which occurs in about 15–20% of patients after primary treatment (Pasini et al. 2003).

Treatment of Locally Advanced Disease

The diagnosis of locally advanced lung cancer is established when tumors have spread to the regional hilar and/or mediastinal lymph nodes. The 5-year survival rates in these patients are heavily dependent on the degree of lymph node burden and can range from 45% to 5% when patients present with stage II–III disease. For this reason, decisions to pursue definitive treatment can be more difficult in an elderly population given the less certain trade-offs of quality vs quantity of life. However, there are key clinical principles that can help optimize and individualize treatment selection for a given patient.

Locally advanced lung cancers are commonly treated with a combination of radiotherapy and chemotherapy. The sequence of these treatments matters, with randomized trials establishing superior local control and overall survival when the treatments are delivered concurrently (Curran et al. 2011). While this intensified approach has been shown to prolong survival, it frequently comes at an increased risk of complications in the lung, esophagus, and heart, which can be permanently debilitating at times. Disclosure of these potential risks, when shared with elderly patients, often leads to decisions for de-intensified therapies such as sequential chemotherapy before radiotherapy, radiotherapy without chemotherapy, and even best supportive care with palliative intent in up to 20% of patients with locally advanced disease (Dickhoff et al. 2016). Fortunately, strategies to reduce toxicity are

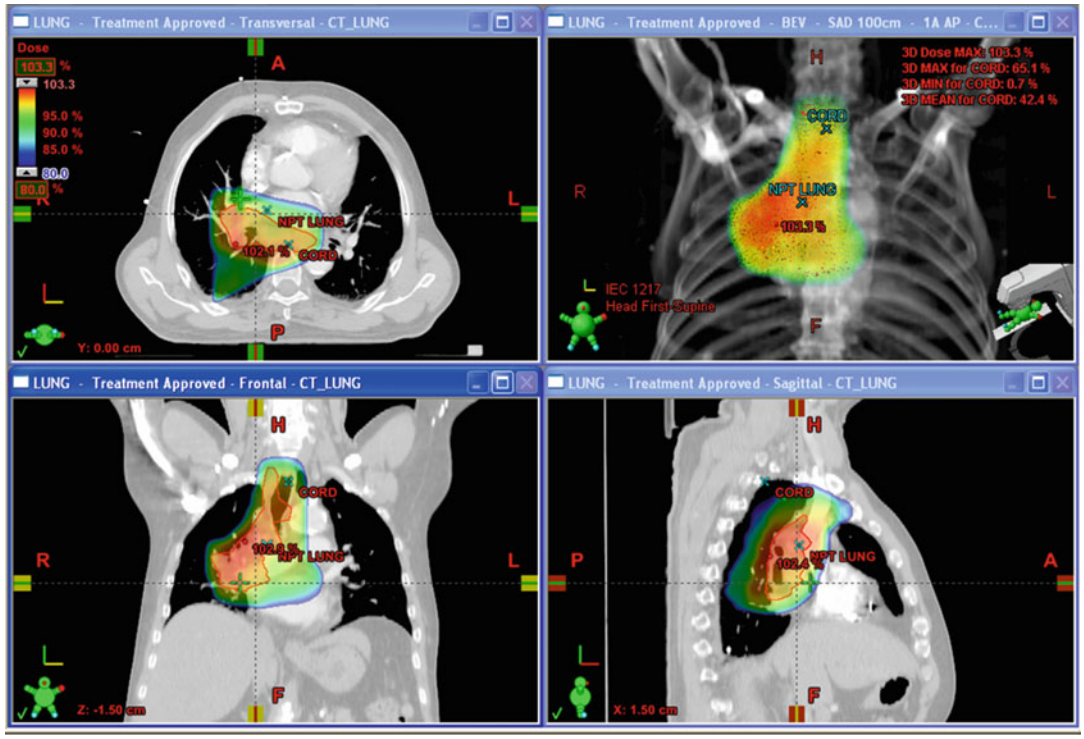

Fig. 2 This screen capture illustrates a radiotherapy treatment plan designed for a patient with locally advanced non-small cell lung cancer that has spread to multiple lymph nodes in the mediastinum. The treatment fields target the primary right perihilar mass and entire ipsilateral hilum and mediastinum. As a consequence, there is an extensive amount of esophagus in the field, and the development of treatment-related esophagitis is inevitable. The degree of esophagitis can be reduced by limiting the total dose of radiotherapy and avoiding concurrent administration of chemotherapy during radiotherapy

frequently possible depending on the tumor's size and location. These include (1) targeting only the involved site of disease (e.g., omitting elective radiation of uninvolved lymph nodes) (Rosenzweig et al. 2007), (2) limiting the total dose of radiotherapy to 60 Gy (Bradley et al. 2015), and (3) using intensity-modulated radiation therapy (IMRT) techniques to reduce the volume of normal lung, esophagus, and heart tissue exposed to therapeutic doses of radiotherapy (see Figs. 2 and 3).

Small-Cell Lung Cancer

Small-cell lung cancer (SCLC) is a more aggressive form of lung cancer and unfortunately presents more commonly at an incurable metastatic stage. However, when locally confined, it is also often controllable with concurrent chemoradiotherapy and prophylactic cranial irradiation (Miller et al. 1969). In fact, the long-term survival rates are more favorable in patients with SCLC versus NSCLC (Turrisi et al. 1999), 5-year survival exceeding 30% (Faivre-Finn et al. 2016).

Patients who are treatable with concurrent chemoradiotherapy must first be classified as having "limited stage" SCLC. This determination is made by radiation oncologists who assess whether the entire extent of disease can be safely encompassed within a tolerable radiotherapy field. As in NSCLC, radiotherapy treatment plans are commonly designed to target only the involved sites of disease (without elective coverage of uninvolved lymph nodes). The radiotherapy treatment schedule can be either twice-daily over 3 weeks or daily over 6–7 weeks, in either setting with chemotherapy. This treatment is typically followed by a short course of consolidation chemotherapy. As the blood-brain barrier can

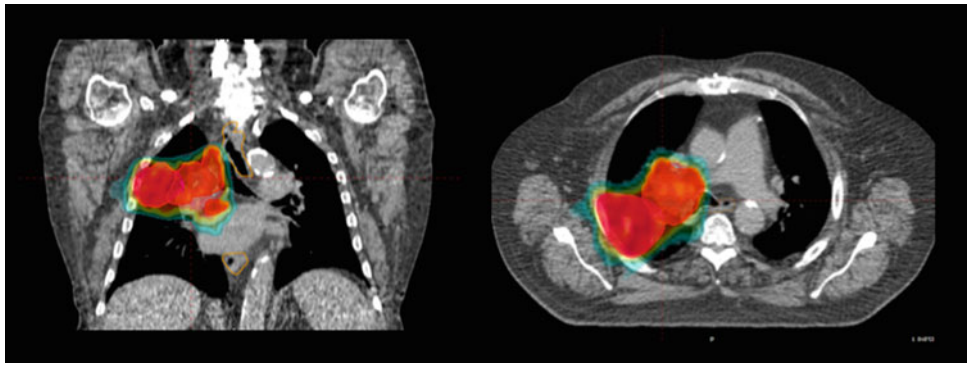

Fig. 3 This screen capture illustrates a highly conformal intensity-modulated radiation therapy (IMRT) treatment plan that avoids elective coverage of uninvolved lymph nodes. As compared to the prior figure, a shorter length of esophagus is in the field which helps minimize the degree of treatment-related esophagitis. In such a case, the concurrent administration of chemotherapy may be reasonably well-tolerated, offering a treatment that improves the probability of local tumor control and long-term survival

limit the bioavailability of chemotherapy to the brain, which is a common site of metastasis for SCLC, a course of low-dose prophylactic cranial irradiation is also routinely delivered, given its association of improved survival by an additional 5% in patients with a complete response after chemoradiotherapy (Auperin et al. 1999). When chemotherapy cannot be delivered, expectations are tempered, and radiotherapy treatment plans may often be designed with only palliative intent.

A role for surgery or SBRT in early stage SCLC. Given the aforementioned potential toxicities with concurrent chemoradiotherapy to the thorax, patients with node-negative SCLC are frequently offered a surgical resection as the definitive treatment in order to avoid the risks of radiotherapy or chemotherapy. SBRT has also been offered as an alternative to concurrent chemoradiotherapy (Stahl et al. 2017), though there are almost no direct comparisons of surgery vs SBRT for early stage SCLC to know whether there are advantages with either. Given the higher probability of occult lymph node involvement vs NSCLC, there are theoretical advantages with surgery over SBRT for early stage SCLC, if it includes a more comprehensive evaluation of the hilar and mediastinal lymph nodes. That is because SCLC has a rapid cell growth rate, and earlier detection of occult higher stage disease would expedite the appropriate adjustment of care to address a previously unrecognized locally advanced disease.

Conclusions

Elderly patients with localized lung cancer are frequently concerned about the risks of treatment and its impact on quality of life. As a consequence, many prefer observation with best supportive care. This is an approach that can lead to rapid deterioration of quality of life and premature death in patients who could have been cured with either minimally invasive surgery or radiotherapy. Each of these treatments is better tolerated than ever before and now appears to offer similar benefits. As such, a recommendation for either might be best made through an individualized approach in a multidisciplinary setting that respects patient values in a shared decision-making process (Berman et al. 2016). This is particularly important for elderly patients who are nearing the final chapters of their lives and may be no longer interested in survival at any cost.

Lung Cancer in Older Adults: Systemic Treatment

49

Elisabeth Quoix

Contents

Abstract

Lung cancer is the first cause of death by cancer throughout the entire world. Its incidence increases with age, and thus median age at diagnosis is 70 years in the USA.

As in younger counterparts, non-small-cell lung cancer represents 85% of the cases, but squamous cell carcinoma is more frequent than in younger patients. Diagnosis is often performed at an advanced stage, and thus systemic treatment is frequently to be discussed. It is only last two decades that clinical trials devoted to elderly patients have been conducted, and until recently, treatment was often suboptimal, with poor results which contributed to nihilistic attitudes among patients, relatives, and doctors.

Regarding small cell lung cancer, the doublet carboplatin-etoposide is the most frequently used in elderly patients. For non-small-cell lung cancer, targeted therapies should be used in those patients with *EGFR* or V600E *BRAF* mutations and *ALK* or *ROS1* translocations whatever the performance status (PS). For patients without targetable mutations, carboplatin-based doublet can be used as

frontline therapy in patients with PS 0–2. Regarding second-line therapy, the most frequently studied in elderly patients has been erlotinib. The role of checkpoint inhibitors in elderly patients is still not well established as the only data we have are subgroup analyses of phase III randomized trials with no age upper limit and with no specific clinical trials.

Introduction

Lung cancer remains the first cause of death by cancer throughout the world. Due to the conjunction of two factors: increased life expectancy and increased incidence of cancers with age, older patients represent now half of the patients with a median age of 70 years at diagnosis in the USA (Siegel et al. 2012). The probability of developing a lung cancer beyond 70 years of age is 1 in 15 men and 1 in 20 women compared to 1 in 44 males and 1 in 58 females between 60 and 69 years (Siegel et al. 2012). Seventy years is also the cutoff most frequently used to define older adults in clinical trials (Gridelli 2001; Gridelli et al. 2003; Pallis et al. 2010a; Quoix et al. 2011). Whereas adenocarcinoma is the main histological subtype nowadays, squamous cell carcinoma remains more frequent in older patients than in their younger counterparts probably because older patients did not use filters and smoked preferentially dark tobacco. The use of filters and Virginia (blond) tobacco results in deeper inhalations favoring the development of peripherally arising lung cancers which are adenocarcinomas, whereas cigarettes with dark tobacco and no filters yield to small inhalations favoring centrally arising lung cancers (squamous cell carcinomas) (Alberg et al. 2013). However, the role of tobacco is less important in the development of lung cancers in elderly patients, and never smokers are more frequent among them than in younger counterparts. Unfortunately at diagnosis almost half of the patients with lung cancer have already a stage IV disease (Chawla et al. 2014). Also, chemotherapy, which is the cornerstone treatment in small cell lung cancer (SCLC), plays an increasing role in the treatment of non-small cell lung cancer (NSCLC). As a matter of fact, (neo)adjuvant chemotherapy is recommended for early stage (stage IIA to IIIA) disease, chemotherapy combined to radiation therapy for inoperable NSCLC (stage IIIA or IIIB) and of course in metastatic stage (stage IV) or locally advanced stage not eligible for radiation therapy (Masters et al. 2015).

Besides chemotherapy, targeted therapies represent a considerable improvement in treatment outcomes in around 15% of Caucasians (far more in Asian people) with NSCLC who exhibit driver mutations ((*EGFR* or *BRAF V600E*) or rearrangements (*ALK* or *ROS1*)). Recently checkpoint inhibitors have been shown to be of considerable interest in second-line therapy and probably as first line (Hanna et al. 2017). Regarding immunotherapy, no specific studies have been performed in older adults.

Specific Factors Helping Therapeutic Medical Decision in Elderly Patients with Lung Cancer?

The therapeutic choice is highly dependent on histological subtype, stage of the disease, and performance status (PS) and comorbidities in patients with lung cancer. For example, chemotherapy with cisplatin + etoposide is the recommended one for SCLC combined with radiation therapy for patients with limited disease stage (LD) (Jett et al. 2013). However this treatment may not be possible in patients with cardiac or renal insufficiency which preclude the use of cisplatin. In patients with stage IV NSCLC with no oncogenic driver, a cisplatin-based doublet is recommended which is not possible in patients with PS2. Thus PS is a very important decisional factor. However, in older adults, PS is not sufficient to predict the outcome of the patients, and this has been shown in several studies (Repetto et al. 2002; Maione et al. 2005). Also physiologic changes in organ function with age

do not allow, for example, the use of cisplatin in older adults. The decline of hematopoiesis may be responsible for greater hematological toxicity of chemotherapy and supports the use of hematopoietic factors which are equally efficacious in older patients (Balducci and Carreca 2002). Comorbidities (assessed usually with Charlson index) are generally speaking more frequent in elderly patients especially those linked with tobacco use and have important consequences on medical decision (Mellemgaard et al. 2015). Polymedication is also frequent in older adults because of comorbidities and addition of self-prescribed over-the-counter drugs which are not reported to the doctors (Lees and Chan 2011). This polymedication may result in interactions with systemic treatment of lung cancer inducing more toxicity and/or less efficacy.

A comprehensive geriatric assessment (CGA) is time-consuming and may not be easily feasible in a nongeriatric environment. Simplified geriatric scores have been developed such as VES-13 and G8 (Soubeyran et al. 2014) and can be used in nongeriatric departments although their sensitivity and moreover their specificity are not optimal (Hamaker et al. 2012). After geriatric assessment, older patients may be classified into three groups (Balducci and Extermann 2000). The first group is made up of patients with no serious comorbidity, who may be treated in the same way as younger patients. Group 2 is made up of patients with dependent instrumental activity daily living (IADL) and a few comorbidities. If the patients' problems are reversible, they may be treated in the same way as Group 1 patients. If they are irreversible, patients must be treated with special precautions, and dose and/or number of drugs reductions should be considered. Group 3 includes patients who are dependent, with severe comorbidities and geriatric syndromes. These patients should receive supportive care only.

However, at least two clinical trials have shown that geriatric indexes may be of prognostic value but that they have no predictive value (Quoix et al. 2011; Corre et al. 2016). Thus, the systematic use of geriatric indexes besides PS is still subject of debate.

Representativity of Elderly Patients in Clinical Trials

Older patients are underrepresented in clinical trials, and their proportion does not reflect at all the frequency of elderly patients with a given cancer (Talarico et al. 2004) This was still the case in a later review (Sacher et al. 2013). As a matter of fact, elderly patients have not been the subject of much research until the end of the 1980s. At the best, they were not excluded from clinical trials (those with no upper limit of age) or partially excluded (when an upper limit was defined, generally speaking 75 years). Even when there was no upper limit defined, most of the elderly patients included were between 70 and 75 years old (Sacher et al. 2013). Moreover, stringent inclusion criteria in those trials designed for a majority of younger patients lead to a selection of the elderly patients included and prevent of any generalizability of the results.

The first phase III study devoted to elderly patients with advanced NSCLC was published in 1999 and compared a single agent therapy vinorelbine to best supportive care in patients aged 70 years and more (Gridelli 2001). Since this study, to the best of our knowledge, only seven phase III studies performed in elderly patients with metastatic stage NSCLC were published (Frasci et al. 2000; Gridelli et al. 2003; Kudoh et al. 2006; Quoix et al. 2011; Abe et al. 2015; Tsukada et al. 2015; Corre et al. 2016), and one is ongoing in SCLC (Eba et al. 2015).

Systemic Treatment in Small Cell Lung Cancer

There have been very few studies conducted in elderly patients with small cell lung cancer, and most of them combined elderly patients and patients with poor performance status. Too many elderly patients either receive no chemotherapy but radiation therapy alone or best supportive care. In the SEER database analysis from 1992 to 2001 (Caprario et al. 2013), more than 20% of the patients aged 65 years or more did not receive chemotherapy.

The chemotherapy recommended in patients with SCLC was not modified since the 1980s and consists in four to six cycles of the combination of a platin salt with etoposide (Jett et al. 2013). The platin salt can be either cisplatin (for fit patients) or carboplatin for PS2 and/or elderly patients. Among the phase II studies devoted to elderly patients, one analyzed the PAVE combination (four cycles of intravenous cisplatin 30 mg/m^2, doxorubicin 40 mg/m^2, vincristine 1 mg/m^2, and etoposide 100 mg/m^2 on day 1 and oral etoposide 100 mg/m^2 on day 3 and 5) in patients aged more than 65 years (median age was 72 in LS, 69 in extensive disease stage (ED) meaning that in fact there were no very old patients). Radiation therapy was delivered concomitantly for LD patients (suppression for one cycle of doxorubicin and vincristine). Median survival was 70 weeks for LD patients and 46 weeks for ED patients (Westeel et al. 1998).

Some randomized phase II or III studies have been performed comparing a lower intensity regimen (either reduced doses of combination chemotherapy schemes (Ardizzoni et al. 2005) or single agent with standard doses (Souhami et al. 1997) regimen). Again these randomized trials were not specifically devoted to elderly patients, although they represented the majority, but also to younger patients with poor PS. In the trial comparing full dose of cisplatin + etoposide (EP) to low dose of the same combination (Ardizzoni et al. 2005), median age was 73 with a range between 70 and 80 years, meaning that the use of cisplatin prevented inclusion of very old patients with standard doses regimen. In the second trial, oral etoposide was compared to standard EP alternating with cyclophosphamide, adriamycin, and vincristine. In both studies, the outcomes were poorer in the attenuated regimens with only small reduction of toxicity.

These trials are quite old reflecting that studies regarding SCLC and moreover SCLC in elderly, are very sparse.

A phase III study comparing EP to carboplatin etoposide was performed in 220 patients with ED (Okamoto et al. 2007). Ninety-two percent of the patients were ≥70 years old with a PS of 0–2, whereas 8% of the patients were less than 70 years old with a PS of 3. In this study, median age was 74 years (range 55–86, indicating that there were quite a number of very old patients included); there was no difference regarding the response rate, progression-free survival (PFS), or overall survival (OS). Toxicity was also similar except for thrombocytopenia grade 3 or 4, which was more frequent in the carboplatin arm. Despite this study, finally the combination of carboplatin + etoposide is the best studied through a number of phase I–II studies (Quoix et al. 2001; Larive et al. 2002; Fukuda et al. 2006) and is the one recommended for the treatment of SCLC in elderly patients.

Systemic Treatment in NSCLC

Adjuvant Chemotherapy

Adjuvant chemotherapy is recommended for stage II and III disease after complete resection and nodal dissection.

In a systematic review (Cochrane database), 35 trials were identified which evaluated surgery plus adjuvant chemotherapy versus surgery alone (Burdett et al. 2015) There was a clear benefit of adding chemotherapy after surgery with a hazard ratio (HR) of 0.86 (95% CI 0.81–0.92) with an absolute increase of survival of 4% at 5 years. There was no significant effect of age in this review, and patients older than 70 years derived a similar benefit. However, again, there is no specific trial for older patients, and thus there was a selection bias of those patients included in the clinical trials.

The recommendations are to perform adjuvant chemotherapy in patients with stage II and IIIA disease (seventh classification) (Pisters et al. 2007), and the most frequently used chemotherapy scheme in the various clinical trials was cisplatin + vinorelbine. In the lung adjuvant cisplatin evaluation (LACE) meta-analysis, a specific analysis of the effect of cisplatin-based chemotherapy was performed according to various categories of age (Fruh et al. 2008). Only 9% of the patients were aged 70 or more (414 among 4584 patients included in five clinical trials comparing

surgery + cisplatin-based doublet to surgery alone). The HR was 0.86 (95% CI 0.78–0.94) for patients aged below 65 years, 1.01 (95% CI 0.85–1.21) for the category of patients aged 65–69, and 0.90 for elderly patients (95% CI O.70–1.16). The elderly patients received significantly less cycles of adjuvant chemotherapy and significantly less cisplatin dose. Although the HR is proximal to that observed in younger counterparts, the upper limit of the CI is above 1. Thus, there is an uncertain benefit for this category of patients. Moreover, almost no patients were aged more than 75 years.

Locally Advanced NSCLC

The standard treatment of locally advanced NSCLC is chemoradiation therapy as shown by meta-analysis of various clinical trials comparing radiation therapy to chemoradiation therapy (Non-small Cell Lung Cancer Collaborative Group 1995). It has also been shown that concurrent chemoradiation therapy is of benefit compared to sequential chemoradiation therapy (Auperin et al. 2010).

Whether this applies to elderly patients remains controversial as there are very limited data regarding chemoradiation therapy for locally advanced NSCLC in patients aged 70 or more. Moreover in two retrospective analyses of the SEER database and the veterans affairs cancer registry (Wang et al. 2012), around 35% of patients aged 65 or more did not receive any treatment. To the best of our knowledge, there is no specific randomized trial addressing elderly patients.

Based on the results of retrospective subgroup analyses of randomized trials including patients with no upper limit of age, the advantage of the combination of chemotherapy and radiotherapy over radiotherapy alone in elderly patients is debatable. A subgroup analysis of the Radiation Therapy Oncology Group (RTOG), ECOG, and Southwest Oncology Group (SWOG) randomized trial comparing sequential chemoradiotherapy with radiotherapy alone showed that the best median survival was observed with radiotherapy alone in patients >70 years (Yuen et al. 2000) In this study, only 50 among 381 patients (13%) were 70 years and more. In the randomized phase III trial of the Hoosier Oncology Group LUN 01-24 (Jalal et al. 2012), chemotherapy (cisplatin 50 mg/m^2 on days 1, 8, 29, and 36 and etoposide 50 mg/m^2 on days 1–5 and 29–33) and chest radiation consisting in 1.8 Gy daily, 5 days a week for a total of 25 fractions (45 Gy) to the primary tumor and mediastinum from day 1, followed by a boost to the primary tumor and to enlarged regional lymph nodes (1.8 Gy/day in eight fractions) were delivered to all patients. Those without evidence of progression and a PS 0–2 were then randomized to observation or consolidation docetaxel (75 mg/m^2 IV every 3 weeks for three cycles). A total of 243 patients were included between 2002 and 2006, and 166 were randomized. Elderly patients were defined as patients aged 70 years or more. Of the 242 patients included in the survival analysis, 64 were ≥70 years of age (26%). Elderly patients included 42 patients between 70 and 74 years, 17 patients between 75 and 80 years, 4 between 80 and 85 years, and 1 patient >85 years. There was no benefit of consolidation docetaxel, on the whole population and in the different age subgroups. Median and 3-year overall survival from baseline was 17.1 months (95% CI: 10.9–28 months) and 21.8% (95% CI: 11.1–34.8) in patients ≥70 years and 22.8 months (95% CI: 18.6–28.3 months) and 34% (95% CI: 26–42%) in patients <70 years, respectively ($p = 0.1461$). There was no difference in PFS according to age. During induction chemoradiation, there was a significantly higher rate of grade 3 and 4 toxicities in elderly patients (87% vs. 73%, $p = 0.02$). Among grade 3 and 4 non hematological toxicities, there was a non-significant excess of esophagitis (22% vs. 15%), infections (13% vs. 6%), and asthenia (17% vs. 6%) but a significant increase of dehydration (17% vs. 6%, $p = 0.008$) and anorexia (8% vs. 2%, $p = 0.03$). Among grade 3 and 4 hematological toxicities, elderly patients experienced significantly more neutropenia (56% vs. 39%, $p = 0.02$). Hospitalization was significantly more frequent in elderly patients (45% vs. 32%; $p = 0.03$). There was no increase in toxic deaths according to age.

[a]Global percent or median survival time for the two arms together

[b]401 patients aged > = 65 years

[c]Response rate by categories of age, the three arms being combined: <70 years, 70–74 years, 75–79 years, 80, and more

[d]Median survival and 1-year survival rate by same age categories, the three arms being combined: significant difference between 70 and 74 years and over

In this trial, elderly patients included were highly selected, and in the absence of studies devoted to elderly patients with locally advanced disease, combination of chemotherapy with radiation therapy should be carefully monitored in these patients. Possibly sequential chemoradiation therapy would be an acceptable alternative.

Systemic Treatment in Stage IV Disease

Chemotherapy

We have some data from randomized trials with no upper limit of age (Langer et al. 2002; Lilenbaum et al. 2005; Belani and Fossella 2005b; Blanchard et al. 2011; Ansari et al. 2011). These randomized trials are displayed on Table 1.

In those trials, either several platin-based doublets were compared between them (with mostly similar outcomes in elderly and younger counterparts, except for one study (Blanchard et al. 2011), or platin-based doublet was compared to single agent therapy in two studies dedicated to PS2 patients, the first one comparing paclitaxel alone versus carboplatin + paclitaxel (Lilenbaum et al. 2005) in 205 patients, among which 74 patients were more than 70 years old, and the second one comparing pemetrexed to carboplatin + pemetrexed in PS 2 patients with 74 among 205 being 70 years old or more (Zukin et al. 2013). In the first study, there was no benefit of survival with the doublet compared to single agent therapy, and there was no difference regarding OS between elderly patients and younger counterparts. In the second study, there was a benefit of survival in favor of the doublet in the whole population of patients and also in the elderly patient subgroup (Table 2).

However, as said above, elderly patients included in clinical trials designed for adults aged over 18 years are highly selected, and thus the results cannot be transposed to the general population of patients.

Dedicated studies for elderly patients are not so numerous. The first one was conducted by Gridelli and included 154 patients aged 70 years and more with stage IV NSCLC (Gridelli 2001). These patients were randomized between

Table 2 Phase III trials of chemotherapy dedicated to older patients with advanced NSCLC

vinorelbine and best supportive care (BSC). There was a very significant benefit of survival in the vinorelbine arm (median OS of 28 weeks vs. 21 weeks; 1-year survival rate of 32% vs. 14%). Following this trial, a randomized study performed by the Italian group SICOG in 120 patients compared vinorelbine to the combination of vinorelbine and gemcitabine (Frasci et al. 2000). Median OS was 29 weeks in the combined arm versus 18 weeks in the vinorelbine alone arm. Surprisingly the median survival time with the doublet was that obtained in the Gridelli's study with vinorelbine alone, and the result with vinorelbine alone was about the same as observed in the best supportive care of Gridelli's study (Gridelli 2001). A larger randomized study was performed by the Multicenter Italian Lung Cancer in the Elderly Study (MILES) group in Italy comparing vinorelbine alone to gemcitabine alone and to the combination of the two drugs (Gridelli et al. 2003). A total of 700 patients were included, and there was no benefit of the doublet compared to either drug alone. In a Japanese study, vinorelbine was compared to docetaxel (Kudoh et al. 2006). Although the differences in response rate and survival were not significant (median OS of 9.9 months in the vinorelbine arm and 14 months in the docetaxel arm, response rate 9.9% vs. 22.7%), there was a numerical advantage in favor of docetaxel.

Following these trials, the recommendations published in 2010 (Pallis et al. 2010b) were to treat elderly patients with a single agent.

Two Japanese trials compared platin-based chemotherapy to docetaxel. In the first one, weekly docetaxel was compared to cisplatin plus docetaxel in 126 patients with a median age of 76 years (range 70–88) (Tsukada et al. 2015). This trial was prematurely closed on ethical grounds because in the age category, 70–74 docetaxel was found not to be an appropriate control arm. The second Japanese study (Abe et al. 2015) compared weekly docetaxel plus cisplatin to docetaxel every 3 weeks and was also prematurely closed after inclusion of 276 patients with a median age of 76 (range 70–87). After the first interim analysis, the probability that the doublet would be of benefit compared to the single agent was less than 1%, and thus the study was closed. Median OS was 14.8 months for the single agent arm and

13.3 months for the doublet with a HR of 1.18 (95% CI 0.83–1.69).

The French Intergroup of Thoracic Oncology (IFCT) conducted a randomized trial comparing monthly carboplatin + weekly paclitaxel to either gemcitabine or vinorelbine alone in 451 patients (Quoix et al. 2011) with a median age of 77 (range 70–89). There was a significant increase of PFS duration in the doublet arm compared to the monotherapy arm (6.1 months vs. 2.8 months) and of median OS (10.3 months vs. 6.2 months) with a 1-year probability of survival of 44.5% versus 24.5%. This benefit was obtained at the expense of increased toxicity grade 3–4 toxicity, especially hematologic, in the doublet arm illustrating the fact that careful monitoring of elderly patients is needed. Although there were also more toxic deaths in the doublet arm (4.4% compared to 1.4% in the monotherapy arm), the difference was not significant, and despite this, the rate of early death (within 3 months) was by far inferior in the doublet arm (16.4%) compared with the single agent arm (26.5%). Moreover, the survival benefit was observed in all subgroups (PS 0–1 and PS2, patients aged 70–80 and those >80 years, those with a body mass index <20 or >20, those with a stage III not amenable to irradiation and stage IV, those patients with a normal activity daily living index (ADL), and those in which the ADL was <6). The only factor for which there was no significant benefit of the doublet was the mini-mental score (MMS). When lower than 24, there was no benefit observed with the doublet. However, very few patients had a MMS <24.

Following this study, the recommendations regarding treatment of elderly patients with advanced stage were modified (Ganti et al. 2012) in favor of the use of carboplatin + weekly paclitaxel doublet whenever possible.

Should the treatment be decided upon a comprehensive geriatric assessment or according to standard factors (PS)? This question was the subject of a French randomized trial (Corre et al. 2016) in which the treatment allocated was decided either according to the PS and age (carboplatin-based doublet if PS 0–1 or age >75) or according to CGA (carboplatin-based doublet for fit patients, docetaxel for vulnerable patients, and BSC for frail patients. There was less toxicity in the CGA arm (but also more patients receiving only BSC) but no improvement of survival.

Maintenance therapy (continuation with pemetrexed or switch maintenance with pemetrexed) after four cycles of induction is now recommended in patients with stage IV NSCLC (Azzoli et al. 2011), but this has not been specifically studied in elderly patients. A post hoc subgroup analysis of 92 patients older than 70 years in the PARAMOUNT study (Gridelli et al. 2014) of continuation maintenance by pemetrexed (median age 73 compared to 60 years in the 447 patients less than 70 years old) showed similar benefit in PFS but no benefit in survival and higher rates of grade 3–4 hematologic toxicities with more hospitalizations and transfusions. A randomized trial comparing in patients older than 70 years maintenance therapy versus no maintenance after four cycles of monthly carboplatin and weekly paclitaxel conducted by the IFCT has just been completed with the inclusion of 522 patients, and results are pending.

Targeted Therapies

The frequency of driver mutations differs between Asian and Caucasians people but also with age. For example, ALK rearrangement in NSCLC is observed in patients with younger age than *BRAF* mutations. Driver mutations are observed in still a minority of Caucasian patients with NSCLC, but they are important to detect because of the development of targeted therapies. *EGFR* mutations are observed in about 11% of patients, *ALK* rearrangements in 4.8%, and V600E *BRAF* mutations in 1.8% as reported by the IFCT in a 1-year recruitment of near 18,000 patients (Barlesi et al. 2016). Median age of the whole population of patients analyzed was 64.5 years, range 18–98. Median ages of patients with *EGFR* mutation, *ALK* rearrangement, and V600E *BRAF* mutation were, respectively, 68.4, 61.2, and 65.9 meaning that, globally, targetable mutations or rearrangements are probably found in the same proportion of elderly and young patients.

Age should not preclude the use of targeted therapies as, although again, there are no dedicated phase III studies for elderly; subgroup analyses of the trials comparing tyrosine kinase inhibitors (TKI) to chemotherapy show that similar outcomes are obtained in elderly and younger patients (Minuti et al. 2015). In a phase II study (Inoue et al. 2015) performed in 32 patients aged >75 years with a median age of 80 years, whose tumor harbored *EGFR* mutations, response rate with erlotinib was 56.3% (95% CI 39.4–72.0%), and the disease control rate was 90.6% (95% CI 75.2–97.6%). Median progression-free survival was 15.5 months (95% CI 11.2 not reached). These results are quite similar to those obtained in younger counterparts with the same mutation.

Regarding patients without driver mutation, it has been shown that erlotinib was of interest as second-line therapy compared to BSC in the Canadian BR21 trial (Shepherd et al. 2005). Again there was no specific study devoted to elderly patients. However in the trial comparing carboplatin + weekly paclitaxel to weekly paclitaxel, second-line therapy was to be erlotinib in those patients whenever possible (Quoix et al. 2014). Erlotinib could be given to nearly 65% of the patients included in this trial, and the outcomes regarding PFS and overall survival were quite similar to those obtained in the BR 21 study (Shepherd et al. 2005). As a matter of fact, a subgroup analysis in this study of patients aged 70 or more showed similar outcomes than their younger counterparts (Wheatley-Price et al. 2008). Thus, erlotinib as second-line therapy could be considered in elderly patients with no driver mutations, although immunotherapy with checkpoint blockers might modify the paradigm (see below).

Bevacizumab has been shown to provide survival benefit in patients with stage IV disease of non-squamous cell carcinoma (Sandler et al. 2006) or only PFS benefit in the AVAIL study (Reck et al. 2010). A subgroup analysis of patients aged 65 or more in the AVAIL study showed similar benefit for these patients compared to younger counterparts (Leighl et al. 2010), but median age of this subgroup of patients was only 68 years. In a preplanned subgroup analysis of patients aged 65 and more in the single arm study assessing the safety and efficacy of first-line bevacizumab in combination with standard chemotherapy in 2212 patients, it was also shown that these patients with a mean age of 70.6 years had similar outcomes as their younger counterparts (Laskin et al. 2012). Another study using the cutoff of 70 years analyzed the outcomes of the patients aged 70 years and more in the Sandler study (Ramalingam et al. 2008) and found increased response rate, a trend toward longer PFS but no OS benefit and more severe toxicities. Thus, one should be very cautious regarding the use of bevacizumab in patients aged 70 years or more.

Immunotherapy

This point is of utmost importance as the increased incidence of cancers in elderly may be at least partly due to immune dysfunction (Ferrara et al. 2017). There is a reduced proliferative activity, reduced effector function, and reduced cytotoxic activity of T cells but also decreased numbers or impaired function of dendritic cells (DCs) and also decreased expression of the co-signaling molecules (CD80 and CD86) on aged DCs, which may contribute to the reduced capacity for T cell stimulation by DCs during aging (Tomihara et al. 2013). All these facts may lead to less efficacy of immune checkpoint blockers in elderly patients. Unfortunately, at this time, there have been no specific studies for elderly patients. Most of our knowledge regarding the potential benefit of immune checkpoint blockers in elderly patients with stage IV NSCLC comes from subgroup analyses from the majority of randomized clinical trials without upper limit of age. These trials (Borghaei et al. 2015; Brahmer et al. 2015) are those comparing nivolumab to docetaxel as second-line therapy and pembrolizumab to docetaxel (Herbst et al. 2016) as second-line therapy. Table 3 shows the age characteristics of the patients included in various randomized second-line trials with immune checkpoint blockers.

The updated recommendations of ASCO are now to use nivolumab or pembrolizumab or atezolizumab (according to the level of expression

Table 3 Phase III trials of checkpoint blockers in second line or first line

Trial	1st/2nd line	Median age range	Nb (%) of pts aged >75	HR for OS 65–74 >75
Non-squamous (Checkmate 057) docetaxel vs. nivolumab	2nd	62	43	0.63 (0.45–0.89)
		21–85	(7%)	0.90 (0.43–1.87)
Squamous (Checkmate 017)	2nd	63	29	0.56 (0.34–0.91)
Docetaxel vs. nivolumab		39–85	(11%)	1.85 (0.76–4.51)
Keynote-010 docetaxel vs. pembrolizumab	2nd	63	?	?
		?		?
Docetaxel vs. atezolizumab	2nd	64	(>65) 397	(>65)
		34–85	(46,7%)	0.66 (0.52–0.83)
Keynote-024 pembrolizumab vs. chemotherapy	1st	64.5	?	(HR for PFS <65/> = 65)
		33–90		0.61 (0.40–0.92)
				0.45 (0.29–0.70)

of PD-L1) as second-line therapy after the use of a platin-based doublet (Hanna et al. 2017). There is no specific recommendation for elderly patients, but at least until 75 years old, the same positive results were observed, and thus they should not be denied to receive this therapy.

Conclusion

Systemic treatment of elderly patients with small-cell lung cancer consists in carboplatine + etoposide 4 to 6 cycles. Whenever mediastinal radiation therapy, is indicated, it will be performed rather sequentially (after induction chemotherapy) than concomitantly.

Regarding non-small cell lung cancer, like in small-cell lung cancer, carboplatine should be used instead of cisplatin whenever a platin-based doublet is to be given. We should be very cautious with adjuvant therapy because of the absence of dedicated studies (only subgroup analyses). After 75 years, adjuvant chemotherapy should not be routinely given. For locally advanced disease, again, chemoradiation therapy should be given rather sequentially than concomitantly with careful monitoring.

For metastatic stage, if there is no driver mutation and PS is 0-2, the doublet monthly carboplatine + weekly paclityaxel is the reference with 4 cycles to be delivered. At this time, there is no published results regarding maintenance therapy in the elderly but results of the trial by IFCT studying this aspect will be presented at ESMO 2018. In case of driver mutation or rearrangement, targeted therapies can be used whatever the PS.

Regarding checkpoint inhibitors, there is no dedicated study for elderly patients although they could be included in all trials as well regarding first line or second line therapy. Taking into account the possible impact of what is called immunosenescence, dedicated studies for elderly patients are urgently needed.

Abstract

Primary tumors of the central nervous system (CNS) comprise a broad variety of neoplasms with specific patterns of age distribution, pathological and molecular genetic features, and outcome. Major recent advances in understanding the molecular pathogenesis of many primary CNS tumors have resulted in a revision of the World Health Organization (WHO) classification of brain tumors in 2016. Secondary CNS tumors are represented by brain and leptomeningeal metastases and are more common than primary CNS tumors. The most common primary CNS tumors, glioblastomas and

meningiomas, are particularly common in the elderly. Notably glioblastomas in the elderly carry a very poor prognosis. Similarly, secondary CNS tumors are common in the elderly since they reflect the increasing risk of systemic cancer with advanced age. Multimodality treatment with its increasing complexity regarding drug interactions and comorbidity-associated risk of toxicity poses specific challenges in the elderly.

Keywords
Elderly · Age · Comorbidity · CNS · Brain · Leptomeningeal metastases · Glioma · Glioblastoma

Introduction

Tumors of the central nervous system (CNS) can be primary CNS tumors originating from cells of the CNS or secondary tumors originating from primary cancers of extra-CNS origin. Secondary CNS tumors, that is, brain and leptomeningeal metastases, are probably five to ten times more common than primary CNS tumors.

Primary CNS tumors are very diverse in terms of morphology, molecular genetic landscape, and outcome. They are classified primarily by morphological criteria based on presumed cell of origin and are assigned a grade of malignancy from I to IV according to assumed natural course of disease. The new World Health Organization (WHO) classification of brain tumors has introduced also molecular markers to aid in defining more homogeneous disease entities, specifically changing the approach to gliomas of adulthood (Louis et al. 2016). Moreover, primary CNS tumors show very distinct profiles of age-dependent incidences: some tumors like medulloblastomas or pineal parenchymal tumors are typical tumors of childhood where primary CNS tumors are common and a major cause of morbidity and mortality. In contrast, some of the most frequent primary brain tumors, glioblastoma and meningioma, have their highest incidence in the elderly (Table 1) (Ostrom et al. 2015). Thus, the annual incidence rate for glioblastoma is 15.24 in the age group of 75–84 years as opposed to 1.21 in the age group of 35–44 years. Similarly, meningiomas are very common with a 39.11 annual incidence rate in the age group of 75–84 as opposed to 5.16 in the age group of 35–44.

Moreover, age is a strong negative prognostic factor for most primary CNS tumors (Table 2). Age-dependent differences in survival are particularly prominent in diffuse astrocytomas: 2 years survival is 85.2% versus 10.8% in patients aged 20–44 as opposed to older than 75, and 10 years survival is 80.3% versus 2.0% in the same age groups. Similarly, 2 years survival is 37.6% from 20 to 44 years as supposed to 3.3% in glioblastoma patients aged more than 75 years. Outcome differences by age are less prominent but still remarkable for meningioma with 2 and 10 years survival rates of 95.4% versus 55.3% and 82.2% versus 36.3% in the age groups of 20–44 years versus more than 75 years.

The reasons for inferior outcome in elderly patients with CNS tumors are probably manifold: there may be reduced tolerance of therapeutic interventions, physicians' bias toward undertreatment, differential response to therapy, potentially related to immunosenescence, and distinct molecular genetic differences which cause a more aggressive clinical behavior of some tumors in the elderly. Clinical trial data on elderly patient populations with primary brain tumors are sparse since advanced age was often an exclusion criterion in clinical trials, or, if this was not the case, exclusion of various comorbidities reduced the proportion of elderly patients.

History, Clinical Presentation, and Clinical Findings

Brain tumors may become clinically apparent either by symptomatic epileptic seizures, by headaches, by progressive focal neurological deficits, or by chronic organic mental changes. The type of clinical presentation largely depends on tumor location and on whether tumors grow as a circumscribed mass or primarily as an infiltrative, locally destructive lesion. Non-infiltrative lesions

like most meningiomas can grow to large lesions and typically cause symptoms and signs of raised intracranial pressure, whereas destructive lesions such as glioblastomas cause focal deficits resulting from impaired function of the affected brain region. Some benign tumors such as meningiomas may be diagnosed as incidental findings when neuroimaging is conducted for other reasons.

There are few considerations that specifically apply for elderly patients. Because of less brain volume and less tendency for lesion-associated edema formation, tumors may grow to larger volumes before being detected. Moreover, subtle mental changes are more likely to be interpreted as symptoms of aging or age-associated neurodegenerative or vascular disease. Delayed diagnoses are particularly common in patients with preexisting diagnoses of multiple strokes or Alzheimer's or other dementive disease.

Diagnostic Strategies

There are no specific diagnostic strategies for elderly patients suspected of having a brain tumor except that repeat neuroimaging must be considered in patients with diagnoses of other neurological diagnoses who exhibit decline or novel symptoms, as outlined above. Cerebral magnetic resonance imaging (MRI), without and with contrast enhancement, is the gold standard of diagnosis of brain or spinal tumors (Wen et al. 2010; Weller et al. 2017). Computed tomography (CT) scans are only indicated if there are contraindications for MRI or in an emergency setting when MRI may not be feasible. There is only a limited role for cerebrospinal fluid (CSF) studies in elderly patients with suspected primary brain tumors because tumors which seed via the CSF are largely restricted to the pediatric and young adult population, e.g., medulloblastomas, pineal parenchymal tumors, and ependymomas. In contrast, CSF studies to rule out leptomeningeal metastasis are often indicated in patients with documented solid brain metastasis or patients with metastatic cancer who develop unexplained neurological symptoms and signs.

Primary Brain Tumors

Gliomas

Gliomas are the most common malignant primary brain tumors in adults. Their diagnostic assessment has been improved in the 2016 WHO classification; while there are still increasing grades of malignancy from WHO grade I to IV, two molecular markers, isocitrate dehydrogenase mutation and 1p/19q codeletion, have now been integrated and redefine three major classes of non-ependymoma gliomas in adulthood: (i) isocitrate dehydrogenase mutant and 1p/19q-codeleted gliomas which are typically oligodendroglial in morphology and carry a favorable prognosis, (ii) isocitrate hydrogenase mutant and 1p/19q-non-codeleted gliomas with dominantly astrocytic morphology and intermediate prognosis, and (iii) isocitrate dehydrogenase nonmutant tumors which are mostly glioblastomas, typically associated with chromosome 7 gains and losses on chromosome 10, advanced age, and poor outcome (Louis et al. 2016; Weller et al. 2015).

Higher age alone is a major negative prognostic factor in patients with diffuse gliomas of WHO grades II–IV (Table 2). In fact, even grading loses its prognostic significance somewhat in the elderly since also WHO grade II and III gliomas are typically associated with poor outcome in the elderly (Hartmann et al. 2010; Wick et al. 2012). The reasons for the profound association of age with outcome have not been fully elucidated. Isocitrate dehydrogenase mutations which define a less aggressive group of gliomas are virtually absent in elderly patients with anaplastic gliomas and glioblastomas (Hartmann et al. 2010). Efforts at defining further molecular signatures that are characteristic of gliomas in the elderly and indicative of poor outcome have not met with great success: there is an increase of classical (receptor tyrosine kinase II, RTK II) and mesenchymal glioblastoma subtypes (Sturm et al. 2012), and transcriptomic analyses based on The Cancer Genome Atlas (TCGA) have revealed age-associated hypermethylation of polycomb group protein target genes as well as

increased expression of angiogenesis-related genes in the elderly (Bozdag et al. 2013).

Age is commonly considered a relevant factor when selecting the most appropriate treatment for patient with gliomas. Wait-and-see strategies are felt to be appropriate for selected younger patients with WHO grade II gliomas notably after macroscopically complete resection, but almost never considered in elderly patients with diffuse glioma of any grade (Weller et al. 2017).

Concomitant and maintenance TMZ chemotherapy plus RT (TMZ/RT→TMZ) became the standard of care in the management of adult patients newly diagnosed with glioblastoma and good general and neurological condition in 2005, with enrolment in the pivotal study limited to patients aged up to 70 years (Weller et al. 2017; Stupp et al. 2005, 2009). An ensuing trial was conducted by NCIC and EORTC focused on patients aged 65 years or more and explored whether the combination of TMZ with hypofractionated RT of 40 Gy delivered in 15 fractions was superior with regard to overall survival, too. Since this was the case (Table 3) (Perry et al. 2016), unlike previous assumptions based on subgroup analysis of the registration trial of 2005 (Stupp et al. 2005), age seems not to modulate the benefit of TMZ when added to RT in the treatment of newly diagnosed glioblastoma.

Methylation of the promoter region of the O6-methylguanine DNA methyltransferase (MGMT) gene has long been identified as a predictor of benefit from alkylating agent chemotherapy in glioblastoma (Hegi et al. 2005; Weller et al. 2010). This observation, combined with the notion that combined modality treatment may not be appropriate for many elderly or frail patients, led to the design of two clinical trials performing a head-to-head comparison of RT alone versus TMZ alone in the elderly, NOA-08 and Nordic (Wick et al. 2012; Malmström et al. 2012). Both trials indicated that patients with tumors without MGMT promoter methylation should not be treated with TMZ alone but that TMZ alone is superior to RT alone if tumors exhibit MGMT promoter methylation. Accordingly, the guideline of the European Association for Neuro-Oncology (EANO) defined testing for MGMT promoter methylation as standard of care in the elderly and advocated clinical decision-making based on MGMT status in the elderly (Weller et al. 2014). In the absence of information on MGMT status, RT should be preferred since MGMT promoter methylation is less frequent with approximately a third of tumors and since the efficacy of RT is clearly superior to TMZ in patients with tumors lacking *MGMT* promoter methylation. The recent NCIC EORTC trial reported benefit from TMZ also in patients with tumors without MGMT promoter, yet MGMT status data were available only in a subgroup of selected patients which explains the observation that survival was longer in MGMT promoter unmethylated patients than in the overall study population (Table 3). Accordingly, the upcoming update of the EANO guideline proposes to use TMZ/RT→TMZ in patients with MGMT promoter methylated tumors if feasible but to

Table 3 Outcome with RT versus TMZ/RT→TMZ in elderly glioblastoma patients (Perry et al. 2016)

		PFS	HR/p	OS	HR/p
All patients					
RT	$n = 281$	3.9 (3.5–4.3)	0.5	7.6 (7–8.4)	0.67
TMZ/RT→TMZ	$n = 281$	5.3 (4.6–6.2)	<0.0001	9.3 (8.3–10.3)	<0.0001
MGMT promoter not methylated					
RT	$n = 96$	4.4 (3.9–4.9)	0.79	7.9 (6.9–10)	0.75
TMZ/RT→TMZ	$n = 93$	4.8 (4.3–5.6)	0.12	10 (8.3–10.7)	0.055
MGMT promoter methylated					
RT	$n = 77$	3.9 (3–4.6)	0.33	7.7 (5.8–10.7)	0.53
TMZ/RT→TMZ	$n = 88$	7.9 (6.4–9.9)	<0.0001	13.5 (10.2–15.3)	0.0001

continue to view RT alone standard of care in elderly (≥70 years) or frail patients with tumors without MGMT promoter methylation (Weller et al. 2017).

Meningiomas

Meningiomas are overall the most common intracranial tumors, and the risk of developing a meningioma is strongly age-associated, with a major female preponderance across age groups (Ostrom et al. 2015). More frequent use of cranial MRI or CT in the elderly may have resulted in the impression of increased prevalence rates of meningiomas. Most meningiomas are biologically benign, are assigned WHO grade I, and can be cured by surgical resection alone if feasible by location. A smaller proportion of meningiomas is considered atypical (WHO grade II) or ANAPLASTIC (AND NOT atypical) (WHO grade III) (1), (Louis et al. 2016), associated with correspondingly decreased overall survival. In contrast to gliomas, watch-and-wait strategies are often appropriate notably in the elderly patient population where meningiomas may have been diagnosed incidentally during work-up for stroke or dementia (Goldbrunner et al. 2016). In contrast, large symptomatic meningiomas with very typical radiological appearance may occasionally be managed by primary radiotherapy alone if the risk of surgery appears to outweigh the benefit of establishing a precise diagnosis associated with cytoreduction. The recently identified mutations suggested to play a major role in meningioma biology appear to be age-associated.

Primary CNS Lymphoma (PCNSL)

PCNSL is another malignant primary brain tumor where age is highly relevant for outcome. PCNSL is potentially curable with high-dose methotrexate-based chemotherapy without or with stem cell transplantation but only in younger patients. Elderly patients tolerate such aggressive treatments less well, but there seem to be additional biological features that render prolonged disease control challenging in this disease: a secondary analysis of the largest PCNSL trial ever performed, G-PCNSL-SG-1 (Thiel et al. 2010), revealed that elderly patients are as likely as younger patients to achieve a radiologically complete or partial response but that responses are rarely sustained in the elderly (Roth et al. 2012). Irrespective of age, whole brain radiotherapy has largely been abandoned in the treatment of PCNSL, both because of moderate and only transient therapeutic activity and because of poor tolerability, notably in the elderly.

Brain and Leptomeningeal Metastases

Up to 30% of patients with systemic cancer develop CNS metastases which are the most common brain tumors if considered collectively. The risk of CNS metastases is highest in melanoma, lung cancer, breast cancer, and renal cell cancer, and this risk appears not to be age-associated. CNS metastases commonly signify a poor prognosis but do in general not respond less well to RT or chemotherapy than organ metastases elsewhere. An increasingly used prognostic index, the graded prognostic assessment (GPA), identified patient age above 60 years as one of the four prognosis-defining factors associated with decreased survival (Sperduto et al. 2008, 2010, 2012). This GPA was subsequently expanded to specific histologies of primary tumor, resulting in the identification of age as relevant particularly in lung cancer, both non-small cell lung cancer and small-cell lung cancer, which are also collectively responsible for 50% of all CNS metastases. Yet, age alone is not a limitation for tumor-specific treatment approaches in patients with CNS metastases, and frailty as opposed to merely age is increasingly used to identify patients who may overall not derive benefit from aggressive tumor treatment.

Symptomatic and Supportive Therapy and Palliative Care

There are few considerations specific to elderly patients with CNS tumors. Such patients often

require corticosteroids for the control of steroid-associated edema, and elderly patients may be prone, because of comorbidities, to steroid-induced hyperglycemia and osteoporosis. Because of increased risks of falls and fractures, symptomatic epilepsy associated with CNS tumors should be treated vigorously in the elderly. There is increased risk of drug interactions, again because of comorbidities, e.g., requiring the use of anticoagulants and antiplatelet agents which modulate the safety profile of systemic chemotherapy.

Outlook

Incidence and prevalence of primary and secondary CNS tumors increases probably steadily with advancing age. Since European societies are aging, this results in an increasing burden not only for affected patients and families but also health-care providers and health systems. As more specific and effective treatments become available, careful assessment of their safety and tolerability by dedicated clinical trials is an important task to improve outcome and quality of life of the growing population of elderly cancer patients.

Abstract

The elderly population has recorded an unprecedented growth over the last 20 years. Despite the evidence that cancer is a disease of the elderly, very little level 1 evidence on its treatment comes from current scientific literature, since patients older than 70 are often excluded from clinical randomized trials.

In addition, information obtained from the methodologically well-designed studies does not always apply to elderly patients. Unfortunately, this may also translate in substandard cancer care delivered to this group as recently flagged by EUROCARE-5, the widest collaborative research project on cancer survival in Europe. The same scenario has been reported by the National Cancer Intelligence Network showing how in the UK elderly patients affected by solid tumor receive less surgery as compared to the younger counterpart. The difficulty in applying the "standard of care" more broadly needs to be searched in a combination of patients' comorbidities, psychosocial issues, and physicians' attitude. All these factors contribute to the challenge in the perioperative decision-making, eventually affecting the treatment outcomes.

Introduction

The elderly population has recorded an unprecedented growth over the last 20 years, and the United States (US) censor bureau projects that by 2050, there will be approximately 90 million elderly people living in the USA. Despite the evidence that cancer is a disease of the elderly, very little level 1 evidence on its treatment comes from current scientific literature, since patients older than 70 are often excluded from clinical randomized trials (Zulman et al. 2011).

In addition, information obtained from the methodologically well-designed studies does not always apply to elderly patients, who experience different benefits, side effects, and life expectancy than younger cohorts (Rutten et al. 2008). Unfortunately, this may also translate in substandard cancer care delivered to this group. EUROCARE-5 (De Angelis et al. 2014), the widest collaborative research project on cancer survival in Europe, including 21 million cancer diagnoses provided by 116 cancer registries in 30 European countries, has recently flagged an unfavorable cancer-related survival rate among the oldest patients. The same scenario has been reported by the National Cancer Intelligence Network showing how in the UK elderly patients affected by solid tumor receive less surgery as compared to the younger counterpart (National Cancer Intelligence Network). The difficulty in applying the "standard of care" more broadly needs to be searched in a combination of patients' comorbidities, psychosocial issues, and physicians' attitude. All these factors contribute to the challenge in the perioperative decision-making, eventually affecting the treatment outcomes.

What Do Elderly People with Cancer Want? The Challenge of Communicating, Patients' Perspectives, and Quality of Life

Becoming old means being less and less independent from a number of perspectives. Among the various causes leading to a decrease in functional

capacity, declining health plays a pivotal role. Elderly patients have multiple comorbidities and unpredictable social/family situations; when cancer is diagnosed, this adds frequently to in an already complicated situation. Among the elderly, those who are vulnerable or even frail are the ones who really deviate from the standard curves. The purpose of surgical care in elderly is to obtain a cost-effective, tailored treatment while focusing attention on the patients' quality of life rather than the mean 5-year disease-free survival.

The vast majority of surgeons recognize now the peculiar characteristics of performing surgery in the elderly as compared to the younger population (Deiner et al. 2014). In particular, the uncharacteristic intensity and duration of postoperative treatments, the specific medicolegal issues of obtaining an informed consent, and the ethical questions related to the end-of-life care (Soreide and Wijnhoven 2016).

Communication in these cases is essential, not only with the family, but with the patients themselves, whenever possible, since in many cases, it's surprising how well-aware and practical outcome-oriented senior adults may be, despite facing a challenging situation. Elderly patients should be assumed to have the mental capacity to make decisions about their treatment, until proven otherwise. This being said, patients' healthcare proxy and family must be involved during the treatment pathway not just once but at several steps during the key decision-making moments and with constant follow-ups. The goal of the communication is not ordinary medicolegal compliance, but it needs to help going through the insidious process of facing challenging circumstances for both the family and the clinician (Desserud et al. 2016) (Table 1). King et al. showed that main reason to withdraw surgical care in this group is mainly due to "contraindication despite lack of comorbidities and patient refusal" (King et al. 2016). As Audisio et al. pointed out on their recent editorial in the *Annals of Surgical Oncology*, this choice is usually "justified" during multidisciplinary discussion as "this patient doesn't want surgery" (Audisio and Balch 2016). But patients are sincerely prone to take under serious consideration physicians' recommendations above all if they're receiving truthful answers about their common fears: postoperative pain, functional recovery, and alternatives in case of nontreatment.

Table 1 Potential pitfalls in communication

Clinical setting	Key element	Challenge
Patient's consent/ advanced directive and living will	Oral or written Consult healthcare proxy/guardian	Patient's mental awareness Non-documented living will Proxy's decision
Do-not-resuscitate order	Patient's documented will Define prognosis Available treatments likely to fail Physician experience/ awareness Expectations	Poor available scientific data Experience versus scientific data Patients/ caregiver unwillingness Caregiver's/ patient's expectations versus physician's expectations False hopes/ expectations The value of "keeping the hope alive" Communication
Withholding and withdrawing life support	Provided limitation in care Poor functional/ organs reserve Define prognosis Define risk of permanent dependence from invasive systems (respiratory-cardiovascular, etc.) Define palliation/ comfort measures	Patient's and proxy's understanding/ awareness of clinical situation Expectations Feeling of "giving up"

Patients' perspectives are essential in establishing a proper understanding of the QoL goals. Despite the prevalence of cancer in the elderly population and the increasing requirement

for QoL measurement, not many studies have been published focusing on patient experience (Dunn et al. 2006). In recent years, some qualitative information has been gained from studies designed for younger patients where "uncertainty," "fears for cancer recurrence," "pain," "fatigue," "managing on a day-to-day basis," and "feeling alone" were described as the highest concerns of patients (O'Connor et al. 1990; Taylor 2001; Persson and Hellstrom 2002). Mental and physical health seemed to be interrelated in both young and senior adults with cancer as reported by Weaver et al. (2012), affecting their perspective regarding their disease and the expectations.

Banks et al. (2010) were able to analyze self-reported questionnaire-based data from 89,574 Australian men and women with cancer sampled from the Medicare database. In their study, they were able to conclude that "the risk of psychological distress in individuals with cancer relates much more strongly to their level of disability than it does to the cancer diagnosis itself." Disability and lack of independence in the activities of daily living seem to impact cancer patients more than the cancer prognosis per se.

Some cancer-specific situations have been historically blamed for being responsible for patients' reduced self-esteem and QoL. Among the possible stressors, having a stoma has been traditionally considered as a factor that increases psychological distress in patients with CRC. This assumption has been reconsidered in the past few years. A large meta-analysis on the impact of a stoma-forming procedure [abdominal perineal resection (APR) vs. low anterior resection (LAR)] on 1443 patients with CRC failed to show a reduction in the QoL of patients with fecal diversion (Cornish et al. 2007). The mean age in the two groups was 66.3 $\pm$ 6 and 65.6 $\pm$ 6 years for APR and LAR, respectively. This was again confirmed by Bossema et al. showing no difference in terms of health-related QoL (HRQoL), emotional function, and understanding of the illness among elderly rectal cancer patients with or without a stoma (Bossema et al. 2011).

Patient-centered outcome studies should be implemented in the oncogeriatric field in order to face modern healthcare system challenges (Gabriel and Normand 2012). Data seem to suggest that disability and lack of independence are considered more important than the cancer diagnosis per se. The risk of postoperative disability needs to be fully discussed with patients and family with the goal of promoting faster functional recovery and regaining independence.

Discussing with patients and family about goals, expectations, and health status seems obvious, but self-reported QoL tools have been for a long while ignored by surgeons. In particular, QoL and functional outcome questionnaire (sexual dysfunction, fecal, and urinary incontinence, etc.) evaluations have been considered too "demanding" and "time-consuming" to be systematically incorporated into busy clinical practices.

Only recently, Fernando and colleagues described the use of two self-administered quality-of-life tools (questionnaires) as part of a prospective, randomized control trial of sublobar lung resection for cancer versus sublobar lung resection with locally applied brachytherapy (Fernando et al. 2015). Regardless of the specific outcomes, authors were able to demonstrate that, firstly, self-assessment questionnaires are feasible in the surgical office and in the postoperative ward. Secondly, self-assessment questionnaires have been useful in predicting adverse outcomes after chemotherapy and surgery (Feng et al. 2015; Jaklitsch 2015).

An interesting prospective multicenter study by Scarpa et al. (2013) analyzed the QoL of elderly versus younger patients undergoing colorectal surgery. A total of 116 patients were enrolled in this study: 33 patients >70 year had a laparoscopic colectomy whereas 24 underwent open resection; 44 patients <70 year had a laparoscopic procedure and 15 of them required an open approach. Authors used three questionnaires regarding generic/specific QoL (EORTC QLQ-C30 / CR29) and treatment satisfaction (EORTC INPATSAT32). As expected, they showed that elderly patients undergoing laparoscopic colectomy experienced fewer postoperative complications than patients undergoing an open procedure.

Nevertheless, elderly patients experienced a poorer QoL compared to younger patients. The main fields that were found to be affected were the presence of fatigue, sleep disturbance, appetite loss, and shortness of breath. Data were confirmed by Amemiya et al. (2007) reporting data about elderly with gastric and colon cancer. After an immediate reduction of functional capacity, they showed that QoL measured at 1 week and 6 months progressively and significantly improved ($p < 0.005$). Functional recovery and activities of daily living status improved after surgery in the majority of patients; however, a temporary or prolonged decline in recovery was found in those who developed postoperative complications.

In conclusion, QoL and patients' perspectives can no longer be considered "secondary outcomes" in terms of their relevance for oncogeriatric patients. Restoration of independence seems to be the highest priority and it directly affects QoL perception. HRQoL data at diagnosis also seem to identify vulnerable subpopulations in elderly patients (Fiteni et al. 2015; Fournier et al. 2016); thus, it could be valuable in selecting fit elderly candidates before the treatment. Regardless of the system of choice, data about QoL need to be incorporated in every surgical practice, putting the patient at the center of the care process.

Preoperative Evaluation and Multidisciplinary Decision-Making

Several systems to evaluate patients in order to stratify operative risk and highlight possible areas amenable for prehabilitation have been proposed and validated. The overall message is that, regardless for the system of choice, it is essential to systematically assess elderly cancer patients in order to determine if the patient is fit for surgery, which is the most appropriate surgical plan and which adjustments might be needed before the procedure. As a rule of thumb, it is mandatory, regardless for the preferred system, to obtain information about three main domains: cognitive status (including history of delirium), independence/living situation, and sarcopenia/gait ability/nutrition (Audisio et al. 2008; Fong et al. 2009; Mohri et al. 2013; Huisman et al. 2014; Hempenious et al. 2015).

Screening for frailty and any possible areas of intervention is only a part of the preoperative assessment and decision-making process. Secondly, but with same significance, is that every possible patient is discussed within a multidisciplinary group. The multidisciplinary approach is, as always, of great value when treating elderly, challenging patients in order to not overlook any aspect of patients' complexity. This is particularly valuable within the field of geriatric oncology where a combination of disease- and patient-oriented approach needs to be pursued. Clinical data have confirmed that this approach can improve measurable outcomes and quality of life in the geriatric population undergoing surgery (Terret et al. 2007). The multidisciplinary team should be ideally built around not only cancer-specific professionals (surgical, medical, and radiation oncologists), but geriatricians, anesthesiologists, physical-therapists, nutritionists, case managers, and geriatric nurse practitioners should also play a role in the discussion and decision-making process.

An algorithm reporting the preoperative sequence of events in order to determine patients' access to treatments has been offered in Fig. 1.

Surgical Planning (Not Only Picking a Calendar Date)

It has been established that surgical care should not be withdrawn from elderly patients only because of age, while comorbidities should be regarded as the main cause or an increased risk of failure. Because of this, several perioperative strategies have been implemented and promoted.

Every clinician and surgeon, above all, should bear in mind that the key element for a successful delivery of high-level care starts with a standardized, individual patient's risk evaluation. Preoperative evaluation has been extensively described in previous chapters but it's worth repeating that in a practical world, where the surgical practice is squeezed into a tight schedule, the need for

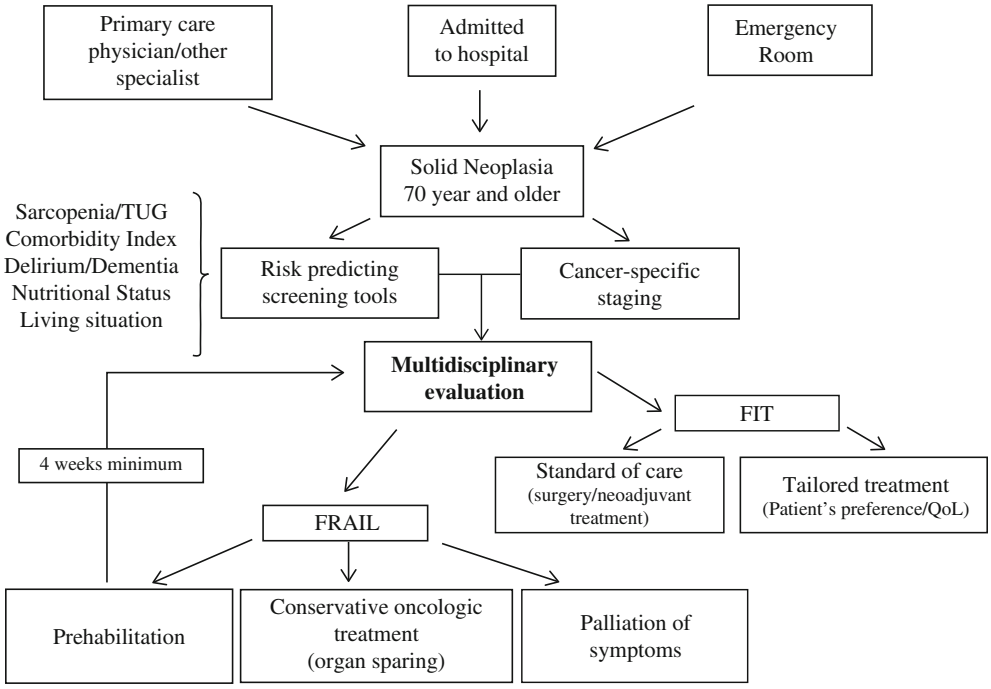

Fig. 1 Multidisciplinary decision-making process flow chart for oncogeriatric surgical patients

simple, easy-to-use risk-predicting systems is a top priority.

Exploring this pathway, the role of the Timed Up and Go (TUG) test, the handgrip strength test, nutritional risk screening, ADL/IADL, and others have been assessed (Audisio et al. 2008; Huisman et al. 2014). Organ-specific diseases, setting, and environmental factors make the pursuit of the "one-size-fits-all" risk-predicting instrument hard to be fulfilled.

The lack of a standardized preoperative assessment is, indeed, one of the main reasons why so few meaningful conclusions can be drawn from too many papers currently published by the "scientific community." In addition, no homogeneity in the study population can be verified or is objectively reported. This is particularly true for elderly patients' literature where intergroup variability is so highly represented and usually so poorly assessed, nullifying the value of possible final conclusions.

The role of a systematic preoperative assessment is focused not only on screening good, fit candidates for surgery but also on identifying situations or conditions that may benefit from a preoperative intervention. After a careful preoperative evaluation, a tailored procedure can be planned with the intent of obtaining the desired result and minimizing stressors. The role of minimally invasive surgery (MIS) has been debated and quite definitive results have been published on the topic highlighting the crucial role of MIS in the elderly. While the role of laparoscopy was extensively addressed (Lacy et al. 2002; Veldkamp et al. 2005; Bonjer et al. 2015), the same could not be reported for the use of other technologies as robotic surgical systems, that while gaining consensus among patients and care providers are failing to show a significant clinical benefit (Patel et al. 2015; Montroni and Wexner 2016). The application of the enhanced recovery protocols in elderly patients will be also briefly described.

Prehabilitation

Despite modern and sophisticated efforts to decrease postoperative morbidity and mortality, there is evidence that, 6–9 weeks after major

abdominal surgery, many patients are not back to their active lives (Wilson et al. 2010). Prehabilitation is a modern strategy, gathering together all the initiatives carried out from the time of diagnosis to the time treatment starts in order to improve functional capacity and functional recovery. Prehabilitation before oncologic surgery is a novel topic compared with the amount of knowledge of posttreatment rehabilitation programs and outcomes for both cancer and non-cancer patients (Silver and Baima 2013). Interestingly, the first study on prehabilitation was published in 1946, describing nutritional and physical training and even recreational intervention in order to turn the unfit military into robust soldiers ready for the battlefield (1946). In recent years, prehabilitation for elderly patients affected by cancer has become more and more intriguing for surgical oncologists as a result of the great benefits shown in the fields of orthopedic and cardiac surgery (Swank et al. 2011; Furze et al. 2009) Medical prehabilitation includes the management and optimization of preoperative conditions, such as diabetes and cardiovascular function and the promotion of smoking cessation. Moreover, the goal of this strategy is to focus not only on muscle strength reinforcement but also on the nutritional and emotional/psychological management of patients undergoing major surgery. The work that Carli et al. (2010) have accomplished in recent years has been of great value from this prospective. They were able to show that functional capacity was improved by prehabilitation, whether by adherence to a strenuous preoperative activity schedule (bike and muscle strengthening exercises) or by a 30-min walking and breathing exercise regimen three times a week. On the other hand, many questions are still open as to how older adults undergoing surgery may or may not benefit from perioperative regimens (Jack et al. 2011).

One of the main issues is the low adherence of patients to the prehabilitation regimen and the need for a prolonged time period from diagnosis to surgery (at least 4–6 weeks) in order to observe tangible improvement in postoperative outcomes. Patients undergoing neoadjuvant treatments seem to be the group with the highest potential (Loughney et al. 2016). What is clear is that prehabilitation is not a substitute for good surgical and tailored postoperative treatment, above all in the elderly. As a consequence, it should not reduce the morbidity and mortality rates. Prehabilitation improves functional recovery and, perhaps, patient independence and active life expectancy (Santa Mina et al. 2014). Li et al. (2013) showed how a trimodal prehabilitation program dramatically changed postoperative functional walking capacity, self-reported physical activity, and health-related quality of life (QoL). This randomized trial was designed for CRC patients awaiting surgical treatment and included 30 min of walking and breathing exercises three times a week, a nutritional supplement of up to 1.2 g/kg body weight, and anxiety reduction techniques. The mean age of the 42 patients enrolled and the 45 patients in the control group was 67.4 $\pm$ 11 years; a prehabilitation protocol was carried out for a mean time of 33 days (range, 21–46 days). Interestingly, the patients in the intervention group increased the distance covered at the 6-min walking test during prehabilitation, surpassing the preoperative results of the control group. Four and 8 weeks after surgery while control patients' physical ability declined and did not reach their pretreatment level, prehabilitated patients regained the ability to walk farther than their preoperative baseline. The same trajectory was shown for self-reported physical activity, while anxiety and depression were shown to be way below the patient baseline 4 weeks postoperatively. Even more interestingly, fewer postoperative complications were recorded in patients who improved their walking ability during prehabilitation while people whose functional capacity declined during the pretreatment time had poorer outcomes. It might help considering the response to the prehabilitation regimen to be an additional screening tool for elderly patients undergoing surgery for cancer (Chan et al. 2016).

Several issues regarding the feasibility and effectiveness of this approach have still not been completely resolved. The lack of time, which often forces surgeons to bring elderly patients with CRC to the operating room sooner rather

than later because of impending obstruction or perforation, might reduce the feasibility for a very large number of patients. At the same time, lack of adherence to prehabilitation regimens is indeed higher in the elderly, above all in cases of inconsistent family or financial support. On the other hand, the results obtained before colorectal cancer surgery are so promising for restoring active life and independence in this frail group of patients that it may be worth a try, above all, for those patients who are able to wait 4–6 weeks before surgery (e.g., neoadjuvant therapy). Good clinical data and larger trials focused on elderly patients are needed to eventually shed light on this fascinating field.

Minimally Invasive Surgery

The aim of this paragraph is merely to address the main key message: MIS is safe and feasible in the elderly and it should be pursued because it promotes faster functional recovery. For the purpose of the discussion, we will mostly refer to the colorectal surgery field where MIS has been routinely used over the last two decades and where the vastest amount of literature has been produced in order to address its usefulness for senior adults.

The term MIS was coined by Dr. John Wickham, urologist, who wrote of it in the *British Medical Journal* in 1987 prophetically foreseeing that "in the next 30 years [. . .] surgeons who practice minimum invasion will do the most non-emergency surgery." The goals of MIS are to obtain the same disease-related and functional outcomes of an open operation while decreasing the surgical stress and consequently the associated morbidity and mortality.

Since the very beginning, MIS became a synonym of laparoscopic surgery, and in the early 1990s, it was introduced to treat benign colorectal diseases. Early studies showed that laparoscopy promoted improvements in return of bowel function, earlier oral intake, decreased opioid analgesia requirements, and decreased length of hospital stay, all while improving cosmesis and patient satisfaction (Dunker et al. 1998). One of the focuses of the use of MI techniques is not only to promote the return of bowel function, expedite oral nutrition, and reduce hospital stay but also to facilitate functional recovery. Such abilities as return to active life and return to independent living or bowel/urinary control are particularly necessary in elderly patients, where reaching those goals often means the difference between an operation's success and failure (Frasson et al. 2008).

Frasson et al. specifically focused on functional recovery after laparoscopic surgery, analyzing a series of 535 patients with colorectal disease randomly assigned to laparoscopic ($n = 268$) or open ($n = 267$) resection. Within the two groups, the outcomes of young patients (under 70 years of age) were compared with those obtained in patients $\geq$70 years old. The authors were able to show how laparoscopy in the elderly, even more than in younger patients, improves the preservation of functional status, permitting a higher rate of postoperative independence at discharge and faster postoperative recovery. Stocchi et al. (2000) were also able to demonstrate that independent status on admission (assessed in 37 patients undergoing laparoscopic-assisted colectomy and 38 undergoing open colectomy) was more frequently maintained at discharge in those undergoing laparoscopic-assisted colectomy (95% vs. 76%, respectively; $P = 0.025$).

Recently, Li Y et al. "sealed" the debate on possible benefits of laparoscopic surgery in octogenarians by publishing a meta-analysis of 11 comparative studies including 1,066 laparoscopic and 1,034 open colorectal resections in their pooled analysis (Li et al. 2016). The result of the meta-analysis is that laparoscopy is safe and carries a lower risk of infectious complications, both pulmonary and at the surgical site, shorter length of stay, and a reduced incidence of postoperative ileus while maintaining the same cardiovascular risk as compared to open surgery.

Enhanced Recovery Programs

Enhanced recovery or fast-track programs include preoperative patient education, no routine bowel preparation, no perioperative starvation, early removal of the nasogastric tube and urinary catheter, tailored anesthesia and postoperative

analgesia, and early mobilization with minimal fluid infusion.

The literature suggests that elderly patients have an advantage in functional recovery if enrolled in a fast-track program. Baek et al. (2013) analyzed a group of 337 patients (87 over 70 years of age and 250 under 70 years of age) who underwent laparoscopic colorectal surgery with a perioperative fast-track program. No significant differences were observed in terms of return of flatus, stool passage, progression of diet, complication rate (26% in the elderly patients vs. 32% in the young patients) or length of hospital stay (12 days for each group). These results were obtained regardless of significant differences between the two groups when considering age, presence of comorbidities (70% in the elderly vs. 44.7% in the younger patients), and ASA score. In particular, they observed a lower than expected cardiopulmonary complication rate, which they acknowledged was most likely due to the use of a low-pressure pneumoperitoneum (8 mmHg). The only significant differences were observed in readmission rate and emergency room visits (11.7% vs. 4%, respectively).

Pawa et al. (2012) achieved similar results, with a median length of stay of 6 days for a 558 patient group under 80 years of age, while a total of 8 days was recorded in a cohort of 130 patients $\geq$80 year ($P = 0.363$). No significant differences in 30-day readmission rate (8.6% of the whole population) were observed in the study.

"Fast-track protocol" has been often used as a synonym of the enhanced recovery after surgery (ERAS) protocol, but the two entities are not the same. The ERAS protocol, promoted through the ERAS® society, refers to a well-designed but necessarily strict list of items that need to be entirely fulfilled in order to obtain the desired effect (Gustafsson et al. 2011). But adherence to the long list of tasks is not easy to achieve and, as demonstrated by several studies and surveys, despite increasing awareness of the importance of structured perioperative management, the implementation of this complex protocol has been slow (Segelman and Nygren 2014).

The above considerations are even more relevant when considering elderly patients who can hardly follow complex processes and who present high variability within their own group.

In addition, some of the items reported in the ERAS protocol such as the use of epidural anesthesia and the absence of oral antibiotic with mechanical bowel preparation have been deeply questioned by the current literature, above all after the implementation of laparoscopy. Epidural anesthesia has been shown to be detrimental when associated to laparoscopic abdominal procedures (Halabi et al. 2014), while the combination of antibiotics and bowel preparation has been reported lowering postoperative infections (Chen et al. 2016).

While promoting accelerated recovery, one of the goals should be to reduce stressors and to decrease the body inflammatory response following surgery. Pursuing this aim, a recent systematic review by Watt et al. examined the impact on the magnitude of the systemic inflammatory response (SIR) for each ERAS component following colorectal surgery using objective markers such as C-reactive protein (CRP) and interleukin-6 (IL-6). While analyzing 19 studies, including 1898 patients, the author showed that, with the exception of laparoscopic surgery, objective evidence of the effect of individual components of ERAS protocols in reducing the stress response following colorectal surgery was limited (Watt et al. 2015).

Based on the current evidence, we should conclude that elderly patients, more than a strict list of prescriptions, do benefit from minimally invasive surgery followed by a "controlled, tailored rehabilitation program including early progressive reintroduction of oral diet, ambulation and physical therapy, early removal of drains and catheters, minimal to nil opioid analgesia, and individualized/limited fluid management. Making the patients and the families engaged with the "controlled rehabilitation plan" via constant, effective communication should be a top priority for the whole care team.

Old Assumptions about Surgery and Poor Cancer Prognosis

In addition to emergency procedures, some other circumstances may result in a theoretical need for aggressive surgical treatment that will most likely

correlate with an elevated rate of disability. This is the case of highly aggressive malignancies like pancreatic cancer, low rectal cancer, or metastatic colon cancer.

Elevated postoperative morbidity and mortality, possible need for permanent bowel diversion or imperfect bowel continence, need for preoperative chemotherapy, and prolonged postoperative course make these scenarios difficult to face for physicians and families.

Pancreatic Cancer

Pancreaticoduodenectomy (PD) is considered one of the most challenging surgical procedures, and the complication risk may vary overall from 5% to 50%, while 5-year overall survival is approximately 15–20% when a malignancy is diagnosed (Riall et al. 2006). PD has been shown to be safely performed in the elderly (Di Carlo et al. 1998; Lightner et al. 2004; Makary et al. 2006; Brozzetti et al. 2006; Hatzaras et al. 2011; Ballarin et al. 2009) even if the higher rate of postoperative complications may be related to comorbidities. Nevertheless, some may debate that the high costs of this procedure, not questioned in younger patients, only bring minimal advantages due to superior postoperative morbidity and poor long-term survival. In order to address this issue, Turrini et al. (2013) prospectively gathered data from 932 patients from 37 institutions, undergoing PD for cancer stratified in <70 (control group), 70–79, and ≥ 80 years old. The three groups were found to be homogeneous in preoperative conditions except for higher incidence of biliary stenting and higher ASA (3–4) in the elderly groups. Senior adults were also statistically less prone to be treated with adjuvant chemotherapy after the surgery. By analyzing this large group of people, they found no difference in postoperative mortality or morbidity in the three groups, but elderly patients recorded a longer length of stay. More surprisingly the overall 1-year, 3-year, and 5-year survival rates of control group/70s group/80s group were 82.2%/75.7%/75.7%, 49.9%/41.8%/31%, and 38.7%/33.2%/0%, respectively ($P = 0.16$) showing no difference in the overall oncological outcomes. Only cancer-related features (vascular invasion and positive lymph nodes) and lack of adjuvant treatment were found to independently predict poor prognosis. The study is affected by a clear selection bias due to the fact that only fit elderly patients were offered massively invasive surgery, but this is exactly the point that should be made. Regardless, the authors managed to make it clear that optimal oncological care should not be withdrawn only based on age since long-term oncological outcomes are no different between fit elderly and the younger population.

The data were confirmed by Riall et al. (2011) who analyzed 9,553 Medicare patients with pancreatic cancer from the Surveillance, Epidemiology and End Results (SEER) database (Riall et al. 2011). They showed that as surgical resection rates increased significantly, 30-day operative mortality rates decreased from 9% to 5% from 1992 to 2005. Comparing patients who underwent a pancreatic resection to the group who did not have surgery, they noticed how participants were less likely to be resected when older. On the other hand, when a resection was performed, the hazard of death was significantly lower, regardless of age, compared with unresected participants.

The authors concluded that, despite previous reports of greater morbidity and mortality after pancreatic resection in older adults, the benefit of resection does not diminish with older age in selected people.

Stage IV Colorectal Cancer with Liver Metastasis

Stage IV colorectal cancer (CRC) is commonly considered a “death sentence,” above all when occurring in elderly patients. Several healthcare professionals have been quoting poor mid-to-long-term survival rates to prematurely withdraw medical and surgical care from this group of patients. Unfortunately, clinicians should also be aware that, even with more modern and tolerable chemotherapy regimens, 5-year survival in patients with colorectal cancer with liver

metastases receiving only palliative chemotherapy is 0–4% (Yun et al. 2007; Okuno 2007).

Guidelines from the National Comprehensive Cancer Network recommend that patients with stage IV CRC should undergo surgery to remove the primary cancer only if they are symptomatic (e.g., bleeding, obstruction, perforation) or have a potentially resectable metastatic localization. Liver resection remains indeed the only chance for long-term survival in patients with CRC liver metastases.

De Liguori Carino et al. (2008) analyzed data from 181 liver resections performed on 178 consecutive senior adult patients. The overall survival rate at 5 years was 31.5%. Similar results were reported by Nagano et al. (2005) who reported 34.1% 5-year survival in 202 elderly patients undergoing surgery for CRC liver metastatic disease.

Adam R. et al. compared 60-day postoperative complications and 3-year survival rate in a group of 999 > 70-year-old patients versus a control group of 6765 younger, consecutive patients who underwent liver resection for metastatic stage IV CRC (Adam et al. 2010). The elderly patients had a higher rate of postoperative mortality and morbidity, but, surprisingly, the 3-year survival rate was similar in the two groups (57.1% vs. 60.2%, respectively).

Unfortunately, liver treatment is usually performed after chemotherapy (named both adjuvant, after CRC surgery, and neoadjuvant, before liver surgery), but this is seldom prescribed to elderly patients due to presumed higher risk of cardiac and liver toxicity secondary to the 5-FU and oxaliplatin, respectively.

De Liguori Carino et al. (2008) were not able to confirm this presumption in their series as only 1 out of the 34 patients receiving FOLFOX developed liver failure. Postoperative complication rates were not found to be higher in patients who did receive preoperative treatment. Although no significant difference in postoperative complication rates is evident between the groups, postoperative mortality was increased after major hepatic resection, thus affecting long-term survival.

It can be concluded that, even for stage IV disease, there should be no upper age limit, but the surgical approach should be planned taking into consideration disease stage and symptoms, patient life expectancy, performance status and the presence of comorbidities (Ugolini et al. 2014).

Conservative Treatment Versus Undertreatment

As previously reported, worse oncologic outcomes in the elderly population are related to suboptimal treatments. The chain of events is most likely to start from the healthcare providers who assess the patients in the first place, as reported by a large survey of primary care physicians in France (Delva et al. 2011). Results showed that the patient's chronological age was highly associated with the decision not to refer patients with advanced cancer to oncologic specialties (odds ratio 0.55; 95% confidence interval 0.35–0.86; $p = 0.009$). But, even if elderly patients are referred to a specialist, it is very likely that a similar age discrimination will be noticed once again. A second survey of 1408 French medical and radiation oncologists showed that breast cancer specialists did not always prescribe potentially beneficial treatments based on chronological age alone (Protiere et al. 2010).

At the same time, we need to acknowledge that "standard of care" is not always synonym with "best possible option" when we deal with elderly cancer patients.

As previously mentioned, quality of life and restoration of independence should be taken sometimes over 5-year survival rate and recognized that "to do less" might be, at times, in the best interest of patients and families. Several strategies to promote conservative, organ sparing, oncologic surgery have been developed in the different surgical fields over the course of the years (Saclarides et al. 1992; Veronesi et al. 1997). While these techniques were initially designed for young patients with early-stage cancer (who would benefit from treatments minimally altering their lifestyle), they seem to perfectly fit with elderly patients' needs.

Balance between "standard of care," "conservative treatment," and "undertreatment" is a fine equilibrium. A tight integration among professionals of different fields can help maintaining the balance of keeping the patients', and not the physicians', best interest at the center of the healthcare process.

Breast Cancer

Breast cancer is the most common neoplasia among women, and age is one of the most important risk factors in developing this disease (Alberg and Singh 2001). It is estimated that 21–30% of cases occur in women older than 70 years (Wanebo et al. 1997). Despite the magnitude of the issue, there is little solid evidence for the management of this specific group of patients, leading to treatments based only on prior incomplete knowledge.

Breast cancer clinical practice is, indeed, mostly based on clinical trials which recorded the exclusion of these patients from the studied population; therefore, there are still many fields in which level 1 evidence is lacking. In addition, physicians are more likely prone to treat elderly patients with cancer following their own "gut feeling," overtreating in some cases and undertreating in some others.

There have been no specific guidelines for the management of elderly patients until 2007, when the International Society of Geriatric Oncology (SIOG) created, for the first time, a dedicated task force to provide precise recommendations to treat elderly women with breast cancer (Wildiers et al. 2007). SIOG guidelines were then integrated with the European Society of Breast Cancer Specialists (EUSOMA) in 2012, and a comprehensive document was published (Boganzoli et al. 2012). This is, to this day, the best source of knowledge to obtain the fundamental information on this topic and should be used by every breast cancer specialist in their daily practice.

Despite this effort, several issues still remain unsolved, as shown by the previously described surveys, and undertreatment of breast cancer in elderly women is more than hypothetical.

Richards et al. (2015) recently presented data from 17,129 women $\geq$70 year from two UK cancer registry regions Richards et al. (2015). Analysis was restricted to patients with stage III disease and estrogen receptor (ER)-positive tumors between 2002 and 2010. Effects of a regimen including primary endocrine therapy (PET) only, and no surgery, were retrospectively investigated. Authors were able to show that nonsurgical treatment of elderly women, with early breast cancer, increases the risk of breast cancer death regardless of age, comorbidity, and disease characteristics. During the same period, a number of randomized controlled trials (RCTs) aimed to compare the efficacy of PET against surgery in older patients. A Cochrane meta-analysis demonstrated the superior local control of surgical approach but no increased survival benefit (Hind et al. 2006). As a result of this, more recent studies have advocated the use of PET only for "the very frail or very old" (Wyld and Reed 2003; Chakrabarti et al. 2011). Unfortunately, two major biases were hidden in this "more conservative" treatment strategy. First, RCT-included patients were deemed, by the studies design, fit enough for surgical treatment, thus not "very old or very frail." In addition, since this data was published, tamoxifen has largely been replaced by the third-generation aromatase inhibitors (AI) as first-line treatment for both PET and adjuvant therapy, again limiting the value of the Cochrane review.

At the same time, improvements in surgical and anesthetic techniques have occurred, and breast surgery today, even in frail patients, carries a very low morbidity and a nonexisting mortality (National Mastectomy and Breast Reconstruction Audit 2011).

A more recent review of six randomized controlled trials and 31 nonrandomized studies (including the previously mentioned RCTs) confirmed the superiority of AI over tamoxifen and the pivotal role of surgery in cancer treatment (Morgan et al. 2014). Surgery showed both better overall survival and breast cancer-specific survival as compared to PET only (67% vs. 49%; $p < 0.01$, 90% vs. 85%; $p = 0.01$, respectively). This could be partially expected because of the likely difference in comorbidities and frailty, but

again, the main message is that treating indiscriminately every patient with the same strategy leads to worse oncological outcomes.

When surgery is performed tailoring the treatment seems no longer doable but mandatory. Giuliano et al., who first promoted only limited approach to axillary surgery (Giuliano et al. 2011), published a retrospective analysis of a series of 140 elderly patients affected by T1–2 N0 breast cancer who only underwent breast-conserving surgery with no lymph node biopsy/dissection (Chung et al. 2015).

After surgery the vast majority of patients did not receive chemotherapy (98% vs. 2%; $p < 0.001$), radiation (76% vs. 24%; $p < 0.001$), or hormonal therapy (59% vs. 41%; $p = 0.04$). Of 140 patients, 5 (4%) experienced a breast cancer-related event. The 5-year overall survival rate was 70%, while the 5-year breast cancer-specific survival rate was 96%. Authors concluded that patients in this subgroup were more likely to die of causes other than breast cancer, and not performing a sentinel node biopsy did not affect survival.

Rectal Cancer

Elderly patients' rectal cancer management is frequently influenced by many factors, which lead to undertreatment and, consequently, poorer outcomes. This was first demonstrated by Chang et al. (2007) in a group of 21,390 patients identified from SEER database (1991–2002). The authors showed that the rectal cancer-specific survival rates decreased as patients' age increased. Unfortunately, this was also associated with a decreased use of multimodal treatment and of radical resection, while local excision rate was found to be higher than the younger counterpart.

Despite elderly patients being often prevented from neoadjuvant chemoradiation (CRT), preoperative therapy has indeed been associated with better oncological outcomes when followed by surgery (Sauer et al. 2004; Maas et al. 2010). The result of medical treatment has been so remarkable that Angelita Habr-Gama and her group decided to explore the possibility of not operating on patients having a complete clinical response (cCR) after CRT. Authors were able to obtain, in this subgroup, similar 5-year disease-free and overall survival as compared to the standard of care (Habr-Gama et al. 2004). Moving forward, the same group of scientists implemented this "watchful waiting" approach in a series of 70 patients with cT2–4, cN1–2 low rectal cancer who underwent only extensive CRT (54 Gy + 6 cycles of 5-fluorouracil and leucovorin) (Habr-Gama et al. 2013). Overall, 35 patients (51%) did not require any surgical treatment and they were free from disease after 56 months of median follow-up. The mean age of the patients in the study was 60.2 ± 12.9 years old; thus, the study was not specifically addressed to elderly patients, but this might be an interesting solution for unfit-for-surgery senior adults. The same hypothesis has been explored by the Memorial Sloan Kettering Cancer Center group and a prospective study is currently enrolling patients (Smith et al. 2015).

A second interesting solution offered by the same two groups is to perform only a local excision (without a formal proctectomy) after neoadjuvant CRT (Perez et al. 2013; Garcia-Aguilar et al. 2015). It should be acknowledged that both studies reported oncological results that are, at the moment, significantly worse than CRT + proctectomy, but with lower postoperative complications and better quality of life. While still debatable, if this could be a novel standard of care for patients with an extended life expectancy, it might be a viable option in the elderly where restoration of independency plays a central role. Once again it is important to appreciate how those surgical treatments, which are considered the standard of care for the general population (level 1 evidence), might not apply to senior cancer patients. As an example, total mesorectal excision has been established and validated on the general population of rectal cancer patients; however, sufficient evidence has been gathered to prove if the opposite is true for older rectal cancer patients, where the increased operative mortality and morbidity exceeds the survival advantage. Patient selection seems again to be the key step in order to offer feasible solutions without perhaps under treating them (Garcia-Aguilar 2013).

Ovarian Cancer

Complete cytoreduction with adjuvant or neo-adjuvant chemotherapy has been established as the main treatment for advanced epithelial ovarian cancer (Bristow et al. 2002; Chi et al. 2006). Peak incidence of ovarian cancer is 61 years old, which means that a high proportion of patients are elderly. Concerns visibly rose when facing the evidence that elderly patients are less likely to be optimally debulked (Cloven et al. 1999), receive standard therapy less often (Markman et al. 1993; Sundararajan et al. 2002; Uyar et al. 2005) , and are less able to tolerate medical cancer treatments (Moore et al. 2008).

Ovarian cancer prognosis is poorer for older women because the treatment is often substandard (Sabatier et al. 2015). Elderly women with ovarian cancer management are extremely challenging. On one side the goal is to achieve complete cytoreduction and improve survival, on the other side, complication rates are much higher; this can lead to severe outcomes including death.

Chi et al. (2008) have proposed a nomogram to evaluate survival in this group of patients, but few data are available (Diaz-Montes et al. 2005).

The role of the surgical strategy is to improve outcomes, regardless of the immediate perioperative morbidity and mortality. Chéreau et al. (2011) reported on 172 patients undergoing surgery for ovarian cancer from 2001 to 2009; 143 patients were <70 years old and $29 > 70$ years old Chéreau et al. (2011). Despite a limited sample size, the authors were able to show that two-year disease-free survival (DFS) was 57% for the group <70 and 35% for the group >70. The 5-year DFS was also reduced in the elderly group (40% vs. 23%, respectively). There was no difference in the rate of complete and optimal cytoreduction; however, a lower rate of pelvic/para-aortic lymphadenectomy and peritoneal surgery was noted in the elderly group. Several studies already underlined the detrimental impact of a limited lymphadenectomy independent from the extension of cytoreductive surgery (Chang et al. 2007; Chan et al. 2007; Rouzier et al. 2010). A publication by Aletti et al. (2006), it was determined that the decision to perform lymph node assessment depends on surgeon's choice, low residual disease, ASA grade and the absence of carcinomatosis. Regrettably, once lymphadenectomy has been decided upon, the main independent criterion to perform a complete lymphadenectomy versus lymph node sampling was shown to be limited to patient age under 65 years. More objective criteria have also been advocated by different authors, but the ultimate reality is that ovarian cancer surgical and medical management often requires extended and debilitating treatments in order to be effective Carli et al. (2010).

Recently, Lin et al. (2016) analyzed 7,938 elderly women from the SEER database Lin et al. (2016). Among this group, 2.9% received no treatment, 15.4% underwent surgery only, 24.8% received chemotherapy only, 41.8% underwent primary debulking surgery and chemotherapy in an optimal timeframe, and 15.1% had primary debulking surgery and chemotherapy, but timing or chemotherapy scheme were suboptimal. Those who underwent surgery only had similar survival as those who received no treatment (2.2 compared with 1.7 months), whereas those who received chemotherapy only, had a better overall survival (14.4 months). Optimal treatment was associated with the longest survival time ($P < 0.001$, median overall survival 39.0 months). The authors also concluded that, despite the fact that survival time associated with optimal treatment has increased over the past decade, the proportion of women who received optimal treatment decreased over time.

Currently no alternatives with more limited impact but similar outcomes have been recommended to effectively treat ovarian cancer. On the other hand, despite the redundant evidence in favor of this risk predictive tool, elderly women with ovarian cancer are prevented from the best available treatment, merely due to their chronological age.

Lung Cancer

The median age at diagnosis of non-small cell lung cancer (NSCLC) is approximately 70 years in Western countries (SEER database 2015). Once again, despite the high incidence of lung cancer in

the elderly, it is well known that these patients are underrepresented in clinical trials, and, therefore, it is difficult to reach evidence-based clinical recommendations for them (Sacher et al. 2013). Numerous studies have proven the feasibility of surgical treatment of elderly patients with lung cancer and even in octogenarians (Fanucchi et al. 2011; Rivera et al. 2011). However, the likelihood of elderly patients with early-stage disease not receiving any treatment is significantly increased with age (Wang et al. 2012). In 2010 and again in 2014, the European Organization for Research and Treatment of Cancer (EORTC), in collaboration with the International Society of Geriatric Oncology (SIOG), created an experts panel that generated a consensus paper for the management of elderly NSCLC patients.

First, the implementation of screening and minimally invasive techniques has significantly decreased mortality rate (Bravo Iniguez et al. 2016). McKenna et al. reported a large series of minimally invasive lobectomies with 1048 cases operated for primary lung cancer. The mean age was 72 years. Perioperative mortality was only 0.8%, and the morbidity rate was 15% (McKenna et al. 2006). This is a dramatic reduction from previously published data reporting a 7% mortality for open lobectomies (Ginsberg et al. 1983). As more authors commented, "to graphically illustrate the importance of these figures, an operative mortality of 7% equals one death for every 14 patients, while an operative mortality rate of 0.8% is one death in every 125 patients" (Pallis et al. 2014).

Secondly, segmental resection in early-stage NSCLC has shown to be an effective alternative to lobectomy that carries instead a higher risk of morbidity and mortality in the elderly population (Bravo Iniguez et al. 2014). Cheng et al. published a nonrandomized prospective, controlled study conducted to compare lobectomy with segmental resection for the treatment of elderly with stage I lung cancer (Cheng et al. 2012). A total of 184 patients were included in the study. The local recurrence and long-term survival rates were not significantly different between lobectomy and segmental resection. Among the patients who underwent segmental resection, those who had regional lymph node dissection showed a higher 3-year and 5-year survival rate than those undergoing selected lymph node resection (77.8% vs. 51.7%; $p = 0.042$; 55.6% vs. 27.6%; $p = 0.034$), but this was not significant in lobectomy. A subgroup analysis of patients with $FEV_1 < 1.5$ L showed that segmental resection, which preserves more normal lung segments, was more suitable for the elderly without decreasing the overall survival rate.

Thirdly, implementation of palliative care is an essential part of lung cancer treatment. Crucial data were reported by Temel et al. (2010) who analyzed the effect of early integration of palliative care in parallel to usual oncological care (Temel et al. 2010). Authors demonstrated an improvement of both health-related quality of life (HRQoL) and depression at 3 months when palliative care was started right from the beginning in addition to usual oncological treatment. Surprisingly, patients treated with early integration of palliative care lived 2.3 months longer than those treated with usual care.

Palliation of Symptoms: The Sooner the Better

When the report *Dying in America: Addressing Key End of Life Issues* (2014) was made public by the Institute of Medicine in 2014, it made clear that improving access to palliative care for seriously ill patients was a national priority.

"Palliative or supportive care" includes all actions that are not directly related to anticancer treatment and has the main goal to help managing cancer−/treatment-related psychological and physical symptoms. Early involvement of a "supportive care system" in the management of every frail patient should be promoted by the MDT (Naeim et al. 2014).

Surgeons play a pivotal role as providers of end-of-life care. It has been shown that among Medicare patients, almost one-third undergo surgery in the year before death, many in the last week of life (Kwok et al. 2011), while up to 25% of patients diagnosed as having stage IV cancer undergo a surgical procedure. As Lilley et al. (2016) pointed out, although surgeons routinely

care for seriously ill patients, the role of palliative care in surgery remains poorly defined.

Despite the wide room to establish roles of surgeons in palliative care teams, it seems to be recognized that timely strategies should be put in place early in the process. Temel et al. (2010) showed that lung cancer patients assigned to early palliative care experienced better QoL with lower rate of depression compared with ones only receiving care from their specialists. In addition to this, despite fewer patients receiving aggressive care, they had a longer survival when enrolled in early palliative treatment groups. Zimmer et al. (1984, 1985) were able to demonstrate that, if physicians and nurses with experience in the geriatric care were added to the equation, patients had fewer hospitalizations and nursing home admissions. Home-care team patients and caregivers reported significantly higher satisfaction.

To improve patients' and families' satisfaction, when end-of-life situations are approaching, shared decision-making seems to be the preferred model. It would be erroneous for physicians to misinterpret this process as simply obtaining an informed consent. Many surgeons struggle to balance the need for open discussions about prognosis with the desire to maintain hope; decision-making about palliative procedures poses a definitive challenge.

Miner et al. (2011) reported a higher rate of symptom resolution, lower morbidity, and longer survival using a shared decision-making approach. "Shared decisions" mean primarily to explain more accurately possible the present and future (possible) scenarios to patients and families. It has been shown that patients who are nearing the end of life and have an accurate prognostic understanding are more likely to prioritize comfort over potentially life prolonging but highly burdensome treatments.

Symptoms relief is a primary goal shared by patients and surgeons. However, patients have their own individual priorities for treatment. Family activities or events may be highly valued by patients over schedules and treatment plans. Modern, patient-oriented clinicians need to be willing to have them influencing the care process.

Abstract

The specialty of radiation oncology has significantly evolved over the past few decades. Historically, large volumes of normal tissue were irradiated along with the tumor due to the prevailing techniques and equipment in the era of two-dimensional delivery. This led to an increased incidence of side effects, causing difficulty for elderly patients to tolerate treatment. Not only were toxicities higher but also the radiation dose could not be escalated due to uncertainty about tumor location and dose to the intended target. With the advent of computer integration into the radiation oncology clinic, the therapeutic window improved dramatically. For the first time, tumors could be visualized in three dimensions so that a new technique called 3D conformal radiation

therapy (3D-CRT) evolved. The tumors could now be delineated such that the dose could be spatially encompassed with more precision than ever before. This led to significant improvements in local control for a variety of tumor types with fewer side effects, which are of particular concern in elderly patients, who usually present with a higher number of comorbidities that can limit treatment toleration. This chapter will discuss advances in radiotherapy and their significance for elderly patients. It will also discuss considerations for neoadjuvant, definitive, adjuvant, and palliative radiation in a geriatric population across tumor sites, with a focus on toxicity and tolerability.

Introduction

The specialty of radiation oncology has significantly evolved over the past few decades. Historically, large volumes of normal tissue were irradiated along with the tumor due to the prevailing techniques and equipment in the era of two-dimensional delivery. This led to an increased incidence of side effects, causing difficulty for elderly patients to tolerate treatment. Not only were toxicities higher but also the radiation dose could not be escalated due to uncertainty about tumor location and dose to the intended target (Stroom et al. 1998).

With the advent of computer integration into the radiation oncology clinic, the therapeutic window improved dramatically. For the first time, tumors could be visualized in three dimensions so that a new technique called 3D conformal radiation therapy (3D-CRT) evolved. The tumors could now be delineated such that the dose could be spatially encompassed with more precision than ever before. This led to significant improvements in local control for a variety of tumor types with fewer side effects, which is of particular concern in elderly patients, who usually present with a higher number of comorbidities that can limit treatment toleration. One example of where this technology integration has had a significant role of decreasing toxicity for elderly patients is in the setting of prostate cancer, where the integration of 3D-CRT has facilitated blocking of the normal tissues precisely in alignment with the position of the tumor (Soffen et al. 1992). This technique, called conformal avoidance, allows a beam's eye view of the volumetric relationships between structures so that an acceptable dose volume histogram (DVH) analysis that achieves the desired tumor coverage while also respecting the allowable dose that the specified volume of the normal organ can receive is achieved (Purdy 1997).

Each year since, more improvements have been developed so that radiation oncologists now have the ability to use 4D CT scans that can measure the position of the tumor as it moves with breathing (Keall 2004). This increased precision has led to the reduction of margins necessary to accurately encompass the tumor, greatly limiting the normal tissue reactions. Furthermore, each day when the patient undergoes radiation, the radiation oncologist now has the ability to ensure the patient's proper positioning by daily image guidance. This resulting image guided radiation therapy (IGRT) has resulted in more accurate daily treatment with less irradiation of the surrounding normal tissues (Bell et al. 2017).

Such imaging can be performed directly on the radiation delivery unit itself, either with kilovoltage x-rays or a conebeam CT. In the example of prostate cancer, these techniques allow the implantation via transrectal ultrasound of radiopaque markers directly into the prostate gland. Each day the patient comes in for treatment, the radiation therapist is able to image the real time position of the tumor and verify the measurements before delivery. This is important because the degree of bladder and rectal filling, as well as the effects of respiration, can significantly affect organ position. For elderly patients, avoiding long-term injury to the adjacent rectum by minimizing radiation proctitis is a central concern, thus IGRT strategies have become the standard of care for the safe delivery of high doses of external beam radiation therapy (EBRT) to the prostate (Gill et al. 2011).

The treatment landscape shifted further with the expansion of treatment tools to include intensity modulated radiation therapy (IMRT) (Purdy

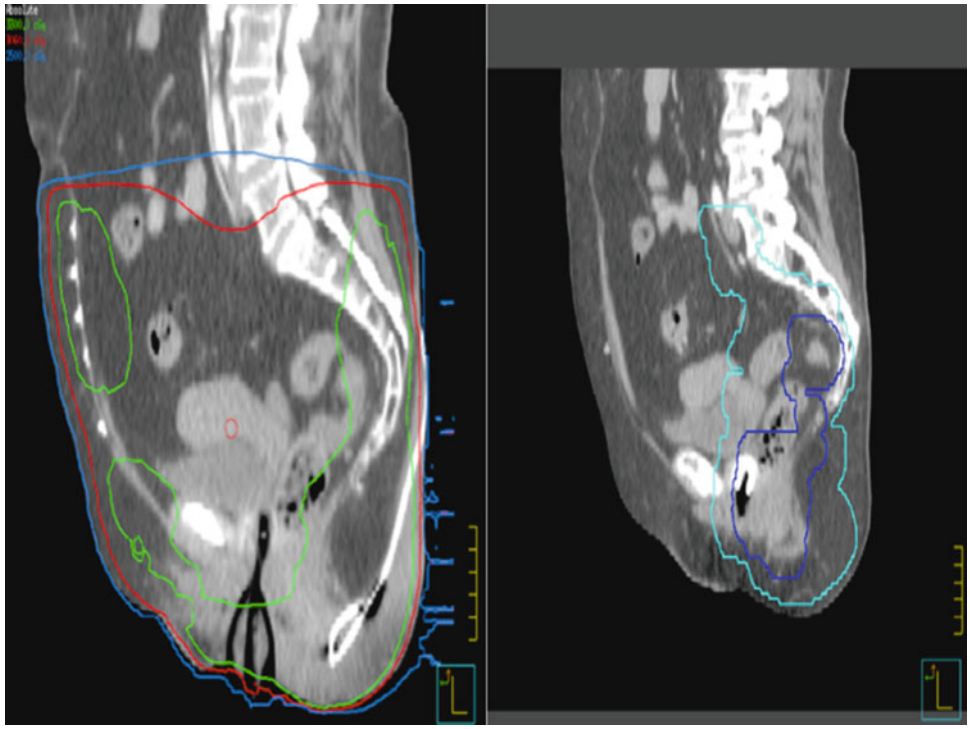

Fig. 1 IGRT: Conebeam CT overlaid with the simulation CT showing the positioning of a liver oligometastasis for SBRT

1999). With 3D-CRT, the dose is delivered with a uniform fluence across the treatment field. However, with IMRT, the physician can change the radiation beam into individual beamlets to focally escalate or de-escalate the dose. The dose is shaped by these individual computerized blocks that move during treatment delivery to create the specific intensity of the doses across the volume of interest. The result is to allow safe dose escalation to improve tumor control while minimizing the morbidity to the adjacent normal tissue (Fig. 1).

In the modern era, radiation therapy can be delivered with conventional fractionation with daily doses of 1.8–2.0 Gy (Gray, the unit of dose) over many weeks or with a newer type of high dose ablative delivery called stereotactic body radiation therapy (SBRT). With SBRT, doses up to 12 times the normal daily dose can be delivered to maximize tumor dose with rapid falloff of dose to the surrounding normal tissue. Research to date indicates there may be a novel mechanism of cell kill with SBRT such that there is apoptotic death of the endothelial cell microvasculature (Kolesnick and Fuks 2003). Although the exact mechanism of cellular injury is not known, clinically these 5-day or less regimens are associated with higher rates of local control. Such intensified treatment is only possible because of the advances in 4D CT, 3D-CRT, and IMRT, which now allow maximization of a conformal approach.

Further, imaging of the tumor has dramatically improved with the addition of scans that incorporate metabolic tumor information that can be fused directly to the planning CT scan for treatment. With many tumor types, a positron emission tomogram (PET) scan is fused to a CT scan and can be directly imported into the treatment planning system. This allows the radiation oncologist the ability to improve the accuracy of the target volume delineation; this certainty of tumor position leads to smaller planning target margins, which aids in normal tissue morbidity relief.

For some patients, internal radiation treatment with brachytherapy may be a better option. With

the example of prostate radiation, this can be delivered either with a low dose rate LDR technique of implanted radioactive seeds or a form of high dose rate HDR delivery (Magnuson et al. 2017).

These techniques have a role for patients with low risk disease as definitive treatment alone or in combination with IMRT for higher risk disease. For those elderly patients who may have difficulty assuming the treatment position for 5 days a week for 9 weeks, brachytherapy may have an enhanced therapeutic ratio.

Consideration of avoiding toxicity is thus significantly heightened in the elderly. Design of treatment fields must take into account how long the patient can tolerate a certain position per day and how many weeks will be needed to deliver the intended dose. For elderly patients, the life expectancy, goals of treatment, and the potential for least acute and late side effects are all factors to be expectantly weighed.

Anticipation of acute toxicity revolves around what organs will be in the radiotherapy field and review of what doses they will receive according to the DVH. With the arsenal of modern treatment planning techniques, modification and adaptation of treatment is more readily accessible than ever before. Incorporation of IMRT and IGRT has been shown across many clinical treatment sites to limit morbidity by virtue of decreasing the volume of healthy tissue irradiated to a high dose. Nonetheless, patients are seen weekly in the radiation oncology clinic to assess the individual's toleration of treatment. Assessment of the skin for erythema and desquamation is routine. This is performed in conjunction with assessment of other normal tissue effects referable to the body part being irradiated. In addition, many patients receive concurrent chemotherapy with the radiation, thus expanding the assessment each week to evaluate for an expanded array of acute symptoms specific to the agents and doses being received. Nutritional support is critical during radiation therapy and, for the elderly patient, this can often mean the difference between treatment toleration and hospitalization. With a multidisciplinary team including a dietician, weight loss can be rapidly evaluated and managed with oral supplements. For elderly patients who may have baseline sarcopenia, vigilance of nutritional status is paramount.

Once the acute effects of radiotherapy have healed, the patient treated with curative intent returns for ongoing surveillance. During these visits, carefully tailored probing of the function of those normal tissues within the treatment field may elicit suggestion of late radiation damage. Each normal tissue has a tolerance dose for radiotherapy, which is considered the "safe" dose for the majority of the population. However, within the population, there are subsets of patients who have increased radiosensitivity of their healthy tissues that may manifest as significant toxicity. Monitoring of those tissues within the field is indicated since radiation damage may not be clinically apparent for years after treatment.

If an elderly patient does develop evidence of a late complication, multidisciplinary evaluation is often needed to place the effect within the full context of the elderly patient's life and social support environment. Supportive care with the appropriate modality based on organ site is done with the intent of improving the microvascular tissue environment. With some delayed injuries, hyperbaric oxygen therapy can improve the local healing of the tissue irradiated, causing notable gains in function (Bennett et al. 2016). However, such therapy takes multiple weeks to deliver in an enclosed space and is not necessarily the most comfortable environment for an elderly patient.

In short, technological advances over the last few decades have revolutionized the delivery of radiation therapy, increasing the escalation of high-dose irradiation to the tumor and lower dose to the surrounding normal tissues. These improvements have expanded options for elderly patients with cancer to include the potential of noninvasive radiation. Depending on the site, radiation therapy can be used as a neoadjuvant, adjuvant, or definitive form of therapy. In this chapter, we will explore some specific examples of how such treatment may have an expanded role for elderly patients.

Neoadjuvant Radiotherapy

Treatment of gastrointestinal tumors often involves trimodality therapy such that chemotherapy and radiotherapy are delivered, either sequentially or concurrently, prior to surgical resection to maximize the potential for local control and to enhance complete excision of the tumor with negative margins for an R0 resection. Prior to the era of conformal therapy, large field irradiation was associated with increased rates of acute toxicity. With integration of advanced technologies, radiation therapy for GI cancers can be delivered with more normal tissue sparing than ever before.

The current standard of care based on data from the CROSS Trial is for concurrent chemoradiation prior to esophagectomy for locally advanced disease (Shapiro et al. 2015). Such concurrent chemoradiation has the potential for significant esophagitis during treatment, which could lead to feeding tube placement as well as the potential for radiation pneumonitis, which could affect the perioperative surgical risks. IMRT has been shown not only to decrease the rates of grade $\geq$3 acute treatment-related toxicity (Shridhar et al. 2015) but also to improve the outcomes with better overall survival, locoregional control, and noncancer death (Lin et al. 2012). With IMRT techniques, it is now possible to endoscopically place fiducial markers to denote the superior and inferior extent of tumor prior to measurement of the tumor's position with breathing on the 4D CT scan such that the gross tumor volume can receive a higher dose than the surrounding clinical volume (Fernandez et al. 2013; Dhadham et al. 201614).

Higher dose >51 Gy data now suggests that this may lead to improved outcomes (Zhang et al. 2005). Since the likelihood of attaining a pCR increases with dose, (Geh et al. 2006) with these new dose escalated techniques improved outcomes for patients with locally advanced tumors may be increasingly possible. Indeed, Donohoe et al. have reported a 71-month median survival for those esophageal patients attaining a pCR versus 17 months for those without a pCR, $P < 0.0001$ (Donohoe et al. 2013). For elderly patients, these treatment improvements are important to consider for patients who are medically inoperable (Li et al. 2015).

As in esophageal cancer, integration of preoperative radiation strategies is associated with improved local control and less acute as well as chronic toxicity in patients with locally advanced rectal cancer (Kapiteijn et al. 2001; Sauer et al. 2004). These improvements in local control are significant for elderly patients who are medically unable to undergo surgical resection, while the decreased toxicity is particularly beneficial in a geriatric population that tolerates side effects more poorly due to a higher presence of comorbidities. Moreover, similar to treatment of locally advanced esophageal cancer, patients treated with concurrent chemoradiation prior to surgery who attain a pCR have improved 5-year disease free survival (DFS) compared to those who do not, 83.3% pCR versus 65.6% non pCR, $P < 0.0001$ (Maas et al. 2010). In the last few decades, comparison of long-course chemoradiation over 5.5 weeks has been compared with short-course external beam irradiation over one week and found to be equivalent (Bujko et al. 2006). In addition, a short course of endorectal brachytherapy has been reported to have equivalent local control outcomes with conventional external beam treatment but with less toxicity given the dose is to the tumor and adjacent mesorectum only (Vuong and Devic 2015). Thus, for the elderly patient, delivery of a short course of pelvic or endorectal radiation alone prior to surgery has the advantage of improving outcomes for patients in whom chemotherapy may be contraindicated or for whom longer-treatment durations would pose challenging. Finally, with the emergence of tumor-regression criteria, there is now an alternative for those elderly patients who achieve an excellent clinical response and in whom rectal surgery may be contraindicated called nonoperative management. (Beets et al. 2015; Smith et al. 2015).

Patients with pancreatic cancer often present with disease that is not amenable to upfront resection, termed either borderline resectable (BRPC) if the tumor abuts the blood vessel or locally advanced (LAPC) if the tumor is encasing the vessel (Schwarz and Katz 2015).

In elderly patients, standard neoadjuvant therapies of systemic chemotherapy followed by chemoradiation may be difficult to tolerate so advanced techniques have now paved the way for integration of a short course of high-dose radiation termed stereotactic body radiation therapy (SBRT). Since the earliest pancreatic SBRT studies (Koong et al. 2004; Hoyer et al. 2005) were introduced in the early 2000s, significant progress has been made to optimize the number of fractions, manage the respiratory associated target motion, and precisely deliver the high dose directly to the gross tumor volume (Pollom et al. 2014). A recent prospective multi-institutional trial (Herman et al. 2015) reported rates of grade $\geq$2 gastritis, fistula, enteritis, and ulcer of only 2%. Indeed, pancreatic SBRT has become exceedingly well tolerated and represents a convenient choice for the elderly patient with multiple comorbidities since the treatment is typically delivered within one week.

Definitive Radiation Therapy

Incorporation of radiation advances has led to exploration of high-dose radiation alone for the treatment of oligometastases. Many elderly patients present with isolated liver metastases but are not candidates for invasive procedures due to their medical comorbidities. Liver SBRT for metastatic disease thus emerges as an attractive option for this group given available data citing excellent local control and minimal morbidity (Rusthoven et al. 2009; Lee et al. 2009; Rule et al. 2011; Meyer et al. 2016). Definitive SBRT has also been reported as effective for those elderly patients with pancreatic cancer who have unresectable disease, decline surgery, or have comorbidities that preclude surgery, with data from the University of Pittsburgh showing no acute or late grade 3+ toxicities (Kim et al. 2013).

In addition to the potentially curative delivery of ablative SBRT to eradicate metastases, there is also the future possibility that focal SBRT to an isolated local site, by virtue of effects on the immune system leading to resolution of distant metastases termed the abscopal effect (Zeng et al. 2013), may lead to enhanced systemic control in an elderly population where chemotherapy may not be a choice given the patient's underlying medical status. The potential of immune-SBRT in patients is already being explored and, pending completion of ongoing trials, could become an excellent option for elderly patients if their local as well as distant disease could be improved by a noninvasive modality.

Oligometastases to the brain offer particularly challenging circumstances to elderly patients who may already be experiencing declining cognitive function. Conventional whole brain radiation treatments for brain metastases are associated with acute effects of increased fatigue and potential late effects of neurocognitive injury with associated deficits (Li et al. 2008; Chang et al. 2009). For elderly patients with limited brain metastases, an approach of stereotactic radiosurgery (SRS) offers highly conformal, high ablative doses without diffuse CNS injury, offering significant sparing of the normal brain tissue. Reports of patients $>$65 years treated with SRS have indicated excellent local control (Noel et al. 2005) and may provide the most appropriate option for these patients with very limited disease in a suitable anatomic location. Unfortunately, elderly patients with inoperable primary glioblastoma multiforme (GBM) undergo much higher volumes of brain irradiation due to the nature of their infiltrative brain tumors. Recent data suggests that incorporation of a patient's MGMT gene methylation status could be useful to select elderly patients for regimens including radiation and temozolomide (Stupp et al. 2005; Brandes et al. 2009; Wick et al. 2012; Malmstrom et al. 2012).

In addition to SBRT integration for patients with metastatic disease, elderly patients who are not optimal surgical candidates with early stage non-small cell lung cancer may also derive significant benefit from this definitive radiation alone approach, with 3-year survival rates of 45% (Haasbeek et al. 2010). Even when the disease is more advanced and concurrent chemoradiation regimens are planned, more tailored techniques can improve toleration for elderly patients (Schild et al. 2007). Patients with more advanced primary lung cancers benefit from a conformal approach

with daily IGRT. In particular, data has emerged that involved-field radiotherapy to the gross disease only is associated with improved outcomes in the elderly population (Yu et al. 2008). Radiation to a moving tumor in the thorax can be associated with the toxicities of radiation pneumonitis, pericarditis, and esophagitis. Limitation of the volumes irradiated with avoidance of healthy tissue can facilitate the tolerance of elderly patients to definitive combined modality and definitive therapy regimens.

Elderly men with prostate cancer benefit from advanced radiation modalities as well, with increased choices titrated to stage of disease ranging from brachytherapy alone to IMRT/IGRT alone to a combination of both modalities. Offering treatment to such elderly patients can be tailored to their life expectancy and geriatric assessment. Indeed, data indicates that low-risk cancers in men >75 with comorbid conditions that are significant do not benefit from aggressive treatment (Daskivich et al. 2011). Similarly, for those patients with higher-risk disease, assessment of the Charlson comorbidity index for patients receiving external beam radiation in combination with brachytherapy and androgen blockade predicts overall survival and can be utilized in treatment decision-making (Hjalm-Eriksson et al. 2017). For those patients who elect to receive treatment, IMRT has shown less grade-3 proctitis (Dearnaley et al. 1999).

With advanced head and neck cancers, advanced modalities have a particularly critical role in treating elderly patients. Historically, head and neck radiation was associated with large-field irradiation that was associated with increased rates of long-term toxicities such as xerostomia, feeding tube dependence, and dysphagia (Prameela et al. 2016). Now, with IMRT, the high-dose regions can be carefully sculpted such that they encompass the primary and nodal tumor volume while keeping the mean dose to the normal tissues below the level at which significant toxicity occurs (Mendenhall et al. 2006; Nutting et al. 2011).

These improvements facilitate more elderly patients being offered organ preservation strategies with concurrent chemotherapy and radiation therapy. The focality of high dose to the PET/CT defined gross tumor volumes has also been associated with improved outcomes, enhancing the therapeutic ratio for this patient population. Finally, with daily imaging, the volume of tissue irradiated can be decreased as the patient responds to therapy. This new strategy is called adaptive radiation and allows real time tracking of tumor response during the weekly therapy so that adjustments can be made that will increase the volume of normal tissue preserved from the high-dose regions (Veresezan et al. 2017).

In addition to better computerized treatment planning and delivery techniques, novel radiation delivery modalities are being explored to further improve outcomes. In recent years, proton therapy administration has been increasing, with clinical trials evaluating whether this modality is significantly superior given its much higher cost (Mishra et al. 2017). Although data is still accumulating, there are some treatment sites in particular, such as primary liver tumors, where proton therapy may have a resonant niche. With primary liver malignancies such as hepatocellular carcinoma (HCC), there is underlying liver dysfunction, which limits the tolerance of the liver (Kimura et al. 2017; Fukuda et al. 2016). For elderly patients in whom there may be underlying comorbidities that preclude consideration of liver transplant or resection, focal liver proton therapy may be especially attractive. With protons, the physical characteristic of the radiation beam is different than that of the traditional photon beam such that there is a Bragg peak, beyond which the radiation dose stops, unlike the photon beam which has low dose delivered along the exit path (Skinner et al. 2011). This feature of protons decreases the volume of normal liver irradiated such that the risk of radiation-induced liver disease is lowered. For elderly patients, as liver proton data matures, this may become an important option.

In addition to EBRT approaches, there are expanding indications for brachytherapy as both curative and palliative treatment in many tumor sites in addition to prostate cancer. For primary and second liver tumors, for example, injection of millions of radioactive spheres can directly irradiate the liver malignancy and minimize the dose to the healthy parenchyma. HCC tumors traditionally undergo radioembolization for palliation, but

there are expanding roles of selectively irradiating a limited volume of the liver to an extremely high dose in an attempt to eradicate very focal disease (Kallini et al. 2016). The advantages of these liver-directed radioactive sphere strategies for elderly patients are limitation of short duration of side effects to fatigue, nausea, and pain with outpatient delivery.

Many elderly patients may have difficulty travelling to outpatient radiation facilities given a living situation in an institutional facility. For these patients, shorter duration of treatment is of particular concern. With nonmelanoma skin cancer incidence rising with increasing age, this becomes a difficult management problem for the infirm patient who is wheelchair bound and so frail that navigating transfer to the radiation treatment couch daily may pose a contraindication. For these patients, short-course brachytherapy may be advantageous with recent evidence showing excellent and good cosmetic results in 94.8% of patients (Delishaj et al. 2016).

Finally, there is new data evaluating the role of the patient's individual tumor histology to influence a personalized radiation dose choice, which could lead to more organ preservation approaches for radiosensitive tumors (Torres-Roca 2012). Within the spectrum of GI cancers, we look to squamous cell carcinoma of the anus for an example. Early work from Nigro et al. (1981) demonstrated that anal cancer represented a far more radiosensitive histology than rectal adenocarcinoma and could be treated definitively, not preoperatively. Data over the past 30 years has refined the treatment paradigm such that IMRT dose-painted definitive chemoradiotherapy is now the standard of care with significantly less acute toxicity than prior techniques (Kachnic et al. 2013). The recognition of the inherent differences in individual tumor radiation sensitivity has led to an appreciation that the future may be to consider the appropriate genomically adjusted radiation dose (GARD) for each patient (Scott et al. 2017). Incorporating this concept into future trials will help identify those elderly patients with radiosensitive tumors that may benefit from a noninvasive radiation approach.

Adjuvant Radiation

One of the best examples of adjuvant irradiation is following lumpectomy for invasive ductal carcinoma of the breast to complement breast preservation. In the setting of early stage breast cancer, the Oxford overview reported postoperative radiation therapy to the whole breast has been associated with a twofold decrease in first recurrence even in older patients (EBCTCG 2011). For patients with early stage invasive breast cancer $\geq$70, breast conservation therapy showed an absolute decrease in ipsilateral tumor recurrence of 7% with over 10 years of median follow-up compared with lumpectomy alone and tamoxifen (Hughes et al. 2004, 2013). Yet, although the whole breast radiotherapy is well-tolerated, elderly patients have sought shorter course fractionation schedules, and data has emerged to support this option as well. Indeed, such hypofractioned regimens have shown no difference in long-term local control or cosmesis (Bentzen et al. 2008; Haviland et al. 2012; Whelan et al. 2010). Advanced radiation techniques, such as treatment in the prone position or with the deep inspiration breath hold technique, have evolved to decrease the amount of normal lung and heart irradiated, which particularly may benefit elderly patients (Kirova et al. 2009; Grann et al. 2000; Smyth et al. 2015).

In addition to whole breast approaches, partial breast radiation has been investigated as an option for breast preserving therapy in selected patients. For elderly patients, delivery of a single fraction of radiation immediately following lumpectomy in the operating room, termed intraoperative radiation therapy or IORT, is especially attractive. Data to support this approach has been reported by investigators from the TARGIT and ELIOT trials. In the TARGIT trial, over 2,000 patients were randomized to receive either a 20 Gy dose of IORT or to standard whole breast irradiation, with 5-year results showing only a slight increase in local recurrence for the IORT group (3.3% vs. 1.3%, $P = 0.042$), which may be key to the decision-making of elderly women (Vaidya et al. 2014; Vaidya et al. 2010). Similarly, in the ELIOT trial, over 1000 patients $\leq$75 were treated with

standard whole breast techniques or single 21 Gy fraction of IORT following lumpectomy (Veronesi et al. 2013), with results showing worse local control in the IORT group, 4.4% versus 0.4%.

Accelerated partial breast radiotherapy can also be performed after surgery, either with external beam or brachytherapy approaches, and evidence to support its effectiveness has now matured (Vicini et al. 2016). As there has not been any difference in overall survival and since some series of APBI patients have noted less acute and chronic toxicity, this option may have a role in those appropriately selected elderly patients at low risk for locoregional recurrence of their disease.

Similar to breast cancer adjuvant strategies, postoperative treatments for patients with endometrial cancer have improved so that women experience less normal tissue morbidity. Within this spectrum of malignancy, tumors that are defined as high-intermediate risk based on age, depth of myometrial invasion, and grade benefit from postoperative radiation, including elderly women with stage I disease (Keys et al. 2004; Scholten et al. 2005). Further studies have refined the optimal extent of radiation, comparing pelvic radiation with intravaginal brachytherapy alone. In the PORTEC-2 trial, women >60 with stage IB G 3 and stage IC G1–2 and IIA G1–2 were randomized to pelvic external irradiation to vaginal brachytherapy (VB) alone (Nout et al. 2012). Although the results showed no significant differences in locoregional or distant recurrence at 5 years, the vaginal brachytherapy alone was associated with better quality of life and less toxicity. For elderly women, the strategy of VB with its improved normal tissue toxicity profile significantly enhances the therapeutic ratio.

Strategies to decrease normal tissue toxicities have also been explored in the adjuvant therapy of resected pancreatic head adenocarcinoma. Incorporation of adjuvant irradiation is currently controversial, with conflicting European data supporting systemic chemotherapy alone (Neoptolemos et al. 2001; Oettle et al. 2013) compared with US data from the RTOG (Regine et al. 2011; Berger et al. 2012). For those elderly patients receiving adjuvant irradiation, contouring should be done according to consensus guidelines (Goodman et al. 2012) with consideration of techniques involving IMRT and IGRT to decrease toxicity (Hajj and Goodman 2015).

Palliative Radiation

Palliative radiation has the potential to reduce pain and improve quality of life without curative intent for end-stage metastatic cancer. The patterns and indications for palliative radiation in an elderly population warrant discussion. There has been data to suggest that patient age influences the likelihood that the patient receives radiotherapy with palliative intent, and specifically that elderly patients are less likely to be administered palliative radiation by their provider. This is a trend that appears to be consistent in palliative care services offered to elderly cancer patients, with some data suggesting that older patients are less likely to be referred or to use a Palliative Care Specialist (Burt and Raine 2006). Wong et al. evaluated Age-related trends in receipt of palliative radiation in 63,221 patients from the Surveillance, Epidemiology, and End Results (SEER)-Medicare linked database with metastatic cancer of the lung, breast, prostate, or colon/rectum between 2000 and 2007 (Wong et al. 2014). Increasing age was significantly associated with a steady decrease in administration of palliative radiation: for patients 66–69 years, 70–74 years, 75–79 years, 80–84 years, and over 85 years, the rates of palliative radiotherapy receipt were 42%, 38%, 32%, 24%, and 14%. Multivariate analysis showed similar results, with 7%, 15%, 25%, and 44% decreased rates of radiation receipt for patients 70–74 years, 75–79 years, 80–84 years, and over 85 years compared to 66–69 year old patients (all $P < 0.0001$). Murphy et al. similarly found that likelihood of receiving palliative radiotherapy decreased with increasing age group from 65 to older than 85 for elderly patients with colorectal, lung, breast, or prostate cancer in their analysis of 51,610 Medicare patients (Murphy et al. 2013). Results from these studies indicate a need for more research investigating the

indications and rationales for decreased administration of palliative radiotherapy in an elderly population that can potentially benefit from its use.

Research has also been done to identify factors associated with greater likelihood of receipt of palliative radiation among elderly patients. Guadagnolo et al. performed an analysis of elderly Medicare patients who received palliative radiation for lung, breast, prostate, colorectal, or pancreas cancers from the SEER database from 2000 to 2007 (Guadagnolo et al. 2013). Elderly patients who had an earlier year of death, had lung cancer as the cause of death, were younger, were male, were not black, were married, had a Charlson comorbidity index of 0, were part of the southern SEER region, lived in an urban environment, had a neighborhood income level in the highest quartiles, and did not receive hospice care were more likely to receive palliative radiation. Moreover, of the 15,287 (7.6%) patients who received palliative radiation, almost 20% (2,721) received more than 10 days of treatment. The authors found that patients who did not receive of hospice care, patients who were treated in a freestanding facility, and Caucasian patients were more likely to receive more than 10 days of palliative radiation in the last 30 days of life.

There is also evidence to suggest that elderly cancer patients are as likely to benefit from palliative radiotherapy as younger patients, and therefore that age is not an appropriate factor to use in determining administration of radiation therapy for palliation. Campos et al. examined response to palliative radiation for painful bone metastases in 558 patients and found no significant differences in pain scores or analgesic intake between patients 65 years or older, 70 years or older, and 75 years and older compared with younger patients at 1, 2, or 3 months following radiation (Campos et al. 2010). Instead, there was a significant correlation between response and performance status, indicating this could potentially be a useful indicator in determining which patients can tolerate palliative radiotherapy for bone metastases. Westhoff et al. found similar results in 1,157 patients treated with palliative radiation for painful bone metastases (Westhoff et al. 2014). The authors compared pain response based on changes in pain score and medication and quality of life between patients less than 65 years ($n = 520$), patients 65–74 years ($n = 410$), and patients 75 years and older ($n = 227$). They found that there were no significant differences in pain response based on age group, and there was comparable overall quality of life between elderly and younger patients, indicating that age should not prohibit receipt of palliative radiation for bone metastases.

In a subgroup analysis of a phase III trial showing significantly better outcomes from palliative chemoradiation compared to palliative chemotherapy alone in poor prognosis patients with unresectable, locally advanced stage III non-small cell lung cancer except those with 2 or worse performance status, Strom et al. studied the effect in patients based on age (Strom et al. 2015). Patients in the experimental group received 42 Gy in 15 fractions, in addition to the four courses of carboplatin and vinorelbine that all patients received. Separating patients into those 70 and older and those less than 70, the authors found significantly increased 2- and 3- year survival in both age groups, and better preserved health-related quality of life and less hematologic toxicity in the older age group, although the increase in overall survival associated with radiation was only significant for the younger age group. These data are promising and suggest that palliative radiation can be feasible and beneficial in a geriatric population in this setting.

Future Directions

In addition to advances in computerized radiation treatment planning systems, novel machine delivery units are also continuing to evolve. Recent interest has focused on the functional information derived from MRI units that are mounted to the radiation emitting linear accelerator. With the ability to image the tumor and surrounding normal tissue on MRI scanners in real time during treatment delivery, there is optimism that this capability will further enhance the therapeutic ratio. For elderly patients, this would

increase the potential for conformal avoidance of healthy tissue, particularly for targets that move with respiration. The increased certainty of both tumor location and normal tissue location would translate to an ever-greater degree of precision such that smaller margins could be used for treatment planning. The resulting sparing of normal tissue could further enhance the ability to dose escalate the gross disease. Moreover, there is the potential to adjust the treatment fields as the course of radiation progresses over subsequent days given the functional assessment of in vivo response. All of these future therapies await data from trials to determine optimization, but, for the elderly population, this could increase the prioritization of noninvasive EBRT as the treatment modality of choice. Increased confidence in tumor location may also come from continued advances in diagnostic imaging. Novel ways to extract mineable data from the images themselves is emerging as the new field of radiomics (Lambin et al. 2012).

These imaging features may be able to direct the delivery of dose painting with the deliberate accounting for discrete habitats within the tumor. For elderly patients this would mean relative sparing of normal tissue adjacent to tumor that requires a lower dose. The future may thus be shaped around more actionable intelligence about the discrete biological features of each patient's individual tumor so that truly personalized radiation can be delivered for each patient. In a frail elderly population, that would be of the highest clinical concern.

Conclusion

In summary, radiation therapy has evolved over the past few decades to include advances in tumor targeting, location, and delivery highly relevant to an elderly patient population. These improvements have increased the safety of both EBRT and brachytherapy and offer elderly patients a highly effective, well-tolerated outpatient treatment. Personalization of technique, treatment position, and fractionation schedule can be more readily adapted to the special needs of a fragile elderly patient. Whether such treatment is indicated in the neoadjuvant, adjuvant, definitive, or palliative setting, patients can benefit from the incorporation of advanced technologies. Further optimization may be possible in the future with the expected developments of increasingly sophisticated imaging equipment on the radiation delivery unit itself.

Stuart M. Lichtman

Contents

Abstract

The aging of the population and the resultant increase in older patients with cancer make the study of this vulnerable group an important focus of cancer care. Older patients are the largest consumer of pharmaceuticals and have the highest incidence of drug toxicity and

adverse events. It is critical for clinicians to have adequate information regarding these therapeutic issues. This chapter will discuss some basics of pharmacology and aging and drug metabolism of specific agents.

Keywords
Chemotherapy · Pharmacology · Pharmacokinetics · Polypharmacy · Toxicity · Assessment

Introduction

Age is the single most important risk factor for developing cancer with 60% of all newly diagnosed malignant tumors and 70% of all cancer deaths occurring in persons 65 years or older. It has been estimated that by the year 2030, 20% of the US population (70 million people) will be older than age 65 years. The median age range for diagnosis for most major tumors is 68 to 74 years, and the median age range at death is 70 to 79 years. The mortality rate is disproportionately higher for the elderly population. There are several potential reasons for this, including more aggressive biology, competing comorbidity, decreased physiologic reserve compromising the ability to tolerate therapy, physicians' reluctance to provide aggressive therapy, and barriers in the elderly person's access to care (Williams et al. 2015). The elderly patient with cancer often has an elderly caregiver or is socially isolated. The older patients have not been participants in clinical trials, and the data necessary to help clinicians care for these patients is lacking. All of these factors contribute to the difficulty of caring for these complex, heterogeneous, and vulnerable patients (Rao and Cohen 2016). The field of Geriatric Oncology has become increasingly recognized as an important component of cancer care and cancer research.

Geriatric Assessment in Oncology

The identification of problems in older patients is critical in prognostication and decisionmaking. Researchers in geriatric oncology have demonstrated that the traditional method of routine history and physical is inadequate in determining elder-specific issues (Extermann et al. 1998, 2000). Clinicians have not been trained to ask the appropriate questions and appropriate interpret the available data. Medical oncologists have used performance status scales such as the Karnofsky and ECOG (Eastern Cooperative Oncology Group) scales to help stratify patients for treatment and as part of clinical trial eligibility. This has been a valuable tool and, for the general oncology population, has been helpful and has withstood the test of time. However, this simple approach is not adequate in the complex, heterogeneous older population. Performance status often does not reflect the functional status of older patients (Extermann et al. 1998). Clinicians will appropriately refer to published clinical trials and established national and international guidelines to assist to decisionmaking and deciding on treatment options. Unfortunately, older patients have been grossly underrepresented in clinical trials, and data reporting has been inadequate (Lichtman 2012a; Hutchins et al. 1999). This includes registration trials for new drugs (Scher and Hurria 2012; Talarico et al. 2004). When they do participate, they are an exceptional group of elders who have passed the often-stringent eligibility requirements and usually have minimal to no comorbidity and an excellent performance and functional status. Therefore, the available data usually do not reflect the average patient seen in practice. The result is that there is a paucity of data to make true evidence-based decisions. In order to obtain this important information, researchers in geriatric oncology have been developing geriatric assessment scales appropriate for the oncology patient. There is a need to assess basic information. Functional assessments include activities of daily living (toileting, feeding, dressing, grooming, ambulation, bathing) and instrumental activities of daily living (using the telephone, shopping food preparation, housekeeping, laundry, transportation, and ability to take medication accurately). Dependence in these areas has shown to be a prognostic factor for poor outcomes and treatment-related toxicity (Audisio et al. 2008; Hurria et al. 2011b; Korc-Grodzicki et al. 2015).

The presence of a geriatric syndrome (delirium, dementia, incontinence, falls, pressure ulcers, malnutrition, osteoporosis, hearing and vision difficulties, and sleep disorders) also has a negative impact (Reuben et al. 1992). The study of the overall evaluation of the older patient has been an extrapolation of the established Comprehensive Geriatric Assessment (CGA) methods. The CGA is a multidisciplinary, interdisciplinary diagnostic process focusing on the medical, psychosocial, and functional capabilities to develop a coordinated and integrated plan for treatment and follow-up (Wildiers et al. 2014). It is recognized that a CGA as performed by geriatricians is not practical in the usual outpatient oncology setting. Researchers are trying to streamline the approach by determining the most important questions in terms of oncologic care and then validating this approach in various settings. A position paper published by the International Society of Geriatric Oncology (SIOG) highlighting issues in this field and discussed the domains which need to be evaluated and the important questions to be addressed (Wildiers et al. 2014). In terms of predictive models, one area that has developed a significant amount of important data is the risk of therapy-related toxicity. Two models have been developed. The Cancer and Aging Research Group developed a predictive for significant (grade 3+) hematologic toxicity (Hurria et al. 2011b). The power of this model is that it has been shown to be better than clinical judgment in predictive value. The study also demonstrated that those older patients with the lowest scores (0–3) still had a 25% risk of $\geq$ grade 3 toxicity. The CRASH (Chemotherapy Risk Assessment Scale for High-Age Patients) score is able to distinguish several risk levels of severe toxicity. It predicts separately hematologic and nonhematologic toxicity (Extermann et al. 2012). Oncology-specific geriatric assessments are also being developed to predict other outcomes (Kenis et al. 2014). These scales include the G8, Flemish version of the Triage Risk Screening Tool (fTRST), Groningen Frailty Indicator, and Vulnerable Elders Survey-13 (Bellera et al. 2012; Kenis et al. 2014). Another important consideration is recognizing frailty. The frail patient can be thought of an individual who have a higher susceptibility to adverse outcomes, such as mortality and institutionalization. From an oncology perspective, it often indicates a patient who has dependence in activities of daily living and if given standard therapies will often not complete the treatment, have excessive toxicity, and therefore will not benefit. The frailty phenotype was established by the work of Fried et al. (2001). Clinicians need to recognize this group to avoid excessive toxicity and suffering (Rockwood et al. 2005). Predictors of mortality can be helpful to clinicians to weight the risk vs. benefits of therapy, particularly adjuvant treatment. The website ePrognosis (www.eprognosis.com) is one such example. Gait speed has been shown to be a powerful predictor of survival (Studenski et al. 2011) and is clearly simple to evaluate. Geriatric assessment can also be helpful in predictions of delirium (Korc-Grodzicki et al. 2014). These scales and predictive models also have been shown not to be time-consuming to the medical staff and are often self-administered by the patient. The functional components such as gait-speed, get up, and go testing can be done by nursing. Newer technologies are beginning to be utilized to capture and evaluate this information (Kelly and Shahrokni 2016).

Physiology of Aging and Drug Therapy

There are a number of physiological changes which accompany aging (Lichtman 2006; Lichtman et al. 2007a). Drug compliance is an important issue particularly with the marked increase in oral anticancer therapies which compound the problem of polypharmacy (Lichtman 2015; Nightingale et al. 2015). Studies have emphasized that obesity is a significant problem in elderly and should be considered in trials (Campbell et al. 2012; Gibson et al. 2014; Renfro et al. 2016). Other variables to be considered are the effect of age and diet and genetic polymorphisms (Walko and McLeod 2014). Polypharmacy can also affect metabolism due to the potential of drug-drug interactions. There is an age-related reduction in GFR which is not reflected by an increase in serum creatinine levels

because of the simultaneous loss of muscle mass which occurs with age. Two common equations used clinically are the Cockcroft-Gault and Jelliffe equations. It should be noted that many older patients who have a serum creatinine in the normal range for a particular laboratory have renal insufficiency (Launay-Vacher et al. 2007b). Dosing recommendations for older patients and those with renal insufficiency have been published (Launay-Vacher et al. 2007a, 2015; Lichtman et al. 2007b). Appropriate dose modifications can result in safe and effective outcomes (Lichtman et al. 2016). The study of the pharmacokinetics of chemotherapy in older patients has truly been lacking. Patients reported generally do not have significant comorbidity and may not be truly representation of the average patient seen in practice. There is very little prospective pharmacokinetic data. Future study is required.

Research

Research is being performed by a growing number of investigators at institutions across the nation, as well as internationally. The International Society of Geriatric Oncology, founded in the year 2000, fosters the mission of developing health professionals in the field of geriatric oncology, in order to optimize treatment of older adults with cancer, through education, clinical practice, and research. The Society's publication, the *Journal of Geriatric Oncology*, is the first journal devoted solely to the field. The Cancer and Leukemia Group B (now, the Alliance for Clinical Trials in Oncology) Cancer in the Elderly Committee has supported furthering research in geriatric oncology through clinical trials and secondary data analyses (Hurria et al. 2010, 2011a). The Cancer and Aging Research Group has developed an instrument to predict chemotherapy toxicity, initiated and supported trials to validate this methodology in different clinical settings, and, most importantly, mentored junior investigators in geriatric oncology and study novel clinical trial designs (Hurria et al. 2014). The Gynecologic Oncology Group Elderly (now NRG oncology) taskforce is supporting the first prospective trial in older women with ovarian cancer and planning further studies in other diseases and modalities. The American Society of Clinical Oncology (ASCO) also has a number of initiatives in geriatric oncology. These include a Geriatric Oncology Issue Exploration Team, educational materials including ASCO University, sessions at the Annual Meeting including a Geriatric Oncology track, the BJ Kennedy Award for Excellence in Geriatric Oncology, articles in the ASCO Post and a Geriatric Oncology component of the Cancer Education Committee. ASCO has also published a position paper encouraging research in older patients to increase the available of evidenced-based data (Hurria et al. 2015). One area of great interest is rethinking clinical trial design. It is important that clinical trials prospectively obtain important patient data such as baseline functional status. The issue of eligibility, appropriate endpoints, and toxicity evaluation need to be reconsidered for older patients (Wildiers et al. 2013; Lichtman 2012b; Kim et al. 2015) . Data analysis and clinical trial reporting also has to adapt for appropriate evaluation and interpretation. These issues are imperative to obtain quality data, so clinicians have the ability to make meaningful decisions.

The care of the older cancer patient is a complex endeavor. It requires careful thought and evaluation. Goals of therapy need to be carefully considered. A multidisciplinary approach is preferred. Geriatric oncology needs to move to the forefront of oncology care. These vulnerable patients need to be the focus of our endeavors.

Pharmacokinetic Evaluation in Older Patients

There is a question whether there is a need to study pharmacology in older patients. If we say that it is not necessary, then we are saying that current clinical trials structure is adequate for older patients. It is definitely not as indicated by the under representation of these patients in trials. In terms of drug trials, the pharmacokinetics of chemotherapy has been primarily studied in the "typical" patients, that is, those patients without

significant comorbidity and good performance and functional status. End-organ dysfunction studies have been performed on many drugs such as irinotecan, paclitaxel, gemcitabine, and pemetrexed (Venook et al. 1998, 2000, 2003; Mita et al. 2006). To date there are few studies which have shown a difference between the "typical" patients and elderly. Few age-related changes have been reported. Pharmacokinetic differences, when present, have not been clinically relevant. In addition, there are virtually no studies which look at changes in pharmacokinetics over multiple cycles. Heterogeneity makes studies in the elderly difficult and results in too much variability to be clinically applicable. Some differences in clinical toxicity are often been a result of drug scheduling not age (Lichtman et al. 2007a). An example is 5-fluorouracil toxicity differences if administered weekly, bolus monthly, or infusion.

One rationale in the past to do pharmacokinetics studies was the avoidance of toxicity. Hematologic toxicity has been minimized due to hematopoietic growth factors. Dose-limiting toxicity is often due to nonhematologic toxicities which are not related to significant differences in pharmacokinetics, i.e., neuropathy from oxaliplatin.

One main issue is that we need to consider which subset elderly patients need to be included when deciding on pharmacokinetics studies. Are they the healthy, vulnerable, frail, anemic, hypoalbuminemic, those dependent in activities of daily living or instrumental activities of daily living and multiple comorbidities? Many older patients have had previous chemotherapy and radiation for treatment of other cancers. In addition, comorbidity may cause further change in organ function and change the patients' sensitivity to toxicity, i.e., diabetes-neuropathy, atherosclerotic heart disease-cardiomyopathy. We should be studying pharmacokinetic tests in these different elderly populations. The factors to be studied should also include oral therapy, compliance, biologic therapy, and drug interactions. The other factors which should be included in data acquisition include longitudinal effects of treatment, changes in cognition, changes in function with treatment, dependency, chronic toxicities, scheduling differences which can affect toxicity, and correlation of toxicity and function. The inclusion of pharmacogenomics is also critical (Shah 2004). In evaluating toxicity, questions which need to be answered are our toxicity scales adequate for older patients? Do they capture enough information, particularly function, such as the effect of neuropathy on activities of daily living and instrumental activities of daily living?

Therefore, pharmacokinetics should be studied, but the trials need to be novel and include these aforementioned factors. Regulatory agencies should require the inclusion of older patients before drugs can be approved, or an appropriate subset should be analyzed to at least provide safety data (Hurria et al. 2015; Lichtman 2012a).

Clinical Trial Design

A number of barriers limit the participation of older patients in clinical trials. Often, for various reasons, clinicians do not offer a clinical trial to eligible older patients. Cognitive dysfunction also interferes with patient understanding of complicated informed consent documents, impairments that affect as much as 36% of adults aged 85 and older and that rules out trial enrollment. There are a number of design issues which need to be addressed. There are specific issues which are particularly pertinent to the older patients including function, comorbidity, and social supports. Clinical investigators and biostatisticians need to develop novel trials to optimize the data derived from these studies. Suggestions have been proposed to "geriatricize" the standard oncology drug design. We have to meld the standard oncology outcomes of disease specific and overall survival with geriatric outcomes of evaluating function, cognition, toxicity, nutrition, and dependence, i.e., quality vs quantity of life. ASCO has published position papers on specific needs to improve the evidence base to improve cancer care of older patients (Hurria et al. 2015; Wildiers et al. 2013). To meet the needs of these vulnerable cancer patient, which will be the majority, these clinical design considerations need to be incorporated in studies as soon as possible. The reluctance to alter our standard designs must be overcome, or

the progress that is urgently needed will never occur. A review of commonly used chemotherapy drugs follows and discusses the issue of pharmacology.

Chemotherapy: Pharmacology

Alkylating Agents

Alkylating agents have been the foundation of therapy for decades, particularly for breast cancer and hematologic malignancies. Their main dose-limiting toxicity is hematologic. The large interindividual variability in terms of bone marrow reserves is well known among older patients depending on comorbidity. Metabolism represents the main route of elimination for most compounds. Hepatic enzymatic processes are often involved. Cytotoxic effects correspond to metabolites rather to parent compounds.

Melphalan

Melphalan is administered to elderly patients for treatment of multiple myeloma. Drug excreted unchanged in the urine represents about one third of the administered dose (Reece et al. 1988). Positive correlation has been observed between melphalan area under the curve (AUC) and the degree of renal insufficiency (Vigneau et al. 2002). However, renal insufficiency did lead to a limited decrease in melphalan clearance compared to the interindividual variations in systemic clearance (Tricot et al. 1996).

High-dose chemotherapy is being increasingly utilized for the treatment of multiple myeloma in older patients (El Cheikh et al. 2011; Klepin and Hurd 2006). Doses up to 200 mg/m^2 by intravenous (iv) infusion has become a standard. Higher toxicity, mainly myelosuppression, has been observed in patients over the age of 70 years (Jantunen et al. 2006). There is no recommendation of melphalan dosing based on renal function, but there is a consensus that reduction of the melphalan dose should be considered in patients with glomerular filtration rate of $<$30 ml/min.

Cyclophosphamide

Metabolism of cyclophosphamide to active metabolites is initiated by cytochrome P450 (subfamily 3A and 2B) mainly in the liver. An accumulation of toxic alkylating metabolites is expected in renal insufficiency justifying a dose reduction of 20–30% depending on the degree of the renal insufficiency. Cyclophosphamide is administered in combination of methotrexate and 5-fluorouracil for treatment (CMF) of breast cancer. A prospective study in patients $>$70 years old concluded that the dose of CMF in patients above 70 years should not exceed 75% of the standard dose. The combination of cyclophosphamide and doxorubicin for the treatment for breast cancer was evaluated (Dees et al. 2000). There was a moderate evidence of age-related decrease in nadir absolute neutrophil count (ANC). Pharmacokinetics analyses did not demonstrate age-related differences in the either cyclophosphamide or doxorubicin plasma exposure, but only the pharmacokinetics of the parent drug (unchanged cyclophosphamide) was explored. The available evidence indicates that dose modification is not required due to age alone.

Bendamustine

Bendamustine is a novel chemotherapeutic agent comprised of a bifunctional mechlorethamine alkylating group, a purine-like benzimidazole ring, and a butyric acid side chain. The drug has been shown to be a potent cytotoxic agent, with in vitro studies demonstrating extensive and durable DNA damage. In a pharmacokinetic trial, bendamustine was administered as a 60-min 120 mg/m^2 intravenous infusion on Days 1 and 2 of six 21-day cycles (Owen et al. 2010). Pharmacokinetic models were developed, with covariate assessment. Following a single dose of bendamustine HCl, concentrations declined in a triphasic manner, with rapid distribution, intermediate, and slow terminal phases. The intermediate $t_{1/2}$ (40 min) was considered the pharmacologically relevant (beta elimination) $t_{1/2}$ since the initial

phases accounted for 99% of the AUC (area under the curve). Age, sex, mild/moderate renal, or mild liver impairment did not alter pharmacokinetics.

Fluoropyrimidines

Fluoropyrimidines are one of the most widely used groups of agents in the medical treatment of solid malignancies. There are marked intraindividual variations in plasma levels of the parent drug and metabolites, and toxicities can vary widely among individuals. In the elderly, these drugs are commonly reduced in dosage often arbitrarily (Raghavan and Suh 2006).

Studies Suggesting an Effect of Age on Toxicity

Stein et al. reported increased toxicity with age on a phase III trial of the Gastrointestinal Study Group treatment of metastatic colorectal cancer (Stein et al. 1995). This was based on a logistic regression analysis using age, gender, treatment, performance status, and length of therapy. These conclusions are also supported by data derived from a meta-analysis of 6 randomized trials of patients with colorectal carcinoma with a total of 1219 patients comparing infusional 5-fluorouracil with bolus 5-fluorouracil (toxicity of fluorouracil in patients with advanced colorectal cancer: effect of administration schedule and prognostic factors. Meta-Analysis Group In Cancer 1998). Older patients and those with poorer performance status had significantly higher risks of diarrhea, mucositis, nausea, and vomiting and older female patients having the highest incidence of this toxicity. Grade 3 or greater hematologic toxicity was sevenfold more common with bolus 5-FU (31 versus 4%, $p < 0.0001$) (toxicity of fluorouracil in patients with advanced colorectal cancer: effect of administration schedule and prognostic factors. Meta-Analysis Group In Cancer 1998).

Studies Suggesting that Age Is Not Determinant of Toxicity

An overview of 7 phase III trials involving 5-fluorouracil with either leucovorin or levamisole showed that no interaction between age and outcome could be identified. Age greater than 70 years correlated with the occurrence of treatment-related leucopenia with borderline significance (Sargent et al. 2001). In an attempt to minimize the bias of patient selection for protocol study, Delea et al. retrospectively examined a 5% sample of Medicare patients who had undergone colorectal surgery. There was no difference in the incidence of hospitalization, but drug dosage and comorbid conditions were not identified (Delea et al. 2002). In a retrospective analysis of clinical trials testing FOLFOX 4 (5-fluorouracil, leucovorin, oxaliplatin), older age was not associated with increased overall incidence of grade ≥ 3 toxicity or 60-day mortality except there was a higher incidence of grade 3 neutropenia and thrombocytopenia. The benefit of FOLFOX4 did not differ by age (Goldberg et al. 2006). In an intergroup study with adjuvant 5-fluorouracil for high risk stage II and stage III colon cancer, the secondary analysis of this trial demonstrated that the elderly are as likely to tolerate the benefit from adjuvant chemotherapy as are younger patients (Haller et al. 2005). In an evaluation of the Surveillance Epidemiology and End Results Medicare-linked database for resected stage III colorectal cancer, adjuvant 5-fluorouracil was well tolerated even among the very old patients without a major comorbidity (Schrag et al. 2001). A retrospective analysis of European trials has showed equivalent benefit and toxicity in "fit" elderly patients as younger patients (Folprecht et al. 2004).

Capecitabine

Studies have compared capecitabine with 5-fluorouracil in patients with a median age over 60 years . From this literature it appears that capecitabine at the recommended dosage of 1250 mg/m^2 twice daily for day 1–14 every 21 days is better tolerated than 5-fluorouracil administered as per Mayo schedule 425 mg/m^2 day 1–5 every 28 days. Hand-foot syndrome is more common with the capecitabine therapy and myelosuppression more common in the 5-flurouracil therapy. Feliu et al. studied prospectively 51 patients with

advanced colorectal cancer who were older than 70 years of age with doses adjusted based on creatinine clearance. Only 12% of patients experienced grade 3 or 4 treatment-related adverse events such as diarrhea, hand-foot syndrome and thrombocytopenia. No treatment-related deaths were reported. The median dose intensity was 88% of predicted (Feliu et al. 2005). Sharma et al. studied the effect of fixed dose oral capecitabine 2000 mg twice daily on days 1–14 every 3 weeks in patients with advanced colorectal cancer with a median age of 72 years. Grade 2 and 3 treatment-related toxicities were diarrhea 34%, fatigue 27%, stomatitis 15%, and hand-foot syndrome 22%. The median overall survival was 11.2 months and the response rate was 28%. The patients with the higher pretreatment levels of serum folate experienced the greater treatment toxicities over the entire treatment period ($p = 0.04$) (Sharma et al. 2006). The toxicities reported could be just a consequence of impaired renal function that occurs with aging. In a prospective evaluation, Cassidy and colleagues have found that patients with moderate renal impairment at baseline (estimated creatinine clearance 30–50 ml/min) experienced a higher incidence of grade 3 or 4 toxicities. Therefore the authors recommended a lower starting dose in patients with moderate renal impairment at baseline (calculated creatinine clearance 30–50 ml/min) and a contraindication in patients with severely impaired creatinine clearance at baseline (<30 ml/min). For patients with normal or mildly impaired renal function at baseline, the standard starting dose is well tolerated (Cassidy et al. 2002). In efforts to further improve the therapeutic index, studies have been performed which alter the schedule to 7 days on and 7 days off. This schedule may be preferable in older patients in terms of toxicity and compliance (Gajria et al. 2011).

Data has been published giving conflicting results as to whether fluoropyrimidines are more toxic in elderly patients. A main determinant of this difference is the schedule utilized. It is clear that the weekly 5-FU regimen is better tolerated than the monthly regimen (Haller et al. 2005). Infusional therapy likely has a more favorable toxicity profile (Folprecht et al. 2004). Intravenous fluoropyrimidines should be given by a weekly schedule or by the published infusional regimens. Recent data suggest no reason to dose reduce fluoropyrimidines unless there is severe renal dysfunction, poor performance status, prior radiation therapy, or comorbidity. The dose of capecitabine should be adjusted to creatinine clearance and a starting dose of no greater than 1000 mg/m^2 twice daily be strongly considered. The interaction with coumadin needs to be emphasized in older patients (Camidge et al. 2005).

Platinum Compounds

Oxaliplatin

The kidneys eliminate approximately 30–50% of the drug. Clearance of total and free platinum is decreased in patients with renal impairment. However, in studies of patients with mild to moderate renal impairment (GFR >20 ml/min), no increased toxicity was seen (Takimoto et al. 2003). Clearance of ultrafilterable platinum after administration of oxaliplatin is not influenced by impairment of hepatic function, sex, or age (Graham et al. 2000).

Principal dose-limiting toxicities are peripheral neuropathy and bone marrow suppression. Few studies have been performed specifically in the elderly population. The retrospective meta-analysis of 3742 patients (614 greater than or equal to 70 years) performed by Goldberg of patients receiving FOLFOX was mentioned previously (Goldberg et al. 2006). A retrospective review of 44 patients median age 78 concluded that treatment in this population was feasible with manageable toxicity (Aparicio et al. 2003). The combination of oxaliplatin/capecitabine has been studied in patients over 70 years. No relationship was seen between response and patient age, ECOG performance status, or the ability to perform activities of daily living (ADL) or instrumental ADL (IADL) (Feliu et al. 2006; Comella et al. 2005). The rate of neurotoxicity secondary to oxaliplatin-based chemotherapy has not been shown to be any greater in the elderly than in younger patients; a bi-fractionated protocol was developed in attempt to minimize this side effect. Grade 3 sensory neuropathy occurred in 6% of patients. ADL and IADL scores did not change significantly during

treatment (Mattioli et al. 2005). Other trials with oxaliplatin combinations in patients over 70 years showed acceptable toxicity and efficacy (Berardi et al. 2005). Future studies need to perform prospective evaluations of neuropathy, and aging needs to be performed with an emphasis on the possibility of functional impairment and long-term toxicity.

Cisplatin

Cisplatin has triphasic elimination and shows the half-life of the initial phase is 20–30 min and second-phase half-life is 48–67 min, with a terminal half-life of 24 h. Cisplatin pharmacokinetics is dependent on normal renal function due to the contribution of renal elimination for cisplatin (Reed et al. 1996). But, the nonreversible plasma protein binding of cisplatin should be also considered as an elimination process since only the unbound plasma cisplatin concentrations represent the active fraction. Plasma protein binding of cisplatin is larger than that of other platinum compounds (e.g., carboplatin). However, renal function should be considered as the major pharmacodynamic parameter since renal insufficiency represents the major toxicity together with magnesium wasting, nausea and vomiting, peripheral neuropathy, auditory impairment, and myelosuppression. Severe nausea and vomiting has been markedly reduced as a significant toxicity by the premedication of patients with a serotonin receptor type-3 antagonist. Intravenous hydration has reduced acute nephrotoxicity to 5%, but intensive hydration regimens may be difficult in older patients (Daugaard and Abildgaard 1988). Dose modification based on age alone is not required. It needs to be emphasized that patients receiving cisplatin in clinical trials are a highly selected group with minimal comorbidity. Calculation of renal function is critical using one of the available formulae but should be used with caution (Marx et al. 2004).

Carboplatin

Carboplatin has a similar mechanism of action compared with cisplatin, with antineoplastic activity against cervical, lung, and ovarian cancers. Carboplatin is completely eliminated through the kidneys. The Cockcroft-Gault, Calvert, and Chatelut formulas allow for accurate and safe dosing, taking into account renal function changes with age and a targeted AUC (Calvert and Egorin 2002). Carboplatin exhibits biphasic elimination with an initial half-life of 1.1–2 h and final half-life of 2.6–5.9 h with creatinine clearances greater than 60 mL/min. Because of the low incidence of nonhematologic toxicity, it can replace cisplatin in the palliative setting, particularly in older patients. Obesity, which is more common in the elderly, may affect the calculation of renal function (Launay-Vacher et al. 2007a; Lichtman et al. 2007b),

Anthracyclines

Anthracyclines are part of regimens for the treatment of many malignancies encountered in the elderly. Toxicity that is observed more frequently is a form of cardiomyopathy that manifests itself during the therapy with doxorubicin in the greatest part of the cases (Von Hoff et al. 1982), and it has been reported that the incidence of congestive heart failure following treatment with anthracyclines increases progressively with age after 70 years (Balducci and Beghe 1999). This may explain why many elderly patients are either excluded from chemotherapy treatment or receive less aggressive chemotherapy. Dose modification of the adjuvant AC regimen due to obesity is not necessary (Rosner et al. 1996). For anthracyclines, some studies suggest that the drug's peak concentration correlates with efficacy when toxicity is most likely a function of both peak and exposure (Aoki et al. 1998). The limited sampling strategies developed for several anthracyclines would facilitate the implementation of pharmacokinetic studies. One example is the case of epirubicin. The studies described a triexponential model for epirubicin behavior. In one study, variability in clearance could be attributed to gender and also to age in women (Wade et al. 1992). If severe renal impairment leads to a decrease in epirubicin clearance, no dose reduction guidelines have been proposed. The pharmacokinetic profile of epirubicin is modified in case

of hepatic impairment (Camaggi et al. 1985). Dosing modifications based on aspartate aminotransferase levels have been proposed (Twelves et al. 1992).

Liposomal Anthracyclines

Liposomal formulation completely alters the pharmacokinetics, pharmacodynamics, and toxicity profile of these agents. Palmar-plantar erythrodysesthesia syndrome is seen more frequently with these drugs; conversely, mucositis, alopecia, and cardiac toxicity are markedly diminished compared with nonliposomal formulations (Safra et al. 2000). The reduced toxicity of this class of drugs may be particularly beneficial in older patients with anthracycline- sensitive diseases (Biganzoli et al. 2006; Theodoulou and Hudis 2004).

Antimicrotubule Agents (Spindle Poisons) in Elderly Cancer Patients

Vinca Alkaloids

Vincristine is excreted primarily by the liver and requires dose reduction, or even avoidance, in liver failure (Donelli et al. 1998). There are no data for dose modification based on age alone.

Vinorelbine is a semisynthetic vinca alkaloid and causes less neurotoxicity than the older compounds in this group. It is highly bound to human platelets (78%) (Urien et al. 1993), and thrombocytopenia seems to correlate with increased hematologic toxicity, probably due to an increased unbound fraction, although high inter- and intraindividual variability in AUC (20–65%) can be present (Gauvin et al. 2002). Vinorelbine undergoes substantial hepatic elimination, but dose modification might only be necessary in patients with severe liver dysfunction, when the liver volume has been replaced by tumor by more than 75% (Robieux et al. 1996). There are conflicting data on the effect of age on pharmacokinetics of intravenous vinorelbine (Sorio et al. 1997). In the largest study, creatinine clearance and hepatic clearance were independent factors of vinorelbine clearance, while age was not (Wong et al. 2006). Several studies in breast and lung cancer and non-Hodgkin's lymphoma (NHL) show that full dose vinorelbine (e.g., 25–30 mg/m^2 weekly with rest points) has a very favorable tolerance profile (Sorio et al. 1997; Monfardini et al. 2005), and improved quality of life has been demonstrated in a large phase III trial in NSCLC in the elderly (median age 74 years) (effects of vinorelbine on quality of life and survival of elderly patients with advanced non-small-cell lung cancer. The Elderly Lung Cancer Vinorelbine Italian Study Group 1999). Although there are conflicting data on the impact of age on vinorelbine exposure, several trials show that vinorelbine is generally well tolerated in elderly cancer patients. There is no evidence that dose modification is required on the basis of age.

Taxanes: Paclitaxel and Docetaxel

Paclitaxel

The majority of paclitaxel is protein bound (97%), and it is extensively metabolized in the liver by the cytochrome P450 system and is excreted in bile, more specifically by the cytochrome P450 isozymes CYP2C8 and CYP3A. Awareness of drug interactions is needed when given concomitantly with drugs metabolized by the same pathways, e.g., ketoconazole (Sonnichsen and Relling 1994). It is preferable not to use paclitaxel in liver dysfunction because of significantly increased AUC and toxicity (mostly neutropenia) (Venook et al. 1998), but if it is necessary, the dose should be greatly reduced. A CALGB trial shows a modest but significant decrease in clearance of total paclitaxel with increasing age (Lichtman et al. 2006). This decrease seems partly induced by decreased clearance of the formulation vehicle CremophorEL (Smorenburg et al. 2003). Moreover, unbound paclitaxel might be a better predictor of clinically relevant exposure than total paclitaxel. Many studies have shown the feasibility and efficacy of administering paclitaxel in elderly patients with various cancer types. Both weekly and 3-weekly regimens have been studied. The every 3-week regimen can be used in fit elderly patients such as those with ovarian and bladder cancer (Uyar et al. 2005). There is a preference for weekly

administration in some patients, particularly breast cancer, as this causes less hematological toxicity without loss of efficacy (Akerley et al. 1997; Seidman 2005), possibly as a result of the more effective antiangiogenic activity in this fractionated regimen.

There are somewhat conflicting data on the impact of age on paclitaxel clearance. Moreover, the importance of unbound versus total paclitaxel clearance is not fully determined. However, several trials indicate the feasibility of both every 3 week weekly paclitaxel in elderly patients. There is no basis for a dose reduction based on age alone for any standard dose or schedule. Neurotoxicity has emerged as a significant toxicity and seems to be more significant in older patients (Lichtman et al. 2011; Tew et al. 2010).

Docetaxel

The majority of docetaxel is protein bound (94%), and it is extensively metabolized in the liver by the cytochrome P450 system (CYP3A4) and is excreted in bile, resulting in increased toxicity when administered to patients with impaired liver function (Venook et al. 1998). There is a large interpatient variability in exposure (AUC) and drug clearance. Hepatic CYP3A4 is by far the strongest predictor of total docetaxel clearance and together with AAG (alpha1-acid-glycoprotein) accounts for 72% of the interpatient variation in clearance (Hirth et al. 2000). In serum, docetaxel is extensively bound to albumin, lipoproteins, and *alpha*-1-acid glycoprotein (AAG); indeed, the latter is the main determinant of docetaxel serum binding variability. There have been attempts in elderly patients to predict variation in AUC of docetaxel through correlations with plasma (AAG) or urinary cortisol ratio (Extermann 2004). Many studies have investigated the efficacy and toxicity of docetaxel in relation to age, mainly in breast cancer (Maisano et al. 2005) and lung and prostate cancer (Tannock et al. 2004) . In a specific phase I trial in elderly cancer patients treated with docetaxel every 3 weeks, maximal tolerated dose was not reached at 80 mg/m^2, and accrual was continued. On the other hand, another phase I trial in elderly breast cancer patients was stopped after four patients at the first level of 75 mg/m^2 every 3 weeks because of excessive toxicity. The Japanese population might be more vulnerable due to ethnic differences in metabolism; the MTD in a phase I trial was 30 mg/m^2/week. As with paclitaxel, weekly dose docetaxel regimens have been investigated and seem to decrease toxicity without loss of efficacy except maybe in prostate cancer where 3-weekly might be slightly more effective than weekly docetaxel (Tannock et al. 2004). Neutropenia was limited with weekly regimens, but fatigue was often invalidating. Various dosages (e.g. 20–35 mg/m^2 weekly or 60–100 mg/m^2 every three weeks) and regimens (rest weeks at various time points) have been used.

There is no significant data to support dose modification based on age alone. Docetaxel pharmacokinetics is at most only minimally influenced by age. Any age-related changes are minimal compared to interpatient variability in metabolism. However, elderly patients are somewhat more vulnerable to side effects, but also here, interpatient variability is larger than age-related variability. Improvement in predicting unbound docetaxel clearance and toxicity by pharmacogenomic-based treatment optimization will hopefully improve correct dosing for the (elderly) cancer patients. In principal, standard regimens of docetaxel can be used, e.g., 30–36 mg/m^2 weekly with a rest week at regular time points or 75 mg/m^2 3-weekly. The choice between weekly and 3-weekly can depend on the setting (e.g., in prostate cancer, 3-weekly at 75 mg/m^2 is the standard) and on potential side effects.

Purine Analogs

Fludarabine

The elimination half-life of this drug ranges from 6.9 to 12.4 h. The total body clearance of this agent is related to both the serum creatinine and the creatinine clearance. After initial dephosphorylation, the subsequent metabolite, 2-fluoro-araA, is eliminated primarily by renal excretion, with approximately 60% of the administered dose excreted in the urine within 24 h after administration (Lichtman et al. 2002). Dose modifications

based on varying degrees of renal dysfunction have been proposed (McEvoy 2000). The most significant toxicities with fludarabine are related to the therapy-related myelosuppression from this agent, as well as the impact on cellular immune function. The severity of fludarabine-related neutropenia is related not only to the total body clearance of this agent but also to AUC and half-life β. No association was found between age and the incidence of either hematologic toxicity or infection during the first cycle of fludarabine therapy. However, patients with an estimated creatinine clearance of <80 ml/min had an increased risk of toxicity during their treatment course (Martell et al. 2002). Fludarabine may be used efficaciously and safely in an older patient population. Response rates tend to be lower in these older patients as compared to a younger cohort. Dose reductions are recommended in the setting of reduced creatinine clearances, in an effort to limit treatment-related toxicities.

Cytarabine

Cytarabine is rapidly metabolized in the liver to inactive metabolites, and 90–96% is excreted in the urine (Launay-Vacher et al. 2005). Due to increase neurotoxicity in patients with renal insufficiency, dose adjustments are required for high-dose therapy.

Gemcitabine

Pharmacokinetic data indicate that small age- and sex-related differences exist. These differences corresponded to differences in mean half-life for men at 42 min versus 61

min in the over 65 age group and women at 49 min versus 73 min in the over 65 group. Despite these differences, dosing guidelines are the same based on age and sex for gemcitabine. Toxicities primarily include neutropenia and thrombocytopenia. Dosing modifications for hepatic and renal dysfunction have been reported (Venook et al. 2000). Gemcitabine as a single agent displays minimal toxicity in older patients.

Pemetrexed

Pemetrexed is primarily excreted unchanged in the urine (70–90% in the first 24 h). It is contraindicated in patients with CrCl <45 mL/min. In patients with impaired renal function, pemetrexed plasma clearance positively correlated with GFR, which resulted in increased drug exposures. Pemetrexed 600 mg/m^2 was well-tolerated (with vitamin supplementation) in patients with GFR >80 mL/min. In patients with GFR 40–79 mL/min, a dose of 500 mg/m^2 along with vitamin supplementation was tolerated (Mita et al. 2006). Further studies are needed to determine dosing in renally impaired patients.

Camptothecins

Topotecan

Topotecan is a topoisomerase I inhibitor approved for the treatment of recurrent or refractory ovarian cancer and small cell lung cancer, and it has activity in myelodysplastic syndromes and acute myeloid leukemia. Topotecan renal clearance accounts for 30% of its elimination, and it has a half-life of 3 h. A large interindividual variability was observed, with clearance varying from 9.1 to 42.51 per hour (mean 21.0). Topotecan clearance was related to serum creatinine level and age (Montazeri et al. 2000). Dose adjustments are required in patients with moderate renal impairment. Severe myelosuppression can occur if doses adjustments are not made. A specific dose modification based on creatinine clearance has been recommended, particularly for older patients (O'Reilly et al. 1997). A review of patients with small cell lung cancer showed no difference in efficacy and minimal toxicity differences in patients 65 years and older compared with younger patients (Garst et al. 2005).

Irinotecan

Irinotecan is a topoisomerase I inhibitor approved for the treatment of metastatic colorectal cancer alone or in combination with 5-FU and leucovorin. It has activity in glioblastoma multiforme, non-small cell and small cell lung cancer, and gastric, esophageal, and pancreatic cancer. It can be given as a weekly and every-3-week dose. The weekly and once-every-3-week regimen showed similar efficacy and quality of life. Patients age 70 years or older independently

predicted occurrence of grade 3/4 diarrhea. Treatment with the every-3-week schedule was associated with a lower rate of grade 3/4 diarrhea (Fuchs et al. 2003). SN-38, the major metabolite of irinotecan, is approximately 1000 times more potent than the parent compound. The major toxicity of irinotecan therapy is delayed diarrhea and myelosuppression. Late diarrhea may be caused by intestinal accumulation of SN-38. The biliary concentration of SN-38 may be predictive of gastrointestinal toxicity, leading to the proposal of a biliary index as a surrogate measure to predict the severity of diarrhea (Mick et al. 1996). Delayed diarrhea was increased in patients with advanced age. Pharmacokinetic parameters, such as mean irinotecan, SN-38, SN-38G, Cmax, AUC0-24, and biliary index values in patients 65 years or older, were within 3% of those in younger patients. In addition, response rates do not vary based on age (Rothenberg et al. 1999). It is recommended that patients over the age of 70 years, patients with prior pelvic irradiation, and patients with poor performance status start at reduced doses (Rougier et al. 1998).

Etoposide

Etoposide is a topoisomerase II inhibitor used in the treatment of refractory non-Hodgkin's lymphoma, lung cancer, germ cell tumors, and a multitude of other malignancies. It is typically given through the intravenous route, although oral therapy is also used. Oral therapy occasionally poses problems with oral absorption and tolerance (Souhami et al. 1997). Etoposide displays biphasic or triphasic pharmacokinetic characteristics with an initial half-life of 0.6–2 h (mean, 0.25–2.5) and a terminal half-life of 5.3–10.8 h (mean, 2.9–19). Etoposide absorption is highly variable estimated at 50% but ranging from 25% to 75% (Dorr and Von Hoff 1994; McEvoy 2000). Impaired renal function leads to a decrease in drug clearance rates. Increasing age has been correlated to increased free etoposide concentrations during oral therapy correlating with leucopenia (Miller et al. 1997). Poor performance status may place older patients at higher risk for grade 4 dose-limiting toxicities such as myelosuppression and mucositis (Miller et al. 1997). Etoposide is eliminated to some degree via hepatic CYP P450 metabolism, but dosage adjustments based on liver dysfunction are controversial. The pharmacokinetics of oral etoposide in patients with liver dysfunction do not differ from patients with normal liver function (Aita et al. 1999).

Conclusion

The data presented will hopefully be able to aid clinicians in the treatment of elderly patients. Unfortunately, prospective data, particularly pharmacokinetic data, correlated with patient's functional status and clinical status does not exist. Particularly for those patients aged 80 years and older, extrapolation and, most importantly, good clinical judgment are an absolute necessity. In general, age-related differences in pharmacokinetics have been demonstrated on a consistent basis. Pharmacokinetic changes that are seen are usually a reflection of end-organ dysfunction (hepatic, renal), hypoalbuminemia, and anemia. The more important clinical issue is the increased toxicity that is seen particularly in those patients with poor function. Also, there is data which already exists from completed clinical trials which has never undergone an analysis by age. This situation needs to be remedied by a reanalysis and journal editors insisting that submitted publications include an age-related analysis where appropriate. Clinical trials evaluating and defining the treatment needs and the goals of therapy in elderly cancer patients are being performed. Methods for identifying high-risk individuals for developing side effects from chemotherapy are being developed. Chemotherapy approaches for several common malignancies, both in the adjuvant setting and for metastatic disease, are changing rapidly at this time. Optimizing therapeutic strategies for cancer patients who are over 65 years of age remains a challenge. Choosing the correct regimen and dose for the older patient can be extremely difficult as there are no accepted algorithms to guide management decisions in this patient group. Older cancer patients who have an adequate performance status and functional status and a reasonable life expectancy should receive the same therapies as younger patients. For those older

patients with a poor performance status or functional status, single-agent reduced-dose chemotherapy options and nonchemotherapeutic approaches should be considered, together with palliative and supportive care options. Pegfilgrastim and filgrastim can reduce the incidence of neutropenia and its sequelae (Smith et al. 2006). The effectiveness of growth factor support has often made nonhematologic toxicity dose limiting. The National Comprehensive Cancer Network has published Senior Adult Oncology guidelines, which can greatly aid the physicians treating (VanderWalde et al. 2016). Investigators need to be encouraged to develop appropriate clinical trials for older patients which will be acceptable to these vulnerable individuals and their families.

Principles of Cancer Targeted Therapy in Older Adults

54

Andrea Luciani

Contents

Abstract

More than half of patients newly diagnosed with cancer are aged >65 years, and as this group is underrepresented in clinical trials there is less evidence on which to base treatment decisions. Geriatric assessment as well as the careful evaluation of comorbidities can help oncologist to better define the clinical complexity of older individuals, in particular the estimation of life expectancy and the risk of toxicity. In this context, the precision medicine (PM) could be extremely important in the approach to cancer treatment management. Precision medicine is defined by the National Cancer Institute as "a form of medicine that uses information about a person's genes, proteins, and environment to prevent, diagnose, and treat disease." Knowledge of the molecular profile of the tumor is necessary to guide selection of therapy for the patient. Several molecules, as tyrosine kinase inhibitors (TKIs) of the epidermal growth factor receptor, monoclonal antibodies, angiokinase inhibitors, and mammalian target of rapamycin inhibitors (mTOR inhibitors), were developed and are now available for the use in clinical practice. Even if the toxicity profile of these drugs is somewhat less than that of conventional chemotherapy, data on older patients are poor and often they are extrapolated from large randomized trials that did not have a planned elderly specific analysis. Except for bevacizumab in colorectal cancer and some TKIs as sunitinib

Elderly Geriatric-assessment Target-therapy Precision-medicine

Introduction

More than half of patients newly diagnosed with cancer are age >65 years. Although this number is expected to increase as the world population ages, there is less evidence on which to base treatment decisions for older patients with cancer, because this group is underrepresented in clinical trials (Crome et al. 2011). Because chronologic age alone is a poor descriptor of heterogeneity of the aging process, a systematic (and maybe evidence-based) way of describing the heterogeneity is needed to help oncology treatment decisions. A comprehensive geriatric assessment (CGA) can fill this knowledge gap as it has the ability to predict severe treatment-related toxicity in some form of tumors, to predict OS, and to influence treatment choice (Hurria et al. 2005).

Comorbidity, defined as a medical condition that exists along with an index condition, is a main issue in older patients with cancer. Comorbidities could impact the cancer management in various ways. They can act as confounders that complicate the diagnosis and treatment of cancer; they mediate cancer treatment effects and pose competing risks for morbidity and mortality. The presence of moderate to severe comorbidities is of greatest prognostic importance among patients with localized and potentially curable cancer, such as early-stage breast or prostate cancer; in contrast, comorbidities have little impact on overall survival in more lethal and aggressive cancers where mortality is dominated by the primary disease (Jorgensen et al. 2012; Read et al. 2004).

Comorbidities can alter the risk/benefit ratio of many treatment decisions. In a study using SEER-Medicare Database, older adults with resected stage III colorectal cancer with comorbidities were less likely to be referred to a medical oncologist for consideration of adjuvant chemotherapy and less likely to be given chemotherapy when seen by an oncologist (Bradley et al. 2008; Dy et al. 2006). In a context of complexity, as geriatric oncology, the precision medicine (PM) could be extremely important in the approach to cancer treatment management. PM, also called "personalized medicine," is defined by the National Cancer Institute as "a form of medicine that uses information about a person's genes, proteins, and environment to prevent, diagnose, and treat disease." PM in oncology was born with the advent of molecularly targeted agents (MTAs) almost two decades ago and is mainly based today on the DNA molecular information of the patients' tumors (Table 1). Knowledge of the molecular profile of the tumor is necessary to guide selection of therapy for the patient. For example, the Oncotype Dx assay (from Genomic Health) for breast cancer; Development of single-gene or multigene expression signatures of response or resistance to particular drug treatments (for example, HER2 and estrogen receptor) to identify patients with breast cancer who are likely to benefit from adjuvant paclitaxel treatment, or ERCC1 expression as a marker of resistance to platinum-based chemotherapy (Le Tourneau et al. 2016). Clinical trial requiring a genomic alteration for enrollment has increased in the past years; however, the number has to be improved (Roper et al. 2015).

The Use of Target Agents in Older Patients

Non–Small Cell Lung Cancer

As median age at diagnosis is 70 years old, non–small cell lung cancer (NSCLC) is a disease of older patients Two classes of drugs had a major clinical development in the last 10 years: tyrosine kinase inhibitors (TKIs) of the epidermal growth factor receptor and monoclonal antibodies (MoAb) directed against vascular endothelial growth factor (VEGF).

Table 1 Recommendations for the use of target therapy in older patients

Drug	Disease	Efficacy	Safety	Data	Practical considerations in elderly
Gefitinib	NSCLC	Effective	Good toxicity profile in elderly patients	Elderly specific data	Well tolerated; monitor for rush and diarrhea
Erlotinib	NSCLC	Effective	Increased toxicity	Elderly specific data	Extreme caution; close monitoring for toxicity
Afatinib	NSCLC	Effective	Increased toxicity	Elderly data from subgroup analysis	Monitor toxicity. Dose reduction is an option
Crizotinib	NSCLC	Limited	Limited	Pivotal trial	Likely reasonable option, although data are limited
Nivolumab	NSCLC	Limited	Limited	Retrospective data	Reasonable option. Limited data
Nintedanib	NSCLC	Limited	Limited	No elderly trials	Use with caution
Bevacizumab	NSCLC	Available; effective	Available; increased risk for HTN	Subgroup analysis	Monitor for HTN; screen for vascular risk factors
Ramucirumab	NSCLC	Limited	Limited	No elderly trials	Use with caution
Sorafenib	Advanced HCC	Limited; appears effective	Limited; appears safe	Elderly specific data	Monitor for GI and skin toxicity
Everolimus	ER-positive MBC; HER2-positive	Effective	Caution; higher incidence of treatment-related deaths in elderly patient	Elderly specific data	Close monitoring for stomatitis, diarrhea, and anemia
Trastuzumab	Breast cancer; HER2-positive	Limited	Limited	Retrospective data	Use in elderly patients with regular cardiac monitoring
Pertuzumab	MBC; HER2-positive	Available; effective	Limited; increased toxicity in all patients	Pivotal trial	Use in elderly patients without cardiac risk factors
T-DM1	HER2-positive MBC	Limited	Limited	Pivotal trial	Favorable safety profile
Vemurafenib	BRAF-mutant advanced melanoma	Limited	Limited	Pivotal trial	Monitor for skin toxicity, fatigue, arthralgia
Dabrafenib	BRAF-mutant advanced melanoma	Limited	Limited	Pivotal trial	Monitor for skin toxicity, fever, fatigue, arthralgia
Ipilimumab	Advanced melanoma	Available	Available	Pivotal trial; elderlyspecific data	Immune-related adverse events: Dermatologic, endocrine, GI
Sunitinib	mRCC	Available	Available; increased toxicity	Elderly specific data	Monitor for GI toxicity, HFS, HTN, fatigue; first-line dose modification may be appropriate

(*continued*)

Table 1 (continued)

Drug	Disease	Efficacy	Safety	Data	Practical considerations in elderly
Pazopanib	mRCC	Available	Available; favorable toxicity profile in elderly patients	Pivotal trial	Monitor for GI toxicity, HTN, anorexia
Sorafenib	mRCC	Available	Available	Pivotal trial	Monitor for skin toxicity, diarrhea, fatigue, and rare serious AEs (HTN, cardiac ischemia
Everolimus	mRCC	Available	Available; well tolerated	Elderly specific data	Monitor for stomatitis, rash, fatigue
Temsirolimus	mRCC	Available	Available; well tolerated	Pivotal trial	Monitor for rash, fluid retention, hyperlipidemia, hyperglycemia
Axitinib	mRCC	Available	Limited	Pivotal trial	Monitor for HTN, diarrhea, fatigue
Cabozantinib	mRCC	Limited	Limited	No elderly specific trial	No data. Use with extreme caution
Nivolumab	mRCC	Limited	Limited	Retrospective data	Reasonable option. Limited data
Cetuximab	mCRC	Available; effective	Limited	Pivotal trial	Monitor for rash, GI toxicity
Panitumumab	mCRC	Available; effective	Limited	Pivotal trial	Well tolerated; monitor for skin toxicity, diarrhea, hypomagnesemia
Bevacizumab	mCRC	Available; effective	Available; increased risk for HTN	Elderly specific data	Monitor for HTN; screen for vascular risk factors
Aflibercept	mCRC	Available; effective	Available; increased risk for toxicity	Pivotal trial	Cautious use in elderly patients, given toxicity profile
Regorafenib	mCRC	Available; effective; smaller benefit than in younger patients	Available; increased toxicity	Pivotal trial	Cautious use in elderly patients, given toxicity profile and small benefit
Trastuzumab	Advanced gastric cancer	Limited	Limited	Pivotal trial	Use in elderly patients without cardiac risk factors
Ramucirumab	Advanced gastric cancer	Limited	Limited	Pivotal trial	Lack of data to support use

Modified from Kelly et al. (2014)

AE adverse event, *ER* estrogen receptor, *GIST* GI stromal tumors, *HCC* hepatocellular carcinoma, *HER2* human epidermal growth factor receptor 2, *HFS* hand-foot syndrome, *HTN* hypertension, *MBC* metastatic breast cancer, *mCRC* metastatic colorectal cancer, *mRCC* metastatic renal cell carcinoma, *NSCLC* non–small cell lung cancer, *T-DM1* trastuzumab emtansine

Bevacizumab

Bevacizumab demonstrated a survival benefit for patients with adenocarcinoma histology (12.3 vs. 10.3 months, HR for death 0.79; $p = 0.003$). A subset analysis of ECOG 4599 showed an higher rate of toxicity for elderly patients in the experimental arm (87% vs. 61%, $P < 0.001$) and nonsurvival advantage (11.3 vs. 12.1 months;

$P = 0.4$) (Sandler et al. 2006). The AVAIL trial compared cisplatin plus gemcitabine alone or plus bevacizumab at two dosage (7.5 and 15 mg/Kg). The primary end point, progression free survival advantage, was met for the bevacizumab arm (Reck et al. 2009). In the subgroup analysis of 304 patients aged 65 years or older (median age 68 years) in the AVAIL trial, the lower dose of bevacizumab (7.5 mg/kg once every 3 weeks) yielded an improvement in progression-free survival (HR, 0.71; *P* 0.023). In the Safety of Avastin in Lung study 623 patients older than 65 years (mean age 70.6) had incidence of adverse events (AEs) and overall survival comparable to that of younger patients (Leighl et al. 2010).

Erlotinib

There are no prospective trials in older patients. In a retrospective age-specific analysis of the BR.21 study, where erlotinib improved survival vs. placebo in second- or third-line setting, 112 had received erlotinib and 51 had received placebo (Wheatley-Price et al. 2008). The median OS was 7.6 months compared with 5 months for those who received placebo (*P* 0.67), and for young patients, the median OS was 6.4 months versus 4.7 months (*P* 0.0014). Despite the same results in terms of progression free survival between older and younger patients, the former suffered of worse toxicity with worse rash, fatigue, and dehydration. An open-label phase II study evaluated survival in chemotherapy-naïve patients aged 70 years with advanced NSCLC treated with erlotinib. The 1- and 2-year survival rates were 46% and 19%, respectively (median, 10.9 months). The presence of an EGFR mutation correlated with prolonged survival (*P* 0.027). The EURTAC trial was a phase III compared erlotinib with chemotherapy in first-line advanced EGFR-mutated NSCLCa. Erlotinib showed a significant improvement in median PFS in both young and older patients with a worse toxicity profile in the latter group (Rosell et al. 2012). A phase II single arm trial showed promising results of the association erlotinib/bevacizumab in NSCLC EGFR mutated patients with a median progression-free survival of 16.0 months (95% CI 13.9–18.1) with erlotinib plus bevacizumab versus 9.7 months (5.7–11.1) with erlotinib alone (hazard ratio 0.54, 95% CI 0.36–0.79; log-rank test $p = 0.0015$) (Seto et al. 2014). A phase III trial is currently ongoing to explore the activity of the combination against monotherapy with erlotinib.

Gefitinib

The only elderly specific trial is the INVITE study (Phase II Iressa versus vinorelbine [INVITE]) that explored the first-line use of gefitinib compared with vinorelbine in patients aged 70 years or more. The PFS was similar in both arms (2.7 vs. 2.9 months; *P* 0.310). Gefitinib was well tolerated, and grade 3 to 5 adverse events were less frequent in the gefitinib arm (12.8% vs. 41.7%) (Crino et al. 2008). The Iressa Pan Asia study (IPASS; first line IRESSA versus carboplatin/paclitaxel in Asia) was not an elderly specific trial, and showed a PFS benefit for gefitinib vs. platinum doublet chemotherapy (24.9% vs. 6.7%) especially in EGFR mutated patients. Other small series show the effectiveness and feasibility of gefitinib in the population of people with more than 70 years age (Takahashi et al. 2014).

Afatinib

Afatinib demonstrated superior PFS vs. doublet cisplatin chemotherapy in advanced NSCLC in two large trial, lux lung 3 (LL3) and lux lung 6 (LL6). A subgroup analysis on patients with more than 65 years old of both studies was performed (Fein et al. 2016). A total of 220 patients were randomized; 134 in LL3 and 86 in LL6. In Del19-positive patients, afatinib significantly improved OS versus chemotherapy in LL3 (41.5 vs. 14.3 months, HR1⁄40.39 [95% CI: 0.19e0.80], p1⁄40.0073) and demonstrated a trend toward improved OS in LL6 (34.1 vs. 21.1 months, HR1⁄40.57 [95% CI: 0.24e1.36], p1⁄40.20). The AE profile in patients aged more than 65 years was similar to that observed in the overall population.

Crizotinib

Crizotinib is an oral small-molecule TKI that targets the echinoderm microtubule-associated protein-like 4 (ELM4) anaplastic lymphoma kinase (ALK) fusion oncogene rearrangement that is found in 5% of patients with advanced lung adenocarcinomas. Crizotinib has been demonstrated

Table 2 New drugs in NSCLC

Study	Design	N	Elderly	RR	ΔPFS/OS	HR os
Lume lung 1	N-DTX vs DTX	1307	≥65.30%	4.7 versus 3.6%	2.7/2.3 mo (adeno))	0.75
Revel	R-DTX vs DTX	1253	≥65.38%	23 versus 14%	1.5/1.4 mo	0.76
Checkmate 0.17	Nivo vs DTX	272	≥65 <75.33% ≥75.8%	20 versus 9%	0.7/2.8 mo	0.59
Checkmate 0.57	Nivo vs DTX	582	≥75.7%	19 versus 12%	−1.9/2.8 mo	0.73

to be superior versus chemotherapy in second-line setting in advanced NSCLC (Shaw et al. 2013). No large data on elderly patients are available.

Nintedanib

Nintedanib is an oral angiokinase inhibitor that targets the proangiogenic pathways mediated by VEGFR1–3, fibroblast growth factor receptors (FGFR) 1–3, and platelet-derived growth factor receptors (PDGFR) α and β. In the LUME Lung 1 trial nintedanib plus docetaxel was superior to docetaxel alone in second-line setting in advanced adenocarcinoma of the lung with a HR for PFS that was 0.85 (95% CI 0.75–0.96, $p = 0.0070$) and HR for OS that was 0.75 [95% CI 0.60–0.92] $p = 0.0073$. Patients with more than 65 years old were 30% of the population without a planned subgroup analysis (Reck et al. 2014) (Table 2).

Ramucirumab

Ramucirumab is a fully human IgG1 monoclonal antibody that specifically binds to the VEGFR-2 extracellular domain with high affinity, preventing binding of all VEGF ligands and receptor activation. In REVEL trial patients with advanced NSCLC were randomly assigned to receive docetaxel plus ramucirumab or docetaxel. Median overall survival was 10.5 months in the ramucirumab group compared with 9.1 months in the control group (stratified HR 0.86, 95% CI 0.75–0.98; $p = 0.023$). Ramucirumab had an overall good safety profile, however patients with more than 65 years old, were only 38% of the population and the trial was not designed to have a subgroup specific analysis (Garon et al. 2014).

Nivolumab

Nivolumab is a fully human IgG4 PD-1 immune-checkpoint–inhibitor antibody that disrupts PD-1–mediated signaling and may restore antitumor immunity. Checkmate 0.17 and 0.57 were two trials in which nivolumab was compared with docetaxel in second-line setting in NSCLC in squamous and adenocarcinoma histology, respectively (Borghaei et al. 2015; Brahmer et al. 2015). In both studies, patients with more than 75 years were 8% and 7%, respectively. A safety analysis across all registration trials, stratified by age, was presented at ASCO 2016 meeting. About 414 patients out of 1020 were 65 years old or more and only 11% of them experienced grade 3–4 toxicities.

Breast Cancer

Trastuzumab

Trastuzumab is a humanized monoclonal antibody targeting the extracellular domain of human epidermal growth factor receptor 2 (HER2). Trastuzumab demonstrated benefit in adjuvant setting in several trials without any toxicity concern in elderly patients with more than 70 years old and without any relevant cardiovascular comorbidities. Several studies have established the benefit of trastuzumab in adjuvant setting (Piccart-Gebhart et al. 2005; Romond et al. 2005). Cardiotoxicity is the main adverse event of trastuzumab and becomes challenging when the regimen contains also anthracyclines. The trastuzumab-related cardiotoxicity is not dose dependent and is usually reversible. An analysis of SEER-Medicare and the Texas Cancer Registry (TCR) on women more than 66 years with a diagnosis of stage I–III breast cancer identified 2203 trastuzumab-treated patients (23.1%) (Chavez-MacGregor et al. 2013). These patients were more likely to develop cardiac heart failure (CHF) than nontrastuzumab users (HR, 1.95; 95% CI, 1.75–2.17) and patients older than 80 years had the highest risk of CHF

(HR, 1.76; 95% CI, 1.48–2.09). Coronary disease (HR, 1.82; 95% CI, 1.34–2.48) and hypertension (HR, 1.24; 95% CI, 1.02–1.50) were associated with increased risk of CHF. About 68.8% of the events occurred within the first 12 months after initiation of treatment. In hormone-sensitive, HER2-positive patients with metastatic breast cancer, the TANDEM study (A study to evaluate the efficacy and safety of herceptin plus anastrozole vs. arimidex alone in patients with metastatic breast cancer) was not an elderly designed trial; however, the combination of trastuzumab and anastrozole was superior to anastrozole alone with no relevant differences on the rate of grade 3 and 4 cardiac events between the two groups.

Pertuzumab

In the CLEOPATRA study, Pertuzumab + Trastuzumab + Docetaxel vs. Placebo + Trastuzumab + Docetaxel in previously untreated HER2-positive metastatic breast cancer, the median age was 54 years (range 22–82), 15.7% of patients were age >65 years and 2% were age >75 years. A PFS advantage for docetaxel trastuzumab-pertuzumab arm was evident across all age groups (Baselga et al. 2012).

Trastuzumab Emtansine

In the EMILIA (An open-label study of trastuzumab emtansine [T-DM1] vs. capecitabine lapatinib in patients with HER2-positive locally advanced or metastatic breast cancer) the major benefit of T-DM1 was in younger population; however, the small proportion of elderly patients did not allow to evaluate the impact of T-DM1 on older population (2.5% had more than 75 years old) (Verma et al. 2012).

Lapatinib

Lapatinib is an orally active small molecule that inhibits the tyrosine kinases of HER2 and epidermal growth factor receptor type 1 (EGFR). In a nonelderly designed trial, lapatinib plus capecitabine was superior with respect to capecitabine alone in women with metastatic breast cancer (HR for time to progression was 0.49 (95% confidence interval, 0.34 to 0.71; P <0.001) (Geyer et al. 2006). Diarrhea is the main issue in patients receiving lapatinib and those older than 70 years experienced more grade 3 events than younger women (33% vs. 19%) (Crown et al. 2008).

Colorectal Cancer

Metastatic colorectal cancer is actually treated with several biological agents. Some of them require the assessment of specific biomarkers. As for lung and breast cancer, there are two types of biological agents, monoclonal antibodies and small molecules.

Bevacizumab

The first biological agent used for colorectal cancer was bevacizumab which demonstrated, in association with irinotecan and fluorouracil, to be superior to fluorouracil alone in first-line setting in metastatic colorectal cancer (median OS 20.3 months vs. 15.6 months, HR for death of 0.66 (P <0.001) (Hurwitz et al. 2004). In the BRITE observational cohort study, 896 patients ≥65 years, out of 1953 advanced colorectal cancer patients, were evaluated for the safety and effectiveness of bevacizumab-based first-line therapy. Arterial thromboembolic events (ATEs) increased with age and the overall survival was worse in elderly patients. Hypertension, the main side effect of bevacizumab should be monitored. The BRITE registry reported 1.5% to 3.4% 60-day mortality rate for patients with CRC age ≥ 65 years who developed or worsened an hypertension (Kozloff et al. 2010). In AVEX trial, elderly patients unsuitable for oxaliplatin- or irinotecan-based chemotherapy with a median age of 76 years (range 70–87) were randomly assigned to receive bevacizumab plus capecitabine (n = 140) or capecitabine only (n = 140) (Cunningham et al. 2013). Progression-free survival was significantly longer for bevacizumab arm (median 9.1 months [95% CI 7.3–11.4] vs. 5.1 months [4.2–6.3]; hazard ratio 0.53 [0.41–0.69]; p <0.0001). In a German observational study, patients received bevacizumab 5–10 mg/kg every 2 weeks or 7.5–15 mg/kg every 3 weeks in combination with chemotherapy (Hofheinz et al. 2014). About

480 (27%) of 1770 patients who were 70 years old or more had worse median overall survival than younger patients (median OS for patients aged <70 vs. ≥70 years and <75 vs. ≥75 years were 25.8 vs. 22.7 months (HR: 1.28, 95% CI: 1.11–1.47; 2-sided log-rank test p <0.0008; and 25.8 vs. 20.8 months, respectively (HR: 1.48, 95% CI: 1.23–1.80; 2-sided log-rank test p <0.0001). The efficacy and safety of bevacizumab plus S-1 was tested in elderly patients with previously untreated mCRC in a phase II trial (the median OS was 25.0 months, and the RR was 57%).

Panitumumab

Panitumumab is a fully humanized recombinant monoclonal immunoglobulin G2 kappa antibody against EGFR. The PRIME study reported the efficacy of adding panitumumab to infusional fluorouracil, leucovorin, and oxaliplatin (FOLFOX4) in the first-line setting of K-ras WT mCRC with an improvement in PFS (9.6 vs. 8.0 months, respectively; hazard ratio [HR], 0.80; 95% CI, 0.66 to 0.97; P 0.02). This was not elderly specific trial; however, the toxicity of panitumumab for patients more than 65 years was relevant. Panitumumab as single agent was explored in a series of frail elderly patients defined by the authors as patients not able to receive chemotherapy. The median PFS and OS were 6.4 months (95% confidence interval [CI]: 4.9–8 months) and 14.3 months (95% CI: 10.9–17.7 months), respectively. The most frequent grade 3 AE was skin rash, with an incidence of 20%. A Spanish phase II study on frail elderly patients confirmed these results.

Cetuximab

Cetuximab is a chimeric monoclonal immunoglobulin G1 antibody that binds to the EGFR. Cetuximab plus FOLFIRI and FOLFIRI alone. The median age of the population was 61 years with a range of 24–79. The hazard ratio for progression-free survival among patients with wild-type–KRAS tumors was 0.68 (95% CI, 0.50–0.94), in favor of the cetuximab–FOLFIRI arm. In a retrospective multicenter study on irinotecan pretreated patients, the age group 66 years and older included 250 patients (50.3%) with a median age of 70 years (range 66–88). 36.7% of patients required supportive treatment independently from age. No significant difference between both age groups (p = 0.51) there was in the rates of hospitalization. Elderly patients had higher grades of toxicities compared to younger ones (p 0.05). Patients >65 years had significantly more comorbid conditions and a higher CCI (Charlson Comorbidity Index), compared with the younger patients group (p = 0.001). Patients 18–65 years showed a PFS of 5.9 months as compared with 6.1 months for patients >65 years (p = 0.99, log-rank test). CCI and age had no negative influence on PFS.

Aflibercept

Aflibercept is an antiangiogenic agent that blocks the activity of VEGFA, VEGFB, and placental growth factor. In the VELOUR study (Aflibercept versus placebo in combination with irinotecan and 5-FU in the treatment of patients with metastatic colorectal cancer after failure of an oxaliplatin-based regimen) (Van Cutsem et al. 2012), the median age was 61 years (range, 21–82 years). The addition of aflibercept to FOLFIRI increased PFS relative to placebo plus FOLFIRI (hazard ratio, 0.758; 95% CI, 0.661–0.869; P 0.0001). Median PFS, based on independent assessment of radiologic progression, was 6.9 months in the aflibercept arm and 4.7 months in the control arm. No subgroup analysis on elderly patients was planned.

Regorafenib

Regorafenib is an oral, small-molecule multikinase inhibitor. In the CORRECT Study Group (Patients with metastatic colorectal cancer treated with regorafenib or placebo after failure of standard therapy), regorafenib demonstrated superior overall survival when compared to placebo in heavily pretreated patients (Grothey et al. 2013). The magnitude of OS benefit was a statistically significant 1.4-month favoring regorafenib over placebo. Median age was 61 (range 54–67) and only ECOG PS 0–1 patients were enrolled. About 285 older patients (≥65 years old) had progression free survival but not overall survival benefit compared to younger patients.

Renal Cell Carcinoma

Biological target agents with activity in renal cell carcinoma (RCC) include antiangiogenic multi-TKIs, mammalian target of rapamycin inhibitors (mTOR inhibitors), and immunotherapy.

Sunitinib

The superiority of sunitinib versus interferon in metastatic RCC was demonstrated in a phase III multinational trial (Motzer et al. 2007). A retrospective pooled data analysis investigated the efficacy and safety of sunitinib in 1059 patients who received sunitinib in either the first-line or cytokine-refractory metastatic RCC setting. About 202 (19%) patients were ≥70 years old with a median age of 73 years (range: 70–87). In patients who received sunitinib on schedule 4/2, the incidences of fatigue, dizziness, dehydration, and hand–foot syndrome were not significantly different between the two age groups, while constipation, asthenia, anorexia, and erythema were significantly more common in older patients. When given in a continuous daily dosing sunitinib caused more nausea, hyponatremia, arthralgia, and pruritus in older patients. Overall, the older patients were more likely to have a highest severity of grade 3. A series of 185 older patients receiving an adapted regimen, i.e., 37.5 mg/day for a 4/2 weeks schedule, were retrospectively analyzed. The median progression-free survival (PFS) was 11 months and discontinuations because of therapy-related adverse events occurred in 25 patients treated with standard regimen (20.3%) vs. 15 with adapted regimen (24.2%), respectively (P 0.679) (De Giorgi et al. 2014a, b; Hutson et al. 2014). Another retrospective analysis in six Italian centers evaluated 68 patients (median age 74 years, range 70–88) treated with sunitinib (Brunello et al. 2013). Hematological toxic effects were mostly grade 1–2 and so were non-hematological toxic effects, with the only reported grade 4 toxic events being neutropenia. The most common nonhematologic adverse events were fatigue (80.9%, 55 patients), mucositis (61.8%, 42 patients), and hypertension (58.8%, 40 patients).

Axitinib

Axitinib is a potent and selective second-generation inhibitor of VEGF receptors 1, 2, and 3. The AXIS trial (Axitinib as second line therapy for metastatic renal cell cancer) showed a significant improvement in median PFS, favoring axitinib when compared with sorafenib in second-line therapy in RCC (Rini et al. 2011). In the study, age is not a baseline prognostic factor for overall survival, and there were no concern about safety in older as well in younger patients (Motzer et al. 2013a).

Pazopanib

Study VEG105192 was a placebo-controlled, randomized, double-blind, global, multicenter, phase III study that compares pazopanib vs. placebo in patients with advanced RCC (Sternberg et al. 2010). The prespecified subgroup analyses showed that PFS was improved for patients treated with pazopanib compared with placebo regardless of MSKCC risk category, sex, age, or ECOG PS (HR range, 0.40–0.52; P 0.001 by log-rank test for all). The most common grade 3/4 AEs in the pazopanib arm were hypertension (4%) and diarrhea (4%). Arterial thrombotic events occurred in 3% of pazopanib-treated patients compared with none in the placebo group. The COMPARZ trial was a randomized, open-label, phase 3 trial of pazopanib versus sunitinib (Motzer et al. 2013b). Overall, 39% of patients were older than age 65 years. The median progression-free survival was 8.4 months with pazopanib (95% confidence interval [CI], 8.3–10.9) and 9.5 months with sunitinib (95% CI, 8.3–11.1). Investigator-assessed objective response rates were similar between the two groups (33% in the pazopanib group and 29% in the sunitinib group, $P = 0.12$). Patients who received pazopanib had a higher risk of increased levels of alanine aminotransferase or bilirubin of any grade and significantly less fatigue and foot soreness.

Sorafenib

Sorafenib is an antiangiogenic, antiproliferative vascular endothelial growth factor receptor tyrosine kinase inhibitor (VEGFR-TKI). Sorafenib

demonstrated this activity in RCC in the TARGET trial that compared sorafenib to placebo in patients resistant to standard therapy (Escudier et al. 2007). Hundred and fifteen out of 902 patients (13%) were 70 years old or more. A subgroup analysis showed similar benefit for younger as well as older patients with regard to progression free survival and clinical benefit. More grade 3 and 4 toxic effects were reported in older sorafenib-treated patients than in younger sorafenib-treated patients (for grade 3 events, 40.0% vs. 29.4%, respectively; and for grade 4 events, 5.7% vs. 7.3%, respectively). Older patients had slightly more gastrointestinal symptoms and fatigue than younger patients. There were no unexpected adverse events attributable to advanced age. Older patients discontinued sorafenib mostly because of gastrointestinal (5.7%, or 4 patients) and dermatologic (4.3%, or 3 patients) issues. Sorafenib treatment improved quality of life among older and younger patients (Eisen et al. 2008). The analysis of a large Sorafenib-RCC (Sor-RCC) Integrated Database on 4684 patients enrolled in eight company-sponsored clinical trials and expanded-access programs showed no difference across age subgroups in terms of clinical benefit and adverse events (Procopio et al. 2013).

Temsirolimus

Temsirolimus is an inhibitor of mammalian target of rapamycin (mTOR) kinase. In the ARCC trial, temsirolimus was compared in previously untreated patients with advanced RCC, to interferon alfa or the combination of both. Compared with interferon alone, treatment with temsirolimus alone was associated with a hazard ratio for death of 0.73 (95% confidence interval [CI], 0.58–0.92; $P = 0.008$), with a median survival of 7.3 months in the interferon group, 10.9 months in the temsirolimus group, and 8.4 months in the combination-therapy group. Older patients ($\geq$65 years old) in the temsirolimus alone arm were 31% and the effect of temsirolimus on overall survival was greater among younger patients (Hudes et al. 2007). Temsirolimus was better tolerated than IFN in older patients.

Everolimus

Everolimus is an orally administered inhibitor of the mammalian target of rapamycin (mTOR). In a nonelderly international, multicenter, double-blind, randomized phase III trial (RECORD-1), everolimus was compared with placebo for the treatment of metastatic renal cell carcinoma in patients whose disease had progressed on treatment with VEGF receptor tyrosine kinase inhibitors (Motzer et al. 2008) and showed a median progression-free survival 4.0 [95% CI 3.7–5.5] vs. 1.9 [1.8–1.9] months. Stomatitis, fatigue, and pneumonitis were more frequent in everolimus arm. About 36.8% were $\geq$65 year and 17.5% were $\geq$70 year of age. Elderly patients had the same benefit as younger patients for PFS. Toxicities in elderly patients were similar to those in the overall study population, being stomatitis the most common AE of any grade in everolimus-treated patients (Porta et al. 2012).

Cabozantinib

Cabozantinib is an oral, small-molecule inhibitor of tyrosine kinases, including MET, VEGF receptors (VEGFRs), and AXL. In the METEOR study, patients with pretreated RCC were randomly assigned in a 1:1 ratio to receive either cabozantinib or everolimus. Median age of the population treated with cabozantinib was 62 (36–83). The estimated median progression-free survival was 7.4 months (95% confidence interval [CI], 5.6–9.1) with cabozantinib and 3.8 months (95% CI, 3.7–5.4) with everolimus. The rate of disease progression or death was 42% lower with cabozantinib than with everolimus (hazard ratio for progression or death, 0.58; 95% CI, 0.45–0.75; $P < 0.001$). The incidence of adverse events of grade 3 or 4 was 68% with cabozantinib and 58% with everolimus; the most common grade 3 or 4 adverse events with cabozantinib were hypertension (15%), diarrhea (11%), and fatigue (9%) (Choueiri et al. 2015). No data on older patients are available.

Nivolumab

Nivolumab is a fully human IgG4 programmed death 1 (PD-1) immune checkpoint inhibitor antibody that selectively blocks the interaction between PD-1, which is expressed on activated

T cells, and PD-1 ligand 1 (PD-L1) and 2 (PD-L2), which are expressed on immune cells and tumor cells. In the CheckMate 025, pretreated RCC patients were randomly assigned to receive nivolumab or everolimus. Median age of the population was 62 years (23–88). The median overall survival was 25.0 months in the nivolumab group and 19.6 months in the everolimus group, with a hazard ratio for death (from any cause) with nivolumab versus everolimus as 0.73 (98.5% CI, 0.57–0.93; $P = 0.002$). The benefit of nivolumab was observed for patients with all age subgroups at least until 75 years. The most common treatment-related adverse events among patients who received nivolumab were fatigue (134 patients, 33%), nausea (57 patients, 14%), and pruritus (57 patients, 14%) with no concern about older age (Motzer et al. 2015).

Melanoma

The common target therapies for metastatic melanoma include BRAF inhibitors (Curtin et al. 2005), antibodies, anticytotoxic T-lymphocyte–associated antigen 4 (CTLA-4), and anti-PD-1.

Vemurafenib and Dabrafenib

These two small molecules are active in tumors with BRAF V600E or V600 K mutations. In the BRIM 3 trial, patients with unresectable, previously untreated stage IIIC or stage IV melanoma that tested positive for the BRAF V600E mutation were randomly assigned to receive vemurafenib or dacarbazine. The study was not elderly specific and the median age was 56 (21–86). The hazard ratio for death in the vemurafenib group was 0.37 (95% confidence interval [CI], 0.26–0.55; $P < 0.001$). About 160 out of 672 patients were older than 65 years, and they seem to have the same benefit in term of both overall survival and progression free survival with respect to younger patients. The most common adverse events in the vemurafenib group were cutaneous events, arthralgia, and fatigue. In another trial, patients were administered either oral dabrafenib (150 mg twice daily) and oral trametinib (2 mg once daily), or oral dabrafenib (150 mg twice daily) and placebo. The most common treatment-related adverse events were pyrexia, chills, fatigue, rash, and nausea in the dabrafenib and trametinib group; the HR for death was 0.71 (95% CI 0.55–0.92; $p = 0.0107$) in the combination group (Hauschild et al. 2012).

Ipilimumab

Ipilimumab is a fully human monoclonal antibody (IgG1) that blocks CTLA-4. It showed its activity in a trial where patients were randomly assigned, in a 3:1:1 ratio, to ipilimumab plus gp100 peptide vaccine; ipilimumab alone; or gp100 alone. The median overall survival in the ipilimumab-alone group was 10.1 months (95% CI, 8.0–13.8) (hazard ratio for death with ipilimumab alone as compared with gp100 alone, 0.66; $P = 0.003$). Overall, 29% of patients were older than age 65 years. Ipilimumab can cause severe and potentially life-threatening immune-related toxicities; however, no difference in survival or safety data between younger and older patients was reported (Hodi et al. 2010).

Nivolumab

In the CheckMate 066 and CheckMate 037 study, Nivolumab monotherapy was superior to dacarbazine in metastatic melanoma without a BRAF mutation in terms of overall survival benefit and objective response, respectively (Weber et al. 2015; Wolchok et al. 2013). Adding nivolumab to ipilimumab resulted in better outcomes than ipilimumab alone in untreated melanoma (Postow et al. 2015). No specific data on elderly patients are available in this setting.

Hepatocellular Carcinoma

Sorafenib

Sorafenib is a an oral multikinase inhibitor of vascular endothelial growth factor receptor (VEGFR), platelet-derived growth factor receptor, and Raf. It has become the standard of care in advanced hepatocellular carcinoma (HCC) after the results of the SHARP trial that showed a survival benefit of 3-months for sorafenib vs. placebo (10.7 months vs. 7.9 months; hazard ratio, 0.69; 95% confidence interval [CI], 0.55–0.87; $P < 0.001$) in treatment-naive patients

with advanced HCC (Childs Pugh class A) (Llovet et al. 2008). This was not an elderly specific trial (median age 64.9 ± 11.2). Two retrospective analyses on elderly patients (age ≥70) analyzed the efficacy and tolerability of sorafenib. In former, full doses of sorafenib were administered in 11 out of 60 patients (18.3%), with no significant change in the quality of life during the study (Montella et al. 2013). In the latter enrolled 51 individuals aged 70–83, Child-Pugh A or B, ECOG performance status 0 to 2 who were not suitable candidates for or had progressed after locoregional therapies. The most frequent Grade 3 adverse reactions were fatigue (15.7%), hand–foot syndrome (15.7%), abdominal pain (11.7%), and hyperbilirubinemia (11.7%). Dose reduction (from 800 to 400 mg/d) due to toxicity was required in 28 individuals (54.9%), mainly because of thrombocytopenia (15.7%). During treatment, IADL score decreased in 13 patients (25.5%) (Francini et al. 2014).

Gastric Cancer

Trastuzumab

Trastuzumab is overexpressed in 7–34% of patients with gastric cancer. The ToGA trial (ToGA Study: A study of trastuzumab in combination with chemotherapy compared with chemotherapy alone in patients with HER2-positive advanced gastric cancer) examined trastuzumab in combination with fluorouracil-platinum chemotherapy in advanced gastric adenocarcinoma. Patients assigned to trastuzumab plus chemotherapy had a median overall survival of 13.8 months (95% CI 12–16) compared with 11.1 months (10–13) in those assigned to chemotherapy alone (HR 0.74; 95% CI 0.60–0.91; $p = 0.0046$) (Bang et al. 2010). About 52% of the patients were age >60 years. Cardiac adverse events were rare with no difference between the trastuzumab plus chemotherapy and chemotherapy alone groups (17 [6%] vs. 18 [6%]).

Ramucirumab

Ramucirumab is a fully human IgG1 monoclonal antibody and VEGFR-2 antagonist. In RAINBOW (Ramucirumab plus paclitaxel versus placebo plus paclitaxel in patients with previously treated advanced gastric or gastro-oesophageal junction adenocarcinoma) study, patients were randomly assigned to ramucirumab plus paclitaxel or placebo plus paclitaxel. Patients more than 65 years old were 38%. Overall survival with ramucirumab plus paclitaxel was significantly longer than with placebo plus paclitaxel (9.6 months vs. 7.4 months, HR 0.807 [95% CI 0.678–0.962]; $p = 0.017$); at the multivariable analysis age did not seem to influence survival outcomes (Wilke et al. 2014). In the REGARD trial (Ramucirumab monotherapy for previously treated advanced gastric or gastro-esophageal junction adenocarcinoma), patients were randomly assigned in a 2:1 ratio, to receive best supportive care plus either ramucirumab 8 mg/kg or placebo. Treatment with ramucirumab resulted in a 52% reduction in the risk of disease progression or death from any cause; more patients in the ramucirumab group had grade 3 hypertension than those in the placebo group (Fuchs et al. 2014).

Pain Management in Older Cancer Patients

Contents

Abstract

As a very frequent symptom, cancer pain in the elderly is an obvious signal for the need to improve the situation, both in physical terms and in terms of a more holistic approach. The multiplicity of causes and expressions of pain and the many means at our disposal for its management should not interfere with a rigorous diagnostic and therapeutic approach based on specific assessment and prognostic scales associated with a comprehensive geriatric evaluation. Thus, knowledge of the precise and safe handling of analgesics and other associated drug products, which can absolutely be offered to these vulnerable patients, is of paramount importance and must always be accompanied by a wish to combine this with consideration and multidisciplinary expertise while pursuing the objective of relief and the maintenance of a level of functional ability and quality of life that are acceptable to the patient.

Keywords

Elderly cancer · Pain management · Frailty · Multidisciplinarity · Holistic medicine

Introduction

In the holistic management of elderly cancer patients, each symptom has to be assessed and treated with a view to achieving the best possible quality of life. In this context, pain is a very frequent reason for consultation. After giving an overview of the many distinctive features of the characteristics of pain and its assessment in elderly patients with cancer, the broad principles of management and the different types of possible treatment will be presented in detail.

Multidimensional Assessment of Pain in Geriatric Oncology

Geriatric oncology, since it was first described in 1983 (National Cancer Institute and National Institute of Aging (U.S.) 1984), is the expression and practical implementation of the acknowledgement that elderly subjects who increasingly face cancer need a multidisciplinary, specific, and customized approach and management. Increasingly, there are studies and clinical trials specifically dedicated to this problem and what emerges from these above all is the absolute necessity of correctly and comprehensively assessing these patients in order to tailor the treatment options to their level of vulnerability, both medical (comorbidities, polymedication, cognitive impairment, etc.) and psychosocial (isolation, need for partnership with home care facilities, etc.) (Falandry et al. 2011) with a view to improving their health status and quality of life. In this context, the comprehensive geriatric assessment is now recognized as an essential prerequisite in the management of elderly patients in oncology (Extermann et al. 2005). The progress made in terms of our knowledge of the aging process and associated frailties allows us to understand the great heterogeneity of elderly patients themselves, who we tend to classify in different categories of greater or less vulnerability or according to whether the aging process is smooth or pathological. Similarly, there is also great heterogeneity regarding pain, both in terms of its nature or mechanism as well as its expression and prevalence (real, reported, or diagnosed). In any event, different literature reviews or meta-analyses show that among the many symptoms presented by elderly cancer patients, pain is one of the most frequently mentioned (Teunissen et al. 2007). Furthermore, according to studies, its prevalence is considered to be equivalent to that found in young adults (Van den Beuken-van Everdingen et al. 2007) (i.e., affecting 20 to 50% of all cancer patients (Fischer et al. 2010)) or even greater as it is largely underestimated and undertreated) (Breivik et al. 2009). Some authors, on the other hand, find a higher incidence among the younger population who are believed to be subject to more frequent episodes of breakthrough pain (Green and Hart-Johnson 2010).Epidemiological data are not therefore all consistent since it is so difficult to standardize the precise assessment of pain. In any event, moderate to severe pain is believed to affect 80% of all patients in an advanced stage of cancer (Bruera and Kim 2003). Against this background, the management of pain in these frail patients is a priority, which increasingly needs to be personalized (Dalal et al. 2012).

Thus, it is absolutely essential that the precise assessment of pain must be rigorous, holistic, and repeated in order to achieve appropriate management. The most spontaneously used tools are self-assessment scales, which nevertheless in many cases must be combined with or replaced by hetero-assessment scales specifically developed for elderly subjects. Pain assessment must also be supplemented by the measurement of its impact on daily activities and overall quality of life and weighted by the patient's psychoaffective environment.

Severity of the Pain

In the area of self-assessment, the visual analogue scale (VAS) and the numeric scale (NS), which are most frequently used, are limited by the patient's powers of communication and abstraction. Only a minority of subjects in an advanced stage of cancer with both cognitive impairment and a deterioration of their general condition are able to use the VAS correctly. The numeric scale may be offered to patients who have difficulty understanding the principle of the VAS but who have retained their powers of abstraction. In its oral form, it can also be relevant for patients with physical handicaps. It is therefore often the simple verbal descriptor scale (SVDS) that, although less sensitive and less precise than the VAS, is preferred by medical staff and elderly patients. Indeed, elderly patients can describe their pain using familiar words. It is easy and quick to use. With the exception of subjects with very severe cognitive impairment, almost all patients are capable of completing it. The same is true of the faces pain scale, which is widely used in geriatric medicine and is

understandable and easy to use including for patients with severe cognitive impairment (Pautex et al. 2006). In certain situations, however, it is necessary to supplement these self-assessments, which are sometimes not very helpful, with observational scales. Numerous teams around the world who are confronted daily with the complexity of the management of elderly patients with cognitive impairment have highlighted the particular diagnostic and therapeutic features of this population (Buffum et al. 2007). Scales have been devised which are generally based on observation of the patient's behavior by the family or nursing staff which have to be repeated in different situations (resting, nursing, mobilization, etc.). These validated simplified behavioral scales include, depending on the country, the PAINAID scale (Pain Assessment in Advanced Dementia Scale) (Warden et al. 2003), developed in New Jersey, the PASLAC tool (Pain Assessment Checklist for Seniors with Limited Ability to Communicate) in Canada (Fuchs-Lacelle and Hadjistavropoulos 2004), or the Algoplus and Doloplus (Rat et al. 2014) scales for French-speaking Europe. Their limitations are mainly associated with the necessity of a multidisciplinary assessment, if possible with knowledge of the patient's normal behavior. These assessments also require the possibility of comparison with a baseline or previous condition. All these scales are often unsuitable for the assessment of acute pain.

It is therefore necessary to be very cautious and to follow certain rules of good practice so as to avoid the pitfall of inconsistency of assessment of the pain severity between the nursing staff and the patient, which inevitably leads to inappropriate pain management (Brasseur et al. 2006). For example, the reliability of self-assessment could be tested by rephrasing the instructions to the patient or by verifying the consistency of the result between the VAS, the SVDS, or the NS during a single consultation (Herr et al. 2011).

Location and Pathophysiological Characteristics

Once the severity of the pain has been measured, its locations, mechanisms, and causes have to be detailed in order the tailor the therapeutic options. One of the particular features of cancer pain is that it often affects several sites, with different pain mechanisms coexisting (Grond et al. 1996). By means of detailed questioning, of both the patients themselves, the family, caregivers, or nursing staff, the characteristics of the pain have to be defined as precisely as possible. The timing of the pain, its frequency, the existence of trigger, aggravating or alleviating factors, the date of onset, the existence of unpredictable episodes of searing pain, or, conversely, of reproducible episodes have therefore to be identified. The aim is to define the acute or chronic, nociceptive, neuropathic, or mixed characteristics of the pain and to recognize the existence of episodes of breakthrough pain. Among the multidimensional tools available is the "McGill Pain Questionnaire (Melzack 1975)," this is a self-assessment tool that allows the patient to link the severity of his or her pain to its subjective sensory and affective characteristics. Similarly, the DN4 questionnaire (Boussahira et al. 2005, Van Seventer et al. 2010) allows adjectives to be suggested to patients to allow them to describe their pain and to guide the clinician in whether or not to make a diagnosis of neuropathic pain. It is a specific diagnostic tool that is easy and quick to use.

Particular Medical, Psycho-Behavioral, and Social Characteristics of the Patient

In the assessment of pain, therefore, the objective, in particular in the case of elderly cancer patients, is to be as comprehensive and as multidimensional as possible. Certain scales have been created in order to measure the impact of the pain on the patient's functioning in daily life, which is an essential concept in the complex problems of geriatric oncology. The Brief Pain Inventory (Hølen et al. 2008) and the PROMIS-PI (Patient-Reported Outcomes Measurement Information System – Pain Interference) (Amtmann et al. 2010) are good examples of this. Even if these tools are not always easy to use in daily practice, they allow the assessment of a patient with pain to be fine tuned in certain complex situations and are good clinical research

tools. Once the pain and the main characteristics of the pain have been assessed, it is important to consider the patient's psychosocial environment and his or her pain coping strategies. The aim of this is to customize the choice of treatment, but also to be able to predict whether or not the pain will be well controlled. Indeed, the perception of pain and the quality of pain relief vary greatly from one patient to another, and some studies even show numerous cases of failure of pain relief in the absence of careful monitoring and regular adjustment of the analgesic treatment (Yennurajalingam et al. 2012).

It is therefore necessary to be familiar with all aspects of one's patient. Medically, the other symptoms should be assessed using the ESAS (Edmonton Symptom Assessment System) (Bruera et al. 1991). On a psychological level, the clinician has to look for anxiety or depression, whether or not this is in reaction to the pain. It is also necessary to understand the ability to adapt and the resilience of the patient with pain. On a social level, the patient's family situation (more or less supportive family members) (Im et al. 2009) and his or her ethnic origin and social background can influence the ability to tolerate pain or the response to treatment. As an example of this, we can cite the great variability in behavior in the face of pain according to a patient's ethnocultural origin (Chen et al. 2012), with the Asian culture in particular not showing or admitting to pain for fear of being regarded as weak and so as not to burden the family, while some Western cultures, in contrast, allow themselves to express their pain loudly. This detailed analysis should also make it possible to identify cases where the patient is completely overwhelmed by pain, physically, psychologically, emotionally, and socially. This is referred to as "unrelieved" pain, and specific therapeutic measures have to be considered (Syrjala et al. 2014).

Obviously, in order to complete the oncogeriatric assessment, it goes without saying that pain management has to take account of the specific comorbidities of the elderly patient and the impact of these on the pharmacokinetics, pharmacodynamics, and tolerability of the treatments under consideration.

Assessment of the Anticipated Efficacy of Treatment

All this attention to detail in the multidimensional assessment of pain in elderly patients with cancer is necessary as this rigor allows the best possible refinement of the proposed analgesic treatment and follow-up. In order to complete this assessment, it is beneficial to use pain prognosis scores, the aim of which is to predict the response to analgesic treatment. The objective is above all to screen patients at high risk of not responding effectively to treatment in order to define, particularly together with them, a policy and realistic pain relief targets from the outset, rather than promising them rapid and complete relief. Examples of this are the ESC-CP (Edmonton Classification System for Cancer Pain) (Fainsinger and Nekolaichuk 2008), which is based principally on the type of pain concerned, the level of psychological distress, past addictions, and cognitive function. The CPPS (Cancer Pain Prognostic Scale) (Hwang et al. 2002), for its part, takes the form of a formula defining a higher or lower probability score for response to analgesic treatment. This formula combines scores for pain intensity, the presence of mixed pain, the necessary doses of morphine, and how the patient copes emotionally. In all cases, it helps the clinician to make pain management more personalized and to guard against the temptation to escalate doses of analgesic, rather than viewing management from a more multimodal perspective in the case of patients considered to have a poor prognosis.

Pain Management in Geriatric Oncology

As has been extensively outlined above, a complete and detailed assessment of the pain suffered by a cancer patient, in particular when the patient is elderly and potentially frail, is the condition sine qua non which enables appropriate, personalized, and multidisciplinary pain relief treatment to be initiated and then to be managed (Fig. 1). In this context, the pain may be associated with either, in about 70% of cases, the disease itself (Gutgsell et al. 2003) or its treatment or the care associated

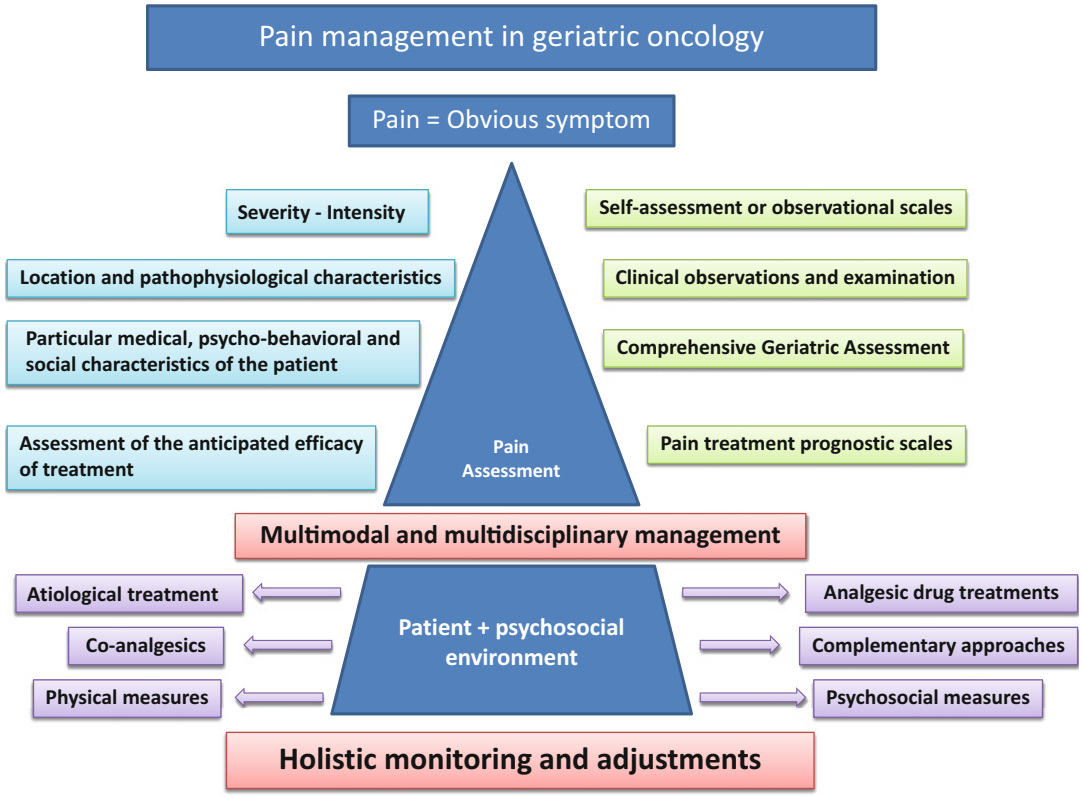

Fig. 1 Cancer pain management in the elderly: a multidisciplinary and holistic approach

with the cancer, or any other comorbidity, as is frequently encountered in this elderly population (approximately 8–15% of pain, generally pre-existing and receiving long-term treatment) (Barbera et al. 2013). The management of these patients still remains holistic, whether or not it combines general measures with specific drug treatments.

Etiological Treatment

In all cases, depending on the level of management desired by the patient and justified by the geriatric assessment, the specific treatment of the cancer remains a standard treatment for the pain associated with the disease itself. This cancer treatment can be viewed in terms of whether the objective is a cure or is purely symptomatic. Once this objective has been clearly defined, the methods of monitoring the efficacy/tolerability ratio of the treatment that has been started should be specified, with a regular reassessment of the symptomatic and functional benefit to the patient in terms of analgesia, as well as, naturally, the undesirable effects of the treatment. It must be borne in mind that the benefit of these treatments declines and the probability of serious complications arising increases with age (Balducci et al. 2015). These specific anticancer treatments are varied and can either involve drug treatment (chemotherapy, immunotherapy, or other targeted treatments) or be physical (radiotherapy) or surgical. Prescription of these remains the prerogative of specialists in oncology, but their indication should be established with caution, following multidisciplinary discussion, again with a view to a comprehensive prognostic assessment, taking account not only of molecular and cellular characteristics and the clinical spread of the disease, but also the functional abilities and initial autonomy of the patient, associated with all his or her comorbidities and psychosocial environment that affect compliance with and tolerability of the

treatment. For example, it can be mentioned here that the indication for radiotherapy for analgesic purposes in the case of bone metastases does have a place in geriatric oncology, but it should be borne in mind that on the one hand there is the possibility of a transient upsurge in the pain within the first 7 to 10 days and on the other that complete efficacy only occurs 3–4 weeks after the irradiation. Throughout this period, the elderly patient will have to be monitored particularly closely and is even at risk of major deconditioning which is essential to prevent and monitor.

Analgesic Drug Treatments

If an etiological treatment is unsuitable for the management of a particular patient, or else to supplement the analgesic effect of the latter, "classic" analgesics will naturally have to be used. This designation covers the analgesics of the WHO's three-step ladder. Prescription of these, for purely symptomatic purposes, is based in geriatric oncology on the same rules as for any other patient. These analgesics will therefore be administered starting with step 1 (paracetamol), then if this is ineffective moving straight on to step 3 (opioid treatments). In the context of oncology and in particular when pain management is associated with cancer, the analgesics in step 2 have little place, perhaps with the exception of buprenorphine. The need to be able to switch easily to strong opioids is explained on the one hand by the fact that pain in geriatric oncology frequently corresponds to nociceptive pain which will respond well to the mechanism of action of opiates and secondly by the fact that step 3 analgesics are more easily manageable and better tolerated than step 2 analgesics as they are available in much more varied pharmaceutical formulations and concentrations, allowing a much more delicate titration of the minimum effective dose and therefore a much more gradual and better tolerated adjustment of the doses required (Bandieri et al. 2016). A unique feature of patients in geriatric oncology is the fact that the therapeutic margin is especially narrow as the iatrogenic risk is increased by renal failure or the failure of other organs, malnutrition, or cognitive impairment.

For the record, step 3 analgesics include primarily morphine, oxycodone, fentanyl, and hydromorphone. All these drug products are pure μ, κ, and δ receptor agonists. Buprenorphine, on the other hand, classified in step 2 by the WHO, is a partial μ agonist and κ antagonist. It has a greater affinity than does morphine, but its activity is weaker. While it has good analgesic efficacy when used alone, its combination with pure opioids is contraindicated as it counteracts their analgesic action. Its role for elderly subjects lies in particular in its purely hepatic metabolism, which makes it a drug of choice in the case of renal failure.

Generally speaking, and in geriatric oncology in particular, the introduction of opioid treatment is a source of uncertainty and concerns for the patient (Potter et al. 2003). Patients should always be reassured as to the fact that this molecule (and its derivatives) is absolutely not reserved for end-of-life treatment, but is a standard analgesic which is also completely safe to use when it is prescribed in accordance with recommendations. The principles for prescription of these drugs are based on a fundamental concept, namely that of titration, where the minimum effective dose is sought, or else the lowest dose that allows sufficient efficacy to be achieved with the fewest possible undesirable effects. In order to obtain this, one starts with very low doses (generally one half, but even as little as one fourth of the dose recommended for a young adult, i.e., 2.5 mg of oral morphine per dose in an elderly subject instead of 10 mg in adults), up to a maximum of 6 times per day, with the frequency having to be reduced according to the patient's renal function and his or her psychological or cognitive vulnerability (Caraceni et al. 2012). As with young adults, back-up doses will be provided for, in order to adjust the fixed basic dose every 2 to 3 days if necessary, which can then be converted to a retard form if symptoms remain unchanged (Bruera et al. 1998). This gradual titration, if carried out correctly in accordance with the adage "start low, go slow," usually allows an appropriate balance to be achieved between efficacy and tolerability, including in frail elderly patients. It will be recalled that these molecules can also be antagonized by naloxone if necessary.

With regard to the tolerability of these opioid treatments, their undesirable effects have to be known in order to anticipate them and to treat them as early as possible, which will improve patient comfort and adherence to the treatment. These side effects include in particular:

- Constipation: this is by far the most common side effect and should be routinely averted whenever opioid treatment is introduced. Laxative treatment generally remains necessary in the long term. In the event of resistance to conventional first-line treatments, the use of methylnaltrexone may be necessary.
- Nausea and vomiting: these symptoms can usually be avoided if titration is carried out very gradually in accordance with the rules described above, but one should never hesitate to avert this undesirable effect at the least complaint by the patient. Rapid-release formulations are likely to encourage the onset of nausea and a switch to longer-release formulations as soon as analgesic stability appears to have been achieved is a good way of improving digestive tolerability of opioid treatment.
- Pruritis: this symptom, again, is often transient and can be treated with antihistamines if it is reported by the patient.
- Drowsiness: this almost always occurs when the treatment is started and whenever the dose is increased. It is a transient effect about which the patient and his or her carers should be warned and which wears off after 48–72 h, especially when a stable dose is achieved.
- Delirium and hallucinations: these manifestations, which are always overwhelming for the patient and carers, are uncommon and above all are multifactorial in the majority of cases (Morita et al. 2001). However, if they persist despite the correction of other associated risk factors, they are a recognized indication for rotation to alterative opioids.
- Respiratory depression: very often feared when dealing with opioids, it is, in fact, extremely rare and, as has been shown in several studies over the last few years, morphine remains the best symptomatic treatment for dyspnea. Thus, whether it is prescribed for analgesia or for the relief of dyspnea, there is no reason to fear the development of respiratory depression, provided the rules of good prescribing have been observed (Clemens et al. 2008).
- Opioid-induced hyperalgesia: a concept that is not yet widely described in the literature, and probably underdiagnosed, this is a situation that requires gradually increasing basic doses, but in which backup doses increase the pain, which distinguishes it from dependency. Currently, the best therapeutic strategy in this case remains opioid rotation, probably with methadone having special status (see below). Another recommendation would be to add in antineuropathic pain treatment, given the similarity between this syndrome and neurogenic pain (Bannister 2015).

Thus, while morphine remains the drug of choice, it may be replaced by another opiate in certain cases. This rotation can be justified by certain pain characteristics (oxycodone accepted in mixed nociceptive-neuropathic pain) or in the case of organ failure (fentanyl indicated in renal failure), or in order to choose a more appropriate route of administration (fentanyl transdermal patch), or, finally, in order to obtain stronger analgesia with an equal volume (hydromorphone) in rare cases of minimum effective doses in elderly subjects. Likewise, the route of administration of choice remains the oral route (Wiffen et al. 2013), which can be replaced by parenteral routes (IV or subcutaneous), transdermal, or transmucosal routes when the clinical context requires this, as in the specific treatment of episodes of acute breakthrough pain with transmucosal fentanyl (Simon and Schwartzberg 2014). However, these opioid rotations should not become routine and remain reserved for three main indications (Fine and Portenoy 2009):

- The presence of major side effects that cannot be controlled by standard measures, or the persistence of neurotoxicity.
- Suboptimal pain control despite well-managed titration, together with the appearance of side effects as an indication of poor tolerability of the dose attained.

– A change that is necessary for logistical reasons such as a change of the route of administration, the development of a new comorbidity or organ failure that is a contraindication to the drug in current use, or possibly financial considerations steering the new choice toward a less costly drug that is expected to have an identical result.

In the area of strong analgesics, the use of methadone sometimes proves necessary. This is a μ-receptor agonist and NMDA (N-methyl-D-aspartate) receptor antagonist. Its anti-NMDA properties make it a useful alternative, in particular if opioids are poorly tolerated or in the case of difficulties of pure opioid dose adjustment when associated hyperalgesia is suspected. Its routes of administration are many and varied and its unique pharmacokinetics, with rapid efficacy but a long half-life, but above all with wide inter-patient variability, make it complex to manage. In particular, the choice of a starting dose in the context of rotation from a strong opioid remains relatively empirical and must be made on a case-by-case basis (McLean and Twomey 2015). This unique feature, combined with its numerous drug interactions and its specific side effects such as prolongation of the QT interval, makes it a drug that requires complex management, prescription of which must be restricted to specialists.

Finally, a new treatment option related to strong opioids is the use of tapentadol, a synthetic opioid that is a μ-receptor agonist and noradrenaline reuptake inhibitor (NRI) which gives it beneficial analgesic properties, in particular in the case of mixed pain. Its efficacy and tolerability appear to be comparable to those of morphine and oxycodone. A recent meta-analysis (Wiffen et al. 2015) did not find that it has additional benefits compared to current standard treatments, but this drug represents an attractive treatment option in the management of pain in elderly cancer patients.

Co-analgesics

As has already been described above, pure analgesic treatments, including those in step 3 of the WHO ladder, remain indicated in elderly patients, provided that the rules of good prescribing and gradual dose adjustment are observed. That said, it is always advisable to try as far as possible to combine them with other types of drug product which have a different mode of action, but the analgesic action of which is able to supplement or potentiate the effect of the first, thereby aiming for a less substantial increase in the necessary doses, while remaining alert to the many possible drug interactions.

These supplementary treatments include, first and foremost, specific treatments for neuropathic pain. This pain, associated either with the disease itself or with the side effects of its treatment, must be identified using the diagnostic tools described above. Pharmacological management of neuropathic pain is the same as for young patients, but with the dosages adjusted according to renal and hepatic function (Attal et al. 2010; Dworkin et al. 2010). The standard drug products recommended for first-line treatment therefore remain the antiepileptics (gabapentin, pregabalin) and then the antidepressants, SRIs or dual SRI-NRIs, or even tricyclic antidepressants, tolerability of which, in particular neuropsychological tolerability, is not always good in elderly patients. In every case, a precautionary strategy should be adopted, starting with low doses and increasing them very gradually.

In the context of geriatric oncology, corticosteroids are obviously a vital part of this analgesic strategy for the control of the inflammatory component of pain. In fact, the most recent meta-analyses do not provide a good level of proof of a pure analgesic effect (Haywood et al. 2015), but the indication for corticosteroids is still accepted, in particular for neuropathic pain on compression (spinal or peripheral nerve) or for headaches caused by intracranial hypertension, as well as their general stimulatory and orexigenic effect which indirectly affects the response to the rest of the analgesic treatment (Paulsen et al. 2014). In this context, they are still recommended for elderly subjects in the same doses as for young adults (0.5–1 mg/kg/day of prednisone in the attack phase), with preference always given to short courses rather than long-term treatment that again fosters numerous complications. The

increased susceptibility of elderly patients to develop undesirable effects will be noted, in particular neuropsychological effects (irritability, sleep problems, and mood disorders), cardiac effects due to water and sodium retention, metabolic effects, in particular in terms of blood glucose, infections and functional effects with a loss of autonomy which may be increased by quadriceps muscle loss, or even increased skin fragility precipitating the development of sores in patients with underlying malnutrition. This functional impact, with a risk of falls, can be extremely detrimental and considerably worsen the patient's overall prognosis.

In addition, the particular place of anti-osteoclastic drugs such as bisphosphonates in the treatment and prevention of metastatic bone pain should be mentioned here (Wong et al. 2012). Their effect is not immediate, but a real benefit in the medium term is shown in the literature, justifying their use both for analgesia and in order to delay the development of bone pain.

In the area of coanalgesics, nonsteroidal anti-inflammatory drugs (NSAIDs) should also be mentioned, bearing in mind above all that their systemic use is very limited in elderly subjects because of their renal toxicity (Hemett et al. 2014; American Geriatrics Society Panel 2009), although there is the possibility of temporary topical administration (in the form of a patch, cream, or gel), in particular for their local anti-inflammatory effect for general, non-cancer-related pain (muscle and joint pain, for example).

Finally, regarding systemic treatments, the place of ketamine is still uncertain. This anesthetic, used in subanesthetic doses, has been shown empirically to have an effective analgesic action against cancer pain that is not controlled by opioids. No precise recommendation can be made at the present time and its place in the treatment of cancer pain in the elderly is not proven (Bell et al. 2012).

With regard to topical treatments, mention should also be made, in ENT indications in particular, of the relief provided by applications of lignocaine or even topical morphine. For peripheral neuropathic pain, TENS (transcutaneous electrical nerve stimulation) can also provide supplementary treatment. The purpose of this type of stimulation is to stimulate the afferent nerve fibers of tactile sensitivity in order to limit and inhibit the communication of nociceptive signals that use the same physiological pathway.

Another strategy for supplementing the action of analgesics is the prevention of foreseeable exacerbations of pain, in particular during nursing care or other invasive procedures. In this connection, the use of a 50% nitrous oxide and 50% oxygen mixture, including in elderly patients, is well known (Krakowski et al. 2010). This technique allows complex and extremely painful wound care procedures to be carried out in conditions that are more acceptable to the patient, while avoiding the use of too high doses of back-up opiates. This treatment is now routinely offered in geriatric oncology, not forgetting the precautions for use associated with possible cognitive problems or difficulties of compliance of patients who have to hold the mask themselves.

However, it will be borne in mind that episodes of breakthrough pain or incidental pain are described as less common in the very elderly population and may be well controlled by opioid doses adjusted after careful titration (Mercadante et al. 2015).

Remaining in a more technical area, the elderly cancer patient may, subject to comprehensive geriatric assessment and prior consideration of the prognosis, be a good candidate for surgical procedures (vertebroplasty, cementoplasty), interventional radiological procedures, or even local/regional anesthetic blocks for specific lesions and in order to achieve functional improvement. The indications for these techniques still need to be assessed on a case-by-case basis in a collective and, above all, interdisciplinary spirit.

Finally, taking a more holistic view of patient pain, this symptom cannot be considered while overlooking the psychological component, either initially or at any rate reactive. In certain cases, the combination of purely analgesic treatment with anxiolytics proves necessary in order to control this symptom more completely. Despite their undesirable effects and their potential impact on

alertness, in this case benzodiazepines remain the class of drugs of choice, with the selection being made on the basis of the half-life (6–12 h: alprazolam; 10–20 h: lorazepam) and the dose and frequency of administration being adjusted according to the patient's cognitive status and organ failures.

Complementary Approaches, Physical Measures, and Holistic Management

As has just been suggested, treatment of the pain suffered by elderly cancer patients in fact goes far beyond merely prescribing the best possible opioid analgesic, possibly in combination with other synergistic approaches. The patient's pain must obviously be considered from a holistic perspective, linking the condition of old age, possibly already severely tested by life or other comorbidities, with the status of cancer patient. The pain, which is often exacerbated at the time an announcement is made (of the diagnosis, a recurrence, or progression of the disease), is a very sensitive indicator of the impact of the disease on the patient's quality of life. In light of this, it merits being linked to the idea of suffering. With the eye of a philosopher, Paul Ricoeur draws a clear parallel between these two concepts, defining them as follows: "Pain: affects experienced as located in particular organs of the body or in the whole body" and "Suffering: affects relating to reflexivity, language, relationship with oneself, relationship with others, relationship to the senses, to questioning". With this perspective, it is therefore essential to use the pretext of pain to in fact consider overall suffering (sometimes described as "total"). Questioning should therefore not apply solely to the treatments to be administered, but also to the way that announcements are made, to the necessity of going through patients' questions concerning the disease, sometimes expressed in the form of pain, with them and to offer psychological follow-up, even going so far as to offer cognitive behavioral therapy in the case of recurrent pain that is difficult to describe or is resistant to different treatments that are tried.

With this in mind, an increasing part is now played by complementary approaches such as sophrology, reflexology, hypnosis, but also touch massage, or even certain techniques from nonconventional medicine (acupuncture). These techniques are only available in certain centers, but they are approaches that should not be ignored, with discussion beforehand with patients, whose response to these types of treatment is very varied.

More conventionally, the role of physiotherapy is essential throughout the period of management of elderly cancer patients, not only to strengthen or develop existing motor functions, but also with the general aim of preserving functional abilities for as long as possible and for the prevention of multiple bone and joint pain which is the inevitable accompaniment to any degeneration of a patient's general condition. The work of the physiotherapist is often accompanied by that of the occupational therapist, whose suggestions are very often able to prevent the escalation of medication by means of physical, environmental, and material improvements at the time of any potentially painful procedure or installation.

From a multidisciplinary perspective, one could add that the management of pain in elderly cancer patients is in fact based on the team as a whole, which also includes psychosocial assessment of the patient's support network.

Indeed, this multidimensional and rigorous management of pain in elderly cancer patients is the key to being able to ensure that their quality of life is maintained and this management model can be summarized according to the following stages (Hui and Bruera 2014):

- Pain screening at each consultation in order to diagnose it as early as possible.
- More in-depth assessment in order to characterize the pain according to severity, semiological characteristics, associated prognostic factors, and above all incorporation within a multidimensional assessment of the elderly, vulnerable patient.
- Formulation of a multidisciplinary, multimodal treatment plan, combining possible pharmacological, analgesic, or coanalgesic measures with nonpharmacological measures.
- Education of the patient and of his or her family and friends in the management of the

treatment, its side effects, and the treatment objectives.
- Close monitoring throughout, with adjustments as often as necessary, both in order to improve the analgesic efficacy and considering a reduction in the treatment if necessary on the basis of the overall progress of the patient and of the disease.

Close adherence to this advice and the multidisciplinary nature of the management of these frail patients therefore remain, in both the area of analgesia and in all the areas affecting the health of elderly patients, the cornerstones of holistic and compassionate medicine.

Conclusion

In recent years, many campaigns have conveyed the idea that pain is not inevitable, thereby fostering much progress in terms of pain assessment and management. This symptom is in fact an obvious signal for the need to improve the situation, both in physical terms and in terms of a more holistic approach. The multiplicity of causes of pain and the many means at our disposal for its management should not interfere with a rigorous diagnostic and therapeutic approach. Thus, knowledge of the precise and safe handling of analgesics and other associated drug products, which can absolutely be offered to these vulnerable patients, is of paramount importance and must always be accompanied by a wish to combine this with consideration and multidisciplinary expertise while pursuing the objective of relief and the maintenance of a level of functional ability and quality of life that are acceptable to the patient.

Digestive Symptoms Control and Nutrition Issues in Older Cancer Patients

Contents

Abstract

Cancer and its treatment can be related to various digestive symptoms: nausea and vomiting, diarrhea, constipation, and stomatitis/mucositis. In an older patient, these issues can be more difficult to tolerate and lead to various types of decompensation. In this chapter, we discuss their management and nutritional issues more specific to older patients.

Introduction

Cancer and its treatment can be related to various digestive symptoms: nausea and vomiting, diarrhea, constipation, and stomatitis/mucositis. In an older patient, these issues can be more difficult to tolerate and lead to various types of decompensation.

Digestive Symptoms Management

Nausea and Vomiting (Based on Roila et al. 2016)

This may reflect an underlying obstruction (peritoneal carcinomatosis or mass), a gastrointestinal infection (including appendicitis or diverticulitis), or the consequence of medical treatments ((chemo)therapy, opioids) or radiation therapy. It is important to always consider all the

Genolier Cancer Centre, Clinique de Genolier, Genolier, Switzerland
e-mail: maapro@genolier.net

M. Extermann (ed.), *Geriatric Oncology*,
https://doi.org/10.1007/978-3-319-57415-8_17

causes of vomiting and not attribute it automatically to one cause. In an elderly person, there may be less abdominal reaction, and on clinical examination, the (rebound) tenderness may well be missing.

Many treatment options exist to avoid chemotherapy-induced nausea and vomiting. These are applied in a preventative fashion, usually depending on the type of chemotherapy the patient receives (Figs. 1 and 2). Regrettably, evidence-based guidelines are lacking for chemotherapies given over several days or weeks. The recent demonstration of the benefit of olanzapine in some settings raises questions about the tolerability and appropriate dose of this agent, particularly in elderly patients.

Radiation-therapy induced nausea and vomiting has also various risk levels depending on the site of radiation; the risk classification is mainly based on incidence of emesis in clinical studies and expert opinions, and use of S_HT3 receptor antagonists, dopamine receptor antagonists, and dexamethasone will depend on the clinical situation.

Opioid-related nausea and vomiting is poorly studied, and while S_HT3 receptor antagonists are often used, many experts suggest the use of very low doses of drugs like haloperidol.

Diarrhea (Based on Bossi et al. 2018)

Diarrhea, when not related to the underlying cancer, has several causes, and one should always rule out infectious causes in cases of severe diarrhea (at least search for Clostridium difficile).

Some chemotherapies are related to diarrhea, with fluoropyrimidines, irinotecan, and signal transduction inhibitors being the most frequent agents inducing this symptom. In addition, various immunotherapies are related to severe diarrhea (colitis).

A well-tolerated diarrhea can be managed with loperamide, oral hydration, and dietary measures. In case of severe diarrhea or neutropenic enterocolitis, with or without fever, appropriate antibiotics and in-hospital observation are mandatory. Octreotide may be introduced in certain settings.

Constipation (Based on Larkin et al. 2018)

A clinical definition of chronic (sometimes termed functional) constipation requires the presence of any two of the following symptoms for at least 12 weeks in the previous 12 months (not necessarily consecutively):

- Straining during bowel movements
- Lumpy or hard stool
- Sensation of incomplete evacuation
- Sensation of anorectal blockage or obstruction
- Manual evacuation procedures to remove stool
- <3 bowel movements per week

Constipation is often related to opioid usage, but it is also a common side effect of S_HT3 receptor antagonists. A frequently mentioned issue is insufficient hydration of the patients.

Appropriate use of laxatives is often essential in the prevention and relief of constipation. There is limited evidence to support the use of one laxative over another. Osmotic laxatives include PEG (Macrogol), Lactulose: Magnesium, and sulfate salts.

Stimulant laxatives are anthranoid plant compounds (senna, aloe, cascara) usually taken in the evening or at bedtime. Care must be taken to avoid overstimulating effects.

Polyphenolic compounds like bisacodyl and sodium picosulfate work similarly to anthranoid laxatives.

Suppositories and enemas are a preferred first-line therapy when digital rectal examination identifies a full rectum or fecal impaction. Enemas (such as hyperosmotic saline) and suppositories increase water content and stimulate peristalsis to aid in expulsion, and both work more quickly than oral laxatives.

Mini Nutritional Assessment

For Adults 65 years of Age and Older

Last name: First name:

Date: Age:

Complete the screen by filling in the boxes with the appropriate numbers.
Total the numbers for the final screening score.

Screening

A Has your food intake declined over the past 3 months? [ENTER ONE NUMBER] *Please enter the most appropriate number (0, 1, or 2) in the box to the right.*	0 = severe decrease in food intake 1 = moderate decrease in food intake 2 = no decrease in food intake	☐
B How much weight have you lost in the past 3 months? [ENTER ONE NUMBER] *Please enter the most appropriate number (0, 1, 2 or 3) in the box to the right.*	0 = weight loss greater than 3 kg 1 = do not know the amount of weight lost 2 = weight loss between 1 and 3 kg 3 = no weight loss or weight loss less than 1 kg	☐
C How would you describe your current mobility? [ENTER ONE NUMBER] *Please enter the most appropriate number (0, 1, or 2) in the box to the right.*	0 = unable to get out of a bed, a chair, or a wheelchair without the assistance of another person 1 = able to get out of bed or a chair, but unable to go out of my home 2 = able to leave my home	☐
D Have you been stressed or severely ill in the past 3 months? [ENTER ONE NUMBER] *Please enter the most appropriate number (0 or 2) in the box to the right.*	0 = yes 2 = no	☐
E Are you currently experiencing dementia and/or prolonged severe sadness? [ENTER ONE NUMBER] *Please enter the most appropriate number (0, 1, or 2) in the box to the right.*	0 = yes, severe dementia and/or prolonged severe sadness 1 = yes, mild dementia, but no prolonged severe sadness 2 = neither dementia nor prolonged severe sadness	☐
Please total all of the numbers you entered in the boxes for questions A-E and write the numbers here:		☐

Fig. 1 Self assessment part 1

Now, please CHOOSE ONE of the following two questions – F1 or F2 – to answer.

Question F1

Height (cm)	Body Weight (kg)			
147.5	Less than 41.1	41.1 – 45.3	45.4 – 49.6	49.7 or more
150	Less than 42.8	42.8 – 47.2	47.3 – 51.7	51.8 or more
152.5	Less than 44.2	44.2 – 48.7	48.8 – 53.4	53.5 or more
155	Less than 45.6	45.6 – 50.4	50.5 – 55.2	55.3 or more
157.5	Less than 47.1	47.1 – 52.0	52.1 – 57.0	57.1 or more
160	Less than 48.6	48.6 – 53.7	53.8 – 58.8	58.9 or more
162.5	Less than 50.2	50.2 – 55.4	55.5 – 60.6	60.7 or more
165	Less than 51.7	51.7 – 57.1	57.2 – 62.5	62.6 or more
167.5	Less than 53.3	53.3 – 58.8	58.9 – 64.4	64.5 or more
170	Less than 54.9	54.9 – 60.6	60.7 – 66.4	66.5 or more
172.5	Less than 56.5	56.5 – 62.4	62.5 – 68.3	68.4 or more
175	Less than 58.2	58.2 – 64.2	64.3 – 70.3	70.4 or more
177.5	Less than 59.9	59.9 – 66.1	66.2 – 72.4	72.5 or more
180	Less than 61.6	61.6 – 67.9	68.0 – 74.4	74.5 or more
182.5	Less than 63.3	63.3 – 69.8	69.9 – 76.5	76.6 or more
185	Less than 65.0	65.0 – 71.8	71.9 – 78.6	78.7 or more
187.5	Less than 66.8	66.8 – 73.7	73.8 – 80.8	80.9 or more
190	Less than 68.6	68.6 – 75.7	75.8 – 82.9	83.0 or more
192.5	Less than 70.4	70.4 – 77.7	77.8 – 85.1	85.2 or more
Group	**0**	**1**	**2**	**3**

Please refer to the chart on the left and follow these instructions:

1. Find your height on the left-hand column of the chart.
2. Go across that row and circle the range that your weight falls into.
3. Look to the bottom of the chart to find out what group number (0, 1, 2, or 3) your circled weight range falls into.

Write the Group Number (0, 1, 2, or 3) here: ☐

Write sum of questions A-E (from page 1) ☐

Lastly, calculate the sum of these 2 numbers. This is your SCREENING SCORE: ☐

Question F2

DO NOT ANSWER QUESTION F2 IF QUESTION F1 IS ALREADY COMPLETED.

Measure the circumference of your LEFT calf by following the instructions below:

Loop a tape measure all the way around your calf to measure its size.

Record the measurement in cm: _____

If less than 31cm, enter "0" in the box to the right.

If 31cm or greater, enter "3" in the box to the right. ☐

© SIGVARIS

Write the sum of questions A-E (from page 1) here: ☐

Lastly, calculate the sum of these 2 numbers. This is your SCREENING SCORE: ☐

Screening Score (14 points maximum)

12–14 points:	Normal nutritional status	
8–11 points:	At risk of malnutrition	
0–7 points:	Malnourished	**Copy your SCREENING SCORE:** ☐

If you score between 0-11, please take this form to a healthcare professional for consultation.

Fig. 2 Self assessment part 2

Stomatitis/Mucositis (Based on Peterson et al. 2015)

The terms oral mucositis and stomatitis are often used interchangeably, but they do not reflect identical processes.

"Mucositis" describes inflammation of mucosa resulting from chemotherapeutic agents or ionizing radiation. It typically manifests as erythema or ulcerations and may be exacerbated by local factors, such as secondary infections and trauma. "Stomatitis" refers more generally to any inflammatory condition of oral tissues and should be used for oral complaints related to other causes than the above, such as targeted therapies.

Oral mucositis of grade 3 or 4 is prevalent in patients receiving radiation to the oral cavity with an incidence up to 85% and is the prime limiting factor of chemoradiation for advanced head and neck carcinoma. Patients should have preventative dental treatment before irradiation. The oral pain associated with the lesions frequently leads to the need for enteral nutritional support with or without use of a feeding tube or gastrostomy, as well as use of intensive pain therapy.

Preventive measures help to reduce the severity of stomatitis.

Sources of trauma should be eliminated, and hot (temperature or spicy) foods and drinks should be avoided. Effective oral hygiene is crucial; it is important that patients be appropriately educated about oral complications before treatment Plain water mouthwashes can usually be used; this approach is typically well tolerated by patients and may promote patient adherence to basic mouth care practices.

With targeted agents, saline-containing mouthwashes should be used instead of plain water because of the microbial burden that is considered to intensify formation of oral injury in this population. In case of use of everolimus, there are data suggesting that a corticosteroid-containing mouthwash may be very effective (Rugo et al. 2017).

The ESMO panel recommends the following measures, relevant to some elderly patients:

1. 1.30 min of oral cryotherapy be used to prevent oral mucositis in patients receiving bolus 5-fluorouracil chemotherapy.
2. The panel recommends that benzydamine mouthwash be used to prevent oral mucositis in patients with head and neck cancer receiving moderate dose radiation therapy (up to 50 Gy), without concomitant chemotherapy (I).

Nutrition Issues in Elderly Patients (Based on Arends et al. 2017)

The prevalence of malnutrition is variable among older patients, with the highest incidences (more than 30% severe malnutrition) among those who are hospitalized and in nursing homes (Leij-Halfwerk 2019). Malnutrition can lead to osteopenia/osteoporosis, immunological deficiencies, iron, vitamin B12 or folate-related anemia, sarcopenia, and other issues.

Malnutrition has a negative impact on clinical outcome and mortality in cancer patients, with adverse consequences including impaired quality of life, higher rates of complications and worse postoperative outcomes, longer duration of hospitalization, and poorer anticancer treatment tolerance due to increased toxicity, poorer compliance, and decreased response. Severity of malnutrition is an independent predictor of shorter survival (Aapro et al. 2014).

The self-administered Mini Nutritional Assessment (Fig. 3) is suggested as an assessment tool in older patients, and the importance of nutrition is highlighted by the G-8 screening tool which comprises of several nutritional questions and is predictive of outcome at 3 years (Bellera et al. 2012).

There is a lack of high-quality randomized clinical trial-based evidence of effectiveness of nutritional therapy. While the negative impact of cancer-related malnutrition and cachexia is striking, the results on the effects of nutrition on patients' overall prognosis are weak or inconsistent (Rauh et al. 2018). Nutritional care and therapy in cancer patients encompass dietician-aided dietary counseling (aimed at improving patients' spontaneous food intake), oral supplementation

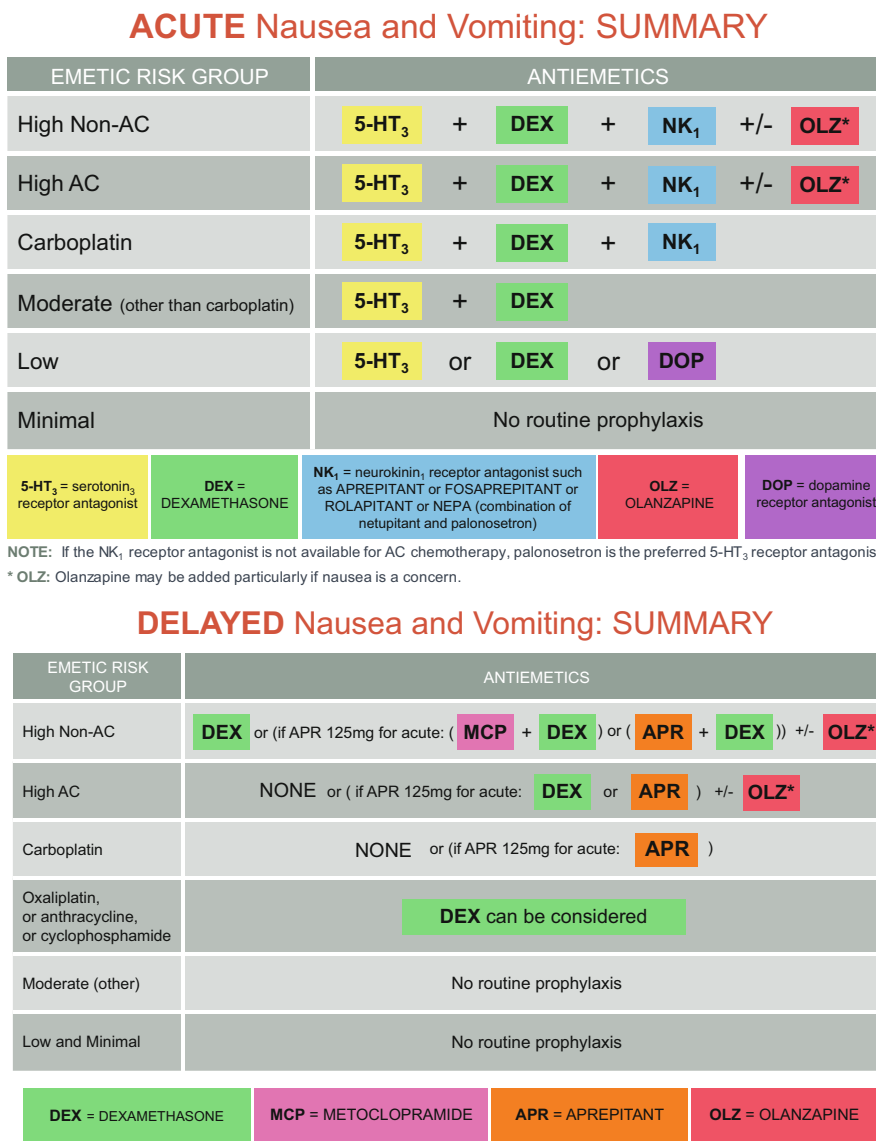

Fig. 3 Summary MASCC/ESMO guidelines

with industry-prepared oral nutritional supplements, enteral nutrition, and parenteral nutrition.

In patients with malnutrition or risk of malnutrition, the use of dietary restrictions is not recommended and considered even dangerous. Theoretical arguments that nutrients would primarily benefit the tumor lack scientific background and thus should not lead to interruption, decrease, or cessation of nutritional intervention in cancer patients. Energy intake should be initially aimed to be from 20 to 25 to 35 kcal/kg body weight, choosing the higher range for ambulatory, younger, underweight, and male patients, while choosing the lower range for bedridden, older, obese, and female patients. During follow-up, energy provisions need to be adapted according to the nutritional status and the metabolic condition. Protein intake should be above 1 and aiming for 1.2–1.5 g/kg body weight per day.

Abstract

Increased survival coupled with an increase in new diagnoses of cancer among elderly adults makes geriatric cancer patients the largest population of cancer survivors in the United States. Cancer and its treatment can lead to a myriad of adverse events (physical or cognitive impairment, psychological distress, and other symptoms) and negatively impact quality of life in older cancer patients and survivors. Physical activity recommendations vary across the cancer continuum and remain an important area of research in this population. Exercise interventions have been shown to be effective in treating both the physical and psychological declines associated with cancer and its treatment, with a potential to improve cancer-related outcomes. Despite the current evidence of benefits, exercise is still underutilized due to lack of awareness and knowledge among health care providers and older cancer patients. For older cancer patients and survivors to maintain or improve their physical function and possibly reduce the cancer-related toxicities, oncology clinicians must be prepared to discuss the short- and long-term benefits of exercise. Exercise professionals should identify risks and contraindications that may affect exercise safety and tolerance and create individualized exercise prescriptions to meet the unique needs of this population. More exercise intervention studies in various settings, including the community and hospital, are needed to gain widespread acceptance. This chapter summarizes geriatric cancer-related toxicities and psychological distress and how exercise mediates these side effects. Exercise guidelines and how oncologists and exercise professionals can provide the appropriate supportive care needed in this population are also described.

Introduction

In 2016, approximately 15.5 million cancer survivors representing 4.8% of the population in the United States need oncologic survivorship care (National Cancer Institute 2016). With increasing rates of early detection and novel more-effective treatment options, oncologic outcomes stemming from cancer treatments have substantially improved (Cancer Facts & Figures 2012). For example, a recent SEER database study demonstrated significant improvements in survival for patients with breast, prostate, colorectal, lung, and liver cancer between the years of 2005 and 2009 as compared to 1990–1994 (Zeng et al. 2015). Consequently, many Americans diagnosed with these diseases are living beyond the once designated life expectancy of 5 years, and a large proportion of these survivors will live into old age. This increased survival, along with an increase in new diagnoses of cancer among elderly adults, makes geriatric cancer patients the largest proportion of the population of cancer survivors in the United States (Berger et al. 2006). In fact, by the year 2024, there will be nearly 19 million cancer survivors in the United States, and 63% or more of these survivors will be age 65 and older (DeSantis et al. 2014; Parry et al. 2011). These elderly cancer survivors constitute a population with a myriad of unique needs that will require changes in the US healthcare system in the coming decades to treat them efficiently and effectively.

Biologically, cancer and aging share a number of common underlying physiologic characteristics. For example, older adults and cancer survivors exhibit chronic inflammation, inadequate DNA repair, and shortened telomere length. Cancer and its treatments stimulate an accelerated aging process characterized by early onset frailty and multiple co-morbidities typically seen in adults over the age of 60 described as an oncologic aging phenotype. Moreover, this oncologic aging phenotype is also seen in young adult survivors of childhood cancers who demonstrate prefrailty and frailty,

with rates similar to survivors 65 years of age and older (Ness et al. 2013). While significant improvements have been made in the toxicity profiles associated with cancer treatments, treatments continue to be associated with a variety of both short- and long-term toxicities that impair physical and psychological function. These toxicities negatively affect a patient's ability to tolerate and adhere to life-saving cancer treatments, maintain independent living and perform activities of daily living (ADL), and maintain a conventional standard of living (Mustian et al. 2012). Older adults are especially susceptible to these acute, chronic, and late toxicities as a result of the cancer itself and/or treatments for cancer. Acute toxicities are those which develop before or during treatment, but have a short duration (days, weeks, or months); chronic toxicities may continue for months or years; and late toxicities develop months or years after treatments are complete. All three types of toxicities at any stage of the cancer trajectory have significant adverse effects on cancer survivors, especially when they are older.

Some of the most commonly reported toxicities stemming from cancer and its treatments are loss of physical function, sarcopenia, cachexia, bone loss, cancer-related fatigue, cognitive impairment, and distress (Mustian et al. 2011, 2012; Peppone et al. 2010). These are also among the toxicities which have the greatest negative effects on elderly cancer survivors.

Physiological Toxicities

Aging is associated with physical and functional decline. This is further exacerbated by the presence of a cancer diagnosis and cancer treatments, leading to poorer function and physical decrements (Sprod et al. 2012a, 2015; Mohile et al. 2011; Mustian et al. 2006a, 2007, 2009a, b; Bellizzi et al. 2008a, b; Mohile et al. 2009a; Bylow et al. 2008). Being able to perform activities of daily living (ADLs) and instrumental activities of daily living (IADLs) is essential for the older adult with cancer to function independently (Sprod et al. 2012a, 2015; Mohile et al. 2011; Mustian et al. 2006a, 2007, 2009a, b; Bellizzi et al. 2008a, b; Mohile et al. 2009a; Bylow et al. 2008). In a systematic review examining factors affecting treatment decision-making, the ability to maintain independence is important to older adults when deciding treatments (Chouliara et al. 2004; Ciambrone 2006; Puts et al. 2015; Sinding and Wiernikowski 2009). Older adults constituted a significant proportion (48.5%) of those reporting these concerns (Burg et al. 2015). In the general geriatric population, functional decline is associated with future disability and mortality (Cesari et al. 2008; Reuben et al. 1992). In the older cancer population, impairment in physical function is also associated with increased toxicity related to chemotherapy and mortality (Hurria et al. 2011; Freyer et al. 2005). Specifically, chemotherapy and radiation treatments can lead to reductions in cardiac and pulmonary function (DeVita et al. 2005; Hofman et al. 2007; Morrow 2007). For example, chemotherapeutic agents such as anthracyclines, taxanes, and/or trastuzumab, which are commonly used for treatment of breast cancer, can lead to acute or chronic cardiac dysfunction in patients, which may or may not be reversible. The side effects may warrant dose reduction or drug discontinuation that may ultimately lead to poorer survival (Allen 1992; DeVita et al. 2006). These cardiac toxicities can develop during treatment or years after treatment is complete and may persist for years (Yeh 2006; Sardaro et al. 2012). Other commonly used chemotherapeutic agents such as methotrexate and bleomycin may cause pulmonary toxicities (Willenbacher et al. 1998; Jacka and Chan 1995; Lateef et al. 2005; Cannon 1997). Similarly, radiation can also give rise to cardiac and pulmonary late effects (Carver et al. 2013). In the American Cancer Society Study for Cancer Survivors-II, a national cross-sectional survey of cancer survivors posttreatment, 38.2% of survivors reported unmet physical activity needs.

Muscle dysfunction is a prevalent occurrence in the oncology setting, and cancer and its related treatments lead to impaired muscle function through atrophy and loss of strength (Tisdale 2002, 2003). The sarcopenia and malaise experienced by cancer patients may impair their ability to perform activities of daily living and remain independent during and following treatment (Mohile et al. 2009b, 2011; Reuben et al. 1992). Cancer cachexia can be defined as a significant reduction in body weight resulting primarily from

loss of skeletal muscle and adipose tissue. Cachexia leads to a reduction in cancer treatment tolerance, quality of life, and increased mortality (Fearon Kenneth et al. 2012). In fact, emergent evidence suggest that muscle wasting (Martin et al. 2013) and weight loss (Utech et al. 2012) are effective predictors of mortality in cancer patients. Cancer cachexia is a multifactorial syndrome that cannot be fully reversed by conventional nutritional interventions and eventually leads to progressive functional impairment (Fearon et al. 2013). Although research is not conclusive on the efficacy of exercise on cachexia (Argiles et al. 2012), it has demonstrated the ability of exercise (specifically resistance training) to increase skeletal muscle mass in cancer patients and survivors (Fong et al. 2012; Strasser et al. 2013; Lønbro et al. 2013).

A large percentage of patients who are diagnosed with cancer experience cancer-treatment-induced bone loss (Chen et al. 2005). In some cases, patients receive treatment for cancer more than triple for the average bone lose seen with normal aging (Confavreux et al. 2007). This reduction in bone mineral density is accompanied by a 1.3–5-fold increase in fracture rate when compared to individuals not undergoing treatment (Chen et al. 2009). Female patients treated with chemotherapy, oophorectomy, and aromatase inhibitors often experience a decrease in the production of endogenous estrogens and develop premature menopause that may lead to reduced bone mineral density which increases the risk of fracture (Bruning et al. 1990; Shuster et al. 2008; Howell et al. 2005). Increasing evidence demonstrates that weight-bearing aerobic and resistance exercise may benefit bone metabolism(Lester et al. 2009) and maintain bone mineral density (Irwin et al. 2009a), and the two combined could offer a valuable intervention for moderating bone loss among cancer patients(Milne et al. 2008).

Patient-Reported Toxicities

Cancer patients and survivors commonly experience poor sleep quality and it is several times more prevalent in this population than in the general population (Savard and Morin 2001; Palesh et al. 2010). Sleep disturbance is reported by 30–50% of patients with cancer, and a history of cancer increases the likelihood of patients reporting persistent symptoms (Savard and Morin 2001; Irwin 2013; Savard et al. 2011; Theobald 2004; Mao et al. 2007). The prevalence varies by age, gender, cancer type, cancer treatment, and duration. In older cancer survivors, the prevalence of sleep disturbance was reported to be between 19% and 25%. On the other hand, in a cross-sectional study that included a convenience sample of older adults receiving active cancer treatments, the prevalence was approximately 60% (Cheng and Lee 2011). Depression (Pirl and Roth 1999), pain (Chang et al. 2000), anxiety, fatigue, and distress are also commonly reported by a large majority of cancer patients and survivors, either occurring on its own or as a symptom cluster (Stark et al. 2002). Similarly, the prevalence of these symptoms is thought to be higher in the cancer population compared to the general population. In a study looking at older cancer survivors, the prevalence of pain, fatigue, and mood disturbance were 49%, 63%, and 87%, respectively (Cheng and Lee 2011). Up to 31% of these patients reported co-occurrence of all four symptoms. Another study exploring symptom burden in older adults with cancer receiving radiation also demonstrated high prevalence of these symptoms prior to treatment: pain (35%), fatigue (69%), distress (44%), and mood disturbance (47%). The differing prevalence across studies likely reflects the heterogeneous population as well as timing and methods of assessment (Mustian et al. 2011). The mixed depression/anxiety phenotype occurs in two-thirds of patients with cancer who are depressed and has been associated with more severe depressive symptoms, with less improvement after treatment, worse quality of life, poorer adherence to treatment, slower recovery, greater suicide risk, and higher cost-utilization (Brintzenhofe-Szoc et al. 2009).

Cancer-related fatigue (CRF) is a dose-limiting toxicity and one of the most commonly reported symptoms by patients on active treatments as well as cancer survivors (Cornelison et al. 2012). It is described as “persistent, subjective sense of

tiredness related to cancer and cancer treatment that interferes with usual functioning" (Mock et al. 2000). The prevalence is reported to be as high as 95% and varies by cancer subtypes and treatments; nearly half report their condition as severe (Hofman et al. 2004). It is more common, more severe, and more persistent in those who undergo more than one treatment type (Mustian et al. 2006a, 2007, 2009c; Morrow 2007). In a study of patients with advanced cancer, older patients had a higher prevalence of fatigue compared to younger patients (W-H et al. 2011). CRF can persists for years in otherwise healthy cancer survivors (Bower 2014). Studies involving long-term cancer survivors suggest that approximately one-quarter to one-third experience persistent fatigue for up to 10 years after cancer diagnosis (Bower et al. 2006; Servaes et al. 2007). It has been reported consistently that CRF is more severe, persistent, and incapacitating compared to fatigue caused by lack of sleep or overexertion and is not alleviated by sufficient sleep or rest (Poulson 2001; Jacobsen et al. 1999; Andrykowski et al. 1998; Cella et al. 2002). Patients often self-reported CRF as being the most distressing side effect of treatment, even more so than nausea and vomiting that affects their quality of life and the ability to perform ADL (Mustian et al. 2006a, 2007, 2009c; Morrow 2007). In older adults, fatigue is further compounded by the presence of comorbidities and age-related decline and accompanied by other symptoms, such as sleep disruption, depression, pain, anxiety, and physical inactivity (Giacalone et al. 2013). CRF negatively affects all domains of quality of life and causes psychological distress and may contribute to lower survival (Bower 2014; Mormont et al. 2000). It is multifaceted and may have physical, mental, and emotional manifestations (Mustian et al. 2006a, 2007; 2009c, Morrow 2007).

The impact of cancer therapy on cognition is becoming increasingly recognized. Up to 75% of cancer patients experience some form of cognitive impairment after a cancer diagnosis and/or during cancer treatments (e.g., chemotherapy, radiation, surgery, hormone therapy). For the majority of subjects, cognition improved with time. However, 20–35% of cancer survivors report long-term changes in cognition (Janelsins et al. 2009, 2011, 2014; Brezden et al. 2000; Ahles et al. 2002, 2010; van Dam et al. 1998; Wefel et al. 2004; Jansen et al. 2008). In addition to patient-reported cognitive decline, neuropsychological testing has also demonstrated changes in cognition associated with cancer and cancer therapy, most commonly diminished memory, executive function, attention, and concentration (Kesler et al. 2013a, b; Kohli et al. 2009). Although the majority of studies regarding cognition in cancer have been performed in younger cancer survivors, a few studies have included older subjects. A study by Ahles and colleagues found that older breast cancer patients with low cognitive reserve were most likely to experience decline in processing speed with exposure to chemotherapy, as compared to younger cancer patients or those individuals with normal cognitive reserve at baseline (Ahles et al. 2010). Hurria and colleagues evaluated older adults (aged $\geq$65) receiving adjuvant chemotherapy for breast cancer with a neuropsychological assessment battery at baseline and 6 months following treatment. In this study, 39% of patients experienced a decline in cognitive function from baseline following receipt of chemotherapy (Hurria et al. 2006). Impairment in cognition can negatively impact the mental and physical well-being of patients, causing decreased quality of life. For younger patients, this may impact their ability to effectively work and maintain an income. A study of breast cancer survivors observed that 57% of subjects reported inability to do their jobs as effectively, maintain the same job, or work at all following chemotherapy due to difficulty with memory and attention (Wefel et al. 2004; Bradley et al. 2005). For older adults, decline in cognition may impact their ability to remain independent. Often older adults live alone and need to be able to manage medications and finances in order to remain independent. Cognitive impairment can compromise the ability of an older adult to perform these tasks, thus compromising independence (Magnuson et al. 2016). Cognitive impairment and loss of independence can negatively impact quality of life. In a study of older adults with cancer, 41% reported significant psychological distress, and this was related to reduced physical function and loss of

independence (Hurria et al. 2009). Cognitive impairment can also impact a patients' compliance with cancer treatments as well as contribute to social isolation (Boykoff et al. 2009; Stilley et al. 2010; Reid-Arndt et al. 2009). These negative consequences are exacerbated when cognitive impairment co-occurs with other symptoms such as sleep disturbance, depression or anxiety, pain, fatigue, and physical inactivity.

These studies highlight the prevalence of toxicity burden in the older adult with cancer. Physical or cognitive impairment, psychological distress, and other symptoms may significantly limit therapeutic options for older adults with cancer, translating to poorer health outcomes (Mohile et al. 2009b). Further studies are needed to evaluate interventions to address symptom burden in this population. Exercise interventions are one of the most promising areas to assist the older cancer patient and survivor.

Exercise as Therapy for the Older Cancer Patient

Recent literature demonstrates that maintaining the recommended amount of physical activity (defined as bodily movement produced by contraction of skeletal muscle that increases energy expenditure above basal level) through structured exercise interventions (defined as physical activity that is planned, structured, and repetitively used for the purpose of enhancing one of the seven components of fitness or psychological fitness or health-related outcomes [i.e., cancer or cancer-treatment-related toxicities and side effects]) is an effective method for treating both the physiological and psychological decrements experienced by older cancer patients and survivors (Mustian et al. 2009a, 2012; Spence et al. 2010; Caspersen et al. 1985; Klepin et al. 2013; Buffart et al. 2015; Campo et al. 2014a). Often, a cancer diagnosis and subsequent treatment result in a reduction in physical activity levels that frequently do not return to prediagnosed levels without a structured exercise intervention (Mustian et al. 2006a; Irwin et al. 2003; Courneya and Friedenreich 1997). The decline in physical activity experienced by these patients is often exacerbated by instructions to avoid or limit activities when fatigued or experiencing other side effects related to the cancer diagnosis (Curt et al. 2000; Winningham et al. 1994).

Exercise mediates a variety of physiological and psychological toxicities including loss of muscle mass and function, fatigue, immune function, insomnia, anxiety, cognitive decline, and impaired quality of life, and these improvements may be more evident in older cancer patients and survivors (Brown et al. 2011; Irwin et al. 2009b; Gleeson et al. 2011; Tang et al. 2010; Salmon 2001). Physical activity has consistently been associated with reductions in the risk of cancer, cancer recurrence, and cancer mortality in all populations (Betof et al. 2013; Ballard-Barbash et al. 2012; Bittoni et al. 2014), but specifically in older individuals (Chao et al. 2004). Despite these published reports about the health benefits of exercise in older populations, it is estimated that up to 70% of cancer survivors do not meet the ACSM's public health recommendations (Irwin 2009). Lack of awareness and understanding among health care providers, patients, and survivors in regards to exercise recommendations and the precise methods for prescribing exercise for the effective treatment of specific cancer and treatment-related outcomes may be two primary reasons for the lack of physical activity compliance among older cancer patients and survivors.

As the rate of cancer survivorship in older populations increase a continued effort has to be made to assess ways to improve health-related quality of life and to treat specific toxicities such as cancer related fatigue and impaired physical function (Mustian et al. 2009a; Leak Bryant et al. 2015a, b). Encouraging older cancer patients and survivors to increase their physical activity may assist them in regaining and improving physical function while reducing and preventing long-term effects of cancer and its treatments.

Exercise and Biological Mechanisms Involved in the Pathophysiology of Toxicities

Exercise is a feasible and effective alternative for the treatment of several cancer-related side effects that cluster together because it can be

designed to fit the specific needs and abilities of older cancer patients and survivors (Chao et al. 2004; Campo et al. 2014b). Exercise is a treatment capable of simultaneously affecting multiple biological pathways that are involved in the etiology of cancer-related side effects. Chronic immune response activation has been suggested to be the primary modulator of biological pathways that are involved in the pathophysiology of common toxicities including hypothalamic-pituitary-adrenal axis, mitochondrial (Saligan et al. 2015), and inflammatory (Saligan et al. 2015; Illman et al. 2005) dysfunction, metabolic adaptations, and genetic and epigenetic influences (Saligan et al. 2015; Oltmanns et al. 2003). For example, inflammatory immune responses that are involved in cell differentiation, proliferation, and apoptosis are associated with several symptoms (Oltmanns et al. 2003). Adaptations that occur in response to a chronic immune response compromise protein synthesis and muscle function and result in the clustering of cognitive impairment, fatigue, pain, and depression (Sprod et al. 2012a; Saligan et al. 2015; Mueller et al. 2015; Oliveira Miranda et al. 2014). The polymorphism of certain genetic strands has also been linked to fatigue. Posttranslational modifications in genotypes are directly related to increases in fatigue in response to hormone and radiotherapy among cancer patients(Saligan et al. 2015), and the burden of this fatigue is increased in older individuals when compared to their younger counterparts(Avlund 2010). Recent research strongly suggests that exercise is an effective treatment for many of the toxicities that result from cancer and its treatments. Exercise has the ability to positively affect many of the biological pathways that cause cancer-related side effects through its impact on the inflammatory response system. It has been shown to reduce the inflammatory immune response, regulate metabolic and neuroendocrine pathways, and improve genetic and epigenetic function in individuals without cancer. Exercise is a viable treatment option because it can both directly and indirectly influence these pathways individually and as they occur in a cluster (Koelwyn et al. 2015).

Exercise Guidelines for Older Cancer Patients and Survivors

In 2014, the American College of Sports Medicine (ACSM) published exercise guidelines as well as guidelines for exercise testing and prescription for older (Ferguson 2014) individuals, cancer patients, and survivors of cancer (Ferguson 2014; Schmitz et al. 2010). Collectively, these guidelines provide evidence-based recommendations for designing safe and effective (1) fitness and functional testing protocols, (2) exercise prescriptions, and (3) exercise implementation, progression, and maintenance plans for older cancer patients and survivors. For these individuals, the ACSM guidelines recommend activities that gradually progress over time to achieving the following: (1) 150 min (moderate intensity) or 75 min (vigorous intensity) aerobic exercise per week, (2) 2–3 days/week moderate-intensity muscle-strengthening training for all major muscle groups, and (3) flexibility stretching exercise of all major muscle groups daily (Sprod et al. 2012a; Schmitz et al. 2010; Haskell et al. 2007; Jones et al. 2010). The ACSM also recommends that older cancer patients and survivors obtain information regarding their baseline levels of physical and psychological function, use caution when beginning a new exercise program, progress slowly, and enlist help from qualified professionals. The goal is to avoid inactivity and to encourage older cancer patients and survivors to return to their normal activities as quickly as possible (Schmitz et al. 2010). Physical activity guidelines are to be used as a benchmark with the understanding that any level of physical activity may result in improved health outcomes. Improvement in health outcomes has been well documented in young and older disease-free individuals and young and older individuals with several types of cancer. These include decreasing fatigue, improvements in physical function, activities of daily living, psychosocial well-being, and, ultimately, improving health-related quality of life (Mustian et al. 2004, 2006a, b, 2007, 2009a, b, c, 2011; Peppone et al. 2010; Sprod et al. 2012a, 2015; Adamsen et al. 2003; Ahmed et al. 2006; Courneya et al. 2007; Crevenna et al. 2003;

Headley et al. 2004; Holmes et al. 2005; Oldervoll et al. 2006, 2011; Porock et al. 2000; Reid-Arndt et al. 2012; Schmitz et al. 2005; Segal et al. 2003; Sprod et al. 2012b; Winters-Stone et al. 2011; Kamen et al. 2016).

Exercise Prescription for Older Cancer Patients and Survivors

Exercise testing, exercise prescription, and exercise monitoring should be done by qualified exercise professionals, especially for older cancer patients and survivors experiencing a high symptom burden and those at moderate cardiovascular risk beginning or continuing vigorous exercise and those at high cardiovascular risk commencing or continuing any level of exercise (American College of Sports Medicine 2016). Exercise prescriptions for older cancer patients and survivors should be individualized and tailored based on their health status, disease trajectory, previous and/or current treatment, symptom burden, current fitness level, past and present exercise participation, and individual preferences in order to be safe and effective (Schmitz et al. 2010; Physical Activity Guidelines Advisory Committee report 2009). The standard goal is to achieve the ACSM exercise guideline for older cancer patients as weekly 150 min of moderate-intensity or 75 min vigorous-intensity aerobic exercise and 2–3 days strength training and daily flexibility stretching exercise. Some recent resistance exercise intervention studies ranging from 12 weeks to 12 months showed that the strength-training exercise program with the intensity of 60–85% 1RM, the frequency of 1–3 times per week, and the duration of 15–30 min per session significantly improved physical function and quality of life, increased muscular strength and fitness, and reduced cancer-related fatigue in older cancer patients (Segal et al. 2003, 2009; Morey et al. 2009; Winters-Stone et al. 2012, 2015; LaStayo et al. 2011). Moderate-to-vigorously intense anaerobic resistance exercise prescriptions schedule three times per week and progressively increasing up to as few as two sets, and no more than four sets of 8–15 repetitions are effective at reducing symptoms (Ahmed et al. 2006; Courneya et al. 2007; Schmitz et al. 2005; Segal et al. 2003; Winters-Stone et al. 2011). Other studies had older cancer patients did aerobic exercise at 50–75% VO_{2peak}, three times a week and 15–45 min each session (Segal et al. 2009). The participated older cancer patients also significantly improved their muscular strength, cardiovascular fitness, social functioning, and reduced fatigue and psychological distress. Combination exercise prescriptions including both aerobic and anaerobic exercise are safe and very effective for most oncology patients and survivors (Cormie et al. 2015). Older cancer patients and survivors may get overwhelmed with the amount of exercise recommended in a day. One study suggested to increase the amount of activity during the day with short bouts of aerobic exercise (3–10 min each) to build up to 30 min a day. Rest breaks are encouraged to reduce toxicities and side effects (Sprod et al. 2012a). Patients with advanced disease or metastasis can safely perform and tolerate low intensity exercise such as walking (Adamsen et al. 2003; Crevenna et al. 2003; Headley et al. 2004; Oldervoll et al. 2006, 2011; Porock et al. 2000). Low to moderately intense mindfulness-based exercise prescriptions including Yoga and Tai Chi Chuan scheduled 1–3 times a week for 60–90 min are also highly effective in reducing symptom burden among older cancer patients and survivors (Mustian et al. 2004, 2006b, 2011; Peppone et al. 2010; Reid-Arndt et al. 2012; Sprod et al. 2012b). Additionally, those with advance disease can safely perform, tolerate, and benefit from low intensity exercise (Adamsen et al. 2003; Crevenna et al. 2003; Headley et al. 2004; Oldervoll et al. 2006, 2011; Porock et al. 2000).

Exercise Professionals

Exercise professionals working in oncology are an excellent resource for older cancer patients to obtain the appropriate supportive care needed throughout the entire cancer diagnosis and treatment process. Research has shown that participation and compliance with

exercise prescriptions during and following cancer treatment is increased when patients are advised to participate and are referred to a qualified exercise professional by their treating practitioner (Cella et al. 2002; Jones et al. 2004; Jones and Courneya 2002; Yeates et al. 2005). Furthermore, patients of all ages prefer to have their practitioners initiate the discussion about exercise and continue to provide information on exercise and appropriate exercise professionals throughout the treatment and recovery period (Yeates et al. 2005; Sprod et al. 2010). Regrettably, a high percentage of older cancer patients and survivors report not discussing exercise with their treating or primary care physician throughout their cancer diagnosis, treatment, or recovery. The exercise professional that is responsible for prescribing and facilitating the exercise protocol to an older cancer patient or survivor should be a certified exercise specialist. The minimum requirements to obtain this certification include a bachelor's degree or higher in an accredited exercise science or kinesiology program. In addition the exercise professional may also be required to be certified in cancer exercise training and in training older populations. These certifications establish that the exercise professional has obtained the minimum education required to safely and effectively prescribe and assist with exercise for older cancer patients and survivors (Schmitz et al. 2010). These certifications, which may be acquired by individuals from a range of career fields (e.g., occupational and physical therapists, nurses, exercise physiology), require specialized training in the area of cancer-specific issues as they relate to older patients or survivor as they begin or progress through an exercise program during treatment and into survivorship. The procurement of these certifications allow oncology professionals the opportunity to refer older cancer patients and survivors to an established professional who has the aptitude to the deliver the high standard of care required when prescribing and facilitating exercise for older cancer patients or survivors (Schmitz et al. 2010; American College of Sports Medicine et al. 2010; Doyle et al. 2006). Routine discussions between practitioners and older cancer patients regarding exercise along with appropriate referrals to a qualified exercise professional could significantly improve exercise participation and compliance, which may lead to improved prognosis, recovery, and numerous aspects of quality of life for older individuals (Sprod et al. 2012a, 2015; Mohile et al. 2011; Mustian et al. 2009a, b; Bellizzi et al. 2008a, b; Mohile et al. 2009a; Bylow et al. 2008; Mustian et al. 2006a, 2007).

Managing Risk and Contraindications for Exercise Professionals Working with Older Cancer Patients

It is always essential to identify an individual's level of risk and address potential contraindications (e.g., orthopedic, cardiopulmonary, oncologic) that might affect exercise safety and tolerance when beginning exercise therapy with older cancer patients or survivors (American College of Sports Medicine 2016). The Five-A Model is a diagram to aid oncology providers in assessing risk and referring their older cancer patients for exercise testing, advisement, and prescription services(Schmitz et al. 2010) (see Fig. 1). Initially it is important for oncologists to determine whether their older patients are currently engaging in an exercise program and to discuss how they can safely begin, progress through, or maintain an exercise program during and after treatment. Paramount to this discussion is the identification and resolution of potential contraindications (American College of Sports Medicine 2016). It is important for both the practitioner and patient to understand that contraindications do not mean that the older patient or survivor should be precluded from exercise entirely, but instead require specific modifications to the exercise design that include only modes of exercise that the patient may engage in safely and still achieve the desired health benefits (American College of Sports Medicine 2016). Based on their age and cancer diagnosis, most older patients will be classified as moderate to high risk as defined by the ACSM guidelines; therefore, they will be

required to obtain medical clearance and assessment beyond their medical team before participating in an exercise program. However, most older cancer patients will be able to safely initiate, progress through, or continue an exercise program (American College of Sports Medicine 2016).

In older cancer patients further medical assessments by surgeons, cardiologists, orthopedists, and

neurologists among others may be necessary to obtain required medical information regarding cancer-specific, cardiovascular, pulmonary, metabolic, orthopedic, neurologic, and other co-morbidities needed by exercise physiologists to safely and appropriately prescribe exercise (American College of Sports Medicine 2016). It is important that these additional medical evaluations be conducted prior to the older cancer patients engagement in baseline exercise testing which precedes the exercise design and participation (American College of Sports Medicine 2016). For the safety of the patient, it is recommended that all exercise testing, prescription, and monitoring be completed by a certified cancer exercise training professional and when needed additional medical professionals may be required during exercise for an older cancer patient and survivor (American College of Sports Medicine 2016).

Conclusion

Regular exercise during and after treatment is shown to have physical and psychological benefits(Sprod et al. 2012a; Mustian et al. 2006a, 2009a), including reduction in symptom severity. For older adults with cancer to maintain or improve their function, oncology clinicians must be equipped to discuss the short- and long-term benefits of exercise. Exercise professionals should be prepared to work with older cancer survivors and to meet the unique needs of this population. Additional studies are needed in the older adult with cancer population in a variety of settings including the community and hospital. Resources that oncology providers can share with their patients include: (1) the American Cancer Society Guidelines on Nutrition and Physical Activity for Cancer Prevention(www.cancer.org); (2) American Geriatrics Society (AGS) Healthy Aging Go4Life program (www.healthinaging.org); (3) Physical Activity Tips for Survivors at the American Society of Clinical Oncology site (www.cancer.net); and (4) National Cancer Institute Physical Activity and Cancer (www.cancer.gov) (Table 1).

Abstract

Developing countries include countries with the lowest per capita gross national income in the world. The majority of these countries are located in tropical areas where cancers and hematological malignancies are generally characterized by frequent viral and microorganism origin, specific biology, advanced stage disease, and poor outcome. Access to treatment is generally resource-limited and must be adapted to resources. In these countries the population is still young, but in the next 20 years, the burden of aging will increase with less perinatal mortality and longer life expectancy, and the number of elderly cancer patients will thus become similar to the one in high-income countries. Principles of contemporary geriatric oncology are not always enforceable to patients from these areas: this is often due to cultural differences, different comorbidities, different socioeconomic environment, and a lack of geriatricians and health professional education. This chapter reflects the present knowledge in this field and discusses specificities and potential propositions for the future.

Keywords

Tropical countries · Low-income countries · Transcultural mediation · Geriatric assessment · Global oncology

Introduction

Geriatric oncology is a relatively new area in oncology as it was conceptualized in the early 1990s (Monfardini and Yancik 1993). Since 2000, the International Society of Geriatric Oncology (SIOG) has developed education, clinical practice, and research (SIOG 2017). SIOG has also favored the participation of oncologists from all over the world. Nevertheless, the significance of the aging process in tropical and low-middle-low-income countries (TLMLICs) will increase the importance of geriatric oncology in this setting.

TLMLICs are defined basically by gross national income (GNI) per capita as classified by the World Bank (Worldbank 2016a). Countries with less $1,006 GNI per capita are classified as low-income countries and those between $1,006 and $3,975 as lower middle-income countries. Additionally the majority of these countries are located in the tropical areas where hematological malignancies and cancers present specific characteristics (Droz et al. 2015).

The objective of this chapter is to attempt to review the most important knowledge compilation on this subject.

Reference searches were performed to try and select the most informative articles. First, issues of Journal of Global Oncology and Journal of

Geriatric Oncology were reviewed: 7 and 6 informative articles were found, respectively. Then three researches were performed with the following MeSH terms: ("aged"[MeSH Terms] OR "aged"[All Fields] OR "elderly"[All Fields]) AND ("neoplasms"[MeSH Terms] OR "neoplasms"[All Fields] OR "cancer"[All Fields]) AND ("patients"[MeSH Terms] OR "patients"[All Fields]) AND ("poverty"[MeSH Terms] OR "poverty"[All Fields] OR ("low"[All Fields] AND "income"[All fields]): 132 articles; ("aged"[MeSH Terms] OR "aged"[All Fields] OR "elderly"[All Fields]) AND ("neoplasms"[MeSH Terms] OR "neoplasms"[All Fields] OR "cancer"[All Fields]) AND ("patients"[MeSH Terms] OR "patients"[All Fields]) AND tropical [All Fields] AND countries[All Fields]): 82 articles and ("geriatric assessment"[MeSH Terms] OR ("geriatric"[All Fields] AND "assessment"[All Fields]) OR "geriatric assessment"[All Fields]) AND ("poverty"[MeSH Terms] OR "poverty"[All Fields] OR ("low"[All Fields] AND "income"[All Fields]) OR "low income"[All Fields]) AND countries [All Fields]): 38 articles.

Geography and Demography

Geography of the Most Important Countries

The tropical area is located between the tropic of Cancer in the north (latitude 23° 26′ 14″° N) and the tropic of Capricorn in the south (latitude 23° 26′ 14″° S), equidistant from the equator. This includes America (a part of Mexico and all countries in Central America, all Caribbean islands, Colombia, Venezuela, Guyana, Surinam, French Guiana, Brazil, Bolivia, Peru, Ecuador), a large part of Africa (except Morocco, Algeria, Tunisia, Libya, Egypt, and South Africa), Asia (the south of India, Bangladesh, Myanmar, Thailand, Laos, Cambodia, Vietnam, extreme south of China, Malaysia and Brunei, Singapore, Indonesia, Philippines, Papua New Guinea, north of Australia), and many islands in the Pacific Ocean (Amat-Roze 2015; Wikipedia 2017).

The tropical area is the hottest and most humid part of the world. Climate is equatorial in a large part of Brazil, the shield of Guyana, coast of the Gulf of Guinea and Central Africa, Indonesia, Malaysia, Philippines, and Papua New Guinea: there is a dry season and a wet season (longer when near to the equator). The Tropical monsoon is observed in parts of the equatorial area but also in India, Bangladesh, and Southeastern Asia, generally the north of the equatorial area. It is characterized by a less pronounced dry season and large amounts of rain during the wet season, usually in the form of frequent thunderstorms. The dry tropical climate can be seen mainly in the north of equatorial area in Africa (Sahel) (Wikipedia 2017).

A great part of this space is occupied by hot deserts. The region is home to nearly 80% of the world's population, a figure likely to reach 90% by the end of the century.

Nominal GIN per capita in tropical countries is less than $12,276 in South America except Venezuela and French Guiana; it is less than $3,976 (and generally less than $1,006) in Africa apart from Botswana, Gabon, Equatorial Guinea, and South Africa; and it is less than $3,976 in Asia, except Thailand, Malaysia, and Indonesia, just like Singapore (Worldbank 2016b).

It is noteworthy that there is not a strict congruence between tropical countries and low- and lower-middle-income countries. However, the two aspects generally fit together. Therefore we will consider here low and low-middle income countries and particularly tropical countries.

Population in Tropical, Low- and Lower-Middle-Income Countries (TLLMICs)

The International Monetary Fund (IMF) (International Monetary Fund 2016) produced projections of the world population through 2050: population in the more developed countries will plateau around one billion (constant since 1950) inhabitants, while it will increase to around eight billion inhabitants in less developing countries (around five billion in 2008). An

important population increase is principally expected in Central Africa, India, and Southeastern Asia.

Health Expenditure

Health expenditure varies widely from one country to another (Worldbank 2015). Nevertheless there is a correlation between income and health expenditure: the lower the country income is, the lower the health expenditure is. Therefore countries with low health expenditure are principally located in the tropical area.

Aging in the World and Aging in TLLMICs

In 2013 the population of people aged 65 and above represents 4% of the whole population in low-income countries and 16% in high-income countries (Worldbank 2016b). Information on aging of the world population has been published by the IMF in 2015 (International Monetary Fund 2016). Projections of the world population through 2050 indicate that the population of persons over 60 increases. Nevertheless, the elderly people population will rise from 0.2 billion in 2008 to 0.4 billion in 2050 in the more developed countries, whereas it will rise, during the same period, from 0.4 billion to 1.6 billion in the less developed countries. Moreover in less developed countries, the size of the elderly population will surpass that of 12–24 age groups near 2045. However, the nonagenarian population is still marginal in less developed countries (United Nations Department of Economic and Social Affairs/Population Division 2015).

Cancer in TLLMICs

Incidence and Characteristics in the Whole Patient Population

Cancer incidence repartition is different in high-income countries when compared to low-income countries (International Agency for Research on Cancer 2012). In low-income countries, the most frequent cancers in women are the following: breast, cervix, lung, colon-rectum, esophageal, and stomach cancers; in men: lung, stomach, liver, prostate, colon-rectum, esophageal, and bladder cancers. In both sexes the mortality is higher in low-income countries than in high-income countries (Bray et al. 2015). Moreover cancers in the TLLMICs have some specific characteristics: more advanced stages and consequently increased mortality (Roue et al. 2016); particular biological features like frequency of triple negative breast cancers (Huo et al. 2009) and of BRCA1–2 mutations (Fackenthal et al. 2012); frequent microorganisms implicated in the carcinogenesis (de Martel et al. 2012; Nacher and Roue 2015).

Incidence and Characteristics in the Elderly Patient Population

Information of cancer burden in low-income countries is scarce. Nevertheless projection to 2035 of estimated number of new cancers in patients older than 65 in less developed countries (International Agency for Research on Cancer 2012) shows an increase by 2.35 in both sexes. Consequently the estimated total number of new cancer patients should increase from 3.2 million to 7.5 million. During the same period, the estimated number of cancer patients younger than 65 should increase by 1.5 (4.8 million to 7.2 million). Therefore the total number of cancer patients in the two age groups will be equal at the horizon 2035. This demonstrates that geriatric oncology is a real challenge in less developed countries. The spectrum of most frequent cancers in elderly patients is not very different from the one of younger patients: breast, cervix, lung, colon-rectum, and stomach cancers in women and lung, liver, stomach, prostate, and colon-rectum cancers in men. However breast cancer (Vanderpuye et al. 2016) and cervical cancer (Roue et al. 2012) in women are of importance. Moreover cancers in these TLLMICs have some specific characteristics: more advanced stage and consequently increased mortality (Roue et al. 2016).

Elderly Cancer Patient Health Status in TLLMICs

Awareness of the need to develop geriatrics is quite recent in western countries (around 50 years) (Morley 2004), but still not completely understood in less developed countries (Gutierrez-Robledo 2002). By 2020, it is estimated that three quarters of all deaths in less developed countries will be attributable to noncommunicable diseases such as diabetes mellitus, cardiovascular diseases, and cancers. Furthermore, older people in these countries are expected to experience more chronic disease and disability than is usual in more developed societies (Gutierrez-Robledo 2002).

Comorbidities

Causes of death are classified in three groups (Mathers et al. 2006): group I (communicable, maternal, perinatal, and nutritional conditions), group II (noncommunicable diseases), and group III (injuries). In less developed countries, 2030 projected death rate in the group II (cancer is one of these causes) is increasing due to demographic growth, increase in life expectancy, and age-related-specific mortality (Mathers and Loncar 2006).

Prevalence of diabetes is however high in western countries, but on a total of more than 340 million patients with diabetes, more than 30% live in Brazil, Africa, India, and Southeastern Asia (Scully 2012). It is noteworthy that prevalence of diabetes is particularly high in some indigenous populations as in Papua New Guinea (40%) and in many Pacific Ocean islands and, one noteworthy fact, also in US Native Americans (Yu and Zinman 2007).

Prevalence of hypertension is high in Russia but also principally in tropical Africa and at a less degree in tropical South America in men. Prevalence is lower in women (principally in tropical Africa) (WHO 2015a, b).

This information is accessible in the whole adult population, but it is difficult to assess it in the elderly patient population. Nevertheless comorbidities are chronic diseases which prevalence increases with age (WHO 2015c). They are an important domain of the aging process.

It is noteworthy that in tropical countries, sensorial impairment may be very important as stated by Allain et al. (1997): 55% of elderly have cataract which is the main cause of blindness in Zimbabwe.

Comorbidities are generally measured by the Charlson Index (Charlson et al. 1987) or CIRS-G (Linn et al. 1968).The Charlson Index is a good prognostic factor of mortality but a poor descriptive tool for comorbidities; the CISR-G is a good screening tool but too complex and time consuming. The specificity of tropical diseases like comorbidities is not included in the common comorbidity screening tools (apart AIDS in the Charlson Index), and no study has been conducted yet to evaluate their impact on health status in elderly patients and especially in elderly cancer patients.

Dependence

Dependence is extremely frequent in low-income countries (Sousa et al. 2014). The author pointed out that physical performance in elderly people in TLLMICs was lower than in western countries and was correlated with childhood social and economic adversity. These disadvantages and inequalities were cumulative lifelong. Health status decline with age is very well correlated with income level of people (WHO 2015c). It is interesting to point out the fact that dependence in the Katz Index of Independence in activities of daily living (ADL) (Katz et al. 1963) in Zimbabwe (Allain et al. 1997) is less frequent in people living in the rural area (not more than 10–15%) than those in urban area (10–35%), independently of visual impairment and comorbidities.

Cross-cultural validation of ADL has been performed and published only in some countries: Morocco, Turkey, the Netherlands (Reijneveld et al. 2007), and Brazil (Lino et al. 2008). In this later, ADL impairment increases with age. Lima-Costa et al. (2003) also demonstrated a relationship between age and dependence but

describe major impairment to bath in 20% of people, 60% to move, and 55% to move at walking distance. Instrumental ADL (IADL) (Lawton and Brody 1969) is not applicable in TLLMICs because of western country cultural conception (Collingwood et al. 2014). Patient interview is more useful to detect the most common deficiencies related to cognitive impairment in this setting.

An important aspect of functional status is the risk of fall. The Tinetti test is an appropriate tool to screen such problems (Tinetti 1986). Nevertheless with respect to TLLMICs, it is a too complex tool to use: the "timed up and go" is more appropriate (Podsiadlo and Richardson 1991). It is a relatively simple test of walking speed and risk of fall: impairment is predictive of morbidity and mortality.

Nutritional Status

Malnutrition is a major factor of frailty, morbidity, and mortality and even leads to complication of cancer surgery and medical treatments in elderly patients (Blanc-Bisson et al. 2008). Worldwide, the number of undernourished people was estimated at 852 million people in 2000–2002, most of them (815 million) living in developing countries (Muller 2005). Investigators in Bangladesh used the Mini-Nutritional Assessment (MNA) (Guigoz et al. 2002) to screen malnutrition in more than 600 elderly patients in rural area. MNA was actually performed in two-thirds of patients. Twenty-six percent and 62% percent of people screened by MNA had severe malnutrition and were at risk of malnutrition, respectively. Prognostic factors of malnutrition were infection, gastrointestinal disorders, depression, cognitive impairment, female gender, illiteracy, and low incomes.

Cognitive and Thymic Impairments

Depression is a frequent problem in TLLMICs. In Nigeria, Sokoya et al. (Sokoya and Baiyewu 2003) showed that the rate of geriatric depression in primary care was 7.4%. Severe depression was only 1.5%. Very low income and subjective report of poor health were significantly associated with depression in the cohort.

In India prevalence of depression was measured to 14% (Rajkumar et al. 2009) and prognostic factors of severe depression were suffering from hunger, malnutrition, diabetes, transient ischemic attack, past head injury, disability, and loneliness. A comparative study of anxiety in different countries part of the 10/66 Dementia Research Group study (Prince 2000) shows that anxiety was more frequent and intense in South America than in China and India (Prina et al. 2011b). Urban centers had higher estimates of anxiety than their rural counterpart. Age, gender, socioeconomic status, comorbid physical illnesses, and disability were all associated with a diagnosis of anxiety.

The prevalence of co-occurring anxiety and depression ranged between around 1% and 4% across sites (Prina et al. 2011a) but was depending on dementia screening tool (Stewart et al. 2016): geriatric screening tools are generally not feasible; other alternative may be better. In a recent study, Palmer et al. (2014), using the Diagnostic and Statistical Manual of Mental Disorders criteria (DMS-IV), found in rural Bangladesh a prevalence of questionable dementia of 11.5% and definite dementia 3.6%. These are similar to prevalence in high-income countries. The same observation was made in Tanzania (Longdon et al. 2013): the age-standardized prevalence of dementia (DMS-IV) was 6.4%, but that one was 21.6% using the 10/66 Dementia tool (Paddick et al. 2013); education was a significant predictor of "10/66 dementia," but not of DSM-IV dementia. The authors concluded that despite its possible flaws, the DSM-IV criteria represent an international standard for dementia diagnosis. The 10/66 diagnostic criteria may be more appropriate when identification of early and mild cognitive impairment is required. The HIV Dementia Scale (HDS) and International HIV Dementia Scale (IHDS) are brief tools that have been developed to screen for and aid diagnosis of HIV-associated dementia; they have been evaluated: both scales were low in accuracy (Haddow et al. 2013). Thus the choice

of screening tools is not yet well established and requires further evaluation.

Nonetheless depression and dementia are important health issues in elderly patients in low TLLMICs.

Socioeconomic Status

In the USA also, education level and socioeconomic status have a major impact on the last years of life (Liao et al. 1999). The same is observed in the UK (Grundy and Sloggett 2003). Apart from the importance of socioeconomic status on healthcare provision, they have an impact on different aspects of elderly patient health status. Low income is a risk factor of dementia and depression (Prina et al. 2011a). Similarly in Bangladesh, poorer household and poverty increase the incidence and mortality due to chronic diseases (Khan et al. 2015).

Geriatric Assessment Tools

The Comprehensive Geriatric Assessment (CGA) is the gold standard not only for evaluating elderly health status but also to propose geriatric interventions (Extermann et al. 2005; Decoster et al. 2015) which require a time-consuming multidisciplinary management. The different health domains in elderly patients could be screened through different tools, to perform a diagnostic procedure. Such tools were described in details (Burhenn et al. 2016; Puts et al. 2012). The majority of these health status screening tools could be performed by trained nurses. The most important domains are functional status, comorbidities and polypharmacy, nutritional status, cognitive and thymic functions, geriatric syndromes, and socioeconomic status. It is important to choose tools with a sufficient clinical signification, and applicable in TLLMICs: it is likely that it should be based on very standardized and simple screening tools and clinical exams.

Short screening tools have been studied in TLLMICs, like the Campbell Assessment of Needs (CANE) which was validated in Brazil, but the clinical usefulness is questionable (Sousa et al. 2009b). EASY-Care is also a screening of elderly patient needs (Craig et al. 2015). It is principally based on ADL and IADL. It was validated in some cross-cultural studies: in Lesotho, Tonga, Iran, and Colombia as well as in the UK (Philip et al. 2014). A study in TLLMICs demonstrated the internally consistency of the scale which is increased by the exclusion of two items: unable to use telephone and manage finances (Jotheeswaran et al. 2016). Clearly geriatric assessment tools in TLLMICs require further studies.

Geriatric Series Published in TLLMICs

Different prospective evaluations of health status performed in different TLLMICs give an overview of elderly health. In Brazil, Lima-Costa et al. (2003) observed in a cohort of about 30,000 people over 60: 45% with poor health status, 15% with a performance status (PS) 3 and 9% PS 4. Comorbidities were multiple: 44% elevated blood pressure, 37% rheumatisms, 19% cardiovascular diseases, 10% diabetes, lung diseases 10%, 7% chronic renal failure, and 1% cancer. Sixty-nine percent of patients had at least one comorbid condition. Interestingly, Zunzunegi et al. studied frailty in women and men in Latin America and Caribbean countries: women showed poorer health outcomes as compared with men for all health indicators and in all cities (Zunzunegui et al. 2009). In the 10/66 study (Sousa et al. 2009a), dependence was linked to dementia, depression, comorbidities, and eyesight troubles. Surprisingly the prevalence of disability in Tanzania looked quite low: 6.2% moderate and 3.7% severe. Independent predictors were age, female gender, memory, and neurological problems (Dewhurst et al. 2012). This prevalence is lower than in high-income countries; the authors hypothesized that this may reflect increased mortality from disabling diseases in low-income countries.

Predictors of disability and mortality were studied in Cuba, Dominican Republic, Venezuela, Mexico, Peru, India, and China within a 10/66 study. Weight loss, underactivity, slow walking speed, and cognitive impairment predicted both

outcomes, whereas malnutrition predicted only mortality and sensory impairment only dependence. Exhaustion predicted neither outcome (Jotheeswaran et al. 2015).

It is pointed out that some domains of health status are not assessable in non-western populations as it has been assessed in Canada (Puts et al. 2011) and Thailand (Jitapunkul et al. 1994). Tools wording are rarely understood in cultures other than western culture: in Hospital Anxiety and Depression Scale (HADS), the questions "I feel tense or wound-up" or "I get a sort of frightened feeling like butterflies in the stomach," had different meanings for participants from different countries (Puts et al. 2011). In Thailand, because of misinterpretation of behavioral and intellectual disability, ADL tool use leads to 99% of subjects being scored as disabled (Jitapunkul et al. 1994).

Geriatric Oncology Series Published in TLLMICs

Few studies have been published on health status evaluation in elderly cancer patients in TLLMICs. Aggaval et al. reviewed the perspectives of cancer in elderly patients in middle-income countries (Aggarwal et al. 2015). They concluded that the burden of cancer in elderly will increase exponentially, and it is a major public health objective to develop geriatric oncology. Nevertheless they pointed out the importance of the cost and the lack of insurance coverage to support such expensive treatments.

An important study was performed in China (even though this country is not strictly a country part of the TLLMICs) (Kanesvaran et al. 2014). A CGA was performed in 800 elderly cancer patients from the Beijing area and treated in tertiary centers. Mean age was 72 (extremes 65–94); 60% were men; only 11% patients had no caregiver; they generally live in their family and the majority received a pension; it is not stated whether some patients had major poverty; around 37% patients had professional activity; 65% had exercise; around 70% of patients were independent in ADL and 40% had no impairment in IADL; and some forms of malnutrition occurred in 24% of patients. Fifty-five percent of patients had three or more comorbidities as assessed by the Older American Resources Service (OARS) Comorbidity Scale; polypharmacy is noted in 38% of them. More importantly 45% of patients take traditional Chinese medicine: these patients have more comorbidities than those who do not take traditional medicine. This interacts also with patient decision-making process.

France introduced the G8 mandatory screening tool in the management of elderly cancer patients (Soubeyran et al. 2014). Within the framework of Geriatric Oncology Coordination Units of the French National Cancer Institute (INCa), a retrospective study and a prospective study were performed in the French Guiana. The retrospective study reviewed the clinical files of 71 cancer patients over 70 treated in the Cayenne hospital, French Guiana, in 2010–2012 (Droz et al. 2012). The population is that of an equatorial country which benefit from a European country health organization. Oncogeriatric evaluation was achievable but was far from being routinely used. Selection of frailty screening tools was difficult. However, specific problems emerged: cultural differences, low income, illegal immigrants, comorbidities, specific tropical diseases, and the incidence of HIV, HTLV1, and hepatitis viral infections (Droz et al. 2012). Two prospective cohorts were analyzed from 01/09/2015 to 30/04/2016: one in the main public hospital in Cayenne (Joachim et al. 2016) and one in Saint-Laurent du Maroni Hospital (Droz 2016 abstract S6). In the Cayenne Hospital, 130 patients >70 were followed for cancer in the outpatient clinic; 60 patients (46%) had a G8 screening of which 57 were abnormal (Joachim 2016 poster 105). The small number of G8 procedures was due to organizational problems, but there were also difficulties in obtaining all G8 items: loss of appetite was biased by the treatment; weight loss during the last 3 months was difficult to measure in these patients who don't follow their weight; number of medications did not take in account traditional medicine intakes; and "feeling of their health status" was biased by cultural perception of health, of disease, and of cancer, by belief and by comparison to their previous heath status. In Saint-Laurent

du Maroni, 23 new cancer patients were older than 70 years (Droz 2016). There were 14 French, 7 Surinamese, and 2 Haitian patients. Language was Sranantongo 10, French 7, Creole 4, and Hmong 2 patients, respectively. Ten patients benefited from the National Health Security, 7 of Emergency Medical Assistance, and 5 of Universal Medical Coverage, and one had no medical coverage. G8 screening tool value was 0 to 16 and only 6 pts. had a value >14. Assessment in health status groups was based on ADL, Cumulative Illness Score Rating-Geriatrics (CISR-G), and malnutrition (weight loss) (Droz et al. 2014). There were fit 4, vulnerable 9, frail 7, and too sick 3 patients. The item "self-rated health" was difficult to assess in 15 pts., due to a lack of understanding and wording (rated 0.5: "don't know"). Correlation between G8 and components of Health Status was poor.

These studies focus on the difficulty in both screening frailty in elderly cancer patients and evaluating their health status for practical problems but also for the use of poorly adapted screening tools, partly due to cultural features.

Nevertheless most of elderly patients from TLLMICs suffer from two or more concurrent diseases. Hussain (Hussain and Sullivan 2012) in Bangladesh found that only 8% of elderly patients with cancer have no other illnesses, 37% have one or two other illnesses, and 55% actually have three or more comorbidities. According to a World Bank report (Worldbank 2015), the health expenditure per capita in Bangladesh is $18.43, whereas according to WHO guidelines it should be a minimum of $44.4. Major limits to the management of elderly cancer patients in TLLMICs are available expenditure and also physician awareness in geriatrics and end-of-life care.

Diagnostics in Elderly Patients

Delay to Cancer Diagnostics in TLLMICs

Aggarwal et al. collected information on the duration of symptoms prior to seeking medical attention in cancer patients according to age (Aggarwal et al. 2015). Delay in patients aged 65–69 years was >12 months in 43% and 38% in men and women, respectively, and in patients aged 75–79 years, it was 41.5% and 34% in men and women, respectively.

The Reasons to Explain Cancer Diagnostic Delay

Cultural factors are important. In Nigeria, sociodemographic factors and reasons associated with delay in breast cancer presentation were ignorance of the nature of illness, belief in spiritual healing, fear of mastectomy and belief in herbal treatment (Ibrahim and Oludara 2012). Nevertheless, the availability of laboratories (and particularly laboratories of pathology) is of importance: a recent survey of laboratories in Kampala, Uganda, demonstrated that only 0.3% of laboratories (3/954) met international quality standards (Schroeder and Amukele 2014). Conversely, density of accredited laboratories in South Africa, Namibia, and Botswana was similar to that of western countries. There is a direct proportionality between density of accredited laboratories and health expenditure per capita. The solution to solve these inequities, particularly for pathology laboratories is to establish collaboration and partnership with laboratories in the western and high-income countries just as they do in Lilongwe (Malawi) (Gopal et al. 2013).

Health Status Evaluation

Health status evaluation of elderly cancer patients is generally based on a three step procedure. The first step is the use of a screening tool: different tools are available like the G8 (Soubeyran et al. 2014) which is recommended by the EORTC Geriatric Oncology Task Force, the INCa, the European Association of Urology (Cornford et al. 2016; Mottet et al. 2016), and the SIOG (Droz et al. 2014). Other tools are also available: the Groningen Frailty Index (Drubbel et al. 2013), the PPT (Terret et al. 2010), and VES-13 (Soubeyran et al. 2014) .The objective of such screening tools is to determine whether a more advanced geriatric evaluation would be

necessary. The use of such tools in TLLMICs is likely difficult, as it has been previously described in various articles. This is often linked to cultural differences between western countries where these tools were developed and TLLMICs. It is unlikely that a universal screening tool may be developed for these countries for the great cultural heterogeneity.

The third and final step is CGA and is the standard of care. It is not only about a series of screening tools but, more importantly, a complete clinical exam, laboratory and imaging additional exams, and finally a comprehensive synthesis of health problems and decision-making for geriatric intervention planning (Decoster et al. 2015). However, CGA is time consuming, requires the intervention of multiple professionals, and is consequently very expensive. It is therefore unlikely to develop such procedures in TLLMICs.

There is nevertheless a second step in the geriatric evaluation procedure: what is sometime called "simplified geriatric evaluation." To date the interest of such procedure is still questionable (Puts et al. 2012, 2014). Still, this has been developed with the pragmatically objective of screening the most important needs of elderly cancer patients (Overcash et al. 2006). Recently it has been used to tailor treatment of elderly prostate cancer patients (Droz et al. 2014). Generally the most important factors of disability are dependence (ADL, IADL), comorbidities (Cumulative Illness Rating Score-Geriatrics – CIRS-G) (Linn et al. 1968), malnutrition (Mini-Nutritional Assessment – MNA) (Guigoz et al. 2002), and cognitive impairment (mini-COG™) (Borson et al. 2003) and Mini-mental Status Evaluation (MMSE) (Folstein et al. 1975). The limits of these tools in TLLMICs have been discussed previously. Table 1 reviews the different tools, experiences in TLLMICs, and possible modified tools.

Therapeutic Tools

Therapeutic tools are not really specific to elderly patients, but it is important to point out the major facts on their availability and use in TLLMICs.

Palliative Treatments

Palliative treatments of cancer are a priority in TLLMICs because many patients are diagnosed at a late stage. Thus quality of life is the most important objective with a priority for pain control and end-stage disease management. Guidelines on pain management in elderly patients have been published and are commonly used (Urban et al. 2010; Malec and Shega 2015; Tracy and Sean 2013). Treatment of pain is nonetheless far from optimal in TLLMICs. As an example, consumption of opioid analgesics in sub-Saharan Africa is low, and at least 88% of cancer deaths with moderate to severe pain are untreated. Access to essential drugs for pain relief is limited by legal and regulatory restrictions, cultural misperceptions about pain, inadequate training of healthcare providers, drug access difficulties, weak health systems, and concerns about diversion, addiction, and misuse (O'Brien et al. 2013). Efforts are made by national governments and local and international organizations to improve access to pain treatment.

Radiotherapy is however a curative treatment but also one of the most active and cost-effective treatments in advanced cancer: it ensures very effective palliation in most advanced diseases (Barton et al. 2006). Less than 25% of cancer patients in tropical Africa have access to radiotherapy.

Surgery

Surgery remains the best curative treatment and also the treatment with the best cost-efficiency (Kingham et al. 2013). A complete situation analysis of surgical services was published by the World Bank group (Gelband et al. 2015). There are four step platforms for surgery: cancer community health center is only able to refer patients; first-level centers (district) can perform biopsies and deliver only simple oral treatments; second-level centers (regional) can perform the majority of exams, surgical procedures, and medical treatments; and finally, third-level centers (tertiary) are able to perform specialized surgery, intensive

Table 1 Possible useful tools to evaluate elderly cancer patient health status in TLLMICs

Domain	Tool	Practice in TLLMICs[a]	Possible substitution[a]
Activities of daily living 1	ADL	Cross-cultural validation	ADL feasible
Activities of daily living 2	IADL	Not adapted for cultural reasons	Interview
Comorbidities	Charlson Index CIRS-G	Not adapted: prognostic tool Time consuming, too complicated	Clinical exam++; BAP; diabetes screening; heart exam, EKG, Echo? creatinine clearance
Functional symptoms	Interview		# ADL and comorbidities
Medications	Number	Traditional medicine	Interview
Cognitive functions	MMS CSID CANE	Cross-validation India, Brazil Cross-validation 10/66 study Cross-validated	In other cultures: interview
Depression	GDS	Not always cross-validated	GDS or more efficient: interview
Nutritional status	MNA	<2/3 evaluable Too complicated	BMI; albumin: lymphocytes;
PS	ECOG PS	Cultural influence	Can be used
Fall risk	Tinetti test		Monopodal station; "timed up and go"
Visual exam	OPH clinics	Cataract 55%	Visual acuity test: 2 fingers at distance
Audition	Audiometry	Impossible	Interview
Caregiver	Interview	Cultural influence	Interview
Social support	Interview	Health organization of TLLMICs	Interview
Income	Interview	Income level of TLLMICs	Interview
Cultural evaluation	Not done	Mandatory	Transcultural mediation if needed

postoperative cares, and radiotherapy; they have also teaching activities. Treating elderly patients by surgery requires specific skills: guidelines were proposed by the SIOG (Audisio et al. 2004). Careful preoperative evaluation of elderly patients is required and is based on PS, ADL, IADL, and comorbidities (Audisio et al. 2008). It is also mandatory to prevent postoperative confusion in frail patients.

Radiotherapy

As mentioned previously, radiotherapy is an important treatment with curative intent (Barton et al. 2006). In high-income countries, half of cancer patients will require radiotherapy during their disease. Many countries in TLLMICs have limited access to radiotherapy facilities and even 22 countries in Asia and Africa don't have any service of radiotherapy at all. In Africa it is estimated that only 20% of the needs are covered. This is a major lack of means in these countries. If radiotherapy facilities are available, treatment in elderly patients should follow the SIOG recommendations (Kunkler et al. 2014).

Medical Treatments

Access to medical treatments is highly variable in TLLMICs (Kingham et al. 2013; Vanderpuye et al. 2015). The major problem is the cost. The following drugs are generally available:

doxorubicin, cisplatin, fluorouracil, capecitabine, folinic acid, steroids, dactinomycin, vincristine, vinblastine, methotrexate, etoposide, hydroxyurea, melphalan, cytarabine, mercaptopurine, L-asparaginase, daunorubicin, and thioguanine to perform the treatment of an important number of cancers and hematologic malignancies. Nevertheless even though access to irinotecan, oxaliplatin, carboplatin, gemcitabine, taxanes, and antiemetics is possible, it is the only available with out-of-pocket payment. Other new and important drugs, as trastuzumab, rituximab, and G-CSF, are rarely available (Kingham et al. 2013). Metronomic chemotherapy – the chronic administration of chemotherapy at low, minimally toxic doses on a frequent schedule of administration, with no prolonged drug-free breaks – has recently emerged as a potential strategy to control advanced or refractory cancer and represents an alternative for cancer patients living in developing countries. This low-cost, well-tolerated, and easy-to-access strategy is an attractive therapeutic option in resource-limited countries (Andre et al. 2013).

However, medical treatments in elderly cancer patients may require specific management and rigorous precautions of administration: the SIOG produced guidelines and reviews in this setting (Biganzoli et al. 2012, 2016; Aapro 2011). Moreover supportive cares are essential and should follow adapted guidelines (Stepney 2016). Unfortunately a large amount of supportive care drugs are not available in TLLMICs.

Difficulties often occur when administrating medical treatments to elderly patients, especially due to renal function decrease (Duncan et al. 2001). Drug interaction is another limitation for elderly patients often receive polypharmacy (Salwe et al. 2016). The frequency may be as high as 50% of elderly patients and 75% of elderly cancer patients.

The incidence of HIV infection in TLLMICs is higher than in high-income countries. Its estimated prevalence in sub-Saharan Africa is estimated to 5% (Shao and Williamson 2012); it is therefore important to consider potential drug interactions between antiretroviral therapy and anticancer drugs (Spano et al. 2016).

Perspectives of Management Optimization

To Develop Interventions That Are Highly Effective, Cost-Effective, and Resource-Level Appropriate

To date there is no specificity in geriatric oncology in TLLMICs. Cancer management is based on principals focused on the development of appropriate and ethical cost-effective interventions (Ngoma 2015). The example of an efficient project is the Breast Health Global Initiative (BHGI) (Anderson 2003; Anderson and Distelhorst 2008; Anderson et al. 2008; Anderson and Jakesz 2008; Anderson and Tsu 2008). The recommendation proposes decision trees for global management, adapted to resources, and with a significant impact on outcomes. Thus, management is focused to screen, diagnose, and treatment of early breast cancer at an early stage, the consequence being to decrease diagnosis at late stage and decrease mortality and global cost. The BHGI model should be applied to the most frequent and curable cancers like breast, cervix, colon-rectum, and head and neck cancers. Another important objective is to promote joint ventures between oncologists from the northern/western countries and southern countries, to develop appropriate decision trees, and to favor skill training through grants from various governmental and nongovernmental institutions (Ngoma 2015). Finally the implementation of tertiary centers ("excellence centers") is important. There are different possibilities of organization, depending on the local prior health organization; these centers should not only be reference centers for treatment but also reference centers for teaching and for implementing of a national network of secondary centers dedicated to routine treatments. These centers should

collaborate to clinical and translational research (Rehman et al. 2016; Adewole et al. 2014). It is a major challenge which main objectives would be efficiency and equity.

To Develop Geriatric Oncology in This Setting

Considering the burden of elderly cancer patients in TLLMICs in the future, such kind of project could be implemented in geriatric oncology. This would involve:

- Geriatric oncology units in "excellence centers"
- Training of either oncologists or internist in geriatrics
- Resource-adapted guidelines based on the SIOG guidelines (Biganzoli et al. 2012; Papamichael et al. 2015; Armstrong et al. 2016; Morrison et al. 2015; Stauder et al. 2016; Pallis et al. 2010)

SIOG would have a key role in this setting. On the one hand, it is important to adapt the ten priorities defined in 2011 (Extermann et al. 2011) to the case of TLLMICs. On the other hand, it is a priority to propose guidelines for health status evaluation which should be adapted to TLLMICs populations on resources and cultures. It is not possible yet to know whether it would be possible to develop a unique model or to tailor models to different area defined by their resources, cultures, or any other characteristic.

It Is Important to Include Information and Transcultural Mediation in These Objectives

SIOG considered the cross-cultural aspect of management (Surbone et al. 2007). Still, the SIOG approach is based on a western view of diseases. In many TLLMICs, the cultural understanding of the body, life, health, disease (illness), cancer, and death is different and may lead to a failure of the conventional approach of elderly patients (Droz et al. 2016; Joachim et al. 2016). The non-western world approaches are widely different from one country to another and from one ethnic group to another within the same country. As an example in the French Guiana, the ethnic group "noirs Maroons" is characterized by a social organization based on the clan, the transmission being matrilinear; a strong relationship between humans, ancestries, spirits, and nature; and alliances between humans, spirits, and duties toward ancestors through strict rites. Good health refers to strength; illness is a disorder which is often due to a spell. Diagnosis is divinatory and requires a medicine man; treatments are based on plants and baths. Death is never natural, but it is due to a spell, a spirit, or an ancestor. A postmortem examination aims to answer the question: Is the defunct worthy to be an ancestor (Vernon 1980, 1993)? The use of such tools in TLLMICs is likely difficult as it has been previously described in various articles. Usually, the doctor and the patient make two discourses that don't take account of each other. The doctor has the universal knowledge and particularly that of the disease. The patient narrative helps him to give sense to something which aggresses himself. This is not universal, but singular, and still it does not exclude understanding of the disease nor therapeutic alliance (Larchanché and Bouznah 2015). Several studies in TLLMICs pointed out the demand of information adapted to the patient culture and their resort to traditional procedures and treatments (Zekri and Karim 2016; Dorio et al. 2016; Berger-Gonzalez et al. 2016; Kanesvaran et al. 2014). These cultural approaches are particularly important in the practical implementation of programs of early diagnosis, cancer screening, and cancer prevention which are the potentially most active process to decrease the cancer burden in TLLMICs (Sitas et al. 2008; Gelband et al. 2015).

Conclusion

Throughout the next 20 years, elderly cancer patients will represent more than half of the whole cancer patient population and the half will live in TLLMICs. The knowledge on cancers and hematological malignancies in TLLMICs enhances rapidly and especially knowledge on the biology of these malignancies. Conversely the characteristics of aging in the TLLMICs populations are still scarce. Furthermore, geriatric evaluation techniques in high-income countries are not necessarily relevant in this setting. It is therefore important to make efforts to develop geriatric oncology in this part of the world. The most important aspects will be:

- Development of adapted screening tools of frailty
- Establishment of a decision-making process to suit resources and cultures and based on very standardized and simple screening tools and clinical exam
- Training of health professionals (MD and other medical health professionals)
- Production of scientific knowledge both in clinical and basic research

This requires cooperation between northern/western institutions and south institutions, a global worldwide willingness to give elderly cancer patients in TLLMICs access to adapted and active cares based on efficiency and equity.

Integrating Geriatric Oncology into Clinical Pathways and Guidelines

59

Nicolò Matteo Luca Battisti and Efrat Dotan

Contents

Abstract

Cancer is a disease of the elderly, and more research is needed to improve geriatric oncology care. The complexity of older cancer patients requires clinicians to consider a declining organs' function and competing comorbidities to balance pros and cons of every treatment choice within the context of estimated life expectancy.

A comprehensive geriatric assessment (CGA) is helpful and mandatory to establish an appropriate care plan as research demonstrated it can detect issues that would remain otherwise neglected and improve the care of older cancer patients. Predictive tools for chemotherapy toxicity may also help complete the assessment for patients eligible for anticancer therapy. Nevertheless, CGA may be time-consuming, and several screening tools have been developed and validated to identify potential candidates for a full assessment.

Due to the underrepresentation of older patients in clinical trials and the shortage of studies specifically addressing this population, a solid evidence base for the management of cancer in this setting is currently lacking. However, less robust levels of evidence may be

Introduction

Cancer Burden in the Elderly

Age is the most important risk factor for cancer. Sixty percent of the incidence of cancer and 70 percent of its mortality occur in patients aged 65 years and older (Ries et al. 2003). By 2030, in the United States, new cancer cases in older patients aged over 65 are expected to increase by 67 percent compared to 11 percent in younger adults (Smith et al. 2009). In Western countries up to 30 percent of the population will be aged 65 or older by 2050, and individuals aged 80 and overrepresent its fastest growing part; worldwide one in six people will be aged over 65 (WHO 2002). Geriatric oncology accounts for a relevant part of the everyday practice for the medical oncologist and is expected to be increasingly important. More research in geriatric oncology is needed in order to improve cancer prevention, its early detection and specific therapies addressing elderly patients, since a solid amount of evidence in the field is still lacking. Developing an appropriate management approach for vulnerable patients is key for oncology care (Thompson and Dale 2015). The American Geriatrics Society's guidelines propose the following: 1) assessing patient preferences, 2) interpreting the available evidence, 3) estimating prognosis, 4) considering treatment feasibility, and 5) optimizing therapies and care plans (American Geriatrics Society Expert Panel on the Care of Older Adults with Multimorbidity 2012). Applying these recommendations to oncology is crucial for optimizing the care of older adults with cancer.

Complexity of Older Cancer Patients

Chronological age alone cannot fully depict the complex care an older cancer patient requires, including special attention to treatment toxicities, quality of life, estimated life expectancy, age-related organ function decline, and competing medical comorbidities.

Aging correlates with a loss of physiologic reserve in critical organs' function, and older individuals are at risk of decompensation upon exposure to stresses such as surgery or chemotherapy. Table 1 enlists some of the specific challenges in elderly cancer patients and their clinical implications. Nevertheless, chronological age may not correlate with functional status due to the heterogeneity of older cancer patients. Older patients are as willing to try anticancer therapies such as chemotherapy as their younger counterparts but less keen on enduring severe treatment-related adverse events (Yellen et al. 1994), and quality of life always needs to be considered in the decision-making process (Sanoff et al. 2007). Prior to treatment initiation, an evaluation is helpful for assessment of the many domains that can affect cancer care in older adults including comorbidities; polypharmacy; functional, nutrition, and cognitive status; social support; and psychological status. Predictive tools including tools to determine expected life expectancy are available online to support decision-making with regard to cancer care in this patient population (ePrognosis n.d.; Walter and Covinsky 2001).

Comprehensive Geriatric Assessment

There is a continuum ranging from functional independence to frailty (Hamerman 1999), with some older patients without any significant limitations and minimal or no reduction in functional reserve, with others who are more vulnerable and suffer from decreased functional reserve. The oncologist is faced with the task of differentiating between the fit older individual who is likely to benefit from and tolerate standard therapy and the frail elderly patient who is prone to experience treatment-related side effects and requires

Table 1 Specific challenges in elderly cancer patients and clinical implications (Sawhney et al. 2005; Sehl et al. 2005; Peterson et al. 2016; Rolland et al. 2009)

Organ system	Aging-related changes	Implications
Liver	Hepatic volume decline Hepatic blood flow decline	Decreased drug metabolism Decreased drug elimination Increased treatment toxicities
Kidney	Decreased glomerular filtration rate	Volume depletion Decreased drug elimination Increased treatment toxicities
Muscles	Sarcopenia	Decreased mobility Impaired functional status Increased risk of falls
Bone marrow	Decreased bone marrow reserve	Increased treatment toxicities
Bone	Osteopenia and osteoporosis	Increased risk of fractures Decrease mobility Impaired functional status
Central nervous system	Neurons loss Reduced brain blood flow	Impaired cognition and dementia Increase risk of falls Increased susceptibility to benzodiazepines
Gastrointestinal	Poor motility Decreased acid production	Poor drug absorption
Cardiovascular	Decrease ventricular compliance Diastolic dysfunction Increased wall thickening	Increase risk with cardiotoxic drugs Higher risk of arrhythmias
Lungs	Decreased lung compliance Decreased sensitivity of the respiratory center Decreased mucociliary function	Decreased pulmonary capacity Higher risk of pulmonary infections Limitation on options for lung surgery/ radiation

different treatment options. Moreover, some apparently fit patients are found to have deficiencies that would have become evident after treatment initiation upon thorough evaluation. A comprehensive geriatric assessment (CGA) evaluating all the factors that may potentially influence the treatment outcomes is particularly useful.

A CGA can predict treatment complications and survival (Ramjaun et al. 2013), aid in therapeutic decision-making (Kenis et al. 2013), detect subtle problems at baseline which are not recognized by routine consultation (Extermann et al. 2004), and improve mental health and pain control (Rao et al. 2005). Despite the recommendations by the National Comprehensive Cancer Network (NCCN) (VanderWalde et al. 2016) and the International Society of Geriatric Oncology (SIOG) guidelines (Extermann et al. 2005), its routine use is limited, likely due to time constraints and challenges of implementation into a busy oncology practice. Hence, screening tools have been developed that can identify patients who will benefit from an extensive CGA (Decoster et al. 2015) such as the abbreviated CGA (Overcash et al. 2005), the Vulnerable Elders Survey-13 (VES-13) (Saliba et al. 2001), the G8 tool (Bellera et al. 2012), the modified G8 (Petit-Moneger et al. 2016), and the Flemish version of the Triage Risk Screening Tool (fTRST) (Braes et al. 2009).

The domains tested by CGA and some useful instruments to evaluate them are enlisted in Table 2. Compared to their counterparts without a history of cancer, older cancer patients have been found to have a statistically significant higher prevalence of limitations in activities of daily living (ADLs) (31.9% versus 26.9%), limitations in instrumental activities of daily living (IADLs) (49.5% versus 42.3%), geriatric syndromes (60.8% versus 53.9%), low self-rated health (27.4% versus 20.9%), a score above 3 on the VES-13 (45.8% versus 39.5%), and satisfying criteria for frailty (79.6% versus 73.4%) (Mohile et al. 2009). Functional disability is common in elderly cancer patients, with 17 percent of them

Table 2 CGA domains and available tools

Domain	Tools	Importance in oncology
Demographic data and social status	History regarding living situation, marital status, educational level, safety of environment, financial resources Caregiver burden	Support in the community
Comorbidity	Charlson comorbidity index (Charlson et al. 1994) CIRS-G	High score correlates with decreased OS and increased chemotherapy toxicity
Functional status	ADLs (Katz index) IADLs (Lawton scale) Visual and/or hearing impairment (glasses, hearing aids) Mobility difficulty (requiring help or use of walking aid) Timed get up and go Hand grip strength ECOG/Karnofsky PS Self-reported no. of falls	Poor functional status correlates with survival, quality of life, treatment toxicity
Cognition	Mini-mental state examination Clock-drawing test Montreal cognitive assessment	Poor cognitive function is a predictor of poor survival. May affect decision-making capacity
Depression	Geriatric depression scale Hospital anxiety and depression scale Presence of depression (as geriatric syndrome) Distress thermometer	Poor quality of life and compliance to treatment
Nutrition	Body mass index (BMI) Weight loss (unintentional loss in 3 or 6 months) Mini nutritional assessment	Increased morbidity and mortality with low BMI
Fatigue	Mob-T	Poor symptom control and compliance to treatment
Polypharmacy	Beers criteria STOPP and START criteria	Risk of drug interactions with chemotherapy
Geriatric syndromes	Dementia Delirium Incontinence (fecal and/or urinary) Osteoporosis or spontaneous fractures Neglect or abuse Failure to thrive Constipation Polypharmacy Pressure ulcers Sarcopenia	

Abbreviations: ADL, activity of daily living; CIRS-G, Cumulative Illness Rating Scale-Geriatrics; ECOG, Eastern Cooperative Oncology Group; GA, geriatric assessment; IADL, instrumental activity of daily living; MOB-T, Mobility -Tiredness Test; PS, performance status; START, Screening Tool to Alert Doctors to Right Treatment; STOPP, Screening Tool of Older Person's Prescriptions

reporting limitations for ADLs and 58 percent for IADLs (Serraino et al. 2001), with impact survival, quality of life, and rates of chemotherapy toxicity (Maione et al. 2005; Extermann et al. 2012; Hurria et al. 2011). Studies have shown that performance status scores as determined by care providers underestimate the degree of functional impairment in older patients (Repetto et al. 2002; Jolly et al. 2015), while the use of validated scales provides a more precise evaluation (Hoppe et al. 2013). The history of falls in an important item (Sattar et al. 2016) and their prior occurrence are consistent predictors of subsequent functional disability among older patients.

Comorbidities and cognitive function are an independent CGA domains and are considered independent prognostic markers (Extermann et al. 1998) (Charlson et al. 1987) (Miller et al. 1992; Williams et al. 2016) (Neale et al. 2001). Comorbidities impact life expectancy and treatment outcomes and correlate with poorer survival (Satariano and Ragland 1994; Asmis et al. 2008; Hines et al. 2009). Cognitive function has direct influence on the decision regarding both cancer diagnosis and treatment with regard to capacity and compliance (Gupta and Lamont 2004; Wolfson et al. 2001; Gorin et al. 2005). As such it should always be evaluated at baseline prior to any cancer treatment and ensure the compliance to the therapeutic recommendations and capacity to make treatment decisions. Nutritional status is also crucial, since weight loss and low body mass index (BMI) increase mortality for older adults (Newman et al. 2001) and impact on survival, performance status, and chemotherapy tolerance (Dewys et al. 1980). Nutritional issues are heterogeneous and may include weight loss during anticancer therapy, malnutrition during advanced disease, and obesity during survivorship (Presley et al. 2016).

A regular and comprehensive review of all medications should be performed in order to remove any unnecessary or potentially inappropriate medications and to assess potential drug interactions (Lichtman and Villani 2000; Vestal 1997). Among elderly cancer patients, medication errors and use of potentially inappropriate medication are more frequent (Coleman et al. 2005; Nightingale et al. 2015). One example is the high sensitivity of older adults to benzodiazepines, that increase the risk of falls and cognitive impairment (Schroeck et al. 2016). This class of drugs should be avoided in favor of alternative medications and approaches (Hurria et al. 2014a). There are also a number of potentially dangerous interactions of some medications with chemotherapy (e.g., warfarin and capecitabine).

Psychological distress is experienced by one third of elderly cancer patients and frequently implicates depression (Kua 2005), especially in the context of inadequate social support, higher risk of functional decline, and increased utilization of healthcare resources (Penninx et al. 1998). Social support should always be evaluated in conjunction with treatment planning (Stuck et al. 1993; Cohen 2002). Also, it should be considered whether the patient is a caregiver for someone else or if there is anybody available to take on such role (Klepin et al. 2015). Caregivers may be exposed to stress and depression, to neglect their own health (Germain et al. 2016) (Navaie-Waliser et al. 2002). Cultural, social, psychological, and behavioral variables should be considered when evaluating the individual situation (Baider and Surbone 2014).

A number of interventions can address the issues detected in each domain of CGA (Mohile et al. 2015), including physiotherapy and occupational therapy, caregiver involvement, reducing polypharmacy, social work and home safety assessment, counseling, oral care, and nutrition consult. CGA should also be repeated throughout the continuum of cancer care, since the needs may be different in different times and settings.

Lack of External Validity of the Current Evidence

A solid amount of evidence is needed in support of the optimal management in this specific patient population. However, older patients are underrepresented in clinical trials (Hutchins et al. 1999; Lewis et al. 2003). Strict trial eligibility criteria, competing comorbidities, and logistic barriers limit enrolment of older patients (Trimble et al. 1994; Kemeny et al. 2003; Yee et al. 2003). As a result 11 percent of elderly cancer patients are excluded from clinical trials a priori on the basis of their age (Javid et al. 2012) despite evidence showing that treatment tolerance in clinical trials is similar across various age groups (Javid et al. 2012; Giovanazzi-Bannon et al. 1994; LoConte et al. 2010; Townsley et al. 2005). An additional factor hindering accrual of older patients on clinical trials is physicians' fear of toxicity, resulting in clinical trial options being discussed less frequently with elderly patients (Javid et al. 2012; Foster et al. 2010). Other potential barriers to trial enrolment of older patients include lack of

autonomy over treatment choice (Townsley et al. 2006), concerns about potential adverse events, relatives opposing participation (Javid et al. 2012), different literacy rates (Townsley et al. 2006), ambiguities in the trust in physicians (Jenkins et al. 2013), and perception of the efficacy of a trial (Jenkins et al. 2013). Nonetheless, altruism remains a powerful incentive to facilitate participation of older patients in clinical trials (Jenkins et al. 2013).

The underrepresentation of older individuals in clinical trials supporting the current available guidelines limits their applicability in the elderly population (Battisti et al. 2015). Therefore, eligibility criteria should be less restrictive to allow for enrollment of real-world patients. Furthermore, research specifically addressing older people are needed and have been proved to be feasible (Cunningham et al. 2013; Muss et al. 2009). Such trials might also inform treatment options for younger patients who are not fit for more intensive treatment. Novel study approaches and methodologies, for example, mandating certain percentages of older subjects on registration studies that would resemble the proportion of elderly patients in the real-world population, can certainly advance this field and improve the evidence base to guide the management of older cancer patients (Hurria et al. 2014b; Hurria et al. 2015). The assessment of vulnerable older patients is the ideal setting to test patient-reported outcomes. There is a consistently high risk of underreporting of subjective toxicities by physicians, even when these data are prospectively collected within randomized studies (Di Maio et al. 2015). Therefore, the incorporation of patient-related outcomes into clinical trials is strongly encouraged.

Integration of Geriatric Oncology into Clinical Pathways

Geriatricians developed and validated CGA as a holistic approach to assess older patients in 1999 (Reuben et al. 1999; Cohen et al. 2002). Following a first attempt to adapt the CGA for use in oncology (Monfardini et al. 1996), its efficacy was prospectively assessed in a large population of elderly cancer patients at the end of last century (Repetto et al. 2002; Repetto and Balducci 2002). During the early 2000s, its importance was validated in routine oncology practice (Monfardini and Balducci 1999; Extermann and Hurria 2007). Some landmark studies demonstrated that CGA domains are associated with poor tolerance to cancer therapies, that they can predict mortality and influence treatment decisions, thus potentially leading to further tailoring care and improving older patients' quality of life (Clough-Gorr et al. 2010; Decoster et al. 2013; Freyer et al. 2005; Pottel et al. 2014). During the last decade, research has focused on the optimization of CGA in routine multidisciplinary cancer care (Sattar et al. 2014), on the most optimal screening tool to detect patients requiring a CGA (Kenis et al. 2013; Soubeyran et al. 2014), and on the proposal and validation of new tools for use within the assessment (Ketelaars et al. 2013; Lycke et al. 2014).

New models have been recently developed and validated to predict chemotherapy toxicity based upon geriatric assessment items. The Chemotherapy Risk Assessment Scale for High-Age Patients (CRASH) score has been designed by Extermann et al. to anticipate the risk of chemotherapy-related hematologic and non-hematologic toxicity in older adults (Extermann et al. 2012). It takes into account the specific chemotherapy regimens to be used as well as clinical and laboratory values including blood pressure, creatinine, albumin, hemoglobin, lactate dehydrogenase and liver function tests, and assessment of functional, mental, and nutritional status including ECOG Performance Status, Mini-Mental Health Status (MMS), and Mini Nutritional Assessment (MNA). Hurria et al. developed the Cancer and Aging Research Group (CARG) model in order to predict which patients are at increased risk of developing severe or fatal toxicity from chemotherapy (Hurria et al. 2011; Hurria et al. 2016). It is based upon a number of parameters accounting for age, type of cancer, the proposed chemotherapy regimen, renal and hematologic function, hearing, and activity levels (ability to take medications, physical activity, social support), and it has been shown to be superior to

the Karnofsky Performance Status. Finally, European investigator showed that advanced disease, a low MNA score, and a long Timed Get Up And Go test are associated with a higher risk of early death (within 6 months) after initiation of first-line chemotherapy (Soubeyran et al. 2012).

A recent analysis demonstrated that a web-based symptom reporting system for adults aged 26 to 91 undergoing chemotherapy resulted in better health-related quality of life, fewer emergency room admissions, fewer hospitalizations, a longer duration of palliative chemotherapy, and a superior quality-adjusted survival (Basch et al. 2016). CGA can also be conducted in an outpatient setting also using a self-reported format, and this approach has been reported as highly reliable and may be more feasible in a busy oncology practice (Ingram et al. 2002). Along with the mailing of a questionnaire, such an approach may save a substantial portion of clinic time. Nevertheless, the use of patient self-assessment tools may be time-consuming and challenging for patients with cognitive impairment. In addition, elderly cancer patients are more likely to perceive symptoms as inevitable and as a consequence of cancer and their treatment; therefore, underreporting can still be an issue in this setting. Hence, patient self-assessment is feasible in the geriatric cancer population, yet further research is needed to allow for its wide spread adoption.

Models of Care in Geriatric Oncology

The proportion of older cancer adults is increasing, and this required more collaborative training in geriatric principles and cancer care. Nevertheless, there are insufficient geriatricians and even less geriatric oncologists to address the unique needs of this population of patients. It has been documented that in North America there are 0.5–1.5 geriatricians per 10,000 adults aged 65 and older (Hsu 2016). Therefore, these low figures make it more difficult for oncologists to refer patients for appropriate geriatric management, and they often have to act as geriatricians themselves despite having received limited training in the principles of older adults' care (Maggiore et al. 2016). The use of appropriate geriatric oncology guidelines can be helpful in such a difficult setting (Hurria et al. 2014a). Three different models of geriatric oncology care have been tested and established in different environments, as shown in Table 3: the consultative model, the shared care model, and the comprehensive care model (Magnuson et al. 2014).

In the consultative model, the oncologist refers older cancer patients to a geriatric oncology/geriatric team in order to request a geriatric assessment and consequent recommendations and to inform treatment recommendations. The geriatrician performs a CGA in a multidisciplinary setting. The advantages include the specific geriatric oncology/geriatric expertise of the team that provide guidance based on a variety of different competencies. On the other hand, this model requires a referral from a physician, and it more frequently implies a one-time visit without any possibility of longitudinal follow-up, and the interventions are often left to the treating team. Moreover, as the visits are usually long, the number of patients per clinic session may be limited. Moreover, frequently patients have to attend multiple clinical appointments, and this may be challenging for older adults. In addition, some institutions do not have a full-time geriatrician or geriatrics service.

According to the shared care model, the oncologist will refer the patient for a geriatric assessment and subsequent interventions or treatment recommendations. A CGA is performed by a geriatrician or a geriatric oncologist, and its results as well as the care plan are reviewed within an interdisciplinary meeting. Then, the geriatric oncology team collaborates with the treating oncologist and provides concurrent care across the disease trajectory. The advantages of this model include a collaborative care through the course of the disease, a geriatric expertise, and the possibility to implement interventions and recommendations over time. Nevertheless, visits may not be centralized, and patients might require extra consultations, and again this model requires a referral from a physician. Both the shared care and the consultative model require routine and strong communication

Table 3 Models of care in geriatric oncology

Model of care	Pathway	Advantages	Challenges
Consultative	• Oncologist refers patient • Reasons: CGA and intervention recommendations, treatment recommendations • CGA performed by geriatrician and multidisciplinary team	• Geriatric/geriatric oncology expertise • Recommendations from a multidisciplinary team	• Physician buy-in need to refer • One time visit • No longitudinal follow-up • Interventions often left to treating team • Long visits: Limit no. of patients per clinic session • Multiple visits and physicians for patients • Need to maintain good communication in the team
Shared care	• Oncologist refers patient • Reasons: CGA and intervention recommendations, treatment recommendations • CGA performed by geriatrician/ geriatric oncologist and multidisciplinary team • Interdisciplinary meeting to review the results and care plan • Geriatric oncology team collaborates with treating oncologist and provides concurrent care across the disease trajectory	• Collaborative care through disease trajectory • Geriatric/geriatric oncology expertise • Interventions and multidisciplinary recommendations can be implemented over time	• Physician buy-in need to refer • Visits may not be centralized • Shortage of geriatricians • Extra visits for the patient
Comprehensive	• Geriatric oncologist is the treating oncologist throughout the patient's disease trajectory • No need for additional referrals. • GA performed • Results and recommendations are reviewed with the patient • Referrals to the multidisciplinary team	• Geriatric oncology expertise throughout the treatment trajectory • Convenience: One-stop shopping (geriatrics and oncology)	• Shortage of geriatric oncologists • Complex patient population (limited no. of patients can be seen)

Abbreviation: CGA, comprehensive geriatric assessment

between the oncology and geriatric team, which may be a challenge.

In the comprehensive care model, the geriatric oncologist is the patient's treating oncologist throughout the disease trajectory. No referral is needed since this is a one-stop shop and the full care is provided by the geriatric oncologist. CGA results and the subsequent recommendations are reviewed with the patient, and referrals may be made to the multidisciplinary team accordingly. The advantages include the benefit of a continuous geriatric oncology expertise and the convenience of combining geriatrics and oncology qualifications. However, there is a shortage of geriatric oncologists, and the number of patients that can be seen may be limited due to the complexity of this population. Therefore, oncologists should be enabled to become familiar with geriatric assessment and be able to perform it following appropriate screening to identify patients requiring a more intense geriatric evaluation. A slightly different version of the comprehensive model has been developed in some centers which involves a combined geriatric oncology clinic where patients are seen by the oncologist and immediately afterward by the geriatrician or up front by a geriatric

oncologist. In these clinics the patients can be offered additional services such as physical therapy, nutrition, and psychiatry based on deficiencies identified in the assessment.

Currently the most relevant challenges across these different models include limitation of resources in terms of space, personnel, and funding. The need for buy in and champions willing to endorse such an activity and the fact that the demand may be greater than the capacity of a geriatric oncology service, due to the demographic changes are the most important challenges. As a geriatric oncology, multidisciplinary team usually involve different professionals including geriatricians and/or geriatric oncologists, nurses, social workers, pharmacists, psychiatrists, physician assistants, nutritionists, rehabilitation services, case managers, and visiting nurses. Certainly a business, financial model, and institutional resources are needed, along with more education and more research in the field. However, the biggest challenge involves choosing the right model for the right setting.

For example, in a community clinic, separate geriatrics and oncology practices may exist, possibly within a hospital-affiliated system. Therefore, the primary care doctor or the geriatrician usually consults the oncologist when a cancer is suspected or diagnosed. Patients may be already known to geriatricians, thus facilitating the use of CGA before the treatment plans. Furthermore, common electronic records may facilitate a shared care model. However, lack of communication between the two disciplines in a timely manner may be an issue and affect the decision-making process. In a setting where oncologists are familiar with geriatrics principles and geriatricians and geriatric oncologists are not available, they can directly refer patients to relevant services and professionals based on a CGA performed by themselves.

In an academic medical center, the relationship may be determined by the size of the geriatrics and oncology departments, and referrals may be made either by the geriatricians or by the oncologist according to patients' entry into the hospital system. Such an environment promotes clinical collaboration and research, although time constraints and lack of understanding between the two areas may have an impact on shared goals.

In a comprehensive cancer center, oncologists usually are the patients' primary care physicians during cancer care and a geriatric consultation may occur at any time. Screening tools can help determine which patients are at risk of increased toxicity and guide appropriate geriatrics referrals. However, the high volume of elderly cancer patients may overwhelm the capacity of a geriatrics service.

The NCCN Senior Adult Oncology guidelines (Hurria et al. 2014a) try to give the tools to the oncologists and provide guidance for the identification of patients requiring more of a multidisciplinary approach. SIOG has issued guidelines about geriatric assessment and screening tools that can provide clinicians further guidance (Decoster et al. 2015; Wildiers et al. 2014): The SIOG panel recommended the use of screening tools for busy oncology practice while emphasizing that these assessments should not replace a full geriatric assessment. In addition, there are several disease-specific guidelines issued by the SIOG regarding the management of older patients with number of cancers (Body et al. 2016; Stauder et al. 2016; Biganzoli et al. 2012; Biganzoli et al. 2016; Ghignone et al. 2016; Biganzoli et al. 2015; Morrison et al. 2015; Droz et al. 2014; Pallis et al. 2014; Papamichael et al. 2015; Aapro et al. 2011; Bellmunt et al. 2009; Launay-Vacher et al. 2007). Implementation of these guidelines in each specific disease setting would further advance and improve the care of the older population.

Survivorship Care of Elderly Cancer Patients

A cancer survivor is defined as any person diagnosed with cancer, from the time of initial diagnosis until the end of life (National Coalition for Cancer Survivorship 2016). Two thirds of all cancer survivors will be aged over 65 by 2020 (Parry et al. 2011), and they will increase to 11 million of people in the United States due to demographic changes and increased survival of older patients after cancer diagnosis. Fatigue, physical

limitations, cognitive impairment, osteoporosis, and chemotherapy-related peripheral neuropathy are cited among the clinically significant long-term outcomes of cancer in this population (Rowland and Bellizzi 2014). As the number of survivors continues to increase, guidelines specifically addressing this topic have been developed by the NCCN (Denlinger et al. 2016).

Survivorship care plans should be incorporated into clinical care and include treatment summaries, surveillance plans, and tailored lifestyle information. The older patient's needs should be assessed in the survivorship care planning process, and some of them may need a CGA in order to define those needs. Based on this, an interprofessional team can develop a plan that is individualized for each patient. It should address needs regarding exercise, nutrition, polypharmacy, comorbidities, and social support. Survivorship guidelines should always be applied to older cancer patient, who should be able to access patient-centered, non-fragmented care.

The use of survivorship care plans in elderly cancer patients may improve the quality of care and health outcomes, but the most appropriate model of care for older adults during survivorship is still debated. Models including shared care, primary care physician only, or cancer-specific survivorship clinics have been proposed. The shared care model involves different professionals whose role may vary over time based on the specific needs of each patient (Cohen 2009); nevertheless, its impact on the management of complex older patients is currently uncertain. There is considerable need for more research to understand pros and cons of survivorship care plans, as their format, timing, and outcomes are still uncertain (Mohile et al. 2016).

Unique considerations about survivorship care plans for older cancer patients include comorbidities, polypharmacy, and the heterogeneity of this population identified through the different domains for the CGA. Fatigue and weight gain may be addressed by all clinicians and prompt an appropriate referral to physical/occupational therapists for energy conservation and function maintenance as well as nutritional services (Morgan and Tarbi 2016).

Long-term effects of chemotherapy are of paramount importance for older cancer survivors. For example, peripheral neuropathy is a debilitating toxicity associated with various chemotherapy regimens, including taxanes and platinum compounds. Taxanes have been documented to cause grade 2 to 4 neuropathy rates ranging from 15% to 23% based on different drugs, schedules, and durations of treatment (Schneider et al. 2015). This side effect which may be permanent is particularly relevant to older adults as it can severely interfere with function and result in increased risk for falls. In addition, effective therapies are lacking for its treatment and prevention (Hershman et al. 2014). Elderly patients with a history of complication from diabetes, receiving paclitaxel, and those treated with a platinum agent have an increased risk or neuropathy (Hershman et al. 2016). A variety of comorbid conditions including hypothyroidism, vasculitis, infections (herpes varicella zoster and HIV), and some medications treating hypertension and hypercholesterolemia, which are more prevalent in the older population, can increase the likelihood of developing peripheral neuropathy. Monitoring of these symptoms and interventions by the rehabilitation team may help improve the management of this long-term treatment related outcome.

Anthracyclines are effective and commonly used chemotherapy agents for both solid and hematological malignancies, but they are known to cause short- and long-term cardiotoxicity, including potentially fatal congestive heart failure (CHF) (Ewer and Lenihan 2008). Older adults with a diagnosis of hypertension or diabetes and a limited cardiac reserve may be at particular risk for these long-term complications of anticancer therapy (Barrett-Lee et al. 2009), and their life expectancy is still sufficient for potential long-term toxic effects to become apparent (Aapro et al. 2011). Doxorubicin has been associated with a 29% increase in risk of CHF in a retrospective series of older patients treated for diffuse large B-cell lymphoma (Hershman et al. 2008). In

elderly breast cancer survivors, the incidence of CHF 10 years after completion of adjuvant chemotherapy has been found to be 38% (Pinder et al. 2007). Regarding breast cancer, the risk of cardiac dysfunction may be exacerbated by the sequential use of trastuzumab after anthracyclines, as this is a known side effect of such monoclonal antibody (Denegri et al. 2016). In case of aggressive lymphomas, options are more limited than in breast cancer; the use of epirubicin rather than doxorubicin, different treatment schedules, liposomal formulations, and non-anthracycline-based regimens may be possible useful approach in this population, along with a closer cardiac function monitoring. As such cardiac monitoring as part of survivorship care should be considered specifically in older patients who received these treatment regimens.

Finally, such plans should consider the specific cultural context and the beliefs, desires, and wishes of this population. The engagement of family, friends, and caregivers is relevant, as some older adults may want to include them as part of the survivorship care process. Also, the way information is delivered is important, as some of them might prefer having a paper copy of their plan rather than going paperless.

Many older adults present a myriad of health issues, and healthcare is often provided by a fragmented group of professionals. Therefore, it is important that survivorship care is well coordinated, comprehensive, and focused on the patient's goals and preferences. Prompt communication between different members of the multidisciplinary team and especially between different specialists is key, while the primary care physician or the geriatrician should coordinate and facilitate the overarching care plan. Older cancer patients should always be at the center of all interprofessional teams, and clinicians must consider that their needs may change over time and that adjustments may need to be made accordingly. Health professionals including medical oncologists, radiation oncologists, surgeons, primary care physicians, registered and advanced practice nurses, physician assistants, psychosocial support professionals, pharmacists, dieticians, rehabilitation specialists, palliative care clinicians, and research coordinators are considered integral part of the survivorship care team, along with any other specialists possibly involved in the care of other medical conditions. Additional members might include patient navigators, nurse aides, home health and home care aides, and patient advocates. Finally, caregivers, who hold the responsibility of the care of older adults at home, have also a crucial role within the team. Each of them contributes uniquely with a broad range of skills, knowledge, and expertise and should communicate clearly, educate one another, and develop clear expectations and accountability in order to deliver and promote coordinated, patient-centered care. Across the continuum from acute cancer treatment to survivorship, the team leader may change based on the patient's conditions and needs.

Integration of Geriatric Oncology into Disease-Specific Guidelines

The underrepresentation of elderly patients in clinical trials and their exclusion from studies due to variety of reasons undermine the applicability of disease-specific guidelines for the care of an older patient (Battisti et al. 2015). Trials' subjects are a selected group of healthy and fit patients whose characteristics do not necessarily reflect those of the senior adults that an oncologist meets everyday in clinic. Due to the lack of evidence to guide therapy in this patient population, significant heterogeneity exists between key opinion leaders regarding the appropriate care, which adds additional challenge to the development of guidelines. Few studies addressing the management of cancer in older adults are available and therefore included into guidelines. When such evidence is lacking, the incorporation of less robust data, including retrospective series, meta-analyses, single-institution studies, and phase II trials, may provide some more guidance for the oncologist.

Assessing whether the expected benefits of treatment are superior to the risks in a population

with a reduced life expectancy and decreased functional reserve and tolerance to stress may be challenging. Moreover, the biology of cancer and its responsiveness to therapy are different in older adults compared to their younger counterparts (Balducci 2006). In addition, elderly patients have decreased tolerance to anticancer treatments and view the benefits of therapy differently. On the other hand, age alone should not preclude patients from receiving effective treatment potentially improving their survival and quality of life (Extermann 2004). Addressing these clinical questions is challenging via guidelines, and therefore most provide the practitioner an overview of the appropriate areas that need to be evaluated, deficiencies that should be addressed and issues that must be discussed with the patient during the continuum of cancer care. In this sense, the NCCN Older Adult Oncology guidelines (VanderWalde et al. 2016) discuss more of the assessment and treatment decision algorithm in older patients rather than specific therapeutic recommendations. For example, they provide guidance on assessing the ability to make decisions and point out specific considerations for using anticancer therapies in the elderly; they also highlight the relevance of estimating life expectancy in this setting and of the assessment of the domains of CGA. These are not specific treatment guidelines, but rather more general tools to allow the oncologist to better evaluate and manage older patients, regardless of their cancer.

In summary, specific problems related to aging formed the basis for the development of the NCCN Older Adult Oncology guidelines in order to suggest to clinicians the adequate mindset and tools and ensure an appropriate evaluation and management of older cancer patients in an individualized manner. Properly selected patients can receive effective and safe cancer therapy, whereas treatments that may potentially affect their quality of life without any significant benefit in survival should be avoided. As oncologists we are tasked with determining the best mechanism to incorporate the available assessment tools and supportive care measures, to ensure appropriate evaluation of the older cancer patient and delivery of a treatment plan that would result in the optimal outcome. Additional research is needed in this field to better inform our approach to this growing patient population.

Decision Making and Safety Issues in Older Cancer Patients

60

Contents

Abstract

More older people will present with cancer and require either curative or palliative treatment in the future. A major fact that influences all treatment is the decision making that occurs prior to treatment and safety considerations that need to be highlighted. As more older individuals with cognitive impairment, multicomorbidity, and polypharmacy are treated, a balance between improved morbidity and mortality must be made against safety issues particularly when addressing treatment in the very frail elderly individual.

Introduction

The older patient with or without cancer starts their cancer decision journey by making choices about primary, secondary, and tertiary screening. For those individuals proven to have cancer, the final decision will be about place of death. It would be difficult to discuss decision making and safety issues without considering the patients' decision, the healthcare provider's decision making, and the effect of family and carers on all decisions made by both patients and healthcare providers.

All decision making needs to consider safety issues as not all older patients have the capacity to make decisions and communicate them due to cognitive or communication issues.

Screening/Prevention

Prevention has been classified into three distinct types: primary prevention aims to prevent the onset of a disease while secondary prevention aims to halt progression of a disease after it has been established. If a disease can be identified early when a patient is asymptomatic, the administration of prompt and appropriate treatment may be given which will stop the disease (Donaldson 2000). In tertiary prevention, the aim is to rehabilitate the patient who already has an established disease in an attempt to minimize residual complications or disabilities. All three are relevant to older people especially as the incidence and prevalence of cancer is increased with aging. Decision making by the patient, doctor, and other healthcare providers will influence all screening either directly or indirectly.

If 80% of all cancers are potentially preventable, the focus even for older people must be on primary and secondary prevention. Unfortunately, it is well documented that older subjects are less likely to decide to participate in screening and cancer detection. This may be due to a variety of factors which include inadequate knowledge about cancer (Young and Severson 2005; Arnold-Reed et al. 2008), a lower educational level than in younger counterparts (Sessa et al. 2008), the older individual's perception of susceptibility to cancer (Shokar et al. 2008), and fear of cancer (Domati et al. 2008). Many older individuals have difficulty differentiating between the normal changes of aging and those symptoms which may be indicative of cancer. Ethnicity (Shokar et al. 2007), fatalism (Farmer et al. 2007), and the fear of the cancer treatment have all been implicated in the older patients behavior. Although most screening is for tumors related to women, e.g., breast and cervix, men are less likely than women to participate in screening.

The general involvement of healthcare providers undoubtedly influences the behavior of older people. An illustration of this is that many healthcare practitioners are more keen to examine the breasts of an older woman than to teach the older woman to self-examine (King et al. 1993). This may be partly due to nurses not believing that teaching breast health is part of their role (Turnbull and Roberts 2004). When breast screening groups of older women, those with a low income and African-American ethnicity are less likely to be screened (Young and Severson 2005; Farmer et al. 2007; Buki et al. 2007) · The negative effect of disability on screening (Schootman and Jeffe 2003; Liu and Clark 2008; Kiefe et al. 1998) and male rather than female radiographers (Fitzpatrick et al. 2008) is predictable.

Colorectal cancer screening which affects both genders uses fecal occult blood testing. Personal factors such as "forgot to undertake the screening" and "did not notice the test in my mailbox" are known (van Rijn et al. 2008). However, the effects of physician recommendation (Sessa et al. 2008) and instruction design (Feufel et al. 2010) are factors that are easily adjusted and can increase compliance. Any negative decision making that stops or reduces screening needs to be challenged especially in older people.

Screening colonoscopy can increase life expectancy but is not entirely without risk, and safety in the most frail individuals must be weighed up. Although patient preferences (Lin et al. 2006) should be considered, the procedure can be safe and worthwhile (Syn et al. 2005) and not avoided in older otherwise fit individuals.

Older patients are less likely to be involved in colorectal cancer screening than younger individuals. When older patients received either a scripted controlled message briefly describing the role of colorectal cancer screening methods, and efficacy, or information about mortality risk reduction in either relative terms or in absolute terms it did not affect the individual's preferences for screening. However, those individuals who received the information about the efficacy of screening rated the information higher than those who received either relative risk reduction or absolute risk reduction (Wolf and Schorling 2000) . Older people therefore should have information about screening targeted to give efficacy data.

A positive screening fecal occult blood test (FOBT) should result in further investigations. Some studies have found that only 41% of patients with positive FOBT undergo a full colon examination within 12 months of the positive test. This is not associated with comorbidity and may therefore reflect that either inappropriate patients were screened in whom further investigations would not be appropriate which is less likely or that the patients subsequently declined further input. This has obvious ethical and financial consequences (Garman et al. 2006). Older patients should only be screened if further investigations or definitive treatment are appropriate and will be accepted. This decision needs to be based on extreme comorbidity but never age alone.

In a study of patients aged 67 years or older who received a diagnosis of colorectal cancer, there was a predictable decreased life expectancy in those with comorbidity. While this may reduce the rigor with which clinicians encourage such patients to undertake screening it highlights that patient informed choice is equally important in such situations (Gross et al. 2006). It is therefore gratifying to see that colorectal screening utilization in some studies is not impacted by the Charlson score of comorbidity (Fisher et al. 2007), thus reassuring us that clinical decision making still outweighs some arbitrary scores.

Decision making by clinicians is influenced by the patient in front of them. An older depressed patient is less likely to receive colorectal cancer screening recommendations than those who are younger and not depressed. Comorbidity and marital status, i.e., those who are younger and married have potentially greater social support and may therefore be more compliant with screening (Sewitch et al. 2007). Such influences are important as a doctor's recommendation has a greater influence on the uptake of the colorectal cancer screening (OR 3.86), than awareness of screening (OR 3.32), higher education level (OR 2.02), or perceived cancer susceptibility (OR 1.76) (Shokar et al. 2008). Therefore, for older people where other factors often impact on decision making, it is important for the physician to recommend such screening if the patient is robust enough for further investigations or treatment.

The benefits of prostate cancer screening are debatable, and this will therefore be discussed no further.

Lung cancer screening trials which have used low dose computed tomography (LDCT) have included present or ex-smokers (Goulart and Ramsey 2013; Pastorino et al. 2003) up to the age of 74 years, and this gives increasing benefits over the routine use of screening (Pastorino et al. 2003). Older people should therefore have equal access if they fulfill screening criteria.

A systematic review of screening intention data for over 2000 women (including data up to August 2016) showed that women who used breast cancer screening patient decision aids (BCS-PtDAs) were significantly more likely not to undergo screening mammography. This was particularly evident in women aged 38–50, and it also had a nonsignificant effect on the intentions of women between the ages of 69 and 89 years to discontinue screening. This further illustrates that while decision aids may influence the behavior of younger women it has less effect on older women (Ivlev et al. 2017). A UK study was undertaken to identify why individuals do not engage with information provided via leaflets prior to organized screening programs. The study focused on breast, cervical, and bowel screening programs. They showed that information engagement was higher for White British participants compared with other ethnic groups when considering breast or bowel screening information. However, this was not consistent for older participants. The higher

rational decision-making scores being associated with reading more of the screening leaflets which again encourages the use of such leaflets in older people although it will not exclusively influence all screening decisions in this group (Ghanouni et al. 2017).

The influence of women on men's screening behavior is still poorly understood. Populations of African descent where incidence and mortality from prostate cancer is high need to be informed about screening in order to make a decision about participation. African-American women's knowledge was low although those women aged over 51 years had a higher knowledge as did those with a family history of prostate cancer. Further information should therefore be focused on informing women not only about the benefits of their own screening but the role of screening for husbands or partners (Eastland 2017).

Ethnicity influences decision-making preferences as does marital status. In a predominantly Spanish speaking Hispanic population, the majority of individuals preferred a collaborative role in healthcare decisions about participation in colorectal cancer screening programs. Those individuals who were married or living with a partner were more likely to prefer an active or collaborative role than their unmarried counterparts. Those individuals who spoke Spanish at home were more likely to prefer a passive rather than active role. Therefore, an individual's preference for decision making is key to decisions about involvement in various screening programs (Molokwu et al. 2017).

While screening is clearly important, the factors that determine an older person's participation are complex and multiple. The healthcare provider is a major influence in the older person's decisions-making behavior and therefore ageist attitudes must be avoided. Information must be delivered in an easy to understand form.

Assessment

Patients, carers, and healthcare providers should not make decisions about cancer treatment until the patient has been fully assessed. The comprehensive geriatric assessment (CGA) is well validated and identifies frailty and its appropriate treatment (Kim et al. 2011). CGA identifies the health economics of cancer care (Ellis et al. 2011), discharge destination, and life expectancy.

Some measures of frailty are undoubtedly reversible with appropriate input and may help the clinician to make appropriate decisions about when to treat or not treat the underlying cancer.

The CGA is used in various forms and can utilize postal or computer-based self-administered questionnaires even in very elderly groups (Kalsi et al. 2014; McCleary et al. 2013). It is important that functional status, mood, cognition, and instrumental activities of daily living are documented in whatever form. Although a mini geriatric assessment has concordance with a full CGA, it does lack sensitivity when assessing the effect of comorbidity and nutritional status.

The key usefulness of a geriatric assessment is how it affects decision making and safety issues. To improve safety, the CGA should be used to predict treatment related toxicity (Versteeg et al. 2014; Hamaker et al. 2012; Baitar et al. 2014). In surgical management, it should be used to focus efforts to optimize patients (Ramesh et al. 2005; Puts and Alibhai 2015), which increases the choices available to patients and cancer specialists. Optimization also improves patient safety irrespective of whether the patient declines or accepts treatment. Although the CGA alone should not be used to make a final therapeutic decision, it can contribute (Chaibi et al. 2011) particularly when identifying survival and therefore allows more frank discussions about relative benefits and risks of decisions made (Kuo et al. 2004; Walter et al. 2001).

Hospital readmission impacts on the safety of older patients; it increases delirium and hospital associated infection and such readmissions can be predicted by CGA (Chiang et al. 2015).

With retrospective data, it is difficult to determine whether comorbidities should affect surgical treatment of cancer. For some individuals, overall decision making and safety will appropriately reduce the amount of surgical treatment after a comprehensive assessment (Parks et al. 2015).

Although there has been much progress in ensuring that older patients are diagnosed early, this is influenced by decision making at all levels. The older person themselves may delay seeking medical advice with the resultant tumor being at a more advanced stage. Once again patient ignorance, atypical presentation, general frailty, or cognitive issues may have influenced decision making regarding early presentation.

Some 30 years ago, there was a clear relationship between age of patient and stage of the cancer at diagnosis (Goodwin et al. 1986; Mor et al. 1985) and treatment received (Bergman et al. 1991; Markman et al. 1993; Silliman et al. 1989). This however is diminishing, probably as a result of better information for patients and clinicians. Better education of geriatricians about cancer management and oncologists about normal aging will further improve this (Kalsi et al. 2013). There is, however, a group that are increasing in number, i.e., patients with cognitive impairment for whom decision making and safety issues are more pertinent. This will be discussed further under cognition.

Management

Prior to much of the advocacy work undertaken in the late 1990s, many older people with cancer were receiving less definitive treatment than younger patients. Although this has now improved mainly due to the decision making of clinicians, the evidence base for these decisions should still be cautiously considered. Patients over the age of 75 years are grossly underrepresented in clinical trials not only in absolute numbers but also in proportion to the incidence and prevalence of different tumors. There is a clear linear relationship that shows participation in cancer trials being inversely related to age (Shokar et al. 2008). The decision making of patients which results in further underrepresentation of certain ethnic groups and women needs further exploration as this finding is not exclusive to the US or the UK (Yonemori et al. 2010; Townsley et al. 2006). Exploration of this negative decision making has identified "anxiety about entering a clinical trial," "not being interested," "no time," or "too sick" as reasons given by older patients for not wishing to be included in clinical trials (Puts et al. 2009).

The ACTION trial which sought to provide evidence on the effects of chemotherapy in women aged over 70 years only recruited four patients in 10 months despite being a well-designed randomized controlled trial. Clinicians were unable to convince older patients to accept randomization, and the trial was terminated early (Leonard et al. 2011).

Outside clinical trials, safety issues about cancer treatments are still expressed by older individuals. Some older patients believe that cancer treatment is worse than the disease itself, although some older individuals do experience less emotional distress than their younger counterparts.

Some older women assume a more passive role in treatment decision making. In breast cancer, older women considered that stage of disease, likelihood of cure, and treatment options are less important than self-care issues. These individuals may need additional support if treatment is being offered and subsequently accepted.

Decision making is affected by how patients receive the cancer diagnosis. Although the relatives of older patients with cancer often wish that the diagnosis is not disclosed (Ozdogan et al. 2004), patients want to be informed even in extreme old age (94 years) (Ajaj et al. 2001).

Any management decision making by patients can be considered in three areas: the actual, the preferred, and the perceived role. Although individual patient preferences regarding the information given to support decision making is difficult to assess, the clinician should attempt to determine what the patient really wants and needs. Patient education should always be tailored to the individual cancer patient (Posma et al. 2009). Older cancer patients predominantly prefer to receive less information about both their illness and its potential treatment and are more likely to assume a less active role in treatment decisions (Pinquart and Duberstein 2004). The clinician and family members must not use this to reduce the involvement of the patient in the decision-making process, but deliver information in a more appropriate way.

During the early 1980s authors became interested in assessing a patients preferred level of participation in decision making. It soon became obvious that preferred and actual levels of patient participation were different and while we have come some way to ensuring that these are more closely matched it is now important that not only actual participation but perceived involvement in decision making is to be understood to increase satisfaction particularly among older adults (Tariman et al. 2010).

Older patients in contrast to younger ones have more difficulty in processing information and then remembering it following consultation. Information given to older people must be reinforced and delivered in a way that increases patient participation in decision making (Posma et al. 2009). Indeed when patients were asked their views regarding healthcare, they rated safety, expertise, performance, and attitude of physicians and nurses as the most important issues in cancer care (Wessels et al. 2009) . Puts et al. found in a systematic review of 38 studies that the important factors for the older person when accepting treatment were convenience and success rate of the treatment; understanding the necessity of treatment; trust in the physician; and when directly following the physicians recommendation. In contrast, those factors considered important when declining treatment included: concerns about discomfort of the treatment, fear of side effects, and transportation difficulties (Puts et al. 2015).

Communication must be tailored to improve the patients understanding of the risk and benefit information and how this affects decision making. Presenting absolute risks, i.e., using frequencies, rather than presenting relative risks, is important for patients. Clinicians must identify how treatment changes risks from preexisting baseline levels. The use of pictures is mandatory in some clinical situations (Fagerlin et al. 2011).

The role of relatives in decisions to limit treatment is fraught with difficulty. One third of relatives act against the known or presume wishes of patients, and this occurs predominantly when relatives hold views that contradict known patient preferences (Hauke et al. 2011).

The initial stages of cancer treatment are very focused on the underlying medical condition. For those older patients with complex health and social care needs, decision-making processes are more haphazard and can result in less effective and workable treatment plans particularly when clinicians have targeted deadlines to deliver care (Bridges et al.2015).

Information is critical for the older patient to ensure optimal care. In a group of 133 patients with cancer who had a mean age of 79.6 years, all patients wanted full information. About 74.2% wanted to participate in decisions about their care although 87.2% would designate a family member to serve as a surrogate in life-threatening situations and of these 15% had already designated a surrogate. When comparing this group with cancer to an age-matched control group without cancer different themes emerged. Those patients with cancer wanted more information particularly in life-threatening situations. Those patients who had children, a higher mini mental state examination (MMSE) score, being of a younger age, without cancer, or being cancer free were all factors independently associated with patients wanting their informed consent to be obtained for all interventions. While a higher MMSE, being younger and without cancer or being cancer free is somewhat predictable, having children may not be (Paillaud et al. 2017).

Comorbidity affects treatment decisions and mortality. Some of the observed differences in breast cancer specific mortality may be due to less extensive treatment as well as other factors. It is therefore important that comorbidity is recorded and acted upon (Berglund et al. 2012). Comorbidity may decrease the likelihood of cancer screening recommendations although conversely some patients with comorbidity with increased preventative services have earlier cancer screening resulting in earlier stage of diagnosis (Gonzalez et al. 2001) although this is not consistent across all studies.

During multidisciplinary cancer team meetings, comorbidity undoubtedly affects treatment decisions. When information about comorbidity is lacking, the MDT delays making recommendations and may become more conservative. While this may

be appropriate, there is little evidence about how comorbidity is considered or impacts on decisions in busy MDT's (Stairmand et al. 2015).

Chemotherapy Safety

There is conflicting data about the willingness of older patients to accept potentially toxic chemotherapy. Yellen et al. (Yellen et al. 1994) assessed patient's willingness to potentially accept toxic chemotherapy to improve survival by the use of various structured scenarios. They found almost equal numbers of young and older patients willing to choose chemotherapy in different scenarios although the older patients when choosing a more toxic regime over a less toxic alternative required a greater survival advantage before being willing to have such a therapy. This has decision making and safety implications.

Older people are less likely to enter clinical trials, thereby reducing the knowledge base particularly around chemotherapy. Older people have altered pharmacokinetics and pharmacodynamics and for some chemotherapeutic agents this will pose particular issues. Some clinicians will decide to reduce the drug dosage, its frequency, or the number of cycles administered. This is not universally supported by evidence and though it may improve tolerance if it results in lower response rates with worsening survival this is neither scientifically nor morally justifiable. Repetto in 2003 considered that age was a risk factor for neutropenia as a complication of chemotherapy and advocated the use of colony stimulating factors in older patients (Repetto 2003). Such factors and other support mechanisms are now mainstay therapies for all ages.

The risks and benefits of using erythropoietin to combat anemia needs to be fully considered (Massa et al. 2006; Bohlius et al.2009), and decision making about concomitant medication and potential drug interactions should be considered by the clinician treating the older cancer patient (Lord et al. 2010; Riechelmann and Del Giglio 2009; van Leeuwen et al. 2010).

Published narratives help us to understand some of the difficult decision making around adjuvant chemotherapy for those requiring it for both curative and palliative intent. Adjuvant chemotherapy is likely to benefit patients only with a life expectancy greater than 5 years and mortality benefits become less pronounced with increasing age. The older patient wants chemotherapy as long as the side effects do not reduce the quality of life or the ability to function independently. The specific barriers that the older person experiences such as sensory and memory problems and poorer health literacy (Johnson 2012) must be considered by healthcare professionals.

Cancer Trials

If older people are to enter into clinical trials, appropriate adaptations will have to be made to ensure that patients are not disadvantaged. This will include choosing therapies that have a low underlying potential for drug–drug interactions assessments of bone marrow reserves, and central and peripheral nerve function to avoid treatment related adverse effects. For those with hepatic and/or renal dysfunction, necessary drug dose adjustments can be made for those agents where pharmacokinetics are affected (Aapro et al. 2005).

While many older people when asked are willing to consider participation in cancer clinical trials, however, older patients do not appear to actively seek clinical trials and even smaller numbers are informed of the availability of clinical trials (Townsley et al. 2006).

When older people are recruited to clinical trials, retention is important and may be affected by the need to have additional tests or interviews although most patients enjoy such participation (Puts et al. 2009).

End-of-Life Care

Advanced care planning is very important before individuals become unable to make decisions for themselves. When considering the quality of life assessment of individuals aged 70 years or over and their desire for specific interventions four particular scenarios (a current health state, mild to moderate stroke, incurable brain cancer, and

severe dementia) were studied. The individuals identified a surrogate who was then asked to predict the older individual's responses. The surrogate and the older individual had significant differences in their quality of life ratings. The surrogate over estimating the quality of life of the older adult compared to the older adults self-assessment. The difference in these ratings then predicted the desire for life-sustaining interventions in hypothetical situations. The greater discrepancy in the quality of life ratings, the more likely the surrogate was to over-estimate the older adults desire to be treated. This indicates that many family members find it difficult to make decisions for their loved ones and this can result in over treatment of the older individual compared to their desires (Bravo et al. 2017a).

To understand public preferences for care toward the end-of-life a large cross-sectional study of the general public in the UK and the USA sought to identify decision making when a patient had deteriorating capacity. There were no significant differences between the UK and the USA but the preference for measures to sustain life at all costs peaked for the scenario where the patient had short-term memory loss. As the neurological condition deteriorated, respondents selecting "measures to help me die peacefully" increased from 3.9% to 37%. The predictors of who would choose "measures to help me die peacefully" at any stage were a previous personal experience of the chosen scenario or increasing age. The latter finding increasing across the decades. The negative predictors of choosing "measures to help me die peacefully" were living with children or being of black race/ethnicity. A significant number chose preservation of life at all costs even in those with end stage dementia. This may affect decision making for those patients with coexisting cancer and dementia (Clarke et al. 2017) and others have reported similar findings (Bravo et al. 2017b) .

Surgery

The older cancer patient who is about to consider surgery needs adequate risk assessments, as complications in hospital are associated with increased death during that period of hospitalization (Marrelli et al. 2000). The risk assessment is undertaken in order to fully explain the relative benefits and risks of undertaking such surgery (Marrelli et al. 2000; Ramesh et al. 2006; Donati et al. 2004; Monk et al. 2005; Khuri et al. 2005; Manku et al. 2003; Seymour 2008). Better predictions can be made by the use of preoperative cardiopulmonary exercise testing (Lai et al. 2013) and cardiovascular interventions such as perioperative beta blockade (Bangalore et al. 2008). Pulmonary complications can be reduced by preoperative intensive inspiratory muscle training which improves pulmonary safety after surgery (Dronkers et al. 2008). Postoperative delirium is predicted by increased blood pressure fluctuations rather than absolute or relative hypotension during surgery (Hirsch et al. 2015). The older cancer patient would therefore be best treated using evidence-based recommendations such as those developed by SIOG (Audisio et al. 2004).

Quality of life is affected by a number of issues including physical activity that are important to patients. Therefore, any surgery that results in reduced physical activity can impact on the patients' quality of life (Santa Mina et al. 2010).

The most appropriate treatment for operable breast cancer is surgery. Only those patients with reduced life expectancy or significant comorbidity should be treated with primary endocrine therapy. Guidelines make it clear that age should not be a factor in this decision. In a 2017 study, a discrete choice experiment was used to determine which key variables impacted on treatment decisions. Overall age, comorbidity, cognition, functional status, and cancer size were all independently significantly associated with treatment preference. However, only comorbidity, cognition, and cancer size correlated with a preference for primary endocrine therapy. Therefore, while age did not influence the use of primary endocrine therapy it was a factor when healthcare professionals were making decisions for an elderly population (Morgan et al. 2017). In a similar study of 106 surgical, 37 radiation, and 31 medical oncologists who provided treatment for older women with breast cancer a variety of scenarios were presented. Altering the age from 84 to 76 increased the recommendation

for breast conserving surgery plus radiotherapy (73 vs. 56% P = 0.001). Adjuvant chemotherapy for an otherwise healthy older women with triple negative breast cancer was considered by 83% of the participants. Appropriately, performance status influenced specialist treatment recommendations but perhaps inappropriately also patient age did as well (Hamelinck et al. 2017).

Patient choice between surgery and primary endocrine therapy for early breast cancer was most influenced by the impact, safety, and efficacy of treatment with patients expressing least interest about cosmetic outcomes after surgery. The patients on the whole preferred information to be provided verbally by doctors and nurses supported by booklets and had little interest in technology-based sources of information (Burton et al. 2017).

Qualitative data also can be used to explore the experience of decision making in older women with invasive breast cancer. Intrapersonal and interpersonal communications challenges (emotional distress, patient provider communication, "making it personal," access to information) are important. If inter professional models of care can be utilized, they may minimize existing barriers to information provision and empower patients to make decisions consistent with their individual wishes (Campbell-Enns et al. 2017).

Radiotherapy

For men with newly diagnosed non-metastatic prostate cancer, black men were significantly more likely to receive radiation therapy and significantly less likely to receive radical prostatectomy. Irrespective of the treatment received, black men received aggressive therapy at rates approaching those of the white men (Rose et al. 2007). Age did not appear to influence such therapy.

When studying the needs of older women with early stage breast cancer who require decision making about radiation therapy, participants viewed benefits and side effects to be the most important factors and more than 96% of participants indicated that they were the main decision maker before receiving radiation therapy (Wang et al. 2017).

Healthcare Professionals Treatment Decision Making

A number of individuals are involved in treatment decision making, and it is vital that ageist attitudes do not creep into this process.

Practicing US medical oncologist's were randomly assigned one of two scenarios with identical vignettes apart from the age of the patient. Intensive therapy was significantly less likely to be recommended for the older than for the younger individual despite the remaining features being identical. This occurred irrespective of the stage of the tumor. While the oncologist did identify that patient age was an influence on treatment choice, they were more likely to cite that it was the performance status rather than the age that determined their treatment decisions (Foster et al. 2010).

There is some evidence that primary care providers in the US are perceived to contribute in the older person's decision making. Such engagement is associated with higher decision satisfaction when compared with lower engagement with primary care providers. However, this involvement did not improve a patient's appraisal of their own individual decision making (Wallner et al. 2016).

Qualitative studies including physicians, patients, and relatives before the treatment of colorectal or pancreatic cancer identifies the complexity of some decision making. Authors encouraged the role of primary care physicians and recommended dividing decision making into more sessions. This may be both beneficial in the decision- making process but also helps emphasize the patient's own responsibility in decisions. This, however, may delay treatment and this was not emphasized by the authors (Geessink et al. 2017).

Cognition

With increasing survival of older patients with a variety of comorbidities, cancer is increasingly likely to be diagnosed in those with cognitive

impairment. Unfortunately, much of the data that relates cognition to diagnosis, treatment, and outcomes is anecdotal and complicated by other comorbidities. Van Deudekom reported that only two of 31 articles reported a cognitive test when assessing outcomes from the treatment of head and neck cancer. Nevertheless, cognitive impairment was associated with adverse outcomes. Of greater concern is that none of the included studies addressed frailty or objectively measured physical capacity using well-documented grip-strength, balance test, or indeed gait speed (van Deudekom et al. 2017). The use of the CGA to support clinical decision making and personalized care plans of the older person with cognitive impairment is essential (Pilotto et al. 2017).

Much further work is required to ensure that older patients have safe, effective treatment that is evidence based. Comorbidity including moderate cognitive impairment should not stop palliative cancer treatment. Overall, what is lacking in this group of individuals is the evidence base. Clinicians must endeavor to recruit such patients to add to our knowledge base.

Abstract

Currently, older adults (age 65 and older) represent about 62% of cancer survivors and by 2040, it is anticipated that 73% will be 65 years or older. The changing demographics of the older cancer population reflect, in part, a growing multicultural, multilingual, and immigrant population. Effective communication is an essential cornerstone of cancer care and influences patient and family experiences and outcomes across the care continuum, from screening and adherence to prevention, to decision-making, adaptation and acceptance of illness and treatment regimens, to resolution of symptoms and rate of recovery, just to name a few. Also, effective communication impacts interest and participation in clinical trials and research and is necessary as clinical trials increase in their complexity in study designs (e.g., multistage adaptive designs) and precision and genomic considerations. Fundamental to effective communication for an increasingly older diverse cancer population, including many whom are socially isolated or marginalized, is attention to culture and literacy and intersectional perspectives to advance health equity. This chapter highlights techniques and skills to improve communication with older patients within the oncology setting, and emphasizes the value of recognizing and appreciating cross-cultural similarities and differences for strengthening acceptable therapeutic care, support, and education. The importance of warm, empathic, and clear interactions also is reinforced to aid in a patient's healing, well-being, and quality of life. Finally, the **REAL** (**r**elatable, **e**ngaging, **a**ctionable, and **l**iteracy-friendly) framework is presented as a useful approach and tool for delivering cancer information that resonates with the everyday lives of patients and their families.

Keywords

Communication · Health literacy · Culture · Language · Patient-centered Care

Introduction

"Talking and listening to patients" is performed more often than any other single medical procedure (Fallowfield and Jenkins 1999). Patients rely upon effective communication to gain critical information about health promotion/disease prevention, treatment and care coordination, cure (when possible), and palliative/hospice care (when cure is not possible). Effective communication is crucial as patients cope with their diagnosis, understand what it means, and figure out how to best navigate a course of treatment (Prip et al. 2017). Three core functions of effective communication are the demonstration of empathic behavior, promotion of information processing, and facilitating decision-making (Van Vliet et al. 2015). Further, a therapeutic relationship requires a commitment to recognizing, appreciating, and negotiating patients' ethno-cultural beliefs and values and responding appropriately to varying learning styles and preferences (Green et al. 2002; Surbone 2006a, 2008; Surbone et al. 2007). At the heart of effective communication is a provider-patient relationship that is deeply rooted in culturally caring, sensitive, and clear communications.

Consider the following scenario:

What might be the most effective way to communicate with an elderly Hispanic patient (71 years) who presents at a cancer clinic as part of follow-up

from a free screening program for colorectal cancer? As background, Mr. Lopez recently arrived from Puerto Rico (relocated due to a hurricane), speaks only Spanish, has completed 8 years of schooling, worked for 25 years as an agricultural/farmworker, and currently lives with his daughter in a rural setting in Southeast Florida (about 3 h from the cancer clinic). He has secured a part-time job at a local strawberry farm. He is a grandfather of six children and the patriarch of his family (his wife died 2 years ago), and he derives great enjoyment from his family. Upon his arrival Florida, at the urging of his daughter, he took part in a free health screening (including colorectal cancer screening) and was navigated to a nearby clinic by a bilingual community outreach worker for follow-up care due to an abnormal fecal immunochemical test (FIT). While unfamiliar with the health care system, he trusts the community worker who helped navigate him to colonoscopy due to an abnormal FIT.

. . . What is Mr. Lopez's understanding of what "abnormal" means? What might a colonoscopy mean to him and to his family? How will he successfully negotiate the health care system (resources, transportation, finances, language, etc.) in order to complete a colonoscopy? What can make this a successful encounter with the gastroenterologist? If the colonoscopy shows cancer and he requires follow-up care and treatment, what treatment options are available? What might the demands of cancer care and treatment mean to his everyday life? What can be done to promote effective communication with the oncologist and treatment team at the cancer center? How can information be provided in understandable, language-appropriate, and acceptable terms and be consistent with his values, beliefs, and obligatory sense of family responsibility that has recently changed due to situational factors?

Such questions remind providers of the importance of effective communication in cancer care and the need to recognize the numerous factors including culture and literacy that can influence the patient-provider relationship and outcomes.

Demographic Shifts in Health Care

While the overall growth in population from 2010 to 2050 is projected to slow down, a large shift is expected toward the oldest age groups, both globally and in the USA. According to a 2015 aging report commissioned by the National Institute on Aging produced by the US Census Bureau, 8.5% of people worldwide (617 million) are aged 65 and over today (He et al. 2016). He and colleagues (2016) reported that projections over the next three decades for America's 65-and-over population will nearly double – from 48 million to 88 million by 2050. Moreover, it is estimated that 62% of all cancer survivors are older adults, and this number may even reach 73% by 2040 (Bluethmann et al. 2016).

Nearly 59 million immigrants have arrived in the USA over the past 50 years, mostly from Latin America and Asia. This accounts for a near-record 14% of the country's population being foreign-born compared with just 5% in 1965, with the majority of the US population's increasing growth over the upcoming decades being related to new Asian and Hispanic immigration (He et al. 2016). In particular, the changing demographic shift associated with an increasing number of racial/ethnic minorities, foreign-born, and new immigrants represent important subpopulations of older adults that are at risk to encounter disparities and potentially suboptimal care. The persistence of health disparities is especially striking among older adults and racial/ethnic minorities and requires comprehensive, highly competent, and strategic approaches to ameliorate such injustices (Williams 2007). The populations shifts bring to light the central imperative that all people should have equal access to high-quality cancer care, treatments, and cutting-edge cancer clinical trials. Inextricably linked with culturally effective communications for a growing and diverse older vulnerable population is making *health equity* part of a larger social justice mandate (Alcaraz et al. 2017; Surbone and Halpern 2016). As such, insights into a patient's worldview are an instrumental step toward effective communication.

Culture, Worldview, and Effective Communication

Communication is contextual and providers need to have knowledge of the concept of culture and its impact on their relationships with patients. As Surbone (2008) relates, each clinical interaction should be viewed as an exercise in cultural effectiveness that aims for understanding,

transparency, and truth-telling. Further, Kagawa-Singer et al. (2014, 2016) describes culture as a socially constructed set of dynamic and ecologically based interrelated elements that function together as a living, adapting system. A cultural group shares an "identity" that shapes norms, values, goals, expectations, perceptions, and behaviors. In short, culture informs health and human behavior, allows people to see the world through their life experiences and gives meaning to their everyday lives.

Kleinman (1978), an anthropologist and psychiatrist, offers additional insights into understanding how culture, religion, ethnic beliefs, and practices influence healthcare-seeking behaviors, since health care systems are both social and cultural in nature. He relates that clinical realities are often culturally constituted and vary cross-culturally across the domains of health care (communication, spirituality, death/dying, etc.). They often are heavily rooted in a patient's explanatory model. *But what is a patient's explanatory model?* Quite simply, it represents a person's notions and ideas about health and disease. For example, Mathews et al. (1994) reported that many Black women who presented late with advanced breast cancer disease came to terms with their illness by drawing on a model of health that emphasized balance in the blood, popular notions about cancer, and biomedical conceptions about breast disease and treatments. Too often, providers felt that women did not use screening services and delayed treatment because they lacked knowledge, were too poor to access care, or were excessively fatalistic. Trying to eradicate "fatalism" by giving them materials obviated the need to understand their beliefs and values within a wider sociocultural context. Hence, the potential positive or supportive aspects of cancer "fatalism" beliefs are not well-appreciated when providers do not consider the fuller social context. Another example by Braun et al. (2014) relate that some Hawaiians believe that good health means a balance among one's responsibilities to the group, the land, and the spiritual world. Or as Venkatasalu (2017) recounts in her examination of older British South Asians' views on dying at acute hospitals, many patients felt that dying in a hospital versus home evokes feelings of guilt among family members and represent missed family responsibilities. As such, these varying perspectives illustrate how important it is to have a biomedical lens that considers a "patient's worldview" in a clinical interaction. These perspectives remind providers to delve into what patients and family members believe and experience both when healthy and when ill. For example, broader questions about health and illness might be: *What does good health look like for you? How are health decisions made in your family and who makes treatment decisions in the family? What role do home remedies play in your recovery? What roles do vs. does faith or religion play in your life and medical decision-making? What is the role of family, church, and/or community toward good health or toward a good death? Where or what do you turn to for support in times of poor health?*

Improving patient-provider communication includes gaining an appreciation and awareness of how culture and worldview influence patients' expressions of their clinical condition. This, in turn, helps to illuminate an understanding of patients' beliefs about their health and illness. It also helps to ascribe personal and social meaning attached to an illness (cancer) as well as expectations about what will happen, what will be done, and the expected therapeutic goals. Incorporating and/or adapting the following questions into patient discussions may provide helpful insights about patients' everyday lives and help understand patients' cultural meaning of health and illness (Kleinman et al. 1978; Kleinman 1980) (See Table 1). Depending on the clinical situation, the wording and ordering of questions may vary.

Culturally effective health care providers demonstrate a number of humanistic and empathic characteristics as summarized by Meleis (1999). First, they value diversity. They are not drained by the constant attempt to understand and interpret meaning and symbols but rather are highly energized by these variations in human behavior. Second, they show expert assessment and communication skills that expertly decipher and deconstruct different and similar patterns of responses that move conversations toward what matters most (as noted in Table 1). Third, they are

Table 1 Examples of questions to elicit patients' meaning of health and illness

Key point	Question(s)
"Comparison between patient and doctor explanatory models should center on the crucial points requiring patient education, clear clinical explanation, or frank negotiation" (Kleinman et al. 1978, p. 257)	• *What do you think caused your problem?* • *Why do you think it started and when did it?* • *What does your sickness/problem do to you? How does it work?* • *How severe is your sickness? Do you think it will last a long/short time?* • *What kind of treatment do you think you should get?* • *What are the most important results you hope to get from treatment?* • *What are the biggest problems your illness has caused for you?* • *What do you fear most about this problem/illness?*

aware of the diversity and complexity of communication patterns and how language and communication are important to the "trustworthiness of the relationship." They recognize that marginalization and noninclusivity increase health risks for patients and their family members, and that the expertise of insiders in the culture or social network enhances therapeutic relationship and outcomes. Finally, they acknowledge and appreciate similarities *and* differences across multicultural groups and do not stand for inequities and injustices. Damaskos et al. (2018) relate that providers have a deep obligation toward the practice of cultural humility, self-reflection, and patient-centered care. As a result of the delivery of culturally competent care and effective communication, providers too can gain a deep personal sense of privilege, honor, and professional fulfillment (Surbone 2008).

Impact of Effective Patient-Provider Communications

Patients and their family caregivers commonly express the need for improved communication with their providers (Puts et al. 2017). Effective communication has been shown to influence rates of emotional and physiological health, patient recovery, pain control, adherence to treatment regimens, improved psychological functioning, decision-making about treatment options, consequences of treatment (or no treatment) and facilitates supportive and psychoeducational care (Cousin et al. 2012; Gilligan et al. 2018; Karnakis et al. 2016; Prip et al. 2017). It is linked to increased rates of cancer screening (Carcaise-Edinboro and Bradley 2008; Underhill and Kiviniemi 2012), acceptance of recommended treatment including chemotherapy (Puts et al. 2015, 2017), end-of-life preparation (Wentlandt et al. 2012), and patient satisfaction and overall enhanced quality of life (Baker et al. 2016; Ernstmann et al. 2017). Furthermore, it has been observed that many older cancer patients experience worse patient-provider communication than their younger counterparts (Shelton et al. 2013). Such differences in the quality of various facets of patient-provider communication (e.g., respecting, listening, explaining, and time spent with the patient) have been noted based upon race/ethnicity (White-Means and Osmani 2017). These reports further underscore the importance of developing strong patient-provider relationships through culturally competent communication.

The importance of culturally effective communication has been further reinforced by the 2017 release of the American Society of Clinical Oncology Consensus Guidelines for Patient-Clinician Communication (Gilligan et al. 2017). This document summarizes best practices for cancer clinicians and offers primary guidance and strategies for implementation across a number of clinical domains (e.g., treatment selection, end-of-life, etc.). These guidelines include a number of recommendations to enhance communications and can be reviewed at: http://ascopubs.org/doi/full/10.1200/JCO.2017.75.2311. Moreover, the Accreditation Council on Graduate Medical Education (http://www.acgme.org/) and the American Board of Medical Specialties (http://www.abms.org/) identify interpersonal communication skills as a clinical competency (ACGME Home 2018). Taken together, these professional guidances help

in shaping competency standards for current oncology providers and the next generation of oncology practitioners, an important measure towards improving effective communication with older cancer patients.

Factors That Influence Culturally Effective Communication

What providers communicate – or believe that they are communicating – and what a patient (or a family) hears is not always identical. As such, culturally effective communication involves getting to know patients as individuals – beyond their diagnosis and medical history – and assessing their goals, information needs, priorities, wishes, and values. It requires a keen awareness of the factors that play a role in communication patterns and recognizing that effective communication is an important part of the healing and the therapeutic aspects of cancer care. Among identified influencing factors of communication are the sheer physical aspects of cancer itself (e.g., pain, suffering, physical changes, disfigurement, etc.), and the multiple psychosocial and emotional aspects and responses to cancer as a potentially life-threatening disease (e.g., anxiety, confusion, uncertainties, depression, changes in familial roles and dynamics, etc.) (Baile and Aaron 2005; Finkelstein et al. 2017; Surbone 2006b, 2008). Furthermore, for many older cancer patients, due to the complexity of health or other multiple comorbid problems and polypharmacy, they may interact more frequently with oncology team members (Armstrong and Holland 2004; Baile and Aaron 2005; Finkelstein et al. 2017; Liang et al. 2006). Such multiple health concerns coupled with cancer concerns and fears can make patients feel quite overwhelmed and ultimately result in feelings of increased vulnerability and loss of control (power shifts) (Sattar et al. 2014). Moreover, the metaphorical value that is often placed on a cancer diagnosis (which might be negative in some instances) plays a crucial role in patient-provider communications and is notably important in many cultures and contexts (Surbone 2006b). To enrich interpersonal interactions, Cain et al. (2018) emphasizes the need for personalization of care and understanding and consideration of patients' "individual circumstances and life histories."

Importantly, there are factors that detrimentally influence effective communications including ageism, classism, discrimination, racism, prejudice, social stigmatization, lack of understanding of the impact of historical trauma, stereotyping, and negative depictions of the elderly (Surbone 2008). These very real risks may reflect providers' and researchers' biases (explicit vs. implicit) and intrinsically call for ongoing self-awareness and reflection (Banaji and Greenwald 2016; Braun et al. 2014; Cain et al. 2018; Herrera et al. 2010). To further broaden providers' cultural relevance and competence and transdisciplinary expertise, specialized and education and training is needed as well as a commitment to mentoring others to develop and share cultural expertise across all sectors of cancer care. This latter point reinforces a strategic need for targeted workforce development via continuing education to raise cross-cultural communication skills and knowledge to advance health equity efforts (Alcaraz et al. 2017).

Intersectionality

Given the proliferation of marked demographic and social change in our society, there are many population subgroups characterized by multiple factors or socio-behavioral identities – *intersectionality* – wherein individuals may be racial-ethnic minorities, older, and self-identify as sexual and gender minorities, for example. These overlapping social identities (intersectionality) represent multiple concurrent (co-occurring) experiences and conditions that coexist and interact to produce complex context that may hinder communications, self-care, or effective care delivery (Evans et al. 2017). Among some older populations such as Blacks/African Americans, historical transgressions in health care may perpetuate mistrust and foster critical biases and failed communications, particularly when conveying complex or new topics such as precision medicine, genomics, or biobanking research (Kraft et al. 2018).

Acculturation

There is increasing cultural diversity of the American older adult population growing beyond the predominant European-centric culture, with exponential growth of the older populations segments from other racial/ethnic groups (Brettell 2007). Level of acculturation to USA culture has also been found to influence health care communication and access to cancer care (Andreeva et al. 2007; John et al. 2005; Katz et al. 2017; Lee et al. 2014; Monroe et al. 2003; Nasseri and Moulton 2011; Nguyen et al. 2014). For example, Latinas diagnosed with breast cancer with low levels of acculturation have been found to experience decreased likelihood of high-quality communication with their medical oncologists and surgeons (Katz et al. 2017). Furthermore, acculturation has been associated with willingness or lack thereof to undergo cancer screenings among diverse groups, including Vietnamese Americans (Nguyen et al. 2014). On the other hand, length of time in the USA (more than 20 years compared to less than 10 years) has been positively associated with likelihood of completing breast, colorectal, and cervical cancer screenings among Vietnamese, Chinese, and Korean Americans (Lee et al. 2014).

In addition, immigration to the USA has been associated with incidence of some cancers; the direction of this association depends upon country of origin and length of time in the USA (Andreeva et al. 2007; John et al. 2005; Monroe et al. 2003; Nasseri and Moulton 2011). Thus, an essential aspect of patient-provider communication is learning about their patient's backgrounds and experiences to fully understand their explanatory models of health and illness within the context of their lived experiences.

Even within the Black/African American population there are potential subgroup differences in worldview about disease etiology and management when comparing African Americans (born in the USA) with immigrant Blacks from the Caribbean, for example (Gwede et al. 2010, 2011). In addition, a combination of religious, spiritual perspectives, and historical experiences with segregation and discrimination also have molded the unique cultural and life perspectives of African Americans that ultimately shape communications and interactions with the health care system (Katz et al. 2017; Penner et al. 2016). Furthermore, one of the contributions of the family reunification amendment (Maddali 2016) has been increased diversity due to immigration of older adults (parents) joining their children in the USA (Brettell 2007). The influx of older immigrants, especially from Asia, Africa, Caribbean, Latin and South America (rather than Europe), has brought into play many new diverse cultures and deepened worldviews.

Communications, interactions, and rooted beliefs about health and disease converge deeply in the context of cancer care (Katz et al. 2017; Lillie et al. 2014; Hawley et al. 2008). Furthermore, the demographic diversity of the older American population includes growth driven by the aging population of Native American, Hawaiian, and Alaskan Natives, as well as immigrant Asians, Hispanic/Latinos, and immigrant Blacks from the Caribbean, Latin America, South America, Europe, and Africa. Along with their rich cultures and communications styles, immigrant populations may take longer to assimilate to the mainstream ways of the USA, and thus, may experience difficulties when seeking health care not only because of language or communication differences (in many cases), but also due to differing perspectives on cancer, and help-seeking. For example, in the arena of cancer screening and early detection, some individuals may not value the goals of these test methods for finding cancer early depending on their experiences. Some new immigrants may not even have heard of the word *cancer.* Also, some may believe that most cancer types cannot be detected early or that early treatment can enhance the chance for cure (Gwede et al. 2011).

Regardless of their prognosis, older oncology patients (and if patients desire, or if, they completely lack the ability to engage) their family caregivers should be involved in the decision-making process. Patients should be given honest and timely information about their diagnosis, prognosis, as well as the risks and benefits of various treatment options to make a well-informed decision. For patients with a terminal

illness, providers should be aware that what constitutes a "good death" in one culture may not necessarily carry over to other cultures. In addition, shifts in beliefs about end-of-life can occur based upon increased acculturation (Mori et al. 2017). As such, the growing need for clear communication in light of the increasing cultural and linguistic diversity in patient populations is a central imperative. In the next section, a number of *essentials of communication* are presented to enhance positive interactions for therapeutic benefit among older cancer patients.

Essentials of Communications to Promote Effective Patient-Provider Relationship

There is insufficient space in this chapter to fully discuss all the potential differences in communication style among all the cultures and geographic regions of the world. Since communication norms vary both between and within cultures, it is important to not stereotype patients based upon their background characteristics, including age. While there may be some cultural differences in communication style, most cancer patients, regardless of age, greatly appreciate providers who listen to them and demonstrate respect, warmth, empathy, and inclusivity (and potentially, their family) in decisions about their care. The following suggestions may seem rather straightforward but serve as important reminders especially in light of a technology-driven environment. These include: *introducing yourself, setting an agenda for the visit collaboratively with the patient, sitting down, facing the patient, making consistent eye contact, using active listening skills, asking open-ended questions, demonstrating respect, warmth, empathy, and interest in each patient, assessing patient goals, priorities, and values, and addressing psychosocial needs of patients and caregivers*, among others (Baile and Aaron 2005; Delgado-Guay et al. 2013; Gilligan et al. 2017). Table 2 outlines several basic communication skills. Descriptions of these skills are highlighted in the literature (Baile and Aaron 2005; Delgado-Guay et al. 2013; Gilligan et al. 2017), which are excellent reference resources.

Creating a Patient-Centric Environment for Learning

Throughout this chapter, suggestions for promoting effective and clear communication are closely tied to enhancing providers' interpersonal skills. As van Vliet et al. (2015) point out, aging is associated with a number of cognitive, physical, and social changes (memory, hearing, visual, social networks, etc.). These changes often (in) directly affect the way older people may process, assimilate, and use information to make decisions. Thus, it is important to be aware of such factors that might get in the way of effective communication. Table 3 outlines a number of techniques to facilitate effective communication and mitigate hidden traps in communication.

Preferred Methods of Learning and Communication Technologies

Preferred Methods

Preferred methods of communication should be considered when communicating – regardless of whether one is coordinating care or providing consultation or education. Although this may change in subsequent decades, many older cancer patients age 65 and older still report that they prefer making medical appointments through phone calls (as opposed to through email, websites, or text message) and many still like receiving educational health information in person or in paper format (as opposed to website or other electronic means) (Saied et al. 2014). Relatedly, in one study, older lung cancer patients reported preferring education provided verbally or in written format compared to online or in class format (Jewitt et al. 2016). On the other hand, it is estimated that 67% of US adults 65 and older now use the internet (Anderson and Perrin 2017) – and this number has increased by 400% since 2000 (Smith 2014; Anderson and

Table 2 Essential interpersonal skills and methods to promote effective communication

Essential interpersonal skill/ method	Helpful tip/information	Example	Sources
Introduce yourself Introduce self and your specialty/area of clinical care and role in patient's care	This introduction can be brief but is important in laying the foundation for developing a strong patient-provider relationship and to get to know what is important to the patient. This sets the stage for a warm trusting relationship	"Hello, Mrs. Green. My name is Dr. Williams. I am a medical oncologist. I provide treatment to patients with breast cancer, including chemotherapy and immunotherapy. I see that you have brought some important people with you today. Would you like to introduce them to me?" "Please tell me about your day so far"	Gilligan et al. 2017
Setting a collaborative agenda At the start of the visit, ask the patient what topics they would like to discuss	This fosters an inclusive environment in which the patient and their family are engaged in a collaborative process of treatment decision-making and healing with the treatment team	"There are number of topics to cover during our time together today, however, I want to check-in to see what your top 3 questions/concerns are so that we can be sure to discuss those"	Gilligan et al. 2017
Sit down, facing the patient/ family, and making consistent eye contact	This helps to create a trusting and positive patient/family-provider relationship and further solidifies the stage for co-learning to occur. This also demonstrates interest in a patient's unique experience by being fully attuned to his/her needs. It also helps to pace/slow down the interaction according to cues that can be readily picked up	Sitting on a chair/stool at eye level with the patient shows engagement. If is absolutely necessary to use a computer, tell the patient that you are going to do so, but that you are still attending to him/her. For example, "Forgive me for turning away from you for just a moment. I am going to pull up your recent scans so that we can look at them together. However, I am still listening."	Hillen et al. 2015; Gilligan et al. 2017
Demonstrate respect, warmth, empathy, and interest	Smile! These simple gesture communications volumes about caring. Demonstrate respect through multiple behaviors, including treating patients as individuals, engaging them in conversations about their experiences and treatment decision-making, and making statements about what you admire about them. Respond with empathy when patients and their caregivers express emotions	"Hello, Mrs. Green (shaking hands, smiling warmly at patient, and making eye contact), it is so good to see you. How have you been doing? How was your grandson's wedding? I know you were really looking forward to it!"	Delgado-Guay et al. 2013; Gilligan et al. 2017; Hillen et al. 2015
Use active listening skills Active listening skills demonstrate to patients that providers are not only listening but actually *hearing* their patients. These skills are largely demonstrated through	Consider facial expressions, head nodding, and body language, asking open-ended questions, and listening to patients' responses to questions during interactions and what they convey	An example of summarizing what a patient has said through active listening. "What I hear you saying, Mr. Smith, is that urine leakage has been an especially troubling problem lately and you are wondering what might be done	Delgado-Guay et al. 2013; Gilligan et al. 2017

(*continued*)

Table 2 (continued)

Essential interpersonal skill/ method	Helpful tip/information	Example	Sources
nonverbal behaviors or gestures		to help improve your symptoms. Is that correct?"	
Assess goals, priorities, and values Engaging patients in conversations about their goals, priorities, and values assists in providing patient-centered care	Multiple conversations about goals and priorities are essential throughout treatment, especially when changes to the care plan are necessary or when therapy transitions from curative intent to end-of-life care	"As we begin to make treatment decisions, I always like to get a sense of what is important for each patient. For example, some patients are concerned about pain control and have that as a primary focus. Others are more concerned about length of life over quality of life. What would you say are your primary goals and priorities?. . .[after a patient has shared goals/priorities]. . . thank you for sharing those with me. I'm glad that we had this conversation. And just to let you know, I may bring this up at various points during your treatment to see if any of your goals/priorities have changed. Please feel free to bring it up with me too."	Balducci and Dolan 2016; Gilligan et al. 2017
Address psychosocial needs of patients and caregivers throughout course of treatment Depression, anxiety, and social support should be assessed throughout the treatment trajectory	Offer to refer patients and caregivers to psychosocial services in a nonjudgmental manner	At start of treatment: "Many patients experience a lot of different emotions and feelings after a cancer diagnosis. It is normal to feel a range of emotions including sadness or anxiety. We have a number of different and helpful services along the way, including counseling. Our team includes social workers, counselors, psychologists, psychiatrists, and members of the clergy. I am happy to refer you to services if you are interested." During treatment: "Coping with cancer is often rough. How have you been doing emotionally?"	Gilligan et al. 2017

Perrin 2017). Yet, many older adults report being less comfortable in using the internet compared to younger adults, having difficulties logging in, reading text on the screen, or understanding the numerous interfaces and levels of a website (Saied et al. 2014; Smith 2014; Price-Haywood et al. 2017). Further, many older adults compared to their younger counterparts report having less access to the internet and lower rates of daily internet use (Saied et al. 2014).

In the age of heightened technology, a number of strategies have been found to be effective in

Table 3 Techniques to facilitate effective communication

Technique	Helpful tip/information	Sources
Schedule adequate time with patients	This allows time to fully establish a relationship and to assess any unique learning needs. It allows patients to ask questions to promote an exchange of information and promotes shared understanding of important information, even when providing patients with extensive written information. It sets the stage for a warm empathic relationship	Puts et al. 2017
Consider the unique/ special needs of older cancer patients	Recognize and assess any patient unique needs that might affect communication needs/ preferences, such as hearing loss, visual impairment, or problems with cognition and memory. Provide cancer information using a variety of alternative formats, if needed. This might include visuals, teaching cards, or simple drawings. Engage family members of the patient's representative/support person	Loh et al. 2017; Mohile et al. 2011; National Eye Institute 2018; National Institute on Deafness and Other Communication Disorders 2017; Meade 2018; Edwards et al. 2018
Cognition	Having metastatic cancer, having a higher level of comorbidity, prior stroke, and taking warfarin have been associated with cognitive issues	
Vision	Vision impairment is common among older adults. In addition, rates are projected to rise in the coming years as the US population ages	
Hearing	Affecting about one in four individuals aged 65–74 and half of individuals 75 and older, significant or disabling hearing loss is common among older adults in the general population	
Promote information recall	Provide information is small chunks, pause, and assess patient and caregiver understanding It is essential for providers to consider that when receiving bad news, it may be especially difficult for patients and their caregivers to attend to, absorb, and retain information shared during the visit	Delgado-Guay et al. 2013; Gilligan et al. 2017
Incorporate teach-back method	After delivering health information, ask patients to summarize what was said in their own words. Then, either affirm what the patient said (if accurate) or edit/correct (if inaccurate) For example, say "I know that I just presented a lot of information about treatment for lung cancer. In your own words, can you tell me about the treatment options I shared?" When patients demonstrate misinformation or misconceptions, providers should respond tactfully and gently correct the patient or caregiver, without blaming or seeming condescending. For example, a provider might respond with a sentence starting "I may not have explained it well. Please let me try to explain it again." and then provide the information using different lay terminology	Badaczewski et al. 2017

promoting information recall among older cancer patients when using online information and adding illustrations such as graphs and icons as opposed to text only (Bol et al. 2015a). Also, online health information, for both younger and older cancer patients, has been found to be more beneficial when the information is provided in a conversational-style narration (Bol et al. 2015b). This may point to the promise of embodied conversational agents (ECAs) to supplement provider interactions (Bickmore et al. 2016). Also, the efficacy of remote symptom monitoring/reporting via technologies (e.g., tablets) may be helpful tools for oncology providers to monitor their cancer patients from home after surgery or treatment (Maguire et al. 2015; Maguire et al. 2017). Thus, questions about patients' preferred methods of learning, current internet access and usage, and whether they like using the internet and electronic tools to obtain information about their health, treatment, and care are especially helpful to ask during initial assessments.

Mobile Technologies

Regarding ownership of cell phones, many Americans (95%) own some type of a cell phone and can send and receive text messages (Pew Research Center 2018), thus, opening new doors for health communications. Since Pew's first survey of smartphone ownership in 2011, US rates have climbed to 77%, up from about 35% (Mobile Fact Sheet [Internet] 2018). While rates of cellphone and smartphone ownership among *older* US adults are lower than the national rates, they are steadily increasing. Indeed, 80% of US adults age 65 and older now own a cellphone and 42% own a smartphone (Anderson and Perrin 2017).

Likewise, smartphone ownership has climbed in many developing countries with a 37% increase in smartphone adoption since 2015 (up 21% since 2013) (Rainie and Perrin 2017). The use of text messaging and/or tablet-based education and/or telemedicine offers novel and promising ways to communicate health information, provide screening reminders, and/or report and manage symptoms, irrespective of distance, as examples. These approaches may be especially appealing to older adults in rural and geographically remote areas, particularly when patients are instructed in their usage. Yet, even in countries with advanced economies, a digital divide exists between more educated and less educated people as well as among the young and the old (Rainie and Perrin 2017). Thus, reducing the digital divide requires finding ways to improve greater access to reliable, easy-to-understand, and language-appropriate information and resources, as well as implementing telemedicine/telehealth systems that increase data integration and boost IT infrastructure among multiple health care systems.

Language and Health Literacy

Language

According to the 2011 American Community Survey conducted by the US Census Bureau, nearly 15% of individuals aged 60 years and older speak a language other than English at home (Ryan 2013). Among this group, less than half report speaking English "very well" (39% among primarily Spanish speakers and 45% among individuals who speak a language other than Spanish or English at home) (Ryan 2013). Furthermore, rates of English-speaking ability are associated with multiple sociodemographic factors, including race/ethnicity, foreign born status, education, socioeconomic status, and insurance status (Ryan 2013). As such, documentation of preferred language for communicating and reading are important aspects of patient intake forms.

Trained professional interpreters should be sought to facilitate high-quality and impartial communication and improve patient satisfaction as opposed to use of nonprofessional interpreters, including family members (especially children) and other staff members (Juckett and Unger 2014). In cases where professional interpretation services were not utilized for discussions with cancer patients with limited English proficiency at end-of-life, worse quality of communication about goals for care as well as end-of-life care

was reported (Silva et al. 2016). A plethora of reliable language-specific cancer educational resources are available from the American Cancer Society and the National Cancer Institute websites in various languages such as English, Spanish, Korean, Bengali, French, Haitian Creole, Hindi, Arabic, Portuguese, and Vietnamese, among others (American Cancer Society n.d, n.d; National Cancer Institute 2016).

Health Literacy

Health literacy is defined as "the degree to which individuals can obtain, process, and understand the basic health information and services they need to make appropriate health decisions" (Kindig et al. 2004). Health literacy skills are needed to help people find health information, engage in interactions, navigate the health system, understand screening and treatment options, interpret charts and tables, and decide what to do with the information. For example, using a map to find the location of the clinic, knowing the importance of cancer screenings and their frequency, reading a medication insert label and recognizing drug actions and interactions or understanding risks of a new experimental treatment (Kindig et al. 2004). Yet, too often, communications are steeped in difficult and unfamiliar terminology and words that are often "over the heads of many patients," and misaligned with patients' cultural backgrounds, beliefs, or views (Meade 2018). As such, the importance of **health literacy** cannot be understated.

A number of factors are associated with being at risk for low health literacy, including age, educational attainment, socioeconomic status, geographic location, and race/ethnicity. In particular, older individuals with lower educational attainment (less than high school), non-native speakers, and those with fewer financial resources are more likely to be at risk for limited health literacy (Kutner et al. 2006). However, it is important not to simply assume that individuals who fit these characteristics have low health literacy. Many individuals, who are educated, middle or of high socioeconomic status may also be at risk for low health literacy, once they "enter the culture of health care."

Patients with limited health literacy may find it difficult to sort and sift through the plethora of medical terminology commonly used in health care settings. As such, the topic has received considerable attention in the Healthy People (2020) imperative that relates the importance of health communications and health IT that advance effective health care and health equity, see http://www.healthypeople.gov/2020/topicsobjectives2020/ for more information. Moreover, with the growing emphasis and emerging role of precision medicine and personalized treatments in oncology, there are even more increasing demands on older adults to become engaged in complex conversations and decisions about their care. For example, patients might ask: *What are the benefits of my tissue to this study? What are the pro/cons of donating a sample of my tumor for research? What can I do to manage and cope with this debilitating fatigue that I have with my meds (*e.g.*, Tyrosine Kinase Inhibitors [TKIs])? What are the chances that this clinical trial will really extend my life?; What will my quality of life be like during and following radiation treatment? or How can I manage the pain associated with my metastatic breast cancer?* This calls for patient-centered communication that encourages older cancer patients to share their questions and information needs. Paasche-Orlow and Wolf (2007) suggest that health literacy be viewed as a "risk factor to be managed in clinical care."

Health Literacy Universal Precautions

Simplified language and clear communication with all patients as opposed to medical jargon is suggested to improve understanding, satisfaction, and positive health outcomes. This includes the use of plain language, that is, concise, well-organized, and direct ways to express an idea (General Services Administration). The Agency for Healthcare Quality and Research (AHRQ) coined the term *Health Literacy Universal Precautions*, whereby improving health literacy is *universal* for all patients regardless of their level of health literacy (AHRQ 2017). Thus, promoting understanding is not just for those who are at risk

for low health literacy but for *all* patients and their family members. Furthermore, numeracy is another important component of health literacy and involves skills that help patients make sense out of numbers, tables, graphs, and probabilities (Jacobs et al. 2016; Schapira et al. 2014). This aspect of literacy is also crucial in comprehending medication schedules, chemotherapy treatment regimens, food labels, genetic risks, and following the myriad aspects of clinical trials including randomization, probabilities of risk or treatment effects, etc.

Assessing Health Literacy

The literature identifies numerous ways to assess health literacy via word recognition lists, health literacy comprehension tools, or through informal methods (e.g., patient states they have low reading skills, or report that they do not like to read, or like having others read for them). One approach is to gauge health literacy through brief single item measures that can be incorporated into the patient's assessment intake form. For example, the single item literacy screener (SILS) asks "How often do you need to have someone help you when you read instructions, pamphlets, or other written material from your doctor or pharmacy?" with response options of 1-Never, 2-Rarely, 3-Sometimes, 4-Often, and 5-Always (Morris et al. 2006). Scores greater than 2 are considered positive, indicating some level of difficulty with reading printed health related material. For a comprehensive listing of available health literacy tools, go to the *Health Literacy Toolshed*, an online database of health literacy measures compiled by the National Library of Medicine (2015).

Deconstructing Information to Improve Communication

A key challenge in health care is to take very specialized, technical, and advanced knowledge and break it down into parcels of information that match older adult's specific and unique language, cognitive, physiological, and social needs, and learning preferences in ways that are understandable and that involve their social, caring network (Sparks and Nussbaum 2008). Striving for a health literacy mindset is essential in today's health care climate and involves deconstructing (or simply breaking down) complex information into manageable and relatable bytes. Regardless of a patient's educational level, most people want and need simple and clear information (Doak et al. 1996). For example, consider how to introduce patients and family members to the topic of precision medicine that requires donation of a biospecimen. This means explaining new concepts and words such as genomics, biospecimens, biobank, annotation, etc. It necessitates clear, patient friendly, and familiar language that aids comprehension, promotes receptivity of information for decision-making, and opens the door to better understanding about a new field of cancer. For example, when explaining the term "biospecimen," it might mean defining it as material from the human body, such as urine blood, spit, nail, or tissue from biopsies or surgeries. When discussing the term "biobank," the analogy of a library collection of books could be used to explain how biospecimens similarly are stored, logged, and catalogued (Meade et al. 2015).

Creating a Literacy Friendly Environment

Another consideration for improving communications for older cancer patients is creating a literacy friendly environment as "*first impressions make a difference*." This means taking time to assess common health care system's communication features such as the phone system, patient portal, webpages, and even ease of navigation of the cancer clinic and facility (e.g., signage). Every interaction has the potential to contribute to or detract from a patient's experience such as clarity in *menu prompts, easy-to-understand patient educational materials, consent forms in relevant languages, easily understandable signage to get to a clinic, and the friendliness of the staff.* For many older cancer patients, navigating the physical environment of a cancer center or clinic may be complex, time-consuming, and arduous, especially if they are not feeling well or have physical limitations. For example, *what does it take for a*

Table 4 REAL framework

Element	Description
Relatable	Communications are important and significant for patients – information resonates with their everyday lives and "worldview." It is highly relevant according to their beliefs, values, and background
Engaging	Communications are interesting and appealing. The messages "catch" their attention and patients are drawn to them
Actionable	Information is specific and points to an action, such as toward a decision or behavior or a task
Literacy-friendly	Communications are clear, straightforward, and easy-to-understand. They allow patients to assimilate the information and to do something with it

patient to park, register, provide information, get their blood work and other tests done, and then locate the clinic where they will see his/her provider? An excellent guide to assessing one's health care environment and implementing empowering patient strategies and organizational policies that support such a climate can be found at the following link: https://cdn1.sph.harvard.edu/wp content/uploads/sites/135/2012/09/healthliteracyenvironment.pdf (Rudd and Anderson 2006).

Effective communication is explicitly connected to health literacy and helps to promote positive, productive, and satisfying patient-provider interactions. To aid this mindset, the REAL framework is a helpful tool or mnemonic that serves as a constant reminder of the importance of effective communication. The utility lies in its simplicity – that is, often the best communications are those that are ***r**elatable, **e**ngaging, **a**ctionable, and **l**iteracy friendly* (See Table 4).

Special Topic: Role of Effective Communication in Clinical Trial Participation and Research

Clinical trials are now commonplace in oncology care and are essential for testing the safety and effectiveness of promising treatments. However, participation in therapeutic clinical trials is low with only 2–3% of cancer patients nationwide ever enrolling in a trial (Hamel et al. 2016; Mendelsohn 2010; Murthy et al. 2004; Stewart et al. 2007). Although 61% of new cancer cases occur among elderly, they comprise only 25% of the patients enrolled in randomized clinical trials (RCTs) (Mahipal et al. 2015). Underrepresentation in pivotal research limits generalizability, and in fact, may result in misleading conclusions about older adults including racial/ethnic minority populations, rural patients, and patients with low socioeconomic status (Roth et al. 2016; Stewart et al. 2007; Baquet et al. 2006, 2008; Baquet 2012; Vanderpool et al. 2011). Impediments to recruitment, enrollment, and retention of underrepresented populations (including the elderly) to cancer clinical trials, as well as innovative efforts to ameliorate such hindrances have been extensively documented (Hamel et al. 2016; Nipp et al. 2016; Trevino et al. 2013; Sohal et al. 2015; Fouad et al. 2016). Barriers to participation in clinical trials are complex and may be attributable to lack of provider recommendation to participate, patient's cultural beliefs and attitudes toward research, lack of knowledge about the importance of clinical or biomedical research to the health of the community, and/or insufficient and inappropriate consent process (Ford et al. 2008; Hamel et al. 2016), in addition to stringent protocol exclusion criteria that are driven by presence of comorbidities and preclude qualification especially among the elderly and racial-ethnic minorities.

As such, a persistent question has been the concern over frailty and potential poorer tolerance of chemotherapy among some elderly patients (Extermann 2012; Muffly et al. 2013; Extermann et al. 2017). Thus, the question whether older patients can safely undergo aggressive regimens has been investigated. A systematic review by Kumar et al. (2007) found that enrollment of elderly in experimental RCTs was not associated with increased harm to this patient population. Overall, results suggested that survival in one trial that exclusively enrolled elderly patients favored the newer treatments (hazard ratio [HR], 0.69; 95% CI, 0.47–1.02; $p = 0.06$). Similarly, in trials enrolling elderly participants at a rate of more than 40%, survival and event-free survival favored the innovative treatments (HR = 0.91;

95% CI, 0.84–0.99; $p = 0.03$; and HR = 0.85; 95% CI, 0.72–1.01; $p = 0.07$, respectively). Treatment-related mortality was similar in both the innovative and standard treatment groups. Thus, increased participation of the elderly remains an important ideal, and may help to find safe new treatments as well as identify ways to assess treatment tolerance and clinically applicable measures to support this cohort of patients (Kumar et al. 2007; Extermann 2012; Muffly et al. 2013; Extermann et al. 2017).

Although clinical trial participation continues to be an important and challenging topic for cancer patients, family members, clinicians, researchers, study sponsors/funding agencies, and policy makers, some studies have shown that racial-ethnic minorities enroll to treatment oncology clinical trials at comparable rates as Whites when they are provided access, are approached, and meet eligibility criteria (Tejeda et al. 1996; Wendler et al. 2005). Furthermore, there is evidence that older patients are comparably receptive to clinical trials (relative to younger patients less 65 years), enroll in trials when asked, and when they are eligible (Ayodele et al. 2016). Research in prostate cancer treatment decision-making suggests that 63% of patients preferred to take an active role in decision-making (and decide on their own after consulting their provider), 29% preferred a collaborative role with their provider, and 8% favored a passive role where the provider tells them what to do (Gwede et al. 2005; Diefenbach et al. 2002). Thus, clinician awareness of the varied communication and decision-making styles of cancer patients is important, and clinicians need to take extra time to make sure that patients ask questions, and involve family members in the decisions. Ultimately, the provider should be ready to accept the fact that patients' decisional support needs may vary widely, and that effective communication may be compromised if there is discordance.

By far the greatest challenge is how to adequately reach and provide access to all patients who could *potentially* benefit from participating in clinical and prevention research. A number of successful communication strategies have been proposed to address participation in oncology clinical trials through community oncology networks (Roth et al. 2016), multilevel approaches (Hamel et al. 2016; Eggly et al. 2017), and patient navigator programs (Durant et al. 2014; Fouad et al. 2016) to address barriers. Given the complexity of the problem of clinical trials participation among older cancer patients and among cancer patients overall, success depends on sustained long-term efforts at all levels (patient, family/social networks, providers, health systems, policy, and community). There needs to be heightened attention to new or emerging communication challenges and concerns for older cancer patients given the proliferation of new (adaptive) study designs in precision oncology trials (Sohal et al. 2015; Ondra et al. 2017; Liu et al. 2017). With the increasing complexity of contemporary clinical trial designs and emphasis on genomics, precision medicine, biospecimens, and biomarker-driven therapies, there are new or difficult questions facing multidisciplinary oncology clinical and research teams with regards to communications to older cancer patients and their families. Table 5 summarizes selected questions and perspectives that may present in the discussion of clinical trial participation in the context of genomic research and precision oncology care.

These and other related questions call for a variety of effective strategies as summarized in the preceding section. Future research also should continue to investigate whether there are subgroups of older cancer patients that require greater attention due to language, cultural factors, literacy, or other contextual influences. Interventions can then be tailored or targeted for these unique attributes to increase equitable participation in research and potential to add rich data in this era of precision medicine and patient-family centered care.

Summary

This chapter highlights the inherent and essential value of effective communication for promoting patient and family participation and engagement in their well-being, healing, and quality of life across the cancer care continuum. The

Table 5 Selected communication questions for older adults in oncology clinical trials and precision cancer care

Key points	Questions
Precision medicine helps to discover unique therapies that treat an individual's cancer based on the specific genetic make-up of their tumor Providers have a key role in helping patients and family members understand and deconstruct research and precision oncology care in ways that are clear and useful	• *Do older cancer patients understand the terms "precision/personalized medicine?"* • *What do older cancer patients think about the role of genomic information when cancer is not hereditary? Is the notion of cancer/tumor genes (*versus *germline genetics) a well-understood concept by older cancer patients?* • *Are there different communication styles or approaches needed with older adults, immigrant populations, or limited English proficiency individuals in this era of genomic research?* • *As new clinical trial designs are introduced, do older cancer patients understand the associated consent forms? For example, adaptive trials that call for breaks in treatment (when patient/disease is responding well) but the cancer is not eradicated; does the concept of adaptive personalized medicine resonate with older adults who may believe the traditional paradigm that all cancer must be eliminated?* • *Clinical, behavioral, or prevention trials involving biobanking of biospecimens are pivotal to advancing genomics research and precision cancer prevention/care.* • *Do older adults have privacy concerns with the approaches involved in the collection, storage, and future testing for the sake of advancing science (with no apparent personal benefit)?* • *What fears do older patients, especially racial/ethnic minorities, have about precision medicine and genomics research?* • *How can oncologists simplify communications on these topics with older adults, particularly with nontrusting patients?*

emergence of a changing multicultural demographic landscape coupled with an increase in the number of older cancer patients and the remarkable advances in cancer care and research and technology create multiple opportunities and teachable moments for improving communication with older cancer patients. At the individual level (patient-provider interactions), communications that foster trust, empathy, compassion and appreciation of differences and similarities in worldview (cultural origins and prevailing perspectives) are likely to produce effective understandings among patients. Use of plain language and teach-back approaches are critical tools in older adult oncology settings. As the proportion of older patients treated on a clinical trial increases, and as genomic precision medicine becomes mainstream, greater use of these effective communication strategies is needed. Oncology practitioners thus must embrace "Universal Health Literacy Precautions" and routinely employ available consensus communication guidances with each of their older cancer patients. The hope is that patients and their families can find value and compassion in the information exchanged between them and their oncology providers and can have a meaningful quality of life that most matters to them during all aspects of their cancer journey.

The Older Cancer Patient: Religious and Spiritual Dimensions

62

Lodovico Balducci

Contents

Abstract

The goals of care are based on the values of each individual: setting the goals of care is a spiritual endeavor. Accordingly, this chapter examines the definition of religion and spirituality, the influence of religion and spirituality on the management of the older person, and the clinical assessment of religion and spirituality.

L. Balducci (✉)

In general religion and spirituality have been associated with better tolerance of chronic diseases and more satisfactory caregiving experience in patients with chronic diseases and their families, and all providers need to recognize that medical emergency that is referred to as spiritual distress can be properly managed by a chaplain. Spiritual distress is a cause of poor quality of life and may lead to treatment failure from desperation and lack of motivation.

Religion and spirituality may play a specially important role in the management of older cancer patient as with aging there is an increased interest in the meaning of life and in spiritual

accomplishments (gerotranscendence). Each person should have adequate evaluation of spiritual and religious resources, and the practitioner should be experienced in utilizing these resources appropriately to improve a patient outcome and to support the patient's quality of life.

Introduction

Setting the goals of care is the first step in the management of serious and incurable diseases (Magnuson et al. 2016; Temel et al. 2016). The goals of care are based on patient's immediate preferences and long-term aspirations related to the treatment (Justin 1987). Preference and aspirations are influenced by each person's spiritual and religious beliefs, that is, by his/her values. A value history is thus implicit to some extent when setting the goals of care. This process is particularly important for the older cancer patients. When the benefits of treatment are reduced and the risks increased, the preservation of meaningful quality of life may become the primary purpose of all medical interventions (Vallet-Regi et al. 2017)

Whether they are explicitly declared or are implicit in a person's behavior and plans, values represent the transcendence of human life, as they provide the frame of reference that allows to judge if life is worth living in each beholder's eye (PDQ Supportive and palliative care editorial board 2016; Koenig 2015). Thus, the delivery of personalized care requires a spiritual connection of patient and provider, which may involve a discovery of the meaning of the disease, of pain and suffering, and of death. There is almost universal agreement in all cultures that this connection is beneficial at multiple levels (PDQ Supportive and palliative care editorial board 2016; Koenig 2015; Memaryan et al. 2016; Gielen et al. 2017; Sherman et al. 2015a; Jim et al. 2015). It may improve adherence to treatment and treatment outcome in addition to patient satisfaction and quality of life. Indeed, suffering and imminent death may represent a healing experience for patients with terminal cancer and their caregivers.

A threefold challenge to personalized care is present nowadays. The first is globalization and the consequent cultural diversity. In the days of old communities were stable over time. Medical care was provided in the same village or in the same neighborhood, and patients and providers might have worshiped in the same church and shared the same values, which were implicit in each encounter. This is rarely the case today, and providers need to be aware that the patients' values and beliefs may be quite different from and even at odds with their owns, and personalized care entails understanding, acceptance and respect of this diversity (Balducci et al. 2017). The second is the fragmentation of medicine into multiple specialties and subspecialties. The scarcity of primary care physicians, whose role is becoming every day more nebulous and whose professional time every day more taxed, and the intervention and interaction of different providers in the management of the same patient may prevent the development of an ongoing relation of trust necessary to negotiate a value-based plan of care (Kuluski et al. 2013; Kocher and Chigurupati 2016). For older individuals used to rely on the advice of a single provider, this change has been particularly disorienting and disconcerting. The third challenge is the mounting use of technology in medical practice. The universal adoption of electronic health records has reduced the face-to-face time for patients and providers (DeRoches et al. 2008). As important, increasing reliance on precision medicine, practice guidelines, and clinical pathways have changed the perception of and the expectation from the provider. Rightly or wrongly, patients are seeing the physician more as a technologist of the human body than as an authoritative and trustworthy counselor.

In this chapter we plan to provide a blueprint for the assessment and management of spiritual needs of older cancer patients. Based on a review of the literature and our personal experience, we assume these needs have become more widespread and unfulfilled in the current medical reality. We also hold that catering to the spiritual needs is essential to healing (Silbermann et al.

2010; Balducci 2012), the ultimate goal of care. Healing refers to the personal experience of the disease and may be achieved in all circumstances, even and mostly when cure is out of reach.

After an overview of the construct and assessment of spirituality, we will explore the role of the practitioner of oncology in addressing the spiritual wants of older cancer patients.

Religion, Spirituality, and Health Care

After trying to define religion and spirituality, we will briefly review the impact of these exquisitely human domains on health preservation and health-care delivery.

Definitions

While an operational definition is wanted, there is general agreement that religion and spirituality are different albeit interrelated dimensions (PDQ Supportive and palliative care editorial board 2016; Koenig 2015). Religion involves the belief in a transcendent power and a number of behaviors, including prayer, meditation, rituals, and social interactions, which allow a person to establish a relation with and become close to this supreme power. This relation may be multifaceted and include worship, petition, and even expressions of love, anger, and disappointment. Communal celebrations are typical, but not necessary expression nor are they exclusive of a religion. Many individuals may profess a belief in a god without being part of any defined "community of faith." A religious community may represent an important support for a patient, especially an older one with limited social resources. It has been recommended that the presence of such community be investigated as part of the medical history (Puchalski 2012).

Spirituality is a relation with transcendence that may be found without and within oneself, which may or may not take the aspect and the name of a deity. The relation with transcendence involves the affirmation of the sacred (from the Latin "*sacer*" that means hallowed, reserved to a special and unique use). For example, in a monogamous relation, the partners sacrifice, that is, they make sacred, their sex to each other. Any violation of this commitment compromises the "sacredness" of the relation and ultimately may destroy its transcendent, spiritual aspect.

Recent studies have found some correlation between religiosity and spirituality and neuroanatomy. They are controversial and are mentioned to allow the reader to follow this new field of investigations. Some authors demonstrated that individuals prone to depression have a thinner cortical cortex at the brain MRI, and religious and spiritual individuals had a thicker than normal cortex (Miller et al. 2014). Following a number of transversal studies suggesting that circulating levels of oxytocin were associated with increased religious and spiritual involvement (Erdman 2016), a randomized placebo-controlled study of middle-aged adults was conducted (Van Cappellen et al. 2016). Individuals receiving intranasal oxytocin showed increased engagement in meditation, prayer, and church attendance (Van Cappellen et al. 2016).

Assessment

Some of the difficulties of assessing the spiritual domain of care are immediately apparent. To start with the theology of different religions may be quite different from and sometimes at odds with each other. For example, the three Western monotheistic religions (Judaism, Christianity, and Islam) teach some form of social justice, based on the assumption that all believers (and in some cases all human beings) have the same value in front of God. The requirement of social justice is conspicuously absent in some of the Eastern religions. The supreme aspiration of Western religions is some type of union with the deity after death, whereas for Hinduism it is the Karma, that is, the final release from the cycle of reincarnation, and for Buddhism it is the Nirvana, a peace founded on the absence of passions. Each main religion is subdivided into different denominations, with different specific beliefs, that have been the causes of many religious wars, some of which persists in our times. Within each religious

persuasion, the expression of spirituality may take different manifestations. For example, Roman Catholicism encompasses the contemplative spirituality of hermits and the active spirituality of missionaries. Second, the assessment parameters are particularly fluids. For example, church attendance, participation in the communal religious activities, and even adherence to a moral code of conduct, such as the ten commandments, may represent an inadequate estimate of a person religiosity and spirituality (Jack et al. 2016; Delkeskamp-Hayes 2005). Despite these difficulties, a number of instruments for assessing religiosity and spirituality produce consistent and reliable results, as long as spirituality is distinguished from humanism, morality, and mental welfare and maintains the relation to transcendence affirmed through the sacred (Koenig 2008) as specific characteristic.

A review of the instruments utilized to assess religiosity and spirituality is beyond the scope of this article, and the reader is referred to recent reviews (PDQ Supportive and palliative care editorial board 2016). Suffice it to say that most of them have been employed exclusively for research purposes, that they may involve quantitative as well as qualitative approaches, and that some of them emphasize participation in religious activities, while others are more focused on spirituality. One of these instruments, the FICA (Puchalski 2012) (an acronym for Faith, Importance, Community, Assessment), has been adopted by many practitioners in the initial assessment of patients, because it is simple and brief and provides information of immediate relevance to patient management, such as the presence of a support community.

The studies of the interactions of religion and spirituality with health maintenance and outcome may essentially be divided into five groups (Koenig 2015):

- Epidemiological studies that correlated the belonging to and attendance of a church/religious community, and outcome
- Studies involving an assessment of personal religiosity and spirituality through standardized instruments and outcome
- Studies of the influence of specific religious and spiritual practices, such as prayer and meditation on personal well-being
- Studies of the feasibility and effectiveness of a religious/spiritual intervention
- Studies of the influence of the disease on religious and spiritual growth and development

Effects of Religion and Spirituality on Health

Table 1 summarizes the various health dimensions that may be influenced by religion and spirituality according to a recent systematic review (Koenig 2015). For what concerns the mental health, the majority of studies indicated that religion and spirituality were helpful to deal with a gamut of

Table 1 Dimensions of health that may be influenced by religion and spirituality

adversities including cancer, other serious diseases, and end-of-life situations. Likewise, the promotion of beliefs that foster hope, optimism, meaning, and purposes and that foster positive character traits, such as forgiveness, gratefulness, and kindness/compassion was found generally beneficial and devoid of adverse effects. More variable were the results related to well-being and happiness, self-esteem, sense of control, and altruism, but the majority of studies found a positive rather than a negative relationship between religion and spirituality and each of these domains. These findings should dispel the common worry that religion may lower one's sense of self-esteem, by promoting guilt or self-deprecation. Religiosity and spirituality had minimal effects on depression, except for one study that deserves mention (Miller et al. 2012). The authors followed for 10 years the adult offspring of depressed patients and found that the risk of depression was decreased by 90% for individuals for whom religion and spirituality had high importance. Spiritual interventions appeared to reduce prevalence and severity of anxiety, and in the majority of the investigations, religion and spirituality had a positive effect on risk of suicide and of substance abuse. The results related to bipolar and psychotic disorders were inconclusive. Religiosity and spirituality by and large promote positive personality traits, including extroversion, consciousness and openness to new experiences, and agreeableness, and disfavor the negative ones, such as psychoticism and neuroticism. Religion and spirituality promoted social stability in the majority of cases, by disfavoring criminality and divorce and supporting caregiving and social involvement.

Religion and spirituality supported healthy behaviors including exercise and healthy diet and discouraging cigarette smoking and risky sex.

Of 121 prospective studies, 82 (76%) reported a positive relation between religiosity/spirituality and longevity, and none of the 17 studies of highest quality indicated a negative relationship. Three systematic reviews of the existent literature demonstrated that religiosity and spirituality were associated with a 37% decline in mortality. It is difficult to disregard these results as statistical flukes, and it is reasonable to conclude that spiritual health is associated with a better and longer life. This conclusion is consistent with the fact that religion and spirituality promote healthier lifestyles, may improve the immune defenses, modulate cardiovascular reactivity to stress (Bertson et al. 2008), and suppress the inflammatory status that is a hallmark of aging (Robins et al. 2016). In addition, religion and spirituality were associated with decreased prevalence and improved outcome of chronic diseases, such as cardiovascular diseases, cancer, and cerebrovascular diseases, and might have slowed cognitive decline in older individuals.

Religion, Spirituality, and Cancer

Three recent meta-analyses have examined the influence of religion and spirituality on physical (Jim et al. 2015), mental (Salsman et al. 2015), and social (Sherman et al. 2015b) health of cancer patients.

These reviews recognized three religious/spiritual domains: affective, cognitive, and behavioral. In addition they included an "other" category that comprised studies in which these domains could not be clearly determined. The affective dimension concerned religion/spirituality as a source of spiritual well-being and spiritual distress. The behavioral one included actions and conducts pertinent to religion and spirituality, such as church attendance, prayer, meditation, and acceptance of and adherence to a moral code. The cognitive domain encompassed individual beliefs such as attributes of the deity, religious fatalism, and opportunity for spiritual growth.

These studies found that

- Overall religiosity and spirituality bore a significant association to physical and functional well-being and to physical symptoms. In particular spiritual well-being was associated with improved and spiritual distress with poorer physical health. Likewise, belief in the opportunity for spiritual growth led to a better physical health (Jim et al. 2015).
- Overall religiosity and spirituality and their affective and cognitive components were significantly associated with all domains of mental well-being, including emotional well-being,

general distress, depression, and cancer-related distress (Salsman et al. 2015).
- Overall, religion and spirituality were significantly correlated with social well-being, social distress, and social support (Sherman et al. 2015b) in social roles, relationships, activities, and perceived quality of this involvement.
- While religion and spirituality seemed to have altogether a positive effect on physical , mental, and social health, spiritual distress was a cause of deteriorating health and may even have led to poorer disease outcome through depression, decreased treatment adherence, and impaired social support. Recognition and management of spiritual distress may represent an important intervention that in some cases may be lifesaving. Common causes of spiritual distress included grief, loss of faith, loss of meaning, feelings of having been abandoned by god, having disappointed god through sin, or being unable to offer an effective and meaningful prayer, to have lost the relation with the deity. The studies of the relationship between religion, spirituality, and cancer outcome are inconclusive (Salaman et al. 2015). It has been proposed that a meta-analysis of the issue as well as defined taxonomy of religion and spirituality assessing the affective, behavioral, and cognitive domain may throw some light on the issue. At present we can assume that religion and spirituality by and large may have a positive effect on the physical function and the quality of life of cancer patients (PDQ Supportive and palliative care editorial board 2016) though in some circumstances they may cause distress, which should be timely recognized and managed. At present it is not clear whether this improvement in quality of life and physical function purports improved outcome nor whether interventions to foster spirituality in cancer patients are beneficial in terms of survival.

Some important practical messages emerged from this review:

- Religion and spirituality are important dimensions in the life of many cancer patients and do influence their quality of life.
- Religion and spirituality may provide important resources in the management of cancer patients, and practitioners should be attuned to assess and exploit them. In particular a discussion of these issues may make patient-physician communication more effective, may improve patient's trust, foster adherence to treatment, and improve the function, the mental health, the social health, and the quality of life of the patients.
- Religion and spirituality may be a source of distress that may compromise quality of life, cause depression, and diminish the motivation to receive any form of care, prevent healing, and ultimately worsen treatment outcome. As part of good health-care delivery, it behooves the practitioner to recognize and investigate the signs of spiritual emergencies.(Puchalski et al. 2009)
- In all cases the physician should make room for and endorse the religiosity and spirituality of each patient. When a specific intervention is needed, beyond the practitioner area of expertise, such as to help the patient overcome a sense of guilt that saps all attempts to provide care or to convince the patient to receive medical treatment if he/she refuses this treatment for religious reasons, the practitioner may refer the patient to the clinical chaplain. Clinical pastoral training enables chaplains to minister to patients of all religious backgrounds and also others such as humanists, agnostics, and atheists and to address the spiritual concerns of individuals without religious beliefs (Mclean 2015).

Religion, Spirituality, Aging, and Cancer

Aging is Dynamic

The life expectancy in the western world is progressively increasing (Walter and Schonberg 2014), in a world in which cultural and technological changes are increasingly more rapid. Seemingly, the religious and spiritual interests of

the baby boomers, who have grown in an increasingly secular and culturally diverse world, may be quite different from those of the previous generation, the current octogenarians, and nonagenarians. In this section we will review the influence of aging on religion and spirituality and the influence of religion and spirituality on older cancer patients and on their caregivers, recognizing that this is a work in progress, affected by rapid cultural changes, not unlike any other areas of medicine. Also, the data we have are based on selected populations and may not be generalizable.

Religion, Spirituality, and Aging

We will examine the influence of religion and spirituality on successful aging , coping with diseases, and disease outcome.

The concept of successful aging has been debated for at least 30 years, since it became clear that the prolongation of survival should have been associated with preservation of independency, function, and quality of life (Freedman and Spillman 2016). Originally, successful aging had been constructed mainly in medical and functional terms (Freedman and Spillman 2016; Edlund 2014). In the last few years, it was realized that a sense of meaning and accomplishment provides the majority of older individuals with a feeling of self-worthiness necessary to endure all age-related losses and to motivate them to remain active and productive (Carver and Buchanan 2016; Trivedi et al. 2016). The assurance that a person may always provide a unique contribution to the society irrespective of age, disease, and disability is essential to the self-esteem of older patients with chronic diseases. A recent systematic review of the literature (Carver and Buchanan 2016) identifies a number of domains outside the medical and physical ones, associated with "successful aging." These included engaging, resilience, optimism and positive attitude, religiosity and spirituality, self-efficacy and self-esteem, and gerotranscendence. Interestingly, religiosity and spirituality were positively correlated with the presence of all elements of successful aging, suggesting that they may represent the fount of successful aging, at least for some individuals. In the meantime, some older persons felt that they had aged successfully even in the absence of religiosity and spirituality. Religiosity and spirituality appear as an important, but not exclusive source of successful aging. Of special interest is the positive interaction of religion/spirituality and resilience, an essential skill to adapt to the unavoidable losses of aging in the medical, functional, emotional, and social domains. This positive interaction has been reported in multiple studies.

The concept of gerotranscendence is germane to this chapter (Tornstam 2005). It implies that aging is associated with a mounting search for meaning that may be found in organized or informal religion, in spiritual practices, in relations, and in humanistic endeavors. Clearly religion and spirituality represent one of the available and time-honored responses to this search. With the aging of the population, a number of fascinating research questions emerge from this construct: Is gerotranscendence a universal event or is it limited to a generation of individuals dwelling in a Western world with a Judeo Christian background? Is the development of gerotranscendence consistent and progressive over time?

Religion/Spirituality, Diseases, and Aging

We have already established how religion and spirituality may be associated with decreased mortality rate, decreased incidence and prevalence of chronic diseases, and improved ability to cope with these diseases. As the risk of chronic diseases increases with age, these data pertain mainly to the older population. Likewise we have reported how religion and spirituality are associated with a decreased risk of suicide, a common cause of death for the aged (Waem et al. 2003).

A number of studies examined the influence of religion and spirituality on depression (Johnstone et al. 2012; Unterrainer et al. 2014; Lac et al. 2017;

Sachdeva et al. 2015), cognitive decline (Sachdeva et al. 2015), coping with the diagnosis of HIV infection in older individuals (Dolittle et al. 2016; Vance et al. 2011), and adaptation of lesbians, gays, bisexuals, and transgender to aging (Orel 2014; Kim et al. 2017; Erosheva et al. 2016; Griebling 2016). Though not directly related to cancer, each of these conditions may complicate the management of cancer in older individuals.

There is universal agreement that religion and spirituality are associated with decreased incidence and severity and better tolerance of depression. This finding is extremely important as depression may compromise the adherence to and the effectiveness of cancer treatment and may also delay or prevent palliative care. The relation of religion/spirituality with cognitive decline is controversial, but the majority of studies indicate that they may be associated with a delay and improved acceptance of cognitive decline. With the aging of the population and the improved treatment of HIV infection, many patients who have contracted the infection when younger survive into an advanced age. In addition the risks of spreading HIV and other sexually transmitted diseases to older individuals are increased due to a number of factors. Thanks to improved health maintenance and sexual rehabilitation, the sexual activity of the population has become more prolonged. Many older individuals are single as they have lost a lifetime partner through death or divorce and may engage in sex with different partners, especially those living in retirement communities where the incidence of sexually transmitted diseases is particularly high (Minichiello et al. 2011). Religion and spirituality appears to be an important resource to face the real or supposed stigma related to HIV, to comply with HIV treatment, and to avoid risky sexual behavior after the diagnosis. Aging gays and lesbians may face particular challenges. Even if homosexuality is becoming more socially accepted, the stigma related to this sexual preference persists, especially in small and closed communities. In addition, these individuals may want the availability of an extended family including children and grandchildren that provide an informal network of social support. Hopefully, the ratification of gay marriage may prevent in the future this social isolation in old age. Religion and spirituality are associated with improved acceptance of this solitude. In addition, organized religion may provide much needed social support, as Christian and Jewish communities have begun to offer ministries to and support group for sexual minorities.

While most studies revealed a positive effect of religion and spirituality in these areas of aging, it is important to remember that they may also be associated with unwanted consequences. For example, guilt may enhance depression and discourage HIV-infected or homosexual individuals from seeking treatment. Some of them may feel that cancer is the right punishment of their sinful behavior or may be ashamed to reveal a condition condemned by most religious persuasions. Homosexuality is still unacceptable in many Christians and Jewish communities and in virtually all Islamic communities. A blank recommendation to join a church is unwise; rather it is important to help patients to find the religious community and the spiritual practices more congruent with their conditions.

Religion Spirituality, Aging, and Cancer

Older cancer patients may face some challenges related to their age (Vallet-Regi et al. 2017). Aging involves progressive reduction in the functional reserve of multiple organs and systems, increased prevalence of comorbidity, and in many cases, reduced social and economic resources. As a consequence the complications of most cancer treatments and especially of cytotoxic chemotherapy are more common and severe in the aged. Treatment may even be more costly as it involves the utilization of expensive antidotes to treatment toxicity, such as the use of hematopoietic growth factors or more prolong hospitalization after surgery (Vallet-Regi et al. 2017).

Emotionally, aging may involve depression and fatalism. It is not uncommon for older individuals to avoid cancer screening or to delay clinical investigations of new symptoms such as pain or constipation, which are considered,

erroneously, as expected manifestations of normal aging (Balducci 2016). Consequently, the majority of cancers are diagnosed at a more advanced stage in older than in younger persons. Likewise older individuals may delay cancer treatment due to the convictions that this treatment is more toxic than beneficial, has minimal effects on survival, and may compromise quality of life and functional independence. These beliefs may be reinforced by acquaintances and even by health-care providers with limited knowledge of new advances in cancer treatment. Diagnostic and treatment delays are commonplace for elderly without independent transportation who have to impose on younger family members or pay a hired driver to reach the clinics. Economic considerations may also play a role, as modern treatments are more and more expensive and cancer is a more and more common cause of "financial toxicity" that may lead to bankruptcy (Huntington 2016). Even when the insurance pays all direct medical-related costs (which is rarely the case), the indirect and medically unrelated costs may be substantial for older individuals. Last but not the least, older individuals may have more difficulties to understand the rationale and the mechanics of cancer treatment due to cognitive decline as well as to hearing and visual impairments. These different unfavorable elements are woven to each other like the threads of a carpet design. The complexity of treatment-related decisions may be overwhelming for the older patients and their families (Vallet-Regi et al. 2017).

A limited number of studies focused on older cancer patients have demonstrated that spiritual and religious beliefs allow a more realistic appreciation of the benefits and risks of cancer treatment and acceptance of the disease and its outcome and may increase the motivation to receive treatment (Caplan et al. 2014; Ripamonti et al. 2016). All in all religion and spirituality may provide a peace of mind that allows older individuals to choose the course of action more appropriate with their personal circumstances and more congruent with their personal values. In addition a religious community may represent a critical source of emotional and social support for older cancer patients and their caregivers.

Religion, Spirituality, and the Caregiver of the Older Cancer Patient

The home caregiver is essential for the successful treatment of older individuals, including those that at the beginning are fully independent, as the treatment itself may cause functional deterioration and mandate the intervention of the caregiver. The caregiver has multiple roles (Rodyhouse and Wilson 2017; Penson et al. 2000; Kurtz et al. 2004; Haley 2003; Mittnick et al. 2010) that include providing emotional as well as physical and social support (taking the patient to the clinics, helping the patient negotiate the most appropriate course of action with the health-care provider, responding timely to medical emergencies, assuring the patient general welfare, especially nutrition and hygiene, and fostering adherence to treatment). In addition when many different members are involved, the caregiver may assuage unavoidable conflicts and disagreements and may act as the family spokesperson. Indeed the caregiver is the practitioner's most powerful ally, and it behooves the practitioner to promote the caregiver well-beings. The management of older patients involves the management of the caregiver in the majority of cases (Mittnick et al. 2010).

The data concerning the health of the caregivers of older cancer patients is limited (Lai et al. 2017), but it is reasonable to use the data concerning the caregivers of patients with other chronic diseases and in particular dementia. We know that the complications of caregiving include increased mortality, increased incidence and severity of depression, increased prevalence of comorbidity, as well as disruption of social and personal relationships. Marriages and other intimate relationships may be compromised and even destroyed as a result of caregiving.

A recent systematic review (Gijsberts et al. 2011) showed that religion and spirituality are helpful to preserve the caregiver's mental and physical health, and indeed organized religion appeared associated with improved survival and decreased risk of complications. A religious/spiritual perspective provided the caregiver with a meaning for her/his sacrifice in taking care of an

older relative, reinforced her/his motivations, and prevented depression and discouragement. Being part of a religious community might have had at least two positive effects: community volunteers were available to give respite to the caregiver and relieve the burden of caregiving. Also the religious community afforded much needed positive reinforcement, by praising the caregiving effort and acknowledging its important and unique role in promoting the cause of humanity. Perhaps the major cause of caregiver frustration is indeed lack of support, respect, and acknowledgment in a secular culture that pays lip service to the sacredness of human life and considers the sick and the disabled as disposable and as an economic burden. Subsequent studies confirmed these finding (Yoon et al. 2016; Kim et al. 2015).

Spiritual and Religious Interventions

Even in the absence of clinical studies, some common sense directions may be derived from this brief reviews:

- Religion and spirituality play an important role in the welfare of many patients with serious and terminal diseases and especially of older cancer patients. It behooves all practitioners dealing with these diseases to become familiar with the patient beliefs, values, and aspirations and to include these beliefs in the individualized plans of care. We recommend the adoption of the FICA in the initial assessment of each patient. This simple instrument that can be executed in few minutes provides information as to the patient beliefs and as to the availability of a religious or other spiritual community such as church, temple, or mosque or family, friends, yoga group, or other support group able to provide spiritual, emotional, and social support.
- Practitioners should be able to differentiate spiritual emergencies from the medical and the emotional ones and to provide proper support or to involve the proper specialist in the management of these conditions. The proper specialist is generally the hospital chaplain. In some case it may be the religious leader of the patient religious community or a trusted friend or family member.
- The extent to which a practitioner may intervene in the religious/spiritual aspects of a patient life is variable and depends in part on the degree of comfort the petitioner has with his/her own spirituality. Under no circumstances, the practitioner should try to use professional authority for proselytism or for disdaining or belittling a patient's beliefs. At the meantime he/she should be able to address a patient's question with religious implications. For example, a practitioner should investigate further common patient's statements such as "I will do what God wants me to do." Whether a practitioner should oblige a patient's request to pray with her/him is a matter of personal choice. In any case the focus of the practitioner should be on the patient's and not on her/his own beliefs.
- The management of older cancer patients may involve the management of the caregiver as well. It behooves the practitioner to identify and exploit the spiritual and religious resources available to the caregiver.

Conclusions and Perspectives

Undoubtedly religion and spirituality play an important role in the management of many patients with chronic and terminal diseases such as cancer. In the same time, they may be a cause of spiritual distress compromising the patient's quality of life and the adherence to and the effectiveness of treatment. Consequently, as part of personalized care, the practitioner needs to assess whether these domains pertain to the patient or whether they may represent a source of support or of distress and to intervene accordingly. As the management of older cancer patients implies the management of the caregiver, this assessment should extend to the caregiver as well. While some people may consider this assessment as intrusive and violating of the patient's privacy, all studies available show that the opposite is the case. Most patients with cancer and other chronic

diseases welcome this inquiry, confirming the statement of the Italian novelist, essayist, and movie director Pier Paolo Pasolini: "the most important answers concern the question that one does not care to ask!"

The mechanic of this assessment depends on the working environment, but it will always entail a team work. For example, the FICA may be executed by a nurse or a social worker, the social worker should be aware of the available religious and spiritual resources, and a chaplain should be at hand to intervene.

A number of important and urgent research questions emerge from this brief review:

- How do specific beliefs influence the quality of life and the well-being of older cancer patients? In particular is the belief in forgiveness and in love as agape instrumental to peace of mind? Is the emphasis on family duties as is emphasized by Islam and conservative Jewish community important?
- Can we try an objective assessment of spirituality, based on beliefs, practices, and behavior, instead of personal statements? Qualitative research and especially content and language analysis may be instrumental to address this question.
- Is gerotranscendence a cultural or a universal phenomenon?
- Can we identify biological correlates to religion and spirituality that may pertain to aging?

Exploring these and other related questions may involve different research methods, questionnaires, patient interview, biological assays, but mainly it requires a team of individuals committed to promote physical health as a component of total health, convinced that healing is always possible even when cure is not achievable.

Abstract

Despite an increase in the number of studies, there is still a lack of evidence-based medicine for older cancer patients, especially for the nonfit and oldest (80 years and over) cancer patients. Randomized controlled trials (RCTs) are still the gold standard in medicine to assess treatment effectiveness and are considered to be the most robust study design to assess treatment effects. Although RCTs are difficult to perform in older cancer patients, it is important to continue work on developing and using alternative designs. Still, some comparative effectiveness questions cannot be answered by existing RCTs, nor they will be studied in future RCTs because of ethical, financial, or other constraints. Observational studies could be an alternative source of data to compare treatment effectiveness in these questions. However, one of the major challenges in observational data is confounders that affect the outcome of the study and differ in proportion between the two treatment groups; effective methods to control for this confounding are essential in nonrandomized studies. A number of strategies including propensity scores and matching are used to control for measured confounders in observational research; however, control for unmeasured confounders presents a greater challenge; the instrumental variable method might provide a better estimate for treatment effectiveness, providing that certain assumptions are not violated.

Introduction

The number of published geriatric oncology papers has increased in the last years, although the proportion remains low as part of all published oncology papers. Most of the papers concern data from observational studies, usually retrospective data analyses, but there are a few prospective (randomized controlled) trials in older patients. Despite an increase in studies, there is still a lack of evidence-based medicine for older cancer patients, especially for the frail or oldest (80 years and over) cancer patients. This limited evidence from randomized controlled trials (RCT) complicates the development of guidelines for the treatment of older patients. This is further complicated by the fact that the population of older cancer patients is characterized by a large individual variation in physical and mental conditions due to differences in comorbidities, functional status, geriatric syndromes, and socioeconomic aspects resulting in decreased physical reserve and a strong influence of personal preferences in the decision-making process (Bastiaannet et al. 2010; Louwman et al. 2007; Bouchardy et al. 2007; Decoster et al. 2015). In addition, cancer and its treatment may further decrease this physical reserve (Decoster et al. 2015). Observational studies usually show that older patients have a worse survival and receive less aggressive treatment than their younger counterparts. Both overtreatment and undertreatment of the older cancer patients could influence the survival of this heterogeneous group of patients. The use of a geriatric assessment in older cancer patients may identify health and functional problems; besides, some studies have shown that several domains from the geriatric assessment are associated with the outcome (Wildiers et al. 2014; Puts et al. 2012; Decoster et al. 2015).

One of the central aims of medical research is to estimate the effectiveness of one treatment versus another in certain patient groups. RCTs are still the gold standard in medicine to assess treatment effectiveness and are considered to be the most robust study design to assess treatment effects. New drugs also need to be assessed in the older cancer patients as specific adverse effects might occur that could change the ratio of toxicity versus benefit (Wildiers et al. 2013). Aging is a highly individualized process that results in changes in organ function, which could affect the pharmacokinetics of anticancer drugs and may alter the drug metabolism and treatment tolerability (Wildiers et al. 2013; Wildiers et al. 2003). Pharmacokinetic studies are therefore needed specifically for older cancer patients to study these aspects. In general, clinical trials should be including patients from the entire age range of the cancer population; however, the heterogeneity of the older population generally does not allow this (Wildiers et al. 2013). Specific trials for subgroups of older patients are therefore needed, with appropriate control arms depending on the setting (Wildiers et al. 2013). As an alternative, to capture older patients who are not included, large observational studies in the nonfit older population should be considered, preferably linked to randomized trials (Wildiers et al. 2013).

Some important effectiveness questions in geriatric oncology concern comparing no treatment with treatment (Wildiers et al. 2013) However, several challenges can exist with this RCT design. First, patient participation in a trial of treatment versus no treatment is generally more difficult than participation in a trial of treatment A versus B (as the impact of random assignment is larger), and selection bias and crossover can occur (Wildiers et al. 2013). Another aspect is that funding is more difficult to obtain for these kind of studies as there is generally no benefit for the industry (Wildiers et al. 2013). Although RCTs are difficult to perform in older cancer patients, it is still important to continue work on developing and using alternative designs, especially for the nonfit and oldest elderly (Wildiers et al. 2013).

Still, some comparative effectiveness questions cannot be answered by existing RCTs, nor

will they be studied in future RCTs because of ethical, financial, or other constraints (Baiocchi et al. 2014). Observational studies could be an alternative source of data in these questions to compare treatment effectiveness (Baiocchi et al. 2014). However, one of the major challenges in observational data is confounders, defined as variables (known pre-treatment) that affect the outcome of the study and differ in proportion between the two treatment groups; effective methods to control this confounding are essential in nonrandomized studies (Baiocchi et al. 2014; Greenland 2000). A number of strategies including propensity scores and matching are used to control for measured confounders in observational research; however, control for unmeasured confounders presents a greater challenge (Baiocchi et al. 2014;D'Agostino 1998).

This chapter discusses the problems with RCTs and extrapolation of study results to the older cancer population, the lack of new RCTs in geriatric oncology, outcome measurements, and challenges in observational research, as well as potential use of observational data in geriatric oncology.

Data from Randomized Controlled Trials

As one of the few RCTs without an upper age limit, the TEAM (Tamoxifen Exemestane Adjuvant Multinational) trial provided an unique opportunity to study the association between age and disease-specific mortality (van de Velde et al. 2011; van de Water et al. 2012c). The TEAM trial is a randomized, phase 3, multinational, open-label study conducted in postmenopausal breast cancer patients with estrogen receptor-positive tumors, progesterone receptor-positive tumors, or both. Patients were randomized to receive either exemestane or tamoxifen, followed by exemestane for a total of 5 years. This study (van de Water et al. 2012c) showed that the disease-specific mortality and breast cancer relapse was higher in older breast cancer patients as compared to the younger patients included in the trial. This is despite the fact that disease-specific mortality as proportion of all-cause mortality decreased with age. The authors discuss several possible underlying mechanisms to explain these results: first, older patients may experience undertreatment; several studies showed that older breast cancer patients have a lower chance to receive standard care (Yancik et al. 2001; Bastiaannet et al. 2010; van de Water et al. 2012a). Second, a previous analysis of the TEAM study showed that older patients discontinued study medication more frequently and received less often subsequent therapy (van de Water et al. 2012b). However, this study showed that discontinuation (within the first year) was not associated with disease-specific mortality (van de Water et al. 2012b). Next, older patients may experience overtreatment; in this situation, adverse events of the breast cancer treatment may result in mortality attributed to breast cancer, e.g., due to toxicity. However, in the study, breast cancer relapse was shown to increase with age, so overtreatment is not likely to explain the findings. The authors also speculate that breast cancer in the older patients might have a more aggressive biology; the older patients did present with larger tumors but nodal status was similar. It was, however, not possible to test this hypothesis in further detail in this study and other studies suggest the opposite (Diab et al. 2000; Wildiers et al. 2007). Besides, adjustment for both treatment and tumor characteristics did not diminish the association between age- and disease-specific mortality. Consequently, other unknown factors might have contributed to the findings, e.g., the immune response to the tumor or the response to therapy which needs further research (Zitvogel et al. 2006; Lichtman et al. 2007).

Extrapolation of Study Results to the General Older Population

Inclusion in clinical trials is often selective to ensure the internal validity of the study, although this may compromise the external validity (Rothwell 2005). For the above-described TEAM trial, it was possible to make a head-to-head comparison of the included patients with breast

cancer patients of corresponding age from the general population (Van de Water et al. 2014). The study confirmed that patients who participated in the trial had more favorable patient and tumor characteristics than patients from the general population; however, for patients aged 65–74 years, both patient groups had a comparable overall survival and thus the selective inclusion could be overcome by taking into account these characteristics. On the contrary, in patients aged 75 and over; differences in overall mortality between the groups could not be explained by patient, tumor, or treatment factors, and unmeasured mechanisms may have a role in the selective inclusion (Van de Water et al. 2014).

In general, the reason for the selective inclusion of older patients in RCTs depends on several factors. Eligibility criteria are the most important to hamper the inclusion of older patients or patients with comorbidities (Van Spall et al. 2007). A recent study (Zulman et al. 2011) showed that in RCTs published in the five major medical journals, 20% excluded patients based on age. For the remaining studies, a large proportion excluded patients with age-related diseases. Besides the inclusion criteria, reluctance of physicians to include (Townsley et al. 2005; Kemeny et al. 2003; Kornblith et al. 2002) and willingness of patients to participate in RCTs may further hamper the inclusion of older patients. Besides, for some older patients, factors related to the trial logistics may play a role (Townsley et al. 2005).

The International Society for Geriatric Oncology (SIOG) as well as many researchers and clinicians have made a plea for new studies in older cancer patients that also address other endpoints, next to survival and recurrence, as functional and cognitive decline and quality of life (de Glas et al. 2014a; Wildiers et al. 2013; Pallis et al. 2011, 2010; Balducci 2000; Biganzoli et al. 2012; Aapro et al. 2009). It may however take several years from the initiation of a trial to the publication of the results. Consequently, new evidence in 10 years is most likely to come from studies that are initiated at this moment (de Glas et al. 2014a). A study published in 2014 with respect to breast cancer presented an overview of all current clinical trials at that moment in breast cancer, with a special focus on older patients (de Glas et al. 2014a). To study this, the clinical trial register of the United States National Institute of Health (www.clinicaltrials.gov) was assessed in November 2013 for all phase II-IV clinical trials with respect to breast cancer which were currently including patients or planning to start (de Glas et al. 2014a). The study showed that of the 463 included trials, only 9 (2%) studied breast cancer in older patients. A large proportion of the trials did not have an upper age limit; however, a majority excluded patients based on performance status. The most common endpoints of the studies were overall survival, disease-free survival, and response to therapy, although the studies in older patients more frequently included endpoints as quality of life functional status and cognition (see Fig. 1) (de Glas et al. 2014a).

There are a number of possibilities when it comes to choosing the endpoints in clinical trials including older patients with cancer, and this requires a careful reflection on the ultimate goals of the studied therapies (Wildiers et al. 2013). As shown in the paper from de Glas et al. (2014a) and Wildiers et al. (2013), the majority uses traditional endpoints as overall survival, disease-free survival, recurrence, or breast cancer survival. Overall survival is a crucial endpoint, but disease-specific survival is as most important as deaths resulted from other causes occurring more frequently in the older population (Wildiers et al. 2013). However, the SIOG position paper states that although these endpoints are important, patient-related endpoints are crucial to assess risks and benefits of treatment in older patients (Wildiers et al. 2013; de Glas et al. 2014a). Composite endpoints allow the integration of multiple endpoints, and could have advantages in RCTs including older patients; quality of life, preservation of functional capacity, cognitive function, and independence are most important for the older population and should be included (Wildiers et al. 2013; de Glas et al. 2014a; Hurria and Lachs 2007). In addition to these endpoints, incorporating a geriatric assessment in the trial is essential to understand the effect of treatments (Wildiers et al. 2013). According to the SIOG position paper, patients across the entire age

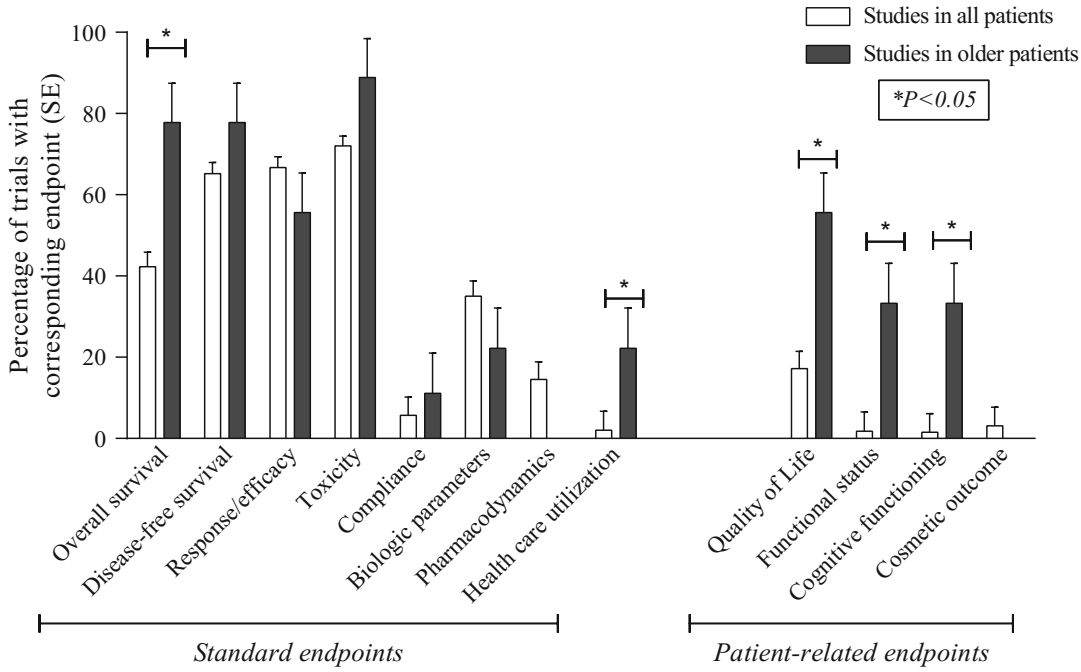

Fig. 1 Endpoints of studies in older patients compared to studies in all patients (Reprinted from de Glas et al. (2014a))

spectrum should be included in trials studying treatments which are expected to be used across all age categories. However, several treatments are not suitable for unfit or frail elderly due to (expected) higher or even unacceptable toxicity; in this setting, elderly specific trials are needed to study appropriate therapy in this group of patients, e.g., comparing modified approaches of adapted chemotherapy with palliative or supportive care (Wildiers et al. 2013).

In general, patient participation in a trial comparing treatment versus no treatment can be challenging; other possible treatment designs might be more appropriate. Several attempts of specific RCTs in the older patients have failed in the past for several reasons. As a consequence of the above challenges, we will not be able to provide a large proportion of the older cancer patients with an evidence-based treatment recommendation (de Glas et al. 2014a). Observational studies – provided that adequate methodology is used – could serve as an alternative to RCTs in older cancer patients and fill some of the knowledge gaps in geriatric oncology, as they are more representative for the entire older cancer patient population (de Glas et al. 2014a; Wildiers et al. 2013; van de Water et al. 2011, 2014).

Observational Studies

Cohort Data from Cancer Registries

One of the main advantages of observational data, especially from cohort data obtained from cancer registries with a high completeness percentage, is that all older patients in the population are included. National differences in the treatment and survival of younger and older patients can be shown, as well as time trends for countries. Studies from Europe have shown that older patients are diagnosed at a higher stage, receive less aggressive treatment, and have a decreased survival as compared to younger patients, and moreover, this survival has not increased at such a fast rate as for younger patients (studies from the Netherlands) (Bastiaannet et al. 2011, 2010). With the inclusion of a large number of patients, trends within the older population in several age categories can be assessed. Studying time trends for both

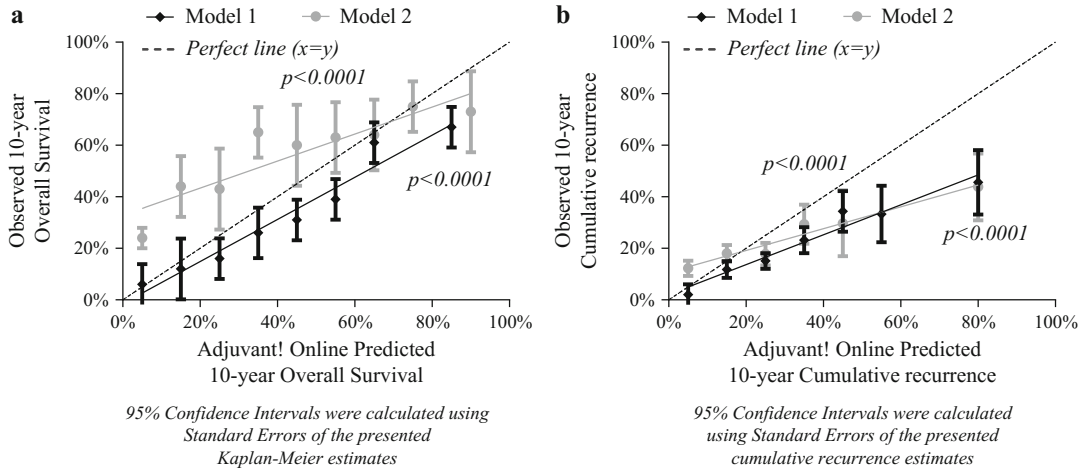

Fig. 2 Observed versus predicted 10-year (**a**) overall survival and (**b**) cumulative recurrence (Reprinted from de Glas et al. (2014c))

treatment and survival in cohort data with a high completeness can show interesting patterns. One of the studies using this method investigated time trends in surgical treatment, overall survival, and relative survival in older patients with resectable breast cancer diagnosed between 1995 and 2011 in the Netherlands (n = 26,292) (de Glas et al. 2014b). The study showed that the proportion of older patients who did not receive surgery increased considerably in the study period; however, overall and relative survival did not change in this period in the Netherlands (de Glas et al. 2014b). The findings of this study suggest that the current therapies, which include the omission of surgery, do not influence the survival. This was confirmed by comparing hospitals with different treatment strategies on outcome; again no differences in both overall and relative survival were shown (de Glas et al. 2014b). Although the study has some limitations, an important one is that the increased omission of surgery was not the only change in treatment strategy over time which limits the attribution of survival trends to the omission of surgery alone, showing these trends can hint to important treatment effects (de Glas et al. 2014b).

Another application of cohort data is the validation of prediction models; usually designed with a cohort of younger patients, for their use in older patients. In breast cancer patients, the correct identification of patients who have a higher risk of breast cancer recurrence and mortality is important to select patients who might benefit from adjuvant therapy (de Glas et al. 2014c). In practice, the Adjuvant! Online prediction tool is the best known (Ravdin et al. 2001). However, this model was developed with a study population of breast cancer patients in the age range 35–69 years from the Surveillance, Epidemiology, End-results (SEER) registry (n = 34,252) (Ravdin et al. 2001). The study of de Glas et al. (2014c), validating Adjuvant! Online in a cohort of older breast cancer patients, indeed showed that the prediction model does not accurately predict overall survival and disease recurrence in older patients with early stage breast cancer (Fig. 2). An important advantage of registry data as performed in this study is that an (large) unselected cohort of older patients can be included. Development of an improved prediction model specifically for older patients is important for several cancer types; this could improve the outcomes and individualize clinical decision making (de Glas et al. 2014c).

International Comparisons

Observational data are also suitable to make international comparisons between regions or counties

to study differences in treatment and survival. One of the larger studies that included an age-specific analysis was the study of EUROCARE, including data from 24 cancer registries in 14 European countries ($n = 114{,}312$) (Allemani et al. 2012). In most part of Europe (northern, western, and southern parts and the UK), survival increased with increasing age up to the age of 69 years, but decreased sharply for older patients (Allemani et al. 2012). In eastern Europe, survival already started to decrease after the age of 50 years and was very low for the oldest age group. The differences between the age categories were most pronounced for northern and western Europe, and less in southern Europe and the UK (Allemani et al. 2012). Another international comparison, comparing several European countries and USA, showed large differences in locoregional treatment of older breast cancer patients (Kiderlen et al. 2012). Further detailed analyses, preferably by using country as pseudorandomization, are needed to study the most effective treatment strategies for older patients. This comparative effectiveness research could provide clues to the most optimal strategy, especially if treatment strategies are different in countries with similar health care systems.

Treatment Effectiveness

One of the major challenges to study treatment effectiveness using observational data are the methods to control for confounding, which is inherent to analyzing observational data for treatment effectiveness. Confounders are defined as variables, known before treatment, that affect the outcome of the study but differ in proportion between the two treatment groups (Baiocchi et al. 2014; Greenland 2000). A number of strategies, including propensity score and matching, are used to control measured confounders in observational research; however, control for unmeasured confounders remains a challenge (Baiocchi et al. 2014; D'Agostino 1998). The instrumental variable (IV) method was developed to control these unknown and unmeasured confounding factors (Baiocchi et al. 2014; Stuart 2010). An IV is defined as a variable that mimics treatment allocation as in a randomized controlled trial (Greenland 2000; Bennett 2010). There are however a few assumptions to which the factor must fulfill. Country may be a suitable IV as place of residence determines the allocation of a patient to one of the cohorts; under the assumption that there are (large) differences in treatment strategy, that patient and tumor characteristics are equally distributed and that the health care systems of both countries are similar.

In more detail, these are the three assumptions which should be met when considering a factor like country as IV. The first assumption states that the IV should be related to the chance of a certain treatment or treatment strategy. In general, a larger contrast leads to a better IV analysis. When comparing countries, it is usually the complete treatment strategy under investigation as cancer management consists of different combinations of neoadjuvant treatment, surgery, radiotherapy, and adjuvant systemic treatments. To assess the strength of the countries used as instrumental variable, an F-statistic can be calculated by performing a regression analyses which predicts treatment as a function of the instrument and covariates (Bennett 2010). An F-statistic of more than 10 is often used to indicate that the instrument is not weak, although there are some discussions in the literature on the use of F-statistics (Bennett 2010). The second assumption is that the IV country should not be related to the prognosis of the patient. So, there should be no differences in the two countries with respect to characteristics of the patients and tumor that are associated with prognosis. If there are large differences in variables which are associated with the outcome, stratification on these variables could provide a solution. The third assumption is that the IV should not have an effect on the outcome other than through the chance to receive a certain treatment (strategy). This means that there should be no important differences between countries with respect to other aspects of the health care system which could influence the outcome. Finding the most appropriate comparisons between countries can be challenging, but worthwhile as bias from confounding by indication in traditional

analyses is large (Bennett 2010;Newhouse and McClellan 1998;Martens et al. 2006).

Using calendar time is another method to assess treatment effectiveness in observational research (Baiocchi et al. 2014). Treatment strategies for most cancer types have changed over the past decades and have been assessed together with changes in outcome over time. Although this technique probably results in more reliable estimates than direct comparison of treatments (Mdege et al. 2011), there might be several factors that can lead to bias in these kind of studies, e.g., information bias (with more reliable data collection in recent years) or other factors explaining the changes in outcome than treatment (e.g., changes in diagnostic work-up) (Baiocchi et al. 2014). Consequently, the use of calendar time is most useful and reliable if a large change in clinical practice occurs in a short period (Baiocchi et al. 2014). This is also the concept of a stepped wedge design, where a change in treatment or a new treatment or intervention is randomly introduced over a certain period of time (Dekkers 2012).

One of the most applied IV statistical analyses technique is the two-stage least squares estimation (Bennett 2010). The first step in this analysis is to obtain a regression estimate by regressing treatment on the instrumental variable country with adjustment for relevant measured confounders. In the second step, the predicted value of the treatment is used in a regression of the outcome, adjusted for the same confounders as in the first step. Standard techniques for regression analyses are available in some software packages; however, solid techniques to analyze survival data are still pending. The GRACE (Good ReseArch for Comparative Effectiveness) and ISPOR (International Society for Pharmaco-economics and Outcomes Research) guidelines and checklist do provide guidance with respect to comparative effectiveness studies in general (Dreyer et al. 2010; Johnson et al. 2009).

As already mentioned by Hernán and Robins, there are some good reasons for skepticism that an analytic method solves one of the major problems in epidemiological research (Hernan and Robins 2006). The effect estimate of the instrumental variable will be biased if country as an instrument does not meet the three main assumptions, but the assumptions (specifically the third) are difficult or not empirically verifiable (Hernan and Robins 2006). Moreover, any bias as a result of these violations will be amplified if the association between country and exposure is weak (Hernan and Robins 2006; Brookhart et al. 2010). At least, studies using an instrumental variable should include a clear description of the assumptions and results to determine whether the instrumental variable is valid (Davies et al. 2013). However, specifically in geriatric oncology, it is recognized that RCTs have important limitations in real-world decision making (Armstrong 2012; Van de Water et al. 2014), as a result of restrictive enrolment criteria and the fact that RCTs are often not feasible in the older population. The instrumental variable method, with further enhancement of the method over time, could serve as a potential solution to perform specific analyses in geriatric oncology, and could provide clues to the most optimal treatment strategy and initiate specific RCTs and tailored treatment for the older cancer patients.

Competing Risks of Death

In many of the studies, cause-specific endpoints such as recurrence or cancer-specific mortality are used (de Glas et al. 2014a, 2016). However, an important consideration in studies with older patients that use these cause-specific endpoints is that the risk of dying from another cause before reaching the endpoint of interest is high (Berry et al. 2010; Pallis et al. 2011). The most commonly used method to estimate survival probabilities over time is the Kaplan-Meier method which can deal with censored follow-up times (de Glas et al. 2016). An important assumption of this method is independent censoring where it is assumed that patients with censored times have (at any time) the same survival prognosis as patients who are still in the study (Verduijn et al. 2011; de Glas et al. 2016). However, in the competing risk setting, this assumption does not hold as patients who die of other causes have a probability of zero to reach the cause of interest in these studies (de Glas et al. 2016). An alternative is the

cumulative incidence competing risks (CICR) method (Andersen et al. 2012; Putter et al. 2007; de Glas et al. 2016), which holds the assumption that patients who experienced a competing event are no longer at risk for the endpoint of interest of the study and estimates the actual probabilities of reaching different endpoints (cumulative incidences) (Verduijn et al. 2011; de Glas et al. 2016). The different statistical time-to-event methods such as the Cox proportional hazards model and the Fine and Gray model also deal with competing events in different ways (Andersen et al. 2012; Putter et al. 2007; Berry et al. 2010; de Glas et al. 2016). The Cox proportional hazards model is the most appropriate when assessing the relative effect size in etiologic studies, while the Fine and Gray model should be used to estimate effects on absolute risk in predictive research and populations with a high frequency of competing events. These challenges are especially present in studies of older patients with cancer types as prostate cancer or low risk breast cancer as the risk of competing events is especially large in these populations and less applicable in studies that investigate highly aggressive tumor types such as pancreatic or lung cancer as the risk of dying from the cancer is high in these populations (de Glas et al. 2016).

For individuals with a cancer diagnosis, one would ideally like to have reliable disease-specific mortality information (Dignam et al. 2009); however, attributing cause of death depends on the judgment of the physician completing the death certificate and the coding medical registry clerk and can be confusing (Dekker et al. 2014). The accuracy of cause of death statements has been debated in several studies (Harteloh et al. 2010; Welch and Black 2002; Brown et al. 1993; Ederer et al. 1999; Dekker et al. 2014). Brown et al. showed that the proportion of non-cancer mortality was considerably higher in cancer patients than in the general population (Brown et al. 1993). This issue is particularly seen in the older population as determining cause of death can be notoriously difficult in this group, as unexpected or unexplained deaths may be attributed incorrectly to the cancer and the risk of competing potential causes of mortality substantially increases with age (Hu et al. 2013; Goldoni et al. 2009). Additionally, cause of death extracted from death certificates of patients with cancer is not always accurate. Relative survival is frequently used as an alternative, and does not require cause of death information (Dignam et al. 2009; Dickman et al. 2004; Ederer et al. 1961; Henson and Ries 1995). Relative survival is calculated as observed all-cause survival in the cohort divided by expected survival estimated from the general population matched by age, sex, and year and is a good alternative to cancer-specific survival in observational data from older cancer patients.

Abstract

Cancer is predominantly a disease of aging, and older adults with cancer represent the majority of cancer diagnoses and deaths in the United States. Despite dramatically increasing numbers of older adults developing cancer, our understanding of this potentially vulnerable population remains limited. We are ill prepared to care for this surging demographic, and the translation of scientific discoveries arising in the lab or clinical research into clinical applications to care for the aging population has never been more important. This chapter will focus on proposed biomarkers of functional age that could complement existing assessments of older adults with cancer. First, we will discuss biological markers of aging such as systemic inflammatory markers and markers of senescence. Second, we will review the role of body composition and imaging for evaluating sarcopenia. Next, we focus on cardiovascular performance and discuss the potential importance of gauging exercise capacity. Lastly, we address potential methodologic challenges and design considerations related to translational research in older adults with cancer. Translational research offers several novel avenues to improve our assessments of older patients to aid in the assessment of the risks and benefits of treatments. Further development of these promising areas is necessary to improve the quality of care for this growing and vulnerable population.

Keywords

Translational research · Geriatric oncology · Biomarkers of aging · Sarcopenia · Cardiovascular fitness · Cellular senescence

Introduction

Older adults represent the majority of cancer diagnoses and deaths in the United States (Surveillance Epidemiology and End Results (SEER) program). By the year 2030 it is expected that nearly 70% of all cancer cases will be in adults 65 years of age or older (Smith et al. 2009). Despite these dramatic numbers, our understanding of this population remains limited (Scher and Hurria 2012). We are ill prepared to care for this surging demographic, and the translation of scientific discoveries arising in the lab or clinical research into clinical applications to care for the aging population has never been more important.

Aging is a heterogeneous process with resultant wide differences in the health status in patients of the same chronological age. These age-related differences contribute to the large variability in treatment tolerance and outcomes seen in older patients. Age-related differences are sometimes readily apparent from the "eyeball test" in assessing patients from the door of the exam room, such as the use of wheelchair, but often outward appearances can be deceiving. Many older patients with cancer rated as having a "normal" performance status have important impairments that go unrecognized (Jolly et al. 2015). Due to inadequate routine measures of tolerability, many older patients do not receive chemotherapy and other cancer therapies based on chronological age alone, despite evidence that some older adults derive similar benefits as younger patients (Sargent et al. 2001). Evaluating a patient's functional age and estimating treatment tolerability can be challenging and requires a detailed and thorough assessment of an individual patient.

Table 1 Potential biomarkers of interest

Biomarker	Source	Test	Associations with	
			Frailty/ function	Mortality
Inflammatory markers (CRP, IL-6, TNF-α, D-dimer)	Serum or plasma	ELISA	Yes	Yes
Telomere length	Leukocyte DNA	PCR, Southern blot, FISH, STELA	Yes	Yes
$P16^{INK4a}$	Peripheral T-lymphocyte RNA	PCR	Unknown	Unknown
Body Composition/sarcopenia	CT, MRI, DEXA, BIA	Commercially available body composition software	Yes	Yes
Maximal oxygen consumption (VO_2 max)	O_2 and CO_2 of inhaled and exhaled air	Incremental exercise testing	Yes	Yes

Modified from Hubbard et al. (2014)
Abbreviations: *CRP*, C-reactive protein; *IL-6*, interleukin-6; *TNF-α*, tumor necrosis factor-α; *ELISA*, enzyme-linked immunosorbent assay; *PCR*, polymerase chain reaction; *FISH*, fluorescence in situ hybridization; *STELA*, single telomere length analysis; *CT*, computed tomography; *MRI*, magnetic resonance imaging, *DEXA*, dual-energy x-ray absorptiometry; *BIA*, bioelectrical impedance analysis

Many tools exist that can aid in assessing functional age and in predicting the risk of morbidity and mortality in older patients. Geriatric assessment provides a detailed evaluation of a patient's functional status, cognition, nutritional status, comorbidity, and social support, thus providing a broader overall understanding of individual characteristics that may impact morbidity and mortality (Hurria 2009). There is a growing literature on the use and benefits of geriatric assessment in older patients with cancer (Wildiers et al. 2014). Short detailed geriatric assessments have been developed and validated for use in cooperative group settings and in community oncology centers (Hurria et al. 2011; Williams et al. 2014). All older adults with cancer are recommended to undergo a geriatric assessment to objectively appraise their health; however, geriatric assessments can be time consuming, and models to incorporate geriatric assessment into routine care are not widely implemented (Magnuson et al. 2016). Frailty is a geriatric syndrome of increased vulnerability for adverse outcomes, and although related to chemotherapy toxicity and long-term survival in older adults with cancer, frailty assessment is rarely employed in clinical practice (Cohen et al. 2016; Guerard et al. 2017). Biomarkers may be able to help fill these gaps. The ideal biomarker would reflect a patient's functional reserve and aid in prediction of tolerance to treatment. Many proposed biomarkers exist (see Table 1) with variable amounts of supporting evidence.

This chapter will focus on proposed biomarkers of functional age that could complement existing assessments of older adults with cancer. A summary of proposed biomarkers is presented in Table 1. First, we will discuss biological markers of aging such as systemic inflammatory markers and markers of senescence. Second, we will review the role of body composition and imaging for evaluating sarcopenia. Next, we focus on cardiovascular performance and review the potential importance of gauging exercise capacity. Lastly, we address potential methodologic challenges and design considerations related to translational research in older adults with cancer.

Potential Biomarkers of Aging

Systemic Inflammatory Markers

Markers of systemic inflammation have been extensively studied as potential biomarkers of functional age. Aging is characterized by a

pervasive low-grade and chronic inflammation, coined as "inflammaging" (Franceschi and Campisi 2014). As most age-related diseases such as atherosclerosis and diabetes are related to chronic inflammation, inflammation is a risk factor for both morbidity and mortality in older adults (Franceschi et al. 2000). These markers of inflammation, which include interleukins (most prominently IL-6), C-reactive protein (CRP), and tumor necrosis factors (TNF-α), correlate with measures of frailty, functional decline, and survival (Franceschi and Campisi 2014). As TNF- α and IL-6 can stimulate production of prothrombotic factors that are notably increased along with inflammatory markers (Kanapuru and Ershler 2009), for the purposes of this chapter, we will also include markers of coagulation system such as D-dimer and soluble vascular cell adhesion molecule (sVCAM) with systemic inflammatory markers. Pro-inflammatory markers increase with advancing age, even in healthy individuals (Fagiolo et al. 1993; Sindermann et al. 1993), and are proposed to accelerate the aging process (Franceschi et al. 2007; Vasto et al. 2007).

Several studies have demonstrated the relationship of inflammatory markers with clinical measures of frailty. In a large analysis from the Cardiovascular Health Study, frail older adults had significantly elevated levels of CRP, factor VIII, and D-dimer compared to non-frail patients that persisted even after controlling for age, sex, race, and comorbidities (Walston et al. 2002). Another study of 110 patients over the age of 75 years of age found similar elevations in TNF-α, IL-6, and CRP with increasing frailty (Hubbard et al. 2009). These markers have also been shown to correlate with physical function and functional decline in older patients. In a study of physical function decline in older adults, Cesari et al. found high levels of IL-6, CRP, and IL-1RA were significantly associated with poor physical performance and reduced muscle strength (Cesari et al. 2004). In another study by Cohen et al., high levels of IL-6 and D-dimer were associated with declines in measures of function and a twofold increased risk of mortality among community dwelling older adults (Cohen et al. 2003). Thus, these inflammatory markers may be beneficial in identifying frail older adults and those with functional decline.

Although inflammatory markers can be collected and easily measured during cancer management, the cancer itself can alter and produce inflammation (Hubbard et al. 2014). This greatly limits the utility of inflammatory markers in oncology and is counter to the principles of an ideal biomarker that should be independent from specific pathologic conditions (Falandry et al. 2013). Nonetheless, several studies have explored the use of inflammatory markers in patients with cancer. In a study by Brouwers et al., inflammatory markers were correlated with increasing chronologic age, worse Eastern Cooperative Oncology Group (ECOG) performance status, and impairments in instrumental activities of daily living (IADL) in patients with breast cancer (Brouwers et al. 2015). Markers of inflammation were also associated with poorer global quality of life and increased fatigue in a study of adults with acute myeloid leukemia. The role of inflammatory markers in older adults with cancer remains uncertain, and whether these markers can predict individual's tolerance to cancer treatment or functional decline associated with cancer treatment warrants further study. Although a focus of age-related research for over two decades, markers of inflammation have not assumed a major role in clinical care. Future studies designed to evaluate if any single marker or combination of inflammatory markers have an independent role in predicting outcomes and/or improving management in adults with cancer are needed.

Markers of Senescence

When cells undergo DNA damage, the cell can activate a response pathway leading to permanent cell cycle arrest (Hubbard et al. 2014). This state of irreversible growth arrest, known as cellular senescence, can be triggered by multiple mechanisms including telomere shortening or epigenetic derepression of the INK4a/ARF locus (Collado et al. 2007). These mechanisms serve to limit aberrant cellular proliferation and protect against the development of cancer. As we age, we

accumulate more and more senescent cells; therefore, measures of cellular senescence could be used as surrogates for physiologic aging. There is also a connection between senescence and increasing levels of chronic inflammation. Senescent cells can secrete a large number of cytokines, chemokines, and other pro-inflammatory proteins known collectively as the senescence-associated secretory phenotype (SASP) (Coppe et al. 2008). SASP related factors are proposed to increase inflammation in the surrounding microenvironment and ultimately contribute to the aging process. Although there is no established circulating marker of cellular senescence, other markers associated with the senescence process, including telomere length and $p16^{INK4a}$, have been explored as possible biomarkers of aging.

Telomeres are protein structures located at the ends of eukaryotic chromosomes that are required for genome stability and progressively shorten overtime with cell division. Short telomeres trigger DNA damage checkpoints that mediate cellular senescence and eventually lead to mitotic arrest known as senescence (Sharpless and DePinho 2004). As telomeres shorten with increasing age and have been correlated with aging-related disease, telomere length has been proposed as a biomarker of aging (von Zglinicki and Martin-Ruiz 2005). In a seminal study of older adult residents of Utah who had donated blood, shorter telomeres in blood DNA were associated with poorer survival (Cawthon et al. 2003). The mortality rate of individuals with shorter telomeres was nearly twice that of those with longer telomeres. The role of telomere length in carcinogenesis and as a predictor of cancer prognosis has also been explored. In a recent systematic review and meta-analysis of seven individual studies with a total of 956 patients with colorectal cancer, short telomere length in peripheral blood leukocytes was significantly and independently associated with poorer overall survival (Hazard Ratio 2.01, 95% CI 1.46 to 2.77, $p < 0.001$) (Jia and Wang 2016). Short telomere length has also been associated with negative prognosis in patients with breast cancer, soft-tissue tumors, and lung cancer in several retrospective studies (Pallis et al. 2014). However, many prospective studies have failed to demonstrate similar results (Pallis et al. 2014). The dysfunction of telomeres may also represent an important role as a biomarker. Telomere dysfunction similarly limits the proliferative capacity of cells with resultant senescence or apoptosis. Several protein markers (including CRAMP, stathmin, EF-1alpha, and chitinase) have been identified as secreted from telomere-dysfunctional bone marrow cells (Jiang et al. 2008). These markers, which can be detected in serum, were able to discriminate between young and old individuals as well as those with age-related disease (Jiang et al. 2008). Although several studies have explored telomere length or dysfunction as a biomarker of aging, the overall results are inconclusive (Mather et al. 2011). Nonetheless, telomere length remains a compelling marker of interest in search for markers of biologic age given its correlation with aging and age-related disease.

The expression of the tumor suppressor $p16^{INK4a}$ sharply increases with age and has also been proposed as a potential biomarker of aging. Expression of $p16^{INK4a}$ codes for a protein that blocks cyclin-dependent kinase, ultimately leading to cellular senescence and permanent cell-cycle arrest (Liu et al. 2009). Although $p16^{INK4a}$ is expressed in most mammalian tissues, it is most readily measured from whole blood via quantitative real-time polymerase chain reaction of T-lymphocyte RNA. Gene expression of $p16^{INK4a}$ increases nearly tenfold with aging over the life span and has also been significantly associated with tobacco use and physical inactivity as well as correlated with the inflammatory marker IL-6 (Liu et al. 2009). This promising biomarker is the focus of several ongoing studies to evaluate its usefulness as a predictor of toxicity and outcomes.

Impact of Cancer Therapies on Biomarkers of Aging

The use of molecular biomarkers not only allows for a better assessment of physiologic aging, but may also provide a surrogate outcome for the aging process itself. Surgical procedures are associated with a cascade of cytokine and acute phase

responses, typically measured by either IL-6 or CRP, and the degree of inflammatory response appears associated with the magnitude of the operative procedure (Watt et al. 2015). For example, simple cholecystectomy procedures have been shown to be associated with modest increases in CRP (52 mg/L), while larger increases in CRP have been associated with colorectal cancer resection (123 mg/L) (Watt et al. 2015). Although these short rises in inflammatory markers after surgery are concerning, these are not likely to result in long-term accelerated aging. Radiation therapy causes radiation-induced injury to normal tissue by depleting tissue stem cells and progenitor cells while also damaging the vascular endothelial microvessels (Kim et al. 2014). This results in the excessive generation of reactive oxygen species and the production of pro-inflammatory cytokines (Kim et al. 2014). The long-term implications of radiation are best demonstrated in survivors of childhood cancers with the accelerated development of secondary malignancies (such as breast cancer) and other comorbidities (Bhatia et al. 2015). Chemotherapy is also another major cause of accelerated aging. Chemotherapy preferentially targets rapidly dividing cells, such as tumor cells, but also results in side effects and toxicities as a result of its indirect effects on normal healthy tissue (Beeharry and Broccoli 2005). While patients may tolerate the acute side effects of chemotherapy, the long-term unintended impact of cytotoxic chemotherapy is only now becoming apparent. Telomeres in individuals treated with cytotoxic chemotherapy are shorter than age-matched control individuals without exposure to chemotherapy (Beeharry and Broccoli 2005). The attrition of telomeres has also been shown to correlate with the intensity of cytotoxic chemotherapy (Diker-Cohen et al. 2013). In another recent study by Sanoff et al., significant increases in $p16^{INK4a}$ expression were demonstrated in 33 women with early stage breast cancer undergoing adjuvant chemotherapy (Sanoff et al. 2014). This rise was comparable to 14.7 years of chronological aging and suggests a potential gerontogenic effect of chemotherapy. Telomere length was not affected by chemotherapy in this study. This finding was collaborated by a cross-sectional study of breast cancer survivors that demonstrated a similar $\log_2$-increase in $p16^{INK4a}$ with the administration of chemotherapy. The long-term impact of the potential accelerated aging phenomenon associated with some cancer therapies remains unknown and is an area of increasing research.

Conclusions

Many promising novel molecular biomarkers exist that may ultimately aid in the assessment of older adults with cancer. There is a clear need to incorporate biomarkers into oncology trials, and many trials are beginning to incorporate the aforementioned markers. The ideal marker would provide additional information to our standard oncologic evaluation and be easily repeated at various time points throughout treatment without undue harm. The best predictive power is likely to be achieved by utilizing a panel of markers that stratify patients into risk or frailty groups (Hubbard et al. 2009). These novel biomarkers also offer an opportunity to study the unintended pro-aging effects of cancer treatments on patients. Further understanding the long-term impacts of these gerontogenic effects and finding ways to minimize these effects are needed.

Body Composition and Sarcopenia

Introduction

Age-related loss of muscle mass and function, known as sarcopenia, is a complex age-related condition associated with an increased risk for adverse outcomes. Rosenberg et al. were the first to introduce the term sarcopenia, to describe the loss of muscle mass with aging. The term sarcopenia is a combination from the Greek words: *sarx* (flesh) and *penia* (loss) (Rosenberg 1997). A step further was made by Baumgartner et al. who investigated the extent of the problem posed by muscle loss seen with aging in describing the age-related loss of muscle mass seen in older adults using dual-energy X-ray

absorptiometry (DEXA) to compare appendicular skeletal muscle mass in older adults to a younger reference group in New Mexico (Baumgartner et al. 1998). Investigators found a marked decline in muscle mass in older adults with more than half of the octogenarians two or more standard deviations below the younger reference group. They also showed that low muscle mass was associated with self-reported physical disability (Baumgartner et al. 1998).

Although the precise underlying mechanisms causing changes in body composition with aging are not yet clear, after the third decade of life, approximately 1% of muscle mass is lost every year (Brzeszczynska et al. 2016). Sarcopenia has been associated with functional impairment, disability, reduced health-related quality of life, loss of independence, and mortality (Gale et al. 2007; Visser et al. 2005; Janssen et al. 2002; Rolland et al. 2008). The yearly financial burden of sarcopenia is estimated at ~$18.5 billion in the USA alone (Janssen et al. 2004). In recent recognition of sarcopenia as a distinct medical condition, an ICD-10 has been established and made available for use as of October 1, 2016 (M62.84). A variety of factors contribute to the development of sarcopenia with aging, including clinical factors (comorbid disease and medications), biological factors (inflammation, hormonal changes, genetics), and behavioral factors (lifestyle and living conditions) (Rolland et al. 2008). Inflammatory cytokines as described above, such as IL-6 and TNF-α, may promote muscle wasting and malfunctioning of skeletal muscle by increasing the systemic inflammatory process and in conjugation with oxidative process in aging adults (Brzeszczynska et al. 2016).

Sarcopenia in Oncology

Although the presence of sarcopenia has been associated with adverse outcomes in numerous chronic diseases, recently there has been increasing interest in the impact of sarcopenia in oncology. Muscle loss in patients with cancer is additionally complicated by cancer-related cachexia. Muscle wasting is a frequent consequence of cancer cachexia along with weight loss, fatigue, and anorexia (Evans et al. 2008). Cancer cachexia is primarily mediated by an activated pro-inflammatory response (with high level of IL-6 and TNF-α) with resultant increased protein catabolism (Rolland et al. 2011). Subclinical changes in weight and lipid metabolism have been shown to start as early as 2 years before a cancer diagnosis is made (Kritchevsky et al. 1991). Of note, the impact of cancer on metabolism and energy imbalance varies greatly by tumor type and stage (Petruzzelli and Wagner 2016). Although cancer cachexia and sarcopenia are clearly distinct concepts, the two conditions overlap. In clinical practice in oncology, the contribution of cachexia or the sarcopenia process in the loss of muscle mass in older adults with cancer is rarely clear. Many factors contribute to the loss of muscle mass seen in patients with advanced cancer (Evans 2010). Recent research into the underlying mechanisms of muscle loss between older adults with and without cancer has demonstrated that in patients with cancer there is blockade of satellite cell maturation, upregulation of apoptotic factors, and reduced oxidative stress defense genes not seen in healthy older adults (Brzeszczynska et al. 2016). This particular study offers a glimpse into the varied underlying mechanisms in muscle loss related to sarcopenia versus cancer cachexia, but more research is needed to understand the similarities and differences between the two conditions to better inform potential interventions. Targeting common pathways of muscle loss in both cancer cachexia and sarcopenia may be most effective in reducing losses in muscle mass and strength in patients with cancer (Rolland et al. 2011).

Assessing Sarcopenia

Many tools are available to aid in the assessment of sarcopenia and body composition. These tools range from simple anthropometric measures to advanced imaging. See Table 2 for a list of commonly used modalities. The gold standard for assessment of body composition, particularly outside the field of oncology, is DEXA.

Table 2 Selected commonly used body composition techniques with pros/cons listed of each approach

Technique	Pros	Cons
Anthropometry	Easily obtained and inexpensive	Relatively insensitive and significant interobserver variability
BIA	Portable, safe, and inexpensive	Relies on population-specific regression equations and less accurate in altered states of hydration
DEXA	High precision and accuracy to differentiate total body fat, lean muscle, and bone Safe for repeated measures	Differences between manufacturers and software versions Unable to quantify muscle density
CT	Highly accurate quantitative and qualitative measurements Useful in clinical settings where used as part of standard medical care	Large radiation exposure and rarely used without other clinical indications Costly and requires specialized personnel
MRI	Excellent resolution images Most accurate method to detect body composition at tissue-organ level Safe	Costly and requires specialized personnel Cannot accommodate very large patients
Deuterated creatine dilution	High accuracy and less bias in interpretation	Requires specialized equipment and personnel Primarily only research tool to date
Ultrasound	Portable, safe, and inexpensive	Lacks standardized techniques causing significant interobserver variability More qualitative than quantitative results Requires specialized personnel

Modified from Prado et al. (Prado and Heymsfield 2014)
Abbreviations: *BIA*, bioelectrical impedance analysis; *DEXA*, dual-energy x-ray absorptiometry; *CT*, computed tomography; *MRI*, magnetic resonance imaging

DEXA provides precise quantification of whole-body and regional composition with minimal exposure to radiation that is safe for repeated measures (Prado and Heymsfield 2014). More advanced imaging techniques are routinely utilized in oncologic care as part of cancer staging, disease monitoring, or surveillance and can be used to quantify body composition. Standardized and practical methods for quantifying body composition from computed tomography (CT) imaging has been developed (Mourtzakis et al. 2008). The L3 landmark from cross-sectional imaging has been identified as the strongest predictor of whole body fat and fat-free mass when compared to DEXA (Mourtzakis et al. 2008). The advantage of using advanced imaging modalities, such as CT or magnetic resonance imaging (MRI), is the ability to provide additional qualitative measurements of muscle and fat beyond purely quantitative measures (Aubrey et al. 2014). Muscle attenuation provides indirect information regarding the composition of muscle that is otherwise only available from muscle biopsy. The attenuation of muscle is inversely related to muscle fat content and can be utilized as a surrogate measure of muscle "quality" (Aubrey et al. 2014). Recent research has developed an integrated measure that combines both muscle quantity and attenuation termed Skeletal Muscle Gauge (Weinberg et al. 2016). Figure 1 illustrates the visual differences between two older adults in terms of skeletal muscle quantity and attenuation. Both patients A and B have a similar body mass index (BMI), but patient B has evidence of low muscle mass and low muscle attenuation. Additional practical tools for measuring muscle mass, such as ultrasound and bioelectrical impedance analysis (BIA), can be performed at the bedside and are preferred methods for clinical practice when advanced imaging is not available (Rubbieri et al. 2014).

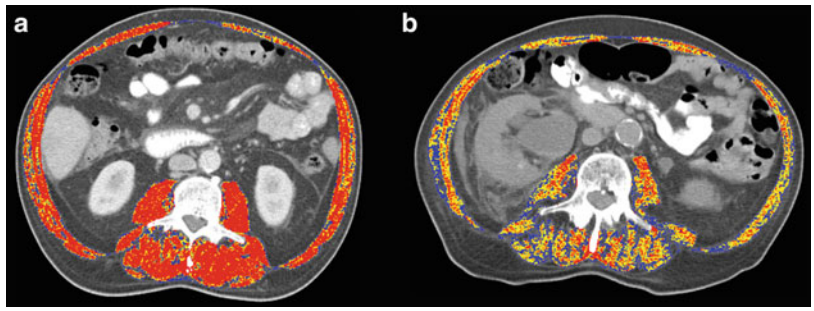

Fig. 1 Representative abdominal computerized tomography (*CT*) images highlighting skeletal muscle differences. Depicts two older adults at the L3 cross-sectional area with the same BMI (BMI = 24), but different quantity (skeletal muscle index A = 47.3 vs. B = 35.3 cm^2/m^2) and composition of skeletal muscle (mean skeletal muscle density A = 36.2 vs. B = 11.6 Hounsfield Units [HU]). The red area represents skeletal muscle within the normal range of radiodensity (+30 to +150 HU), the yellow represents +1 to +29 HU, and the blue represents 0 to −29 HU. Abbreviations: *BMI*, body mass index

More novel research methods, such as deuterated creatine dilution, can estimate total body muscle mass from urine collection of D_3-creatinine enrichment that is strongly correlated with estimates from MRI or DEXA (Clark et al. 2014).

As the consensus definitions of sarcopenia include measures beyond muscle quantification alone, it is important to incorporate measures of strength and physical performance to more accurately define sarcopenia (Cruz-Jentoft et al. 2010; Studenski et al. 2014). The rationale for incorporating measures of muscle strength and performance in the definition of sarcopenia is from the observation that the relationship between muscle strength and mass is non-linear, and muscle strength is not solely a function of muscle mass (Goodpaster et al. 2006; Delmonico et al. 2007). In particular, CT-based muscle mass poorly correlates with impairments in physical function and performance on Timed Up and Go (TUG) (Williams et al. 2017). Well-validated measures of muscle strength and performance exist that can be easily performed in the clinical or research setting. Handgrip strength is the simplest available measure of muscle strength and correlates well with leg strength, poor mobility, and disability in activities of daily living (Lauretani et al. 2003). However, handgrip strength in older adults can be less reliable as it is impacted by common comorbidities and the compensatory use of hands and arms by frail older patients (Rantanen et al. 1998). Other alternative measures include stair climb power or knee flexion/extension, but these can require additional equipment. Several measures of physical performance are available, including usual gait speed, Short Physical Performance Battery (SPPB), TUG, and 6-minute walk test (Cruz-Jentoft et al. 2010).

Impact of Sarcopenia on Outcomes in Oncology

Emerging literature in oncology has described the association of sarcopenia with adverse outcomes (Kazemi-Bajestani et al. 2015; Rier et al. 2016). A recent meta-analysis that included 7843 patients from 38 studies demonstrated overall survival was significantly shorter among sarcopenic cancer patients (HR = 1.44, p <0.001) as well as cancer-specific survival (HR = 1.93, p <0.001). Inferior survival was shown among both early and late stage solid tumors as well as in a variety of different types of malignancies (Shachar et al. 2016). Also of note, many studies across the literature have shown the more subtle sarcopenic obese patients to be particularly at-risk for poorer survival compared to non-sarcopenic obese patients (Prado et al. 2008).

Several studies have demonstrated the inverse relationship between chemotherapy or biological

treatment and muscle mass with higher toxicities rates (Kazemi-Bajestani et al. 2015). The association of chemotherapy toxicity with lower muscle mass or lean body mass is most apparent in therapeutics dosed based on BSA. Prado and colleagues studied 5-flouracil/LBM ratio and showed that higher toxicities were in patients with lower lean body mass; this observation was particularly significant in females (Prado et al. 2007). Another study on patients with metastatic breast cancer receiving first line taxanes-based chemotherapy demonstrated that sarcopenic patients had higher percentage of hospitalizations, dose adjustments, and grade 3–4 toxicities (Strulov Shachar et al. 2016). Antoun et al. also showed higher dose-limiting toxicity in biological oral drugs that are given in fixed doses such as sorafenib for metastatic renal cell cancer. In his study dose-limiting toxicity was significantly higher in sarcopenic patients whose BMI <25 kg/m^2 than patients who were not sarcopenic and/or BMI >25 kg/m^2 (41% vs. 13%, $p = 0.03$) (Antoun et al. 2010). Mir et al. demonstrated that dose limiting toxicities occurred more frequent in patients with sarcopenia and advanced hepatocellular carcinoma ($n = 40$) and showed that median AUC of sorafenib was significantly higher in sarcopenic patients ($p = 0.013$) (Mir et al. 2012).

Sarcopenia in the surgical patient prior to cancer surgery appears to also be a predictor for surgical complications. Peng et al. demonstrated in a large series of patients undergoing liver resection for colorectal liver metastasis ($n = 259$) that sarcopenic patients had an increased risk of major postoperative complications (OR 3.33; $p = 0.008$) (Peng et al. 2011). Low muscle mass in patients with colorectal cancer undergoing surgery ($n = 234$) showed a longer length of stay (15.9 vs. 12.3 days, $p = 0.04$) and low muscle mass was also an independent predictor of surgical infections (odds ratio [OR] 4.6, $p < 0.01$) (Lieffers et al. 2012). Not only was sarcopenia associated with increased postoperative infection risk and prolonged length of hospital stay, but this finding was especially pronounced in older adults (29.6% vs. 8.8%, $p = 0.0005$, and 20.2 vs. 13.1 days, $p = 0.0008$) (Lieffers et al. 2012).

Conclusions

As sarcopenia is highly prevalent in patients with cancer, particularly the elderly, and associated with adverse outcomes, this has many potentially important clinical implications. Many decisions in oncology require a careful balance of the risks and benefits of treatment, and the presence of sarcopenia may impact the risk/benefit balance of many treatments. The presence or absence of low muscle mass could influence and alter treatment decision-making in some settings and allow for a more personalized oncologic treatment approach. Identifying patients that are sarcopenic or at risk for sarcopenia (pre-sarcopenic) may also help target potential interventions that could help mitigate adverse outcomes. The research field of body composition in cancer holds great promise in better assessing and treating older adults with cancer, yet the research of body composition and geriatric oncology has many unanswered questions. How is the mechanism of muscle loss different between aging patients with and without cancer? How should sarcopenia be defined in oncology? Are the adverse trajectories the same in sarcopenic older versus younger adults with cancer or is it even worse? How can we best treat and help to maintain muscle mass? The use of body composition in assessing older adults with cancer is a promising avenue to provide more personalized oncologic treatment that could ultimately improve outcomes.

Cardiovascular Aging

Introduction

In current practice, assessment of performance status, either by Karnofsky Performance Status (KPS) or the Eastern Cooperative Oncology Group (ECOG) scale, is a part of our routine evaluation of patients with cancer. These simple measures are the basis of clinical trial eligibility for most trials, yet are mostly subjective and lack sensitivity to detect impairments in older adults with cancer (Jolly et al. 2015). Due to these drawbacks, these measures are frequently

supplemented with other more objective measures of overall physical functioning. Cardiorespiratory fitness is an objective measure of global cardiovascular function and reserve that reflects the ability of the cardiopulmonary system to deliver adequate oxygen and substrate to active skeletal muscles for adenosine triphosphate resynthesis. Assessing peak oxygen consumption (VO_{2peak}) via incremental cardiopulmonary exercise test with gas-exchange measurement is the gold standard assessment of cardiorespiratory fitness and exercise capacity (Hurria et al. 2016a). As aging is associated with a progressive decline in the health of the cardiovascular system (North and Sinclair 2012) and emerging literature has demonstrated the inverse relationship of VO_{2peak} with all-cause mortality in a variety of adult populations (Jones et al. 2010; Kavanagh et al. 2002), cardiorespiratory fitness represents a possible useful marker of physiologic aging.

Assessing Cardiorespiratory Fitness

Assessing VO_{2peak} or VO_{2max} is most often performed with the use of cardiopulmonary exercise testing. Cardiopulmonary exercise testing involves the measurement of ventilation and respiratory gas parameters during exercise (Albouaini et al. 2007). A non-rebreathing valve is connected to a mouthpiece to prevent inspired and expired air from mixing. There are many different protocols used for testing cardiopulmonary exercise, but most often utilize either a treadmill or cycle ergometer. Patients undergo progressive increases in workload while having gas exchange continuously measured. VO_{2max} is reached when VO_2 remains steady state despite an increase in workload (Sagiv 2012). VO_{2peak} is the peak VO_2 at peak exercise (American Thoracic and American College of Chest 2003). Although VO_{2max} is considered the best index of aerobic capacity and the gold standard, in many clinical situations a clear plateau may not be achievable before a symptom limitation to exercise (Noakes 1998). Therefore, VO_{2peak} is often used as an estimate for VO_{2max} and for practical purposes the terms are used interchangeably. As VO_{2peak} is more often measured in the clinical setting and predominately used in recent publications in oncology, we will use the term VO_{2peak}. Accurate estimation of VO_{2peak} requires an all-out effort by participants to fully stress the aerobic system and is typically performed in an exercise physiology laboratory with a strict protocol. Per the Fick principle, VO_{2peak} is the product of cardiac output and arteriovenous oxygen difference ($VO_2 = [SV \times HR] \times [CaO_2 - CvO_2]$). Thus, VO_{2peak} reflects the maximal ability of a person to take in, transport, and use oxygen (Albouaini et al. 2007). VO_{2peak} is impacted by several factors including genetic factors, quantity of muscle, age, sex, and body size. VO_{2peak} can be affected by training and is typically expressed in liters/minute and as a percentage of the predicted value (American Thoracic and American College of Chest 2003). The safety and feasibility of cardiopulmonary exercise testing in patients with advanced cancer has been demonstrated (Jones et al. 2007). Given the intensity required to obtain VO_{2peak} testing, this test can be a challenge for older adults and especially those with comorbidities. Anyone with unstable angina, uncontrolled hypertension, syncope, or the presence of serious cardiac dysrhythmias should not be allowed to perform exercise testing (American Thoracic and American College of Chest 2003). Also, patients that are unable to exercise due to either orthopedic or neurological conditions are unable to undergo exercise testing. Submaximal testing with measurement of oxygen uptake kinetics may be a reasonable alternative and practical approach to assessing exercise capacity for some older adults (Alexander et al. 2003). Formalized exercise testing guidelines are also available from the American Thoracic Society/American College of Chest Physicians (ATS/ACCP) and are a good source for a more comprehensive overview of exercise testing methodology (American Thoracic and American College of Chest 2003).

Cardiorespiratory Fitness in Oncology

There is growing interest and literature on cardiorespiratory fitness in adults with cancer; however,

the methods of performing and reporting data is frequently inconsistent and does not always comply with national and international guidelines (Jones et al. 2008). The purpose of performing cardiopulmonary testing in oncology usually falls under two broad categories: (1) as a prognostic measure to be used in risk stratification or (2) as an outcome measure to assess the impact of an exercise intervention or the impact of cancer treatment on cardiorespiratory fitness.

In a seminal article by Jones et al., the authors investigated the prognostic significant of preoperative cardiopulmonary fitness (VO_{2peak}) among patients with potentially resectable non-small cell lung cancer (NSCLC). For patients in the highest tertile of VO_{2peak} (>1.29 L/min^{-1}) compared to the lowest (<0.96 L/min^{-1}), the adjusted hazard ratio for all-cause mortality was 0.56 (98% CI, 0.39–0.80) and remained significant whether or not the patients underwent resection (Jones et al. 2010). In a separate study by Moyer et al., investigators examined the value of cardiopulmonary exercise testing in predicting complications in patients with gastroesophageal cancer undergoing resection. Higher rates of cardiopulmonary complications occurred in patients with low anaerobic thresholds compared to patients with higher levels (42% vs. 20%) (Moyes et al. 2013). Similarly, in another study of patients undergoing major colonic surgery (90% oncological surgery), a higher VO_{2max} was associated with decreased postoperative morbidity (West et al. 2014). In their final multivariable model, an increase of 1.0 ml kg^{-1} min^{-1} in VO_{2max} was associated with a ~20% reduction in the odds of surgical complications (West et al. 2014).

The impact of cancer and its treatments on cardiopulmonary fitness has also been investigated. Although no prospective observational studies of exercise capacity have been performed, the usual care arm in the context of randomized controlled clinical trials of exercise training allows for an exploration of longitudinal changes in patients undergoing cancer treatment. In a study by Courneya et al. of an exercise intervention in patients with breast cancer undergoing adjuvant chemotherapy, an approximate 5% decline in VO_{2peak} was measured from baseline to the completion of chemotherapy (Courneya et al. 2007). Other studies of chemotherapy have found similar declines in cardiopulmonary fitness across multiple different tumor types including breast, rectal, and esophagogastric malignancies (Sinclair et al. 2016; West et al. 2015). Other anticancer treatments have been associated with declines in exercise capacity. In a study of men with advanced prostate cancer, 6 months of androgen deprivation therapy with or without radiation therapy was associated with a 10% decline in VO_{2peak} (Segal et al. 2009). As VO_{2peak} declines approximately 10% every decade, this suggests that chemotherapy may cause nearly a decade of physiologic aging. Most concerning is that declines in cardiopulmonary function seen in adults with cancer may not improve even years after the completion of therapy. In a cross-sectional study of breast cancer survivors, patients with breast cancer had marked impairments in VO_{2peak} across the entire survivorship continuum compared to age-matched healthy sedentary women (Jones et al. 2012). The average VO_{2peak} of women with early-stage breast cancer was 22% less than that of the women without breast cancer with an average follow-up of 27 months after the completion of primary adjuvant therapy (Jones et al. 2012). The clinical importance of these declines in the long term remains unknown but are alarming and require further research.

Exercise as a Countermeasure to Improve Cardiorespiratory Fitness in Oncology

The field of exercise interventions in oncology has dramatically increased over the last few decades with nearly 100 published studies investigating the impact of structured exercise in oncology (Sasso et al. 2015). In healthy, non-cancer populations, aerobic exercise is the most effective therapy to improve VO_{2peak} (Jones et al. 2009); however, few trials have examined the impact of exercise on exercise capacity in oncology (Hurria et al. 2016a). The available literature is predominately derived from interventions in women with early breast cancer. Several studies have

demonstrated the safety (low adverse rates), tolerability (high adherence rates), and feasibility of aerobic training in patients with cancer (Hurria et al. 2016a). A recent meta-analysis of six randomized controlled exercise studies involving 571 patients showed improvements in VO_{2peak} compared with non-exercising controls (Jones et al. 2011). These exercise interventions frequently abrogated the declines in VO_{2peak} observed in the usual care group (Courneya et al. 2007; Jones et al. 2013). As exercise interventions in clinical trials vary greatly, from generic home-based exercise prescriptions to supervised tailored exercise treatments, more research is needed to determine the optimal timing, type, and schedule of exercise (Hurria et al. 2016a). Among the field of "exercise oncology," it is felt that individualized and non-linear training holds the greatest promise to improve outcomes, and randomized clinical trials comparing the impact of generic versus individualized interventions are ongoing (Sasso et al. 2015). Given the heterogeneous aging process and the wide ranging differences in health status between older individuals, generic exercise prescriptions can be challenging and less impactful. More tailored interventions are necessary for older adults with cancer that are adaptable to individual patients.

Conclusions

Assessments of cardiorespiratory fitness hold great promise in providing additional prognostic information in adults with cancer. Guidelines for accurately and safely measuring cardiorespiratory fitness are available (American Thoracic and American College of Chest 2003), but more work is necessary to learn how to best adapt these tests to older and more frail adults. Several studies to date have shown marked impairments in exercise capacity during and years after the completion of cancer therapy in adults, but the long-term implications of these declines are not yet known. Exercise interventions appear safe, tolerable, and potentially efficacious in offsetting these impairments in exercise capacity related to cancer therapy. Determining the optimal exercise training for patients with cancer and understanding the long-term clinical impact of declines and/or improvements in exercise capacity are areas of high research priority.

Methodology and Design Considerations

Many obstacles exist in studying older adults with cancer that directly pertain to and impede translational research. First and foremost, although older patients make up the majority of new cancer diagnoses and cancer deaths, they are underrepresented in the majority of cancer clinical trials (Scher and Hurria 2012). Sixty percent of individuals diagnosed with cancer are over the age of 65; however, they make up only 36% of the patients enrolled on US Food and Drug Administration (FDA) registration trials (Talarico et al. 2004). As a result, there is less safety and efficacy data regarding cancer therapeutics for this growing population compared to younger patients and also less opportunity to perform translational research in the older adult cancer population as a part of clinical trials (Hurria et al. 2014). Besides improving the participation rate of older adults on clinical trials, studies that focus specifically on older adults with cancer are also needed to help fill knowledge gaps and optimize care.

Due to the heterogeneous nature of older adults, adequately defining the population of interest is necessary for all clinical studies. The specific inclusion of older and/or frail patients in clinical trials is made more difficult by a lack of consensus regarding both "older" and frail. There is no precise age that denotes "older" patients, and many of the participants in cancer clinical trials are the most robust and healthiest of older patients with nearby access to specialized cancer centers (Gross et al. 2005). When considering age alone and the lack of representation on cancer clinical trials, those aged >75 are especially unlikely to be included (Scher and Hurria 2012; Talarico et al. 2004). Similarly, defining frail patients or those patients with less reserve and more vulnerable to develop cancer treatment toxicity is hindered by the lack of a validated and practical definition for

use in clinical studies (Hurria et al. 2014). The most commonly employed measures of frailty include the Fried phenotype and the Rockwood method; however, how these methods apply to identify at-risk older adults with cancer is less understood (Fried et al. 2001; Rockwood and Mitnitski 2007). For geriatric oncology specific studies, there is growing interest in defining frailty using validated chemotherapy toxicity tools to identify those at greatest risk for chemotherapy toxicity (Extermann et al. 2010; Hurria et al. 2016b).

Depending on the study and question of interest, thinking broadly about confounding variables that may be more prevalent in older adults is important. Many older adults face unique challenges ranging from loss of peers and loved ones to loss of functional and mobility independence to multimorbidity and polypharmacy. These stressors can vary from individual to individual, and this variability must be incorporated into study design. Comprehensive Geriatric Assessment is recommended for use in older adults that assesses a broad range of domains relevant to the older patient, including social support, nutrition, physical function, comorbidity, medications, etc. (Wildiers et al. 2014). This holistic evaluation includes many potential confounders common among older adults and should be included in studies of the geriatric oncology population.

Several study designs have been proposed to help fill the knowledge gaps in treating older adults with cancer. Randomized controlled trials (RCTs) still remain the gold standard to ascertain the superiority of one treatment or approach over another; however, RCTs are particularly costly and require large sample sizes. Embedded studies, otherwise known as correlative or ancillary study, are placed within the infrastructure of a larger parent study and can help provide additional metrics or translational aspects specific to older adults even if they are not the focus of the overall study. A prospective cohort study can help answer many questions regarding the toxicity and feasibility of certain treatment regimens or intervention strategies, but is unable to identify the best treatment as there is no randomization. Additionally, an extended trial design is a novel method that could be employed for trials in which a drug or intervention is deemed superior, yet failed to accrue an adequate number of older adults (Hurria et al. 2014). Although this method has not yet been employed to date, it offers the opportunity to fill the knowledge gap on the tolerability of a new therapy or intervention in older adults while not altering the structure or focus of the original trial.

Selecting the most pertinent and appropriate endpoints for clinical trials is also critically important (Wildiers et al. 2013). Many clinical trials focus predominantly on efficacy outcomes such as tumor response or overall and progression-free survival; however, many older adults emphasize quality of life and functional independence as much as or than survival (Wedding et al. 2007). In order to accurately balance the benefits and risks of a treatment or intervention in older adults many factors are relevant beyond efficacy measures alone. Older adults are less willing to trade increased survival for current quality of life (Yellen et al. 1994) and maintaining cognition and function is paramount (Fried et al. 2002). Measuring functional endpoints such as maintenance of functional capacity and/or incorporating composite endpoints that can take into account multiple dimensions of treatment benefit can be beneficial when designing studies for older adults with cancer (Wildiers et al. 2013).

General Conclusions

The aging of the United States population and abroad is resulting in a dramatic increase in older adults with cancer (Smith et al. 2009). Many challenges exist in treating older adults, but none more apparent than the need to better assess the aging process and improve our ability to predict the variability in outcomes evident in older patients (Hubbard et al. 2014). Translational research offers several novel avenues to improve our assessments of older patients to potentially aid in the assessment of the risks and benefits of treatments. Biomarkers obtained from peripheral blood, such as markers of inflammation, have been correlated with chronological age, frailty, and functional decline (Walston

et al. 2002; Brouwers et al. 2015). Sarcopenia has been associated with increased chemotherapy toxicity, surgical complications, and inferior survival, and body composition analysis from routine imaging could easily improve our ability to estimate risks with minimal additional resource allocation (Kazemi-Bajestani et al. 2015; Rier et al. 2016). Cardiopulmonary exercise testing and assessments of VO_{2peak} have been associated with surgical outcomes and overall mortality (Jones et al. 2010; Moyes et al. 2013; West et al. 2014). These tools not only help assess older adults, but also offer insight into the impact of cancer and its treatments on physiologic aging (Hurria et al. 2016a). Translational research may help identify subgroups of patients at high risk for adverse outcomes that can be targeted for intervention. Translational research must also consider the methodology challenges and design considerations relevant for studying older adults. Further development of these promising avenues of translational research are necessary to improve the quality of care for this growing and vulnerable population.

Abstract

For various reasons, older adults are underrepresented in cancer clinical trials. As the selection criteria in randomized controlled trials are well controlled, younger and fitter patients are usually only eligible, making it difficult for clinicians to draw conclusions on the effects of drugs in older, frail, or unfit adults. With an aging world population, more attention needs to be focused on geriatric oncology, but the challenge lies in designing trials that capture the heterogeneity of an entire population, particularly the elderly and frail.

Separate trials for older patients are needed that incorporate more appropriate end points and suitable control arms. Pharmacokinetic studies should also be undertaken given the effect of aging organs on drug pharmacokinetics. How to design such trials in the absence of global standardized geriatric assessment tools and definitions is, however, challenging.

Randomized or single-arm phase II trials in older adults can provide important information on efficacy and toxicity where a phase III randomized controlled trial (RCT) is not feasible. Observational cohort studies are proposed as an adjunct to RCTs. Large and well-designed observational cohort studies can capture relevant and clinically meaningful data in real-world settings on older patients ineligible for RCTs.

Better clinical trial design is crucial to understanding the impact of new cancer therapies on older patients. Trials in older cancer patients should be compulsory.

Observational cohort studies · Older patients · Randomized · Trial · Geriatrics

Introduction

Cancer is a complex disease associated with aging and so it is not surprising that the majority of new diagnoses and cancer deaths occur in people over the age of 65 years (Hurria et al. 2014). The world's population is also aging with the over-65-year-olds making up the fastest growing segment. By 2050, it is estimated that the number of people aged 65 and over will be 16% of the global total, which was just 5% in 1950 (United Nations 2010).

In the USA, for example, 65-year-olds made up 13% of the population in 2010. By 2030, it is estimated that this will increase to 20% and that by 2050 the number of 65-year-olds will have doubled. Eighty-five-year-olds are the most rapidly increasing segment of the US population and are projected to make up 21% of the country's population by 2050 (Hurria et al. 2015). As a further example, the projection over the next 40 years is that the proportion of the Australian population over 65 years will almost double. To put these figures into perspective, Australians aged 65 and over are expected to increase from around 2.5 million in 2002 to 6.2 million in 2042. For Australians aged 85 and over, the projected increase is from 300,000 to 1.1 million over the same period (The Australian Government, the Treasury 2016).

Despite these statistics, older adults are underrepresented in cancer clinical trials, and this raises clinical questions with regards to the efficacy and tolerability of cancer drugs in older people because they respond differently to cancer treatments compared to their younger counterparts (Hurria et al. 2015). It also raises questions about how to accurately define older patients and recruit them to clinical trials, given the heterogeneity of the group. With an expected increase in

cancer incidence and prolonged life expectancy of diagnosed individuals (Hurria et al. 2014), there is an obvious need to pay greater attention to geriatric oncology and to clinical trials in this population.

This chapter discusses the importance of trial designs that incorporate older adults into the development of new anticancer treatment strategies. A need also exists for trials that evaluate geriatric assessment and related interventions, but this is beyond the scope of this topic.

Definitions of "Older" and "Frailty"

Given the heterogeneity of older adults, the ability to accurately define older patients entering clinical trials is problematic. In 2012, the Cancer and Aging Research Group held a conference in collaboration with the National Cancer Institute, the National Institute on Aging, and the Alliance for Clinical Trials in Oncology (USA) from which the following definitions were recommended:

Older: Based on age alone, older patients are defined as aged 75 years or more for the purpose of study design and recruitment.

Frail: Based on a geriatric definition of frailty, frail patients are defined as older individuals who are at higher risk for cancer treatment toxicity because of associated conditions such as functional losses, cognitive impairment, or physiologic changes (Hurria et al. 2014).

These definitions alone, however, do not provide enough substance and a complete geriatric assessment should be mandatory in registration trials and encouraged in all trials that recruit older people. Without a geriatric assessment, it is impossible to know the characteristics of older trial patients or to whom the data can be extrapolated – were they older and fit only, or were they older and a mix of fit and frail? The European Organisation for Research and Treatment of Cancer (EORTC) and the Cancer and Leukemia Group B (CALGB) groups have proposed geriatric assessment tools, but other options exist, and there is no current universally accepted standard (Wildiers et al. 2013). Adopting a universal approach to definitions is just one of the challenges of geriatric cancer trials.

Implications of Underrepresentation of Older Patients in Cancer Trials

Multiple research studies have shown that older adults have historically been underrepresented in cancer clinical trials. Various reasons exist including physician recommendation, transportation or caregiver issues, "excessive" visits, financial aspects, restrictive eligibility criteria, trial design, perception of aggressive therapy, and limited expectation of benefit (Lichtman 2012b). Compared to younger patients, older patients are more likely to experience severe toxicities resulting in treatment discontinuation or receive a reduced dose which could dilute or affect the true treatment benefit. Older patients are also more likely to have comorbidities that can result in death from noncancer causes. Together, these issues have resulted in age limits and strict trial inclusion criteria which have excluded large numbers of older patients from clinical trials (Wildiers et al. 2013).

More recent evidence suggests that the lack of data in older cancer patients remains a concern (Scher and Hurria 2012; Hurria et al. 2014, 2015). For example, a review of the patient information leaflets of 24 cancer drugs approved between 2007 and 2010 showed that only 33% of the trial participants were aged 65 years, compared with almost 60% of the cancer population for the same age range (Scher and Hurria 2012).

National Cancer Institute (NCI) sponsored trials emanating from the USA have not fared better over time. From 1997 to 2000, of the 59,000 research participants in 495 NCI trials, only 32% were older adults compared with 60% of patients with cancer. Despite calls from as far back as the 1980s to pay more attention to geriatric oncology (Kennedy 1998), data from the NCI show that the percentage of older adults enrolled onto cooperative group trials between 2001 and 2011 has remained at just 20% (Hurria et al. 2015). Another study (Le Saux et al. 2016) showed that the

proportion of phase III trials reporting at least one analysis dedicated to elderly patients has grown since the creation of the International Society of Geriatric Oncology (SIOG): 46.7% between 2011 and 2014 versus 19.3% between 2001 and 2004. However, these data were mostly extracted from subgroup analyses and therefore the evidence can only be considered as preliminary.

Underrepresentation of older adults in cancer clinical trials has significant clinical implications. Organ function is affected by the aging process which, in turn, affects drug pharmacokinetics and metabolism (Wildiers et al. 2003). The biology of certain cancers also changes with aging. These factors, combined with the comorbidities expected in an older population, may result in substantial differences in the efficacy and safety of cancer treatments (Wildiers et al. 2013). While there is an increased understanding that chronological age and physiological age can differ substantially, many older adults receive less aggressive treatment, or chemotherapy less frequently than recommended by practice guidelines, because of questions surrounding tolerability and benefit (Hurria et al. 2014, 2015).

The underrepresentation of older cancer patients, coupled with a routine lack of reporting of age-related issues in clinical trials, often leaves clinicians with unanswered questions: Which patients experience serious adverse events? Do older patients experience more toxicity than their younger counterparts? Are there certain toxicities that are more prevalent in older patients? Do older patients complete treatment to the same extent as younger patients? Do older patients derive as much benefit from treatment? (Lichtman 2012a). Generally, there is a significant lack of information on the safety and efficacy of cancer treatments in older patients.

Recently, in an effort to respond to the crucial need for meaningful data in older patients, interest in geriatric oncology has been gaining momentum (Lichtman 2015). The Cancer and Aging Research Group (CARG), in collaboration with the National Institute on Aging (NIA) and the NCI, the American Society of Clinical Oncology (ASCO), and SIOG, have held a series of conferences to examine research priorities in geriatric oncology and provide recommendations on improving the evidence base in older patients with cancer (Hurria et al. 2014, 2015; Lichtman 2015; Mohile and Wildiers 2012). This has led to discussion on clinical trial design, wider eligibility criteria, and how to select the most appropriate endpoints relevant to the older population.

Suitable Endpoints in the Older Population

Endpoints are essential in clinical trials to assess the effectiveness of therapy. In oncology, well-established and standard clinical endpoints exist for randomized controlled trials (RCTs). While endpoints such as overall survival (OS) and disease-free survival (DFS) in the curative/adjuvant setting are gold standard, they may not be the most appropriate measures to balance the benefits against the risks of treatment in the elderly.

Table 1 provides a summary of the pros and cons of standard endpoints in randomized controlled cancer trials (Wildiers et al. 2013).

Overall Survival (OS)

OS is viewed as the gold standard among endpoints in cancer RCTs. It is a distinct and easy to measure end point, but its relevance in the elderly is complicated by noncancer-related deaths. It also does not take into account the importance of quality of life (QoL) parameters from the patient's perspective.

Disease-Specific Survival (DSS)

DSS better indicates how many patients die as a result of disease and how many die as a result of other causes, although this can be subjective as the cause of death may be difficult to evaluate. Trials should ideally report DSS in addition to OS as DSS can evaluate the "true benefit" of an anticancer therapy (Wildiers et al. 2013).

Table 1 Relevant end points in clinical trials in the older cancer population

Endpoint	Definition	Current situation	Pro	Con
Overall survival (OS): Time or proportion	Time from diagnosis of treatment situation/ study entry until death or rate of patients alive at a specified time point	Considered as the gold standard in clinical trials, especially when evaluating the superiority of new treatments	Remains hardest endpoint, also in elderly Easy and distinct to measure High impact for patients	"Oncological" relevance in elderly can be hampered by increased number of non-cancer related deaths (all life ends with death) Does not include aspects of quality of life
Disease-specific survival (DSS): Time or proportion	Time from diagnosis of treatment situation/ study entry until death from the index disease or rate of patients without death related to the index disease at a specified time point	Important to collect besides OS since it gives better insight into the contribution of non-cancer related deaths	Cancer treatment primarily aims at decreasing cancer death	Some cancer treatments might also influence non-cancer related deaths (e.g., treatment related mortality) May lead to an overestimation of the true benefit for patients in presence of competing risks (e.g., treatment benefit in localized prostate cancer) The reason for their death will be of no/minor meaning for patients Reason of death can remain unclear
Co-primary endpoints	Combination of two or more equal primary endpoints	Rarely used in oncology	Allows capturing more than efficacy alone	Difficult statistical design since the correlation between different endpoints is rarely known Might increase sample size
Composite endpoints	Combination of different endpoints in one defined endpoint	Rarely used in oncology (example is "skeletal related events"), but should be more encouraged. Example of TFFS and TTF here below	Can take into account multiple dimensions in the definition of "treatment benefit," including efficacy and toxicity Simple and efficient statistical design Allows also separate reporting of the different endpoints as well	Requires individual components of the composite that are clinically meaningful and of similar relative importance Difficult interpretation if there are divergent results for each component separately
Treatment failure–free survival (TFFS) and time to treatment failure (TTF):	TFFS is the time elapsed between randomization and early treatment discontinuation due to any reason (including disease progression,	Often used in addition to OS	Integrates efficacy and toxicity	Difficult to distinguish between efficacy and toxicity (e.g., toxic, but very effective) Treatments might be stopped for other

(*continued*)

Table 1 (continued)

Endpoint	Definition	Current situation	Pro	Con
Time or proportion	treatment toxicity and early death), disease progression, death (from any cause), or any other event of interest. TTF is similar but deaths from other causes are not considered as events			reasons (e.g., "chemotherapy holiday")
Quality of life related endpoints: Level at a specified time point or time until deterioration compared to baseline	Evaluation of the quality of life through validated instruments at baseline and during the course of the disease/treatment/ study	Often used as secondary endpoint in clinical trials, but should be more promoted as primary endpoint or part of a composite endpoint	QoL may be more important than duration of life for many older individuals	Difficult to measure and to determine clinically relevant cutoffs that make a therapy worthwhile or not
Maintenance of functional capacity/ dependence: Level at a specified time point or time until deterioration compared to baseline	Evaluation of the evolution of functioning and (in) dependence through validated instruments during the course of the disease/treatment/ study	Rarely measured in oncology trials, but crucial to include	Main contributor to quality of life in elderly cancer patients	No general consensus on optimal measurement and clinically relevant cutoffs that make a therapy worthwhile or not

Coprimary Endpoints

Coprimary endpoints enable researchers to capture more than efficacy alone. Multiple single endpoints can be chosen as coprimary endpoints of equal importance, and a statistical design, albeit difficult, can be built to test each separately. Coprimary endpoints, however, require a larger sample size if the trial objective is to have positive results for at least one or all coprimary endpoints, and the type I or II error, respectively, must be adjusted for multiple testing (Wildiers et al. 2013).

Composite Endpoints

A composite endpoint in a RCT is when multiple single endpoints are combined so that an event is triggered if any of the endpoints occur. Composite endpoints enable other parameters of interest, such as QoL or the ability to carry out daily tasks, to be incorporated. All components of a composite endpoint should be analyzed and reported separately. The separate reporting of endpoints is essential to facilitate cross-study comparisons (within limits) or to generate assumptions for future trial designs. The major advantages of a composite endpoint are the simple statistical design based on a single endpoint (i.e., the composite one) and the resultant increase in statistical efficiency.

An interesting example of a composite endpoint in older individuals is therapeutic success. This endpoint combines efficacy, toxicity, and patient compliance with treatment and is defined as a patient receiving at least three cycles of chemotherapy at the planned dose (without dose reduction) and schedule (no treatment delay

beyond 2 weeks) and having a response (either complete or partial) without experiencing grade 3 or 4 toxicity according to the Common Toxicity Criteria. Variations on this definition are possible. As an endpoint, therapeutic success is particularly interesting in the metastatic setting to compare toxicity, which in this situation should ideally be low, against a supposed treatment benefit. In the curative setting, however, higher levels of toxicity may be generally more acceptable if there is a considerable survival benefit. The adjuvant setting is also more challenging for composite endpoints given that toxicity is short term compared to the potential long-term benefit of treatment. While looking simultaneously at toxicity and efficacy has its advantages and disadvantages (therapies may be temporarily toxic, requiring dose reduction, but they may also be efficacious), therapeutic success is useful in settings where significant differences in toxicity between two treatments are expected and require further investigation.

Despite major advantages in terms of statistical design and efficiency, composite endpoints are not risk free. More information on the pros and cons of composite endpoints can be found in Kleist (2016) (Wildiers et al. 2013).

Treatment Failure–Free Survival and Time to Treatment Failure

Treatment failure–free survival (TFFS) and time to treatment failure (TTF) are well-known composite endpoints. TFFS is defined as the time that elapses between random assignment and early treatment discontinuation because of any reason (including treatment toxicity and patient refusal), disease progression, death resulting from any cause, or any other event of interest. While TTF is similar, only disease-specific and treatment-related deaths are considered events.

TFFS and TTF are interesting endpoints in elderly cancer trials. Both enable toxicity to be taken into account rather than just concentrating on efficacy. Older patients may prefer quality over quantity of life, so it is important to be able to capture treatment discontinuation due to toxicity. Treatment breaks or "chemotherapy holidays" that are unrelated to toxicity or disease progression should be taken into consideration rather than being viewed as treatment failures. Similarly, early treatment discontinuation should not be seen as a failure in situations where significant toxicity is followed by positive disease outcomes (Wildiers et al. 2013).

QoL-Related Endpoints

Improving or maintaining QoL is a major goal of cancer treatment. In the palliative setting in particular, the main aim should be to reduce the symptoms and discomfort arising from progressive disease such as loss of functionality, pain, and deterioration of overall QoL.

Health-related QoL (HRQoL) is a multidimensional parameter that focuses on the impact of health status on QoL. HRQoL is a major concern for patients with cancer and it can be influenced by symptoms due to cancer as well as treatment induced toxicity (Bottomley et al. 2003). While younger patients with children may prioritize survival over quality of life and therefore be willing to accept greater toxicity, it has been shown that older patients are less willing to compromise their HRQoL for an increase in survival potential (Wildiers et al. 2013; Yellen et al. 1994).

As a measure of outcome, HRQoL is appropriate in elderly trials and should be captured in all trials of palliative chemotherapy in older patients regardless of the primary endpoint of the trial. It is, however, fraught with issues on how it can be optimally measured given its complexity. How the different measures of QoL, such as physical, emotional, and social functioning, can be combined into one score, how they can be made relevant to older people, and which cut-offs are suitable endpoints are not well defined (Wildiers et al. 2013).

In an attempt to provide an instrument that focuses on HRQoL issues that affect older people with cancer, the European Organisation for Research and Treatment of Cancer (EORTC) QoL Group developed an elderly-specific questionnaire module to supplement its general QLQ-C30 core questionnaire (Wheelwright et al. 2013). Another valuable approach, incorporating

QoL considerations into treatment comparisons, is quality adjusted life years (QALY).

Compared to composite endpoints, quality of life adjusted survival approaches address the situation in which each component of the composite endpoint may not be equally important. One method for assigning weights that reflect the patient's perspective is to incorporate HRQoL into survival analyses. This endpoint is also interesting because it enables economic evaluations using cost-utility analyses (Cole et al. 1993; Glasziou et al. 1990). However, QALYs assume a certain consistency with choices over time, and the relation to individual and social preferences for health remains unclear (Woodward et al. 2013).

Preservation of Functional Capacity/ Independence

An endpoint closely related to HRQoL is the preservation of independence and function, and it should be a major aim of elderly patient cancer management. As survival has been shown to be linked with functional capacity, incorporating this measurement into outcome events would be highly valuable (Reuben et al. 1992; Wildiers et al. 2013).

Cognitive Function

Cognitive function can also be an important endpoint for older patients. In a French prospective study, approximately half of the patients experienced objective cognitive decline after adjuvant therapy for breast cancer (Lange et al. 2016). Cognitive deficits may affect a patient's quality of life and their compliance to treatment.

Surgical Trial Endpoints

A number of elderly cancer patients do not receive standard surgery as they are considered unfit for surgery due to an inaccurate estimation of their risk. The Pre-Operative Assessment of Cancer in the Elderly (PACE) assesses operative risk and is recommended for all elderly patients prior to surgery (Audisio et al. 2008). While surgical trial endpoints in the elderly are relevant, they should be accompanied by long-term outcome endpoints.

Improving Cancer Trial Design in Older Patients

Age Limits

The evidence demonstrates that cancer clinical trials do not adequately represent older adults and yet it is in this growing subset of the population that the use of cancer drugs will greatly increase as the population countries continues to age. In registration studies, drugs intended for use across the entire adult age spectrum should have outcomes evidence across the same age range. Therefore, trials should include older patients without an upper age limit and a minimum cohort of all older patients. Failure to do so creates a selection bias towards younger patients, or to older patients who may have been eligible for the trial on the basis that they are fitter. In this situation, the trial conclusions are unable to be generalized across the entire population, and this is especially true for patients who are considered older and frail.

While increasing the number of older patients into trials, specifically registration or phase III studies, sounds relatively easy, there are numerous factors at play. Ensuring sufficient accrual of older patients may require a trial to remain open once it has met its target until a minimum number of selected older patients have been enrolled. Documented information on the fitness status of the older enrolled patients is important, as is documentation on ineligible patients, so that the results can be correctly interpreted across the older subset.

The characteristics of the drugs under investigation may also pose an issue. Some standard treatments (control arm) are not suitable for unfit or frail older patients, or even those who are fit, because of their expected toxicity risks or other competitive risks. These include, but are not limited to allogenic bone marrow transplantation – high-dose cytarabine, anthracycline, or cisplatin; major

surgery; and concurrent chemoradiotherapy. In many ways, a "catch 22" situation arises out of the drugs being compared – a RCT with a "heavy" control arm and a "soft" experimental arm will never include frail older patients; a RCT comparing two "soft" treatments is unlikely to include fitter older patients who may be candidates for a "heavier" standard treatment. In such situations, specific trials in the frail or older patient that modify a chemotherapeutic or biologic regimen and compare it against supportive or palliative care may be a better approach. Another option, depending on the setting, could involve comparing standard therapy to less aggressive therapy or to no therapy (Wildiers et al. 2013).

Phase III Versus Phase II Trials

While phase III studies are gold standard in clinical research regardless of age, phase III RCTs are usually reserved for younger populations as designing trials that address the heterogeneity of older populations is challenging. Due to an enhanced risk of toxicity or other adverse events that could hamper drug development, there is probably also reluctance from the pharmaceutical industry to develop significant trials (registration or other) in older patients, despite an aging global population offering huge market potential.

The ability of phase II trials to provide insight into the efficacy and toxicity of cancer drugs in older adults may, however, provide an adequate solution. A randomized phase II study in elderly unfit patients could serve to quickly establish if a drug is too toxic compared to the results of a phase III study in younger and fitter patients. Similarly, if a phase II study in older unfit patients produced efficacy and toxicity results in line with a previous phase III study in younger patients, there may not be a need to repeat the phase III trial again in the older unfit population. Elderly-specific clinical trials are therefore relevant for unfit patients. As the definition of frailty is not consensual, stratifying patients according to their life expectancy, toxicity risk (using the Chemotherapy Risk Assessment Scale for High-Age Patients (CRASH score)) and geriatric covariates (such as activities of daily living or nutritional status, etc.) may enable data to be extrapolated to clinical practice. The difficulty with this approach is the selection of an appropriate control arm, but this could be overcome by leaving the control arm to the investigator's discretion.

In the event that an appropriate control arm is not feasible, a single arm phase II study with toxicity as an end point is a possible practical solution. Despite single arm phase II studies being less robust than randomized phase II or phase III data, a single arm phase II elderly study would at least provide an indirect comparison of the efficacy and toxicity data from previous studies as well as information on relevant end points, as previously discussed. While they are not perfect, single arm phase II studies are sometimes the only feasible option and do translate across to clinical care. The adoption of the R-miniCHOP (rituximab plus low-dose cyclophosphamide, doxorubicin, vincristine, and prednisone) in patients over the age of 80 years with B-cell lymphoma is one such example (Wildiers et al. 2013; Peyrade et al. 2011).

Pharmacokinetics and Phase I Trials

Aging organs affect the pharmacokinetics of drugs and the metabolic process which often causes enhanced drug toxicity compared to that seen in younger patients. Having a thorough understanding of the pharmacokinetics of anticancer drugs in older and frail patient populations is therefore highly valuable. Pharmacokinetic and phase I studies specific to these populations should be designed for new drugs and could run parallel to standard phase I trials or shortly thereafter, assuming the results of standard studies have shown promise.

Another interesting concept is to progressively increase the inclusion criteria in phase I/II trials. The drug or regimen being evaluated is administered first to patients in good condition. Cohorts of patients with increasing comorbidities or functional limitations are subsequently added, providing thresholds for dose reductions or changes. Geriatric assessment tools such as the CRASH

Table 2 Issues in clinical trials design in older cancer patients

Randomized controlled trials (RCT) remain the gold standard when possible
Clinical trials should preferably integrate the whole age range including fit and frail older individuals
Elderly specific clinical trials in older cancer patients are required if standard therapy is different from younger patients
Trials on treatment strategy comparing different strategies (e.g., therapy vs. best supportive care) should be encouraged
Randomized phase II or even single arm phase II trials in specific subsets of older patients can provide insight in the range of efficacy and toxicity in older populations, but ideally need to be confirmed in large phase III trials that might be very hard to perform for various reasons (insufficient interest from sponsors/investors, difficulty to find sufficient patients,. . .)
Not all questions can be answered with randomized trials, and large observational cohort studies or registries even in the community can provide further insight for the frail population with much less selection bias (preferably in parallel with or linked to RCTs)
Comparable/uniform geriatric assessment should be integrated in future trials in geriatric oncology
Regulatory authorities should require evaluation of efficacy and safety of new drugs also in older/frail patients

score and the CARG (Cancer and Aging Research Group) score could be incorporated into this approach in order to predict chemotherapy toxicity, but stratifying patients using risk indicators is hindered by the exact definition of frailty or vulnerability which is still not universally clear. Table 2 summarizes the key issues in clinical trial design for older cancer patients (Wildiers et al. 2013).

Randomized Controlled Trials, Observational Cohort Studies or Both?

Randomized Controlled Trials (RCTs)

The history of clinical trials dates back to approximately 600 BC. Credit for the first modern randomized trial is usually given to Sir Austin Bradford Hill, a professor of medical statistics who pioneered the design while evaluating the use of streptomycin as a treatment for tuberculosis. Today, RCTs are seen as the gold standard for establishing the efficacy of one intervention over another and this is due to the randomization process which reduces the risk of bias. Stolberg and colleagues define RCTs as quantitative, comparative, controlled experiments in which a group of investigators studies two or more interventions by administering them to groups of individuals who have been randomly assigned to receive each intervention (Stolberg et al. 2004).

RCTs require carefully controlled environments, populations, resources, and time. To achieve a controlled environment, RCTs have strict inclusion and exclusion criteria which limit the heterogeneity of each study arm. Patients are then randomly assigned to one intervention (control) or another (comparison) so that the only known major variable is the exposure to the intervention being tested. While this is excellent for quality control, the results of randomized trials have the potential to establish a new standard of care that may not necessarily be applicable across broad populations, particularly the elderly (Mohile and Wildiers 2012). A good example of this is the BCIRG001 trial. It demonstrated that adjuvant docetaxel, doxorubicin, and cyclophosphamide (TAC) is superior to 5-fluorouracil, doxorubicin, and cyclophosphamide (FAC) in node-positive breast cancer (Mackey et al. 2013). Despite the superior OS and DFS of the TAC regimen, it was not taken up as a treatment option in older patients principally due to its toxicity profile. The cut-off age in the trial was 70 years.

While there are many clinical questions in geriatric oncology that require investigation, their assessment within the context of a RCT is challenging. For example, what are the outcomes in older patients with indolent prostate cancer who undergo surgery versus those who do not? Does adjuvant chemotherapy in older breast cancer patients provide a worthwhile benefit versus no chemotherapy? Treatment strategy trials, such as those in which an active intervention is compared to no intervention, find recruitment difficult compared with trials that compare one intervention against another. Selection bias and crossover due

to "resentful demoralization" may also occur when patients are aware of a new treatment not available to them and comply poorly with the standard treatment. For example, the CASA and ACTION adjuvant breast cancer chemotherapy trials, which compared chemotherapy to no chemotherapy, did not meet their accrual goal due partly to poor patient acceptance. Conversely, the CALGB 49907 trial that compared the efficacy of standard chemotherapy (either cyclophosphamide, methotrexate, and fluorouracil [CMF] or doxorubicin plus cyclophosphamide [AC]) with capecitabine in women with early-stage breast cancer aged 65 years or older was more feasible (Mohile and Wildiers 2012). The impact of the assigned intervention on a patient also needs consideration – the impact of being assigned to an active treatment versus no treatment in older patients is far greater than being assigned to either one of two possible active treatment arms.

There are novel trial designs available that address the difficulties encountered when patients recruited to RCTs do not receive their preferred treatment. The most well-known is the post-randomization consent design, proposed by Harvard School of Public Health statistician Marvin Zelen (1927–2014). The Zelen design randomizes patients before consent to participate in the trial has been obtained. There are two types of Zelen design: the single and the double consent method. In the single consent approach, only study participants allocated to the nonstandard intervention are asked for consent to receive the new intervention. If they refuse, they are given standard (control) therapy. In the double consent method, the control arm participants are also given the opportunity to refuse treatment and can access the alternative approach. While the Zelen design may be more ethical in some circumstances and remove the bias due to "resentful demoralization," there are inherent issues with Zelen's design. As consent for randomization is not sought, "consent bias" can arise because participants can refuse consent after allocation, and crossover may be more likely as patients are fully aware of the treatment to which they have been assigned (Torgerson 2004).

Fixed 2:1 or Bayesian adaptive randomization trials (Thall and Wathen 2007) are other designs that may be more attractive to patients and clinicians as the number of patients assigned to the effective, or supposedly effective, treatment is higher. These trial designs can therefore provide a solution to the expected poor accrual rates.

While the issues discussed above are relevant across all ages, and treatment strategy trials are challenging, it is important to continue to find novel solutions and experiment with designs applicable to the older unfit population. While there is currently no ideal trial design, one practical solution may be to invest more in large observational cohort studies.

Observational Cohort Studies

At the 2011 SIOG meeting in Paris, an international group of leaders recommended that observational cohort studies be developed to increase the much needed evidence in geriatric oncology. An observational cohort study prospectively follows a group of individuals who have specific features in common over a defined period of time. Unlike registries which monitor events, the information collected in observational cohort studies is prospectively defined for outcomes, sample size, and duration of follow-up. Used in conjunction with RCTs, robust observational cohort studies have the potential to provide timely and cost-effective data on efficacy, safety, and compliance in real life older patients (Mohile and Wildiers 2012). The key word here is "robust" as careful consideration needs to be given to the design of observational cohort studies so that clinically meaningful results can be obtained.

Single Versus Multicenter Observational Cohort Studies

Single-center cohort studies in older patients, while useful, provide limited meaningful information as individual treatment centers tend to use the same, and potentially biased, approach. Large, multicenter observational cohort studies are therefore preferred as they have the ability to provide useful data about the consequences of specific treatment decisions. However, because the treatment approach towards older cancer patients

between centers and countries no doubt differs, it is vital that these studies collect similar, if not identical, data across different tumor types and settings to enable the creation of large databases and cross-trial comparison. The EORTC minimum data set has been proposed for this purpose (Mohile and Wildiers 2012; Pallis et al. 2011).

Overcoming Bias in Observational Cohort Studies

Observational studies can provide important, unbiased, and accurate information on the toxicity of new drugs or therapies in the general older population. However, caution is required when an evaluation of efficacy compared to other treatment strategies is the goal. The sheer fact that treatments are not randomly assigned in observational cohort studies means that they are subject to bias and that the causal effect from treatment may not be entirely accurate. An example of this is the 2016 publication of an analysis by McGale and colleagues on the causal effects of radiation therapy on breast cancer according to the SEER public-use data set versus the meta-analyses of randomized trials of radiation therapy or not from the Early Breast Cancer Trailist's Collaborative Group (EBCTCG) (McGale et al. 2016). Despite the SEER data set being one of the largest and most detailed data sets available, the analysis found major qualitative differences between the EBCTCG and SEER data. The SEER data showed that radiation therapy after mastectomy in women with one to three positive nodes causes death from breast cancer and that radiation therapy prevents mortality from all causes except breast cancer, including from heart disease and from accidents and violence. These results contradict the results of randomized trials, prompting the authors to conclude that nonrandomized comparisons are liable to provide misleading estimates of treatment effects and require careful justification each time they are used (McGale et al. 2016).

Careful study design is therefore vital if clinically meaningful results are to be obtained from observational cohort studies. One way to help overcome issues with bias and still collect valuable additional data is to establish a RCT and to include ineligible patients, or those who declined, in a parallel observational cohort study.

Table 3 Observational cohort studies – considerations for improved trial design (Mohile and Wildiers 2012)

Include patients ineligible for a RCT into an observational cohort study
Include sensitivity analyses – to assess the effects of decisions on outcomes
Include propensity score analyses – to compare the characteristics of patients with a healthy control group
Ensure a prospective design and capture defined outcomes as they occur
Prospectively collect confounding variables and power the study so that it can be adjusted for these variables
Ensure that comparison groups across the cohorts are as similar as possible
Consider pre- and post-comparisons at individual level to foster validity

RCT randomized controlled trial

Integrating patients into an adjunct observational cohort study would increase the quality of the RCT because the patient selection would be better described. In practice, this would offer clinicians a broader understanding of the types of patients in whom the results of the RCT can be generalized (Wildiers et al. 2013). Additional considerations to improve the design of observational cohort studies are listed in Table 3.

In contrast to the McGale publication, the EURECCA Breast Cancer Group study (Derks et al. 2017) is a well-conducted cohort study with interesting results. Data from national and regional population-based or hospital-based cancer registries were collected from six European countries. 214,673 patients with nonmetastatic invasive breast cancer (BC) aged $\geq$70 years at the time of diagnosis were included. For patients aged 70–79 years with stage I BC, the large variation in adjuvant endocrine therapy use between countries (17.9% in The Netherlands vs. >80% in other countries) was not linked to the variation in relative survival. In stage III BC, the proportion of patients receiving chemotherapy in The Netherlands (16.6%) was considerably lower than in Belgium (52.6%). For patients aged 70–79 years with stage III BC, a high proportion of chemotherapy was linked with a significantly better relative survival. This study highlights the fact that some countries tend to over-treat their older stage I BC patients with endocrine therapy (and radiotherapy) with no impact on survival,

while other countries tend to undertreat their stage III BC patients where survival can be positively impacted with chemotherapy.

So while observational cohort studies can give bias, if well designed they can be used to collect data relevant to older populations including efficacy, safety, adherence to treatment, patient-reported outcomes, HRQoL, resource utilization, and patterns of care and cost. As shown, they can enhance the quality of RCTs and potentially inform and guide RCTs that compare different treatment approaches in older patients with cancer. Finally, as older cancer patients with comorbidities are usually excluded from RCTs, observational cohort studies can address this shortcoming by evaluating the relationship of comorbidities or underlying health problems with cancer treatment outcomes (Mohile and Wildiers 2012).

Expanded Access Programs

Expanded access programs (EAPs) make investigational new drugs available, under certain circumstances, to treat a patient(s) with a serious disease or condition who cannot or who can no longer participate in a controlled clinical trial. While the primary intent of an EAP is to provide treatment rather than to collect data, EAPs are useful in that they can provide real life safety data and give information on the wider use of the drug by different patient subtypes. For example, in the TARGET trial, the proportion of patients aged over 70 years receiving sorafenib for renal cell carcinoma was 12% (Escudier et al. 2007), but in the real life EAP it was 29% (Stadler et al. 2010).

Conclusion

Despite an aging world population, older adults are underrepresented in clinical trials leading to selection bias and difficulty in drawing conclusions on the effects of interventions in this segment. The oncology community is now more aware of this issue, but the challenge lies in designing trials that capture the heterogeneity of an entire population, particularly the elderly and frail.

Separate trials for older patients with cancer are needed incorporating pharmacokinetic studies, appropriate end points, and appropriate control arms. OS is a crucial end point, but DSS should be recorded in all cancer trials with older patients to capture deaths from causes other than cancer. Composite end points allow additional parameters, such as QoL, preservation of functional capacity, and independence, to be recorded, all of which are important for older adults.

Randomized or single-arm phase II trials in older adults can provide important information on efficacy and toxicity where the feasibility of a phase III RCT is hindered by insufficient interest from sponsors or lack of patient numbers. Large observational cohort studies have been recommended, ideally alongside a RCT, to capture data on ineligible trial patients such as the older and unfit.

Geriatric assessment in elderly-specific trials is important to better understand the characteristics of the elderly population and their fitness, but a global and standardized approach to definitions and assessment tools is required. The European Medicines Agency (EMA) has an established plan to ensure that drugs are examined appropriately in pediatric patients and, in a recent paper, suggest that the same should be devised and compulsory for older adults (Cerreta et al. 2016).

In conclusion, better clinical trial design is crucial to understanding the impact of new therapies on older individuals and to improving care for this growing population.

Abstract

Big data is widely seen as a major opportunity for progress in the practice of personalized medicine, attracting the attention of medical societies and presidential teams alike as it offers a unique opportunity to enlarge the base of evidence, especially for older cancer patients underrepresented in clinical trials. The methodology to access such data for research and clinical practice is evolving rapidly. In this chapter, the authors share their experience using such data for research and clinical practice. We review key principles in managing and searching such health and research informatics databases. We share methods to conduct research in the basic and translational sciences, clinical research, and personalized medicine for older cancer patients.

Keywords

Cancer in the elderly · Clinical decision making · Big data · Health and research informatics · Geriatric oncology research

Introduction

Big data is one of those words that generate a general understanding, while their definition is harder to pinpoint. A general definition for the purpose of this chapter could be: "A very large, diverse, and rapidly evolving set of data collected in a structured fashion, and retrieved via analytic software." Functionally, big data is that whose scale, diversity, and complexity require new architecture, techniques, algorithms, and analytics to manage it and extract from it. More specifically in our setting, big data is referring to a medical, biological, or population dataset that is relevant to older cancer patients.

Potential Uses in Geriatric Oncology

While a main driver for the creation of large databases accessible by computerized algorithms has been molecular biology, increasingly these databases are being extended or developed specifically for clinical decision support purposes. Data from cancer registries and other sources are integrated in these extensions as well.

Cancer Registries and Insurance Claims Databases

A large dataset that has been extensively used in epidemiologic studies is the Surveillance Epidemiology and End Results (SEER)-linked Medicare database. For example, Barnholtz-Sloan and team evaluated treatment patterns and survival among elderly patients diagnosed with malignant astrocytoma utilizing SEER-Medicare linked data (Barnholtz-Sloan et al. 2008). An advantage from a geriatric oncology point of view is that it is focused on patients aged 65 and above (the Medicare eligible age). While this registry is a population-based one, it has several limitations. The first one is that it doesn't cover the entire United States (US). The SEER registry focuses on nine States and four specific areas to balance a representative sample of the US population. Another limitation is that oral medications (with a few exceptions) are not tracked. Furthermore, it is a claim-based database. For patients in some bundled insurance plans, the information may therefore be limited as well. Histological details are not tracked, and staging is rudimentary. Many developed countries have tumor registries, with various levels of detail on tumor characteristics, treatment, and outcomes. As a general rule, while mortality is tracked extensively, relapse, recurrence, and disease progression are not tracked by cancer registries. Despite these limitations, the

SEER-Medicare database and cancer registries still have a lot of unexplored opportunities to understand and develop the care of older patients. Access to the SEER-Medicare database can be obtained by submitting a new application, a signed/completed SEER-Medicare data use agreement indicating the specific data files of interest, documentation of institutional review board (IRB) approval, and a signed/completed request form if restricted data elements such as patient zip code or patient census tract are needed in order to answer the research question(s).

Some large health maintenance organizations (HMOs) such as the Kaiser Permanente group also have very detailed datasets. Another example of a large claim-based database is the Japanese national receipt database, which combines claims and results of health checkups in older patients (Ishikawa 2016).

Health and Research Informatics Databases

To overcome some of the limitations of the epidemiologic and claims databases, a strong emphasis is ongoing to leverage electronic medical records (EMRs) to build databases with more granular information and links to clinical pathways. These offer powerful potential tools for older patients with comorbidities. Clinical trials, despite ongoing efforts to improve accrual of older patients, still have an underrepresentation of older subjects (Hurria et al. 2014). Evidence for those complex patients could come from these big datasets. The oldest of these projects is the Total Cancer Care (TCC)^{TM} database. The TCC concept was created in 2003 and implemented in 2006 at H. Lee Moffitt Cancer Center and Research Institute (MCC) in Tampa, Florida, and has expanded into a multicentric network of 18 additional institutions (Fenstermacher et al. 2011). More recent databases are CancerLinQ, coordinated by the American Society of Clinical Oncology, and Watson, based at MD Anderson Cancer Center in Houston, Texas, both started in 2013. These large databases collect information from EMR documented patient data and restructure it into a single database that can be used to ask a variety of questions. Parameters including age, comorbidities, treatments, and outcomes can help to focus on populations of interest and provide detailed output. To facilitate this, these big datasets work with large software partners, Oracle, System Application Products (SAP), Microsoft, and International Business Machines (IBM) respectively.

Methods for Effective Big Database Digging

There are various methods for big database digging; however, this section will focus on the top 6 methods that we have found to be effective and successful. Figure 1 highlights the building blocks for effective and successful big database digging and will be referenced throughout this section. One of the first and essential methods for effectively executing a deep dive into a large database with oncology data is to have a basic understanding of relational databases and database design. For example, it is important to know whether you are working from multiple tables, spreadsheets, and/or databases or whether you are working from a single table, spreadsheet, or database. Knowing how multiple tables are linked on the backend of the database as well as a thorough understanding of the individual source systems populating the database is critical. Having this knowledge is one of the key building blocks (Fig. 1) because this knowledge will allow you to determine the database primary key and foreign key(s) and where to extract the data from if you are utilizing a programming language such as structured query language (SQL) or statistical analysis software (SAS).

Secondly, it is important to have an understanding of the cancer language for each cancer site. This building block specifically targets data analysts or a similar employee who is responsible for extracting or summarizing the data in the form of reports, charts, or graphs from the database. Having a firm understanding of the data you are extracting will allow you to accurately interpret and provide guidance to those who plan to

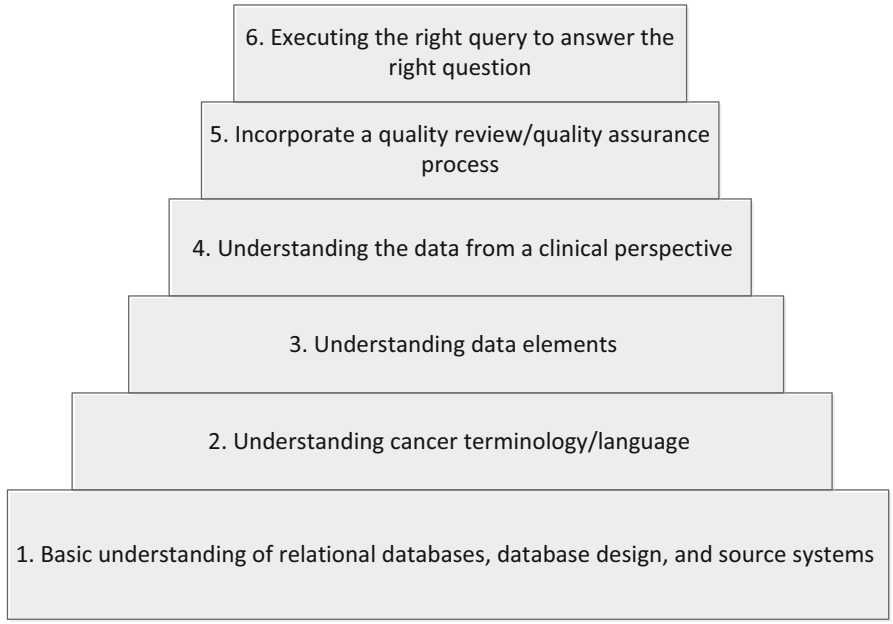

Fig. 1 Top 6 methods (building blocks) for effective and successful big database digging

interpret the data. In addition, successfully understanding this building block will prepare you for the fifth building block, being able to complete a quality assurance/quality review. It is important to have working knowledge of the cancer jargon and know that some of the cancer language has changed over time. This is important when executing a data query to search for cases that meet a specific inclusion/exclusion criterion. For example, when looking for patients that were diagnosed with small cell lung cancer, it is important to have historical knowledge that you need to look for small cell and oat cell using the histology/morphology data element because historically small cell was called oat cell. On the other hand, if you are executing a data query to identify neuroendocrine cases, then you need to include carcinoid because historically neuroendocrine tumors were classified from a histologic/morphology perspective as carcinoid. Without this background knowledge, it is easy to exclude cases that actually meet the inclusion criteria, potentially underestimating your sample size. Hawhee and Williams created an online resource guide for training and education targeting cancer registrars; however, the training guide is useful for anyone seeking cancer-related reading material and training resources (Hawhee and Williams 2016).

Thirdly, it is pertinent to make sure there is complete understanding of the data elements contained within the database. Having an in-depth knowledge of the data elements, the source system that contains the data elements, as well as start and stop dates for the collection of the data elements, is critical. Without this knowledge, it is difficult to understand the capability of data queries that can be executed using the big data. For example, it is important to know the transition of data codes from the International Classification of Diseases, Ninth Edition (ICD-9) to the International Classification of Diseases, Tenth Edition (ICD-10). Also, from a database perspective are the values for ICD-9 codes consolidated into one data element with ICD-10 or do you have to pull data from two different data elements by creating an OR statement in order to accurately execute a data query. In addition to knowing the data elements, it is also important to have a data dictionary available for reference that clearly defines each data element along with other descriptive information about the data element such as data collection start date, data collection end date, data

element permissible values, numeric code, and corresponding description. If you do not have a data dictionary, it is highly recommended that you create one, preferably electronic, and update it every quarter or monthly if data elements are consistently being added.

The fourth building block is to ensure understanding from a clinical, hospital operations, and research perspective. The policies and standard operating procedures of healthcare are often times the driver for the various nuisances in the way that data are collected and coded. Knowing from a high level how data are captured in the electronic health record by the cancer registry and by decision support or financial teams will help ensure that you are accurately interpreting the data. Also, having some knowledge on how the data are entered into the source system (s) will help because this will be beneficial when the data are extracted and there are questions regarding specific data elements and potential missing data.

Next, it is highly recommended to have a quality assurance/quality review (QA/QR) process in place so those working directly with the data queries can collaborate with the clinicians to confirm the data are clinically feasible and interpretation of the data is accurate. During the QA/QR process, it will be helpful to provide a summary at the data element level on the percentage of missing values, blank values, unknown values, and complete values. In addition, it will be helpful to create a process to identify any errors in data entry and the errors being corrected in the source system.

Finally, when executing a query, it is important to know what question(s) you are trying to answer. A clinician and data analyst speak different languages, so it is important for data analyst to understand from a clinical perspective what question is being asked. In addition, it is worthwhile for the clinician to understand the data elements that are readily available that can answer the question(s). In working with data, you will get an answer or number when executing a query, but the key is to make sure that you are answering the right question and you have executed the query accurately.

Specific Research Applications and Methods

Mutations, Gene Expression, Epigenetics

Big data has been used the longest in basic sciences: genome databases, proteomics, metabolomics, and other databases abound. Such databases can be very helpful to explore the biology of aging and cancer, the molecular impact of comorbidities, and more. We list below potentially useful databases. Multiple softwares are available to analyze such data and minimize the false discovery risk (FDR). We recommend using a statistician familiar with these softwares for analysis. The identification of pathways and clinical potential require biological knowledge of the diseases involved. It is also important to have a notion of how the tissue was collected, how the patients were selected, and which clinical correlates are available.

Examples of publicly available big data websites:

GEO database: GEO (Gene Expression Omnibus) is a public functional genomic data repository supporting MIAME-compliant data submissions. Array- and sequence-based data are accepted. Tools are provided to help users query and download experiments and curated gene expression profiles. GEO is an international public repository that archives and freely distributes microarray, next-generation sequencing, and other forms of high-throughput functional genomic data submitted by the research community.

https://www.ncbi.nlm.nih.gov/geo/

GEO database is organized by individual projects, each represented by a (usually) published manuscript. For many journals, it's required to upload your data to GEO before you can get your manuscript accepted for publication.

GEO provides browsing and keywords searching functions. For keyword searching, it returns documents, samples, and datasets whose descriptions contain any of the keyword combinations you are searching for. The search results are displayed as a list of manuscript titles, followed by short descriptions and links to full-

length articles, clinical data, and full-size datasets in different formats. You can select to download datasets as raw cell files and/or normalized expression intensity values in tab-delimited format. These datasets can be used for data mining for new discoveries or for validating biomarkers already developed.

TCGA (The Cancer Genome Atlas) is a collaboration between the National Cancer Institute (NCI) and the National Human Genome Research Institute (NHGRI) that has generated comprehensive, multidimensional maps of the key genomic changes in 33 types of cancer. The TCGA dataset, comprising more than two petabytes of genomic data, has been made publically available, and this genomic information helps the cancer research community to improve the prevention, diagnosis, and treatment of cancer (https://cancergenome.nih.gov/).

Unlike GEO, TCGA is not organized by individual projects, but by disease type. All samples for a certain disease type from multiple projects are incorporated into one big dataset. TCGA provides browsing and querying functions. You can browse their data by primary site, disease type, data category, experimental strategy etc. You can download data from TCGA as well as upload data to TCGA for online analysis.

ICGC (International Cancer Genome Consortium) Data Portal is a confederation of members that share the common goals and principles described in the policies and guidelines document and have agreed to work in a coordinated and collaborative manner within a defined structure. The members of the committees and working groups will help to provide clarity to the ICGC structure as it moves forward. The ICGC Data Portal provides tools for visualizing, querying, and downloading the data released quarterly by the consortium's member projects.

https://dcc.icgc.org/

ICGC contains most of the datasets TCGA has, plus more datasets from non-US countries. ICGC provides keyword search and browsing functions similar to GEO and TCGA. It also provides online data analysis functions such as enrichment analysis, cohort comparison, set operations, and some simple visualization functions.

MetaCore™ is an integrated software suite for functional analysis of next-generation sequencing, variant, CNV, microarray, metabolic, SAGE, proteomics, siRNA, microRNA, and screening data. MetaCore is based on a high-quality, manually curated database of:

- Transcription factors, receptors, ligands, kinases, drugs, and endogenous metabolites as well as other molecular classes
- Species-specific directional interactions between protein-protein, protein-DNA and protein-RNA, drug targeting, and bioactive molecules and their effects
- Signaling and metabolic pathways represented on maps and networks
- Rich ontologies for diseases and processes with hierarchical or graphic output

https://lsresearch.thomsonreuters.com/pages/solutions/1/metacore

IPA (Ingenuity® Pathway Analysis) is a powerful analysis and search tool that uncovers the significance of omics data and identifies new targets or candidate biomarkers within the context of biological systems. IPA has broadly been adapted by the life science research community and is cited in thousands of articles for the analysis, integration, and interpretation of data derived from omics experiments, such as RNA-seq, small RNA-seq, microarrays including miRNA and SNP, metabolomics, proteomics, and small-scale experiments.

https://www.qiagenbioinformatics.com/products/ingenuity-pathway-analysis/

Potential Application: Diagnostic and Targetable Mutations for Personalized Medicine

The evolution of massively parallel sequencing technology has facilitated the translation of somatic genomic sequencing from being confined to the research realm into standard clinical practice, and its role in both prognostic aspects and treatment direction continues to evolve.

The genetic analysis of tumor tissue and "liquid biopsies" using cell-free DNA (cfDNA) can now be performed at reasonable costs with clinically relevant mapping. The technology has evolved to allow for higher specificity/sensitivity and quicker turnaround times in a cost-effective manner. The benefits of this in terms of prognostic aspects and treatment direction continue to evolve as do the analytic tools facilitating its use and the ability to leverage the data for optimizing future decision making. As cancer centers develop a workflow for integrating genetic tumor analysis into practice, there is also a need to create and maintain databases to store tumor genetic data. These results, in connection with patient characteristics and outcomes, can be used for standard of practice identification of EGFR, KRAS, BRAF, etc. mutations to help with informing both prognosis and classification of specific subtypes of common cancers, as well as tracking response over time and sequential sampling.

Numerous institutions have published their site-specific descriptions of data handling and patient outcomes (Knepper et al. 2017; Radovich et al. 2016; Wheler et al. 2016; Schwaederle et al. 2014). These databases typically include patient demographics, disease characteristics including prior therapies, the type of genetic assay performed, source and date of the tissue acquired for the assay, and the actual gene and mutation results, along with copy number or allele frequencies. Databases may be directly integrated with a site's EMR which may aid in documenting outcomes, or this may be done manually on a regular rolling basis as patients progress through therapies. Since these databases often contain identified patient data, handling and accessing the information must be in compliance with HIPAA and require an IRB application for access. Certain research and shared databases, such as CancerLinQ, are de-identified and require different agreements. The ongoing creation and maintenance of this data provides a valuable resource for addressing some of the current challenges faced by the integration of genetic tumor profiling into standard practice. In the advanced disease setting, big data can be used to identify novel treatment targets for patients who have progressed through multiple lines of therapy or in those with rare tumor types and few standard treatment options and are now incorporated into the standard work-up and management of numerous solid tumors and hematologic malignancies. This approach can also help direct patients into clinical trials, including the novel basket and umbrella trials like the NCI MATCH study.

Challenges include the rare nature of many genetic alterations. Somatic mutations can serve as either prognostic or predictive biomarkers or, in some cases, both. Prognostic biomarkers are measurable variables that provide information about cancer outcomes, including disease recurrence and overall survival, independent of the treatment received (Ballman 2015). For example, in acute myelogenous leukemia (AML), TP53 mutations and internal tandem duplications of FLT3 (FLT3-ITD) are associated with poor outcomes, while CEBPA and NPM1 alterations are associated with more favorable outcomes (Dohner et al. 2015). Predictive biomarkers are measurable variables that are associated with treatment outcomes. These can include alterations that predict benefit from a certain drug or class of drugs, such as epidermal growth factor receptor (EGFR) activating mutations in non-small cell lung cancer (NSCLC) that predict responsiveness to inhibitors of EGFR such as erlotinib and gefitinib. They may also include negative predictive biomarkers associated with resistance to a certain drug or class, such as KRAS mutations in colorectal cancer and the lack of response to monoclonal antibodies that inhibit EGFR, such as cetuximab and panitumumab (Ballman 2015; Bardelli and Siena 2010). Given the importance both prognostic and predictive biomarkers have in cancer management, comprehensive guidelines now incorporate those with robust data into the standard diagnosis and treatment for numerous malignancies. Somatic genetic assessment can also be used in the setting of more advanced disease and/or when there are limited or no treatment options for patients. In these instances, less common alterations can be uncovered and their actionability may be less clear. The goal of clinically interpreting a genetic variant is to determine those alterations considered to be "drivers" of

the malignant process from "passenger" or germline alterations. Cancer cells depend on "driver" mutations that provide a growth advantage to these rapidly proliferating cells, while "passenger" mutations do not have a direct effect on the neoplastic process (Vogelstein et al. 2013). Generally, clinically actionable alterations are defined as those with evidence supporting:

1. Correlation with benefit or resistance to a particular therapy
2. Effect on the function of a gene associated with cancer biology that can be targeted with either an FDA-approved therapy, off-label therapy, or a clinical trial
3. Specific inclusion criteria for a clinical trial
4. Prognostic information that establishes a diagnosis or disease prognosis
5. Germline alteration association with a hereditary cancer syndrome or alters the pharmacokinetic or pharmacodynamic nature of a specific therapy (Meric-Bernstam et al. 2015)

Genetic alterations that cannot be classified as clinically actionable may be considered variants of unknown or almost known significance. Variants of almost known significance (VAKS) are genomic alterations with functional consequences located in a clinically significant gene specifically in an area of the gene known to be clinically relevant (i.e., the tyrosine kinase domain) but has not been reported in the literature previously (Knepper et al. 2017). The strength of a clinically actionable determination is based on the strength of the literature available for the particular genetic alteration. Large, appropriately powered prospective comparative trials with biomarker stratification in the patient's specific tumor type are preferred but are uncommon. Most evidence is from retrospective cohort or case-control trials in addition to case studies or case series. This is partially due to the rare nature of many genetic alterations. Since the clinical interpretation of somatic genetic alterations is only as good as the data informing these recommendations, the generation of datasets across facilities and sharing of this information are essential to optimizing genetic-guided treatment decisions (Table 1).

Specific challenges amenable to leverage of shared data in terms of both findings and outcomes include assigning clinical actionability to specific variants in diverse tumor subsets, prioritizing actionability of variants, and discerning "driver" mutations from "passenger" and germline mutations that may be less relevant to the oncogenic nature of the cancer. Interrogating variants of unknown and almost known significance is also essential and may yield additional treatment options or prognostic information as our understanding of cancer biology continues to grow. Numerous databases exist to help identify germline mutations, pathogenicity of specific alterations, the incidence of mutations across tumor types, and ultimately the guidance toward a treatment recommendation. Several examples of these are listed in Table 2 along with the types of information each may provide. The need to classify variants in a real-time manner to facilitate clinical care underscores the importance of these integrated databases and the ongoing need for continued contribution and data analysis.

The personalized nature of this method of directing treatment may be especially relevant in the senior adult oncology population as it may reveal novel and more appropriate treatment options for individual patients who may have comorbidities or conditions limiting the ability to receive standard therapies (Table 3).

Using HRI for Clinical Studies

A feature common to clinical HRI is an analytic software for retrieval. Such a software may contain two retrieval modes: identifiable data and anonymous mode. Whereas access to identifiable data requires the same IRB approval as retrospective studies, retrieving data in anonymous mode can be leveraged in several ways to strengthen clinical trial design and practice improvement. We list below some examples from the software used at Moffitt's Transmed™.

Table 1 Examples and characteristics of big datasets

Dataset	Data type	Strengths	Weaknesses
Surveillance epidemiology and end results (SEER)/ Medicare	Diagnostic and claims data on patients aged 65 and older enrolled in Medicare. Covers nine US states and four urban areas	Population-wide claims data linked to cancer demographic and clinical data	Does not collect oral medication information
			Does not collect ECOG or KPS (scores used to measure a cancer patient performance status or functional impairment in their ability to complete activities of daily living)
National Cancer Database (NCDB)	Hospital registry data collected from 1,500 facilities	Collects treatment and outcome data for newly diagnosed malignant diseases	Hospital/facility must be accredited by the American College of Surgeons, Commission on Cancer (ACoS, COC)
Health research and informatics enterprise-wide data warehouse – Total Cancer Care (TCC)	Patient consented to the TCC protocol that may or may not have cancer across 19 hospitals/facilities	Collects biospecimen samples (somatic and/or germline)	
		Includes cancer cases as well as noncancer cases (controls)	
		Data and biospecimen collected from 19 hospitals across the United States	
		Molecular or genomic data available	
		Optional completion of patient self-reported data via an electronic patient questionnaire	
The Cancer Genome Atlas (TCGA)	NIH-driven dataset	Public access extensive gene array data	Links to clinical data are limited
CancerLinQ	ASCO-coordinated database	Large set of clinical data linked to private practice oncologists via EMRs	Still in testing/building phase
North American Association of Central Cancer Registries (NAACCR)		All cancer registries are not a SEER state and therefore do not report their data to SEER; however, their cancer registry data may be reported to NAACCR	
		Include registry data from Canada	
State- and hospital-level cancer registry databases		May have additional data available at the patient level that is not available using larger population data such as chemotherapy, hormone therapy, and immunotherapy drug names	
		The option to manually abstract patient level outcome data such as recurrence and progression	

Table 2 Databases usable for precision medicine use

Table 3 Tips and pitfalls: all that glitters is not gold

Using HRI to identify a potential population for accrual in clinical trials is highly effective and more accurate than clinical estimates
As diagnostic codes change over time and are not always entered correctly in regular clinical practice, they need to be verified with chart data unless very large scale population analyses are conducted
Tumor tissue samples in gene expression databases such as TCGA are typically microdissected to contain at least 80% of tumor tissue for homogeneity. Certain tumors have heavy inflammatory infiltrates that may affect gene expression in cancer cells in these areas, and this would be missed in such databases
Clearly define the limits of your search. Searches get easily diluted by "tantalizing" data, and the risk of hidden heterogeneities in data is high

1. **Estimating accrual for trial design**. It is often difficult to estimate the potential accrual into a clinical trial. Investigators' estimates of their clinical volumes are notoriously unreliable. Cooperative groups often rely on past accrual rates in similar trials, which tend to be fairly accurate. Some previous phase II data may exist in a given institution, but accrual may be more variably influenced by competing trials, change in treatment or referral patterns, or biologic marker selection. The Transmed software allows the creation of search strategies that can either identify a specific population (capsules) or be used repeatedly (filters). A filter can be created to identify the number of patients seen at the institution with similar cancer types, stages, treatments, and eligibility criteria. We recommend checking 2–3 recent years to account for variability. Once the number is obtained, we recommend applying the following rule of thumb: for survey trials, estimate an accrual of half the number of patients seen. For therapeutic trials, estimate one fourth of patients seen. This allows for the typical patient acceptance rate (Kemeny et al. 2003), as well as for imponderables such as distance from hospital, comorbidities etc. In our experience, estimates obtained this way, while often sobering, are quite reliable upon trial implementation.
2. **Process improvement research**. As big data often includes EMR information, this creates an opportunity for geriatric oncology research. Elements of a geriatric assessment and interventions can be digitalized in the EMR, and outcomes can be tracked over time. Research is still nascent in that area.

Digging for Therapeutic Use in Individual Unusual Cases

Utilizing the methods (building blocks) for effective big database digging provides the foundation for identifying therapeutic use among individuals with unusual cases.

Identifying therapeutic use in individual unusual cases first requires the need for known demographic and clinical characteristics. This also includes gathering requirements or the inclusion/exclusion criteria for the patient cohort of interest. Once this information is known, it is important to work with someone familiar with the data elements and database to extract the data in a predetermined format. For example, there was a case seen at MCC and the patient was diagnosed with both breast cancer and multiple sclerosis. In order to properly treat this patient, the team identified if there were other patients treated at MCC with similar demographic and clinical characteristics. There were other patients identified with similar characteristics, and the clinical team collaborated on the best course of treatment utilizing the availability of retrospective data.

One of the key drivers behind big data efforts in clinical medicine is the ability to help the patients' treatment in real time. One of the efforts underway is to integrate clinical guidelines and pathways into patients' EMRs. The software would analyze information about tumor stage, patient's characteristics, and previous treatment and offer guideline-based treatment suggestions on screen. Research is ongoing to assess issues such as incomplete data and pathway building (e.g. Bettencourt-Silva et al. 2015).

A more ambitious effort, but of particular relevance to older patients is generating real-time evidence for patients who do not match eligibility criteria from the studies on which the guidelines are based. For example, in lung cancer, a substantial number of guideline recommendations have limited validity in patients aged 80 and above (Battisti et al. 2017). Our group piloted an approach using HRI to do remote consultation for a community practice group (Dougoud-Chauvin et al. 2016). The outside oncologist was sending an e-mail with structured patient information. Similar patients were retrieved from TCC, and a summary case report was created with expert comment. Information was collected as to the impact of the information provided. The median turnover time was 2 working days, but the staff effort needed was substantial. Future research efforts should focus on a better selection algorithm to retrieve information, better coding of the disease and treatment phases in HRI (likely using language recognition software), and the generation of data pools for frequently asked questions. Outcomes research should track outcomes beyond modification of decision making.

Conclusions

Big data will play an increasing role in geriatric oncology (and in medicine in general). This is an incredible research opportunity for this highly heterogeneous population. It can be applied to basic science, helping to understand the interaction of aging and cancer and the modification of tumor biology and host-tumor interaction with age. It can be applied for translational research: finding targetable mutations to propose individualized treatments. It can be applied to clinical medicine, for generating evidence for complex patients or for assessing the impact of oncogeriatric interventions. While this is a new research area, the authors drew from their collective experience with this research to provide information to help oncogeriatric researchers leverage these powerful tools efficiently.

Research Methods: Systematic Reviews and Meta-analysis in Geriatric Oncology

67

Gary H. Lyman and Marek S. Poniewierski

Contents

Abstract

Cancer is largely a disease of aging with increasing incidence with age for most malignancies and the majority of cancer patients diagnosed after age 65. At the same time, aging is associated with a progressive increase in the number of major medical comorbid conditions that may complicate the disease course and increase treatment-related complications and their adverse consequences. Unfortunately, age restrictions in clinical trials have led to limited data on the special characteristics, comorbidities, and outcomes of older patients with cancer. Geriatric Oncology has emerged as a subdiscipline within oncology with a focus on clinical management and research related to cancer in the older patient.

Topics in Geriatric Oncology studied in randomized or nonrandomized clinical studies including those captured in systematic evidence reviews and meta-analyses cover a broad range of subjects related to cancer in the elderly. In this chapter, the basic methodology for conducting high quality systematic reviews and evidence summaries including meta-analyses is summarized. Such studies range across areas of prevention and screening, diagnosis and staging, functional assessment including comprehensive geriatric assessment, cancer treatment, supportive care, and survivorship and end-of-life. Systematic reviews start with defining the specific question and then establishing the relevant clinical setting including the target patient population or problem, the exposure, prognostic factor or intervention, any relevant comparison(s), and clinically important outcomes. Subsequently, a rigorous explicit and transparent process of identifying, appraising, and selecting or excluding the relevant evidence is undertaken. The resulting evidence from the systematic review may then be summarized descriptively or, when appropriate, in the form of a formal meta-analysis. Later in the chapter, a summary of reported systematic reviews and/or meta-analyses related to Geriatric Oncology over the past two decades is presented and summarized. Finally, available tools for the conduct, analysis, quality appraisal, and reporting of systematic reviews and meta-analyses are provided for the reader interested in a better understanding of such systematic evidence reviews.

Introduction

The discipline of Geriatric Oncology covers a broad range of topics including prevention and screening, diagnosis and staging, functional assessment studies including comprehensive geriatric assessment, cancer treatment, supportive care, and survivorship and end-of-life, among others. The evidence base for the field of Geriatric Oncology includes the highest level of evidence represented by randomized clinical trials (RCTs) as well as systematic reviews and meta-analyses of such trials. The totality of evidence also includes a range of prospective and retrospective nonrandomized clinical studies related to cancer in the elderly. The methodologic approach to systematic reviews and meta-analyses may vary somewhat depending upon the specific topic and the type of outcome measures captured. Nevertheless, there are important general principles related to systematic reviews and evidence summaries including meta-analyses that should be consistently applied across topics and diseases. These will be reviewed here with a primary focus on studies relevant to Geriatric Oncology.

Overview of Evidence Reviews and Summaries in Geriatric Oncology

The Cochrane Collaboration defines a systematic review as a review of a clearly formulated question that uses systematic and explicit methods to identify, select, and critically appraise relevant research and to collect and analyze data from the studies that are included in the review. Statistical methods to summarize the evidence including meta-analyses may or may not be used to summarize and analyze the results of the included studies. Systematic reviews should be objective, systematic, transparent, and reproducible. As in most clinical research, the process starts with defining the specific question(s) and then establishing the relevant clinical setting, including (1) the appropriate patient population or problem; (2) the exposure, prognostic factor, or intervention of interest; (3) any relevant comparison(s); and (4) the clinically important outcomes (PICO) (Richardson et al. 1995). A systematic search to identify studies addressing each research question should be conducted followed by a systematic review, selection, and synthesis of the results pertinent to the question. The criteria for inclusion and exclusion should be objective, explicitly stated, and consistently implemented as well as transparent such that other investigators would likely identify the same studies and outcomes using the same criteria. Future researchers may also update the

review at a later time in order to integrate new findings. This explicit approach minimizes the risk of bias and allows readers of the review to assess the author's assumptions, procedures, evidence, and the validity and applicability of the conclusions.

Systematic reviews may include a formal meta-analysis, which attempts to generate a quantitative weighted summary of the major results from similar but separate individual studies. Meta-analyses may be based on aggregate data as reported in published clinical trials or based upon individual patient data (IPD) from each study, when available. While the later represents an ideal setting for summary analysis and interpretation, few such analyses are feasible, affordable, and available. Therefore, the majority of meta-analyses are based on aggregate patient data reported in published manuscripts and not on IPD from each of the trials (Lyman and Kuderer 2005). The strengths and weaknesses of both approaches are summarized below. While IPD meta-analyses often strive to obtain unpublished data and provide greater opportunities for data checking and updating, such features are not inherent to this approach but largely attributable to the considerable resources and time devoted to such studies (Lyman and Kuderer 2005). Failure to obtain data on all patients and all trials may lead to acquisition bias since the missing studies or patients may not be missing completely at random. As discussed later in this chapter, summary effect measures based on study aggregate and IPD results have been shown to be very similar or identical when based on the same studies and patients. While both approaches permit exploration of study level sources of heterogeneity, only access to IPD permits full exploration of and adjustment for patient characteristics and therefore provides the best opportunity for full exploration of the results across multiple studies. However, the resources, time, and cooperation required for IPD studies will continue to limit their use in many important areas of clinical medicine which can be meaningfully and cost-effectively approached by properly performed aggregate meta-analyses.

Conducting a High Quality Systematic Review

While narrative reviews by subject experts have always been a part of the medical literature, the principles for performing high quality, rigorous systemic reviews have only been made explicit in the past two to three decades and are now widely accepted and practiced by professional organizations and investigators worldwide. A systematic review is an integrated and comprehensive review of the literature on a specific clinical question, characterized by explicit methods of data searching, selection, review, and quality appraisal. Major differences between a systematic review and a narrative review are the transparency of the processes utilized and the greater effort to minimize bias in the former. Systematic reviews are more likely to be guided by explicit statements about the literature search strategy and study selection criteria. Inclusion and exclusion criteria for the review are precisely stated with the overriding goal of reducing the risk of bias in the identification, selection, and reporting of the evidence. A systematic review checklist based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) Statement is provided in Table 1 (Moher et al. 2009). After defining an important question, a systematic search for relevant studies is undertaken. Initial searches often start by identifying existing systematic reviews, practice guidelines, and technology assessments on the topic in question. Systematic reviews proceed through a well-defined series of stages addressing clinical outcomes, including (a) defining the question, (b) searching the literature, (c) screening and selection of eligible articles, (d) critically appraising study quality, (e) data extraction, and (f) data synthesis across acceptable studies (Deeks 2001a, b; Vamvakas 1998). Optimal systematic reviews require a dynamic collaboration between experienced clinicians or content experts and methodologic colleagues familiar with the rigorous methods applied to systematic reviews in an effort to avoid bias and provide reliable and trustworthy summary results.

Table 1 Systematic review checklist (PRISMA)

Section/topic	#	Checklist item	Reported on page #
Title			
Title	1	Identify the report as a systematic review, meta-analysis, or both.	
Abstract			
Structured summary	2	Provide a structured summary including, as applicable: background; objectives; data sources; study eligibility criteria, participants, and interventions; study appraisal and synthesis methods; results; limitations; conclusions and implications of key findings; systematic review registration number.	
Introduction			
Rationale	3	Describe the rationale for the review in the context of what is already known.	
Objectives	4	Provide an explicit statement of questions being addressed with reference to participants, interventions, comparisons, outcomes, and study design (PICOS).	
Methods			
Protocol and registration	5	Indicate if a review protocol exists, if and where it can be accessed (e.g., Web address), and, if available, provide registration information including registration number.	
Eligibility criteria	6	Specify study characteristics (e.g., PICOS, length of follow-up) and report characteristics (e.g., years considered, language, publication status) used as criteria for eligibility, giving rationale.	
Information sources	7	Describe all information sources (e.g., databases with dates of coverage, contact with study authors to identify additional studies) in the search and date last searched.	
Search	8	Present full electronic search strategy for at least one database, including any limits used, such that it could be repeated.	
Study selection	9	State the process for selecting studies (i.e., screening, eligibility, included in systematic review, and, if applicable, included in the meta-analysis).	
Data collection process	10	Describe method of data extraction from reports (e.g., piloted forms, independently, in duplicate) and any processes for obtaining and confirming data from investigators.	
Data items	11	List and define all variables for which data were sought (e.g., PICOS, funding sources) and any assumptions and simplifications made.	
Risk of bias in individual studies	12	Describe methods used for assessing risk of bias of individual studies (including specification of whether this was done at the study or outcome level), and how this information is to be used in any data synthesis.	
Summary measures	13	State the principal summary measures (e.g., risk ratio, difference in means).	
Synthesis of results	14	Describe the methods of handling data and combining results of studies, if done, including measures of consistency (e.g., I^2) for each meta-analysis.	
Risk of bias across studies	15	Specify any assessment of risk of bias that may affect the cumulative evidence (e.g., publication bias, selective reporting within studies).	
Additional analyses	16	Describe methods of additional analyses (e.g., sensitivity or subgroup analyses, meta-regression), if done, indicating which were pre-specified.	
Results			
Study selection	17	Give numbers of studies screened, assessed for eligibility, and included in the review, with reasons for exclusions at each stage, ideally with a flow diagram.	
Study characteristics	18	For each study, present characteristics for which data were extracted (e.g., study size, PICOS, follow-up period) and provide the citations.	

(*continued*)

Table 1 (continued)

Section/topic	#	Checklist item	Reported on page #
Risk of bias within studies	19	Present data on risk of bias of each study and, if available, any outcome level assessment (see item 12).	
Results of individual studies	20	For all outcomes considered (benefits or harms), present, for each study: (a) simple summary data for each intervention group, (b) effect estimates and confidence intervals, ideally with a forest plot.	
Synthesis of results	21	Present results of each meta-analysis done, including confidence intervals and measures of consistency.	
Risk of bias across studies	22	Present results of any assessment of risk of bias across studies (see Item 15).	
Additional analysis	23	Give results of additional analyses, if done (e.g., sensitivity or subgroup analyses, meta-regression [see item 16]).	
Discussion			
Summary of evidence	24	Summarize the main findings including the strength of evidence for each main outcome; consider their relevance to key groups (e.g., healthcare providers, users, and policy makers).	
Limitations	25	Discuss limitations at study and outcome level (e.g., risk of bias), and at review-level (e.g., incomplete retrieval of identified research, reporting bias).	
Conclusions	26	Provide a general interpretation of the results in the context of other evidence, and implications for future research.	
Funding			
Funding	27	Describe sources of funding for the systematic review and other support (e.g., supply of data); role of funders for the systematic review.

A study protocol is compiled detailing the question, goals, and each step planned for the systematic review. This should be thoroughly reviewed and agreed upon *a priori.* The protocol should include details of the search algorithm, the inclusion and exclusion criteria, and the data elements to be extracted ideally into predefined data forms or spreadsheets. A clear record of the systematic review process is important to reflect decision/choices made during the design and conduct of the review and serve as a resource when the results are presented. Prior to finalizing the review process, it is often worthwhile identifying a few recognized studies, e.g., 5–20, that appropriately address the question at hand. The database indexing of these studies can be very informative in finalizing the criteria to be utilized in the final search. The databases to be searched should be prespecified and can include published literature, meeting presentations, and other sources determined by the investigators to be relevant and credible. The time frame of the search (start and end dates) should be specified. Likewise, as noted above, it is important to determine whether previous systematic reviews or technology assessments have been performed related to the same topic and review these critically as well as to inform any novel or updated review. An updated review permits a more efficient and effective use of resources and can build upon and even improve upon rather than simply replicate credible previous work of qualified investigators. An explicit search algorithm should be established often in collaboration with a highly experienced search analyst or experienced librarian. This is often best done by breaking the search into individual important and relevant components and then combining into the overall search algorithm. Search categories might include study design, demographics, disease, stage, other clinical characteristics, treatment, and outcomes, among others. Synonyms, plural forms, and different spellings should be considered. PubMed searches should take advantage of MESH headings and filters provided to

optimize and target the search as desired. The use of Boolean logic for appropriately combining search components is critical. The investigator will have discretion between a more focused search with greater specificity in the interest of time and efficiency but with risk of missing some relevant articles or conducting a very broad and highly sensitive search to minimize missed articles but with the need to eliminate many more irrelevant studies during the subsequent review. It is often useful to further review the citations listed in known eligible studies to extend the review beyond that provided by the electronic database. However, as with the identification of studies by content experts, the potential for selection bias exists and should be guarded against.

Once launched, an exhaustive search for relevant studies should be conducted and careful data collection based on dual data extraction is encouraged to reduce investigator bias. Criteria for study inclusion and exclusion should be defined *a priori* but may be amended early in the search process once the initial studies identified are reviewed for relevance to the topic of interest. Inclusion and exclusion criteria should be justified on the basis of prior studies or clinically or biologically relevant rationale. In general, the broader the search strategy, the more detailed inclusion and exclusion criteria are required. Inclusion and exclusion criteria may address a range of parameters including timeline, research design, disease, patient characteristics, outcomes, etc. While inclusion and exclusion criteria may occasionally be modified early in the search process, once finalized, they should be rigorously and uniformly applied across studies usually starting with review of title and abstract often permitting rapid exclusion of irrelevant studies to the question being addressed. The full text of remaining studies should then be reviewed for eligibility. Both steps are best accomplished with a minimum of two experienced reviewers working independently with a third reviewer resolving any eligibility conflicts. Data extraction from the final collection of eligible studies then should proceed with a minimum of two experienced abstractors working independently to complete the predefined data worksheet with reconciliation of differences resolved by either further review of the manuscript jointly or a third independent reviewer.

Systematic reviews summarize the results from several individual studies, identify reasons for variation in the results across studies, and potentially improve the quality of future primary studies by better defining the methodological inadequacies of previous reports. As will be discussed in the next section, results from individual studies may be formally analyzed first by assessing heterogeneity and, if appropriate, combining of results of similar studies by providing weighted summary estimates of the treatment effect. Observed heterogeneity generally relates to either differences in the population studied or the study methodology employed. Variation in study populations, the clinical settings, as well as the interventions employed can each result in variation in effect estimates. Likewise, variation in the type and quality of study methodology represents an important source of heterogeneity related to the selection of an appropriate population sample, careful measurement and the absence of missing data, and blinding of investigators to test results and the absence of missing data.

A systematic review may be presented as a standalone publication or in support of a formal meta-analysis or clinical practice guideline. As summarized in section "Summary of Major Recommendations/Guidelines for Quality Appraisal or Reporting of Systematic Reviews and Meta-Analyses," several professional organizations and journals have established formal criteria for the conduct and reporting of systematic reviews and meta-analyses. Uniformly, these criteria include presentation of a flow diagram (PRISMA) of the search and inclusion and exclusion results presenting the numbers of studies included or excluded at each step of the process. Ideally, the reasons for study exclusion can be explicitly stated and catalogued to reassure the reader of investigator objectivity. The formatting of the systematic review results is similar to other scientific reports including background and rationale, a discussion of the methodology including the search strategy and algorithm, inclusion and exclusion criteria, the process and steps for study selection and data extraction, quality appraisal, and any

formal summary analysis performed. The methods section should be sufficiently detailed and explicit to permit an independent investigator following the provided search algorithm and inclusion and exclusion criteria to replicate the results presented when applied to the same timeframe. As noted previously, a flow diagram summarizing the types and number of studies identified at each stage of the review should be presented. Ideally, the number and reasons for study exclusion should be provided. The results are presented primarily in tabular form supplemented by useful graphics and annotated for further clarification. Importantly, results for each study should be presented including the name of study, citation, year published, number of participants in each arm, primary outcomes observed, and other relevant study and overall patient characteristics if reported. A formal assessment of the quality of included studies should be presented along with evidence for study consistency or heterogeneity. A discussion of the results in the context of prior studies should be provided including the strengths and weaknesses of the reported studies. It is important to include a discussion of the limitations as well as the strengths and additional issues encountered in the conduct of the review. Potential conflicts of interest and publication bias should also be discussed. Objective interpretation of the final results is important along with identification of gaps in available evidence and need for further studies. All eligible studies included in the final review should be cited in the text. Often some tabular material will, of necessity, need to be presented as appendices or supplemental material online separate from the primary publication.

Evidence Summaries and Meta-analyses

After completing the initial steps of a systematic review including specification of the question, search, study eligibility, and data abstraction, many systematic reviews are then often utilized in a formal evidence summary analysis in the form of a meta-analysis. The purpose of a meta-analysis is to systematically identify, review, and synthesize the results of previous research in order to provide valid conclusions related to the totality of reliable evidence on a subject in order minimize bias from selective citation commonly encountered in narrative reviews. If inconsistency across studies or heterogeneity of results is too great, a formal meta-analysis may not be appropriate and the results should be presented descriptively. However, when appropriately applied, a meta-analysis will have greater power than small individual studies and can sometimes explore any inconsistency of findings across studies and the reasons for heterogeneity. Most commonly, meta-analyses are conducted of similar RCTs or rigorously conducted prospective cohort studies with reasonable controls. The analysis should only proceed when the conditions are appropriate including the identification of relatively consistent and similar studies with reasonable similarity in study design, population characteristics, and management as well as outcomes reported. Summary results reported generally include an estimate of the effect size (standardized mean difference, odds ratio, relative risk, hazard ratio, etc.), variance (standard error or 95% confidence limits), and formal tests for heterogeneity and publication bias. Several generic and specialty software packages are available for conducting meta-analyses but should be applied cautiously by an experienced analyst. The decision to use fixed effects models or more conservative random effects models goes beyond the discussion here but should be decided before conducting final analyses by experienced methodologists. While heterogeneity across studies can be assessed formally for significance, such tests have low power and are generally combined with a measure of the impact of heterogeneity on the overall effect estimate using the inconsistency index (I^2). In general, if significant heterogeneity is present, a random effects model is more conservative and preferred. The summary results are often presented as Forest plots presenting the effect size estimate and variation in that estimate for each study individually and with all studies combined. The area of the box representing the effect estimate is inversely related to the variance or weight

of the study. Subgroup analyses and meta-regression analysis based on study design or population characteristics may be useful in exploring the causes of heterogeneity. Other informative approaches include use of a different effect measure or exclusion of studies considered outliers. However, these analyses should be planned a priori and increase the risk of false positive results. In meta-regression analysis, the treatment effect represents the dependent variable while study design and population characteristics may represent independent or explanatory variables. The potential for systematic error or bias (confounding) or effect modification (interaction) should always be considered. Sensitivity analyses across studies or population factors as well as quality metrics may be useful and may inform subsequent definitive studies. Funnel plots may be presented plotting the effect size of each study against the study sample size to qualitatively assess publication. While the absence of smaller negative studies may represent publication bias, formal tests for assessing publication are available and should be considered. In section "Summary of Major Recommendations/Guidelines for Quality Appraisal or Reporting of Systematic Reviews" below, selected formal guidelines and checklists for the conduct and reporting of meta-analyses are presented.

Special Considerations

Diagnostic and Prognostic Studies

Systematic reviews and meta-analyses of studies of diagnostic accuracy differ from other such analyses in the statistical methods used to combine individual study results. When the results lack significant heterogeneity, sensitivities, specificities, and likelihood ratios can be directly combined (Bland and Altman 1994). Study results may also be summarized as a Receiver Operating Characteristic (ROC) curve reflecting the pattern of sensitivities and specificities at different threshold cut points. The diagnostic odds ratio can also be useful when combining studies in a systematic review, as it often remains relatively constant across various cut points. Summary estimates of sensitivity and specificity or likelihood ratios will underestimate test performance if heterogeneity between the studies arises from variation in the diagnostic threshold (Deeks 2001b). The reference standard must be explicitly defined and be considered diagnostic of the condition. Ideally, the investigator and test interpreter should be blinded to disease status. Separate unblinded recruitment of disease and control subjects results in an overestimate of test performance (Lijmer et al. 1999).

Individual Patient Data Meta-analysis

Although few would argue that properly conducted meta-analyses based on individual patient data has distinct advantages, meta-analyses are most often based on aggregate patient data from completed studies that have been published in the medical literature. Meta-analyses based on aggregate data are far more common and continue to be the mainstay of systematic reviews conducted by many professional societies. A search for individual patient data meta-analyses related to cancer in 2000 revealed 38 of which eight were unpublished (Tierney et al. 2000). A more recent search of Medline by the authors identified 1595 reported meta-analyses related to cancer of which 76 (4.4%) were apparently based on individual patient data not changing significantly over several years (Fig. 1). The considerable use of meta-analyses based on aggregate patient data suggests that they are generally considered relevant and valid to editors, reviewers, and readers. Proceeding with a written study protocol with a prespecified search process, inclusion and exclusion criteria, and the hypotheses to be tested is critical to both. In both situations, an exhaustive search for relevant studies should be conducted with careful data collection based on dual independent data extraction and entry. Primary and secondary outcomes of interest should be specified in advance and the results from individual studies systematically analyzed providing summary estimates of the treatment effect. Pooled analyses of aggregate patient data are

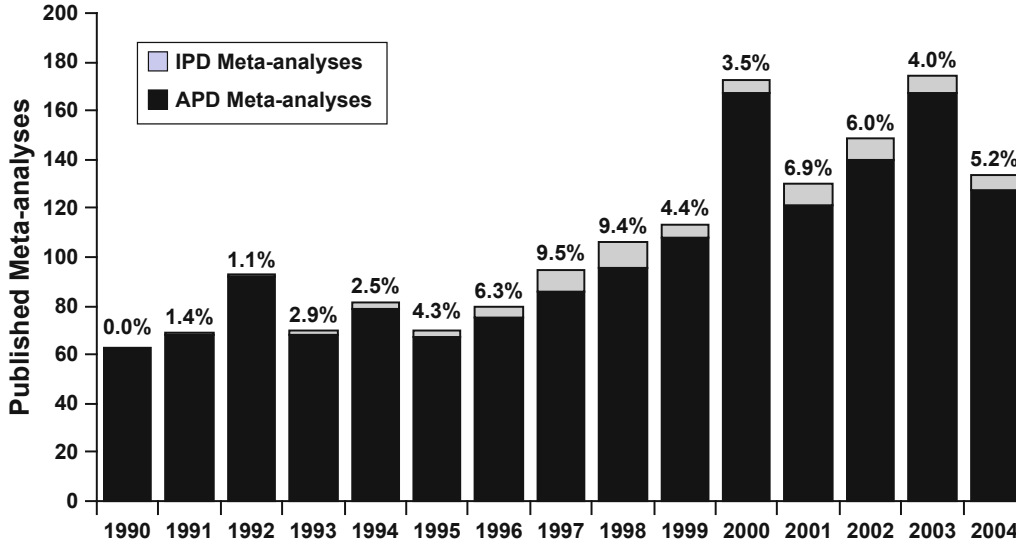

Fig. 1 Published aggregate and individual patient data meta-analyses (Lyman and Kuderer 2005)

conceptually the same as for individual patient data including estimating study-specific treatment effects, assessing heterogeneity, estimating a summary effect size, and evaluation of heterogeneity. Such meta-analyses employ essentially the same summary and statistical measures. While secondary analyses may explore the reasons for any heterogeneity, the exploration of patient-level characteristics is best undertaken with individual patient-level data. The use of averages or proportions of patient characteristics in aggregate analyses of trials may lead to the common ecological bias, underestimating the influence of such characteristics (Bossuyt et al. 2003). Such analyses are often not prespecified in individual trials which are generally underpowered to address subgroup evaluations and, therefore, should be considered as exploratory or hypothesis generating. Publication bias represents an important limitation of any review, and retrieval of data from all relevant studies should be the goal in order to avoid publication bias. An acknowledged limitation of individual patient data meta-analyses is the need to exclude studies for which data are not available due to proprietary interest or other concerns.

Summary estimates from aggregate meta-analyses have been shown to be similar to the least squares estimate of effect from individual patient data computed from a two-way fixed-effects model where the effects in the model are those due to treatment and due to different studies (Olkin and Sampson 1998). If the same studies are used for both approaches, there appears to be limited difference in the summary effect estimates between study aggregate and individual patient meta-analyses. Table 2 summarizes potential advantages of individual patient data meta-analyses (Lyman and Kuderer 2005). However, many of the specific processes providing

Table 2 Potential advantages of individual patient data meta-analyses (Lyman and Kuderer 2005)

1. Ability to use common definitions, coding, and cut-points
2. Address questions not addressed in original publication
3. Assess adequacy of randomization
4. Permits data checking
5. Permits data updating
6. Permits checking of analyses
7. Allows adjustment for the same variables across studies
8. Permits ready use of time-to-event data for estimating survival
9. Ability to address long-term outcomes
10. Facilitates exploration of heterogeneity at the patient level and subgroup analyses of patient level data

Table 3 Comparison of individual patient data (IPD) and aggregate patient data (APD) meta-analyses (Lyman and Kuderer 2005)

systematic reviews with an advantage over narrative reviews are shared by both types of analyses (Table 3). Aggregate study meta-analyses can be used to determine whether proceeding with more resource-dependent individual meta-analysis is worthwhile (Tudur et al. 2001). Efforts to obtain updated data and assess the quality of source data in individual patient data meta-analyses require considerable collaboration of the original investigators, institutions, organizations, or companies. Individual patient data meta-analyses rarely provide access to the source data such as patients, medical records, laboratory results, etc., to assure that data collection was properly conducted, that randomization was appropriate, and the same data items were actually collected. Differences in estimated outcomes are rare when comparing checked data to unchecked data (Burdett and Stewart 2002). At the same time, publication bias due to studies unwilling to collaborate may limit the validity of the analysis. Unpublished studies may be the result of low observed treatment effect either leading the investigators not to pursue publication or editorial bias against negative study results or may reflect the poor quality of the study. It is critical to avoid combining patients across studies as if they came from a single very large clinical trial. Several studies have demonstrated that when the same studies and outcome measures are utilized, effect size estimates are similar for both types of meta-analysis (Olkin and Sampson 1998; Steinberg et al. 1997). Updated data obtained after completion of the study may be influenced by crossover between arms, unblinding, and retrieval bias. Proper Institutional Review Board review, informed consent, and data privacy compliance are essential for analyses beyond those planned in the original study.

Survival Outcomes

When reporting an RCT with survival type data, the most appropriate summary statistics are the log hazard ratio and its variance, which are particularly designed for comparing two survival curves. The hazard ratio is a global summary of the difference between two survival functions and represents the reduction in the risk of death with treatment compared to controls over the entire period of follow-up. In a meta-analysis of such studies, the overall log hazard ratio is a weighted average of the log hazard ratios of each study where the weights are inversely proportional to the variance of the log hazard ratio for each trial. While the log hazard ratio and its variance are often directly reported in the trial results, there are also indirect methods for estimating the log hazard ratio and its variance either from summary trial results or the published survival curves. While survival curve estimates tend to underestimate the treatment effect provided directly from the papers, a number of methods may accurately

reproduce summary survival estimates statistically similar to that derived from individual patient data (Earle et al. 2000). If the time to an event and censoring are ignored, the log hazard function becomes simply the log relative risk.

A Summary of Systematic Reviews and Meta-analyses in Geriatric Oncology

A comprehensive systematic search of the English language literature published between 1990 and 2016 was undertaken for published systematic reviews or meta-analyses related to geriatric oncology including studies related to prevention, diagnosis, staging, treatment, supportive care, survivorship, or end-of-life. The search algorithm, inclusion and exclusion criteria, and data items for extraction were defined *a priori*. Titles, abstracts, and full text manuscripts were reviewed when needed. The initial search identified 1088 potentially eligible records of which 703 were not limited to elderly patients, 89 were not cancer studies, and 236 were deemed not be a systematic review or meta-analysis (Fig. 2). Hand search of citations identified one additional study. A total of 61 systematic reviews or meta-analyses were in geriatric oncology published since 1990 were identified in the peer-reviewed literature with more than half published over the past 5 years (Fig. 3). Systematic reviews were reported in 39 studies (64%), meta-analyses in 43 (70%), and both were reported in 23 (40%) studies. Published systematic reviews and meta-analyses in geriatric oncology were conducted across geographic regions including Europe (Whiting et al. 2003), US (Steinberg et al. 1997), Canada (Tierney et al. 2000), Asia (Bland and Altman 1994), and South America (Richardson et al. 1995) (Fig. 4). Most publications (N = 44) addressed a specific cancer type while 17 included studies across cancer sites. Many studies were designed to evaluate multiple outcomes including survivorship or end-of-life issues (40), cancer treatment (Moher et al. 1999), geriatric assessment (Olkin and Sampson 1998), treatment related toxicity, or supportive care (Lijmer et al. 1999). At the same time, the primary outcome reported in trials included in the systematic reviews included overall survival (39), progression-free (including disease- or relapse-free survival) (Sylvester et al. 2000), response or recurrence (Olkin and Sampson 1998), treatment-related toxicity (Horton et al. 2010), and geriatric assessment or frailty (Tierney et al. 2000). While studies including younger patients were not included, others reported results for different elderly

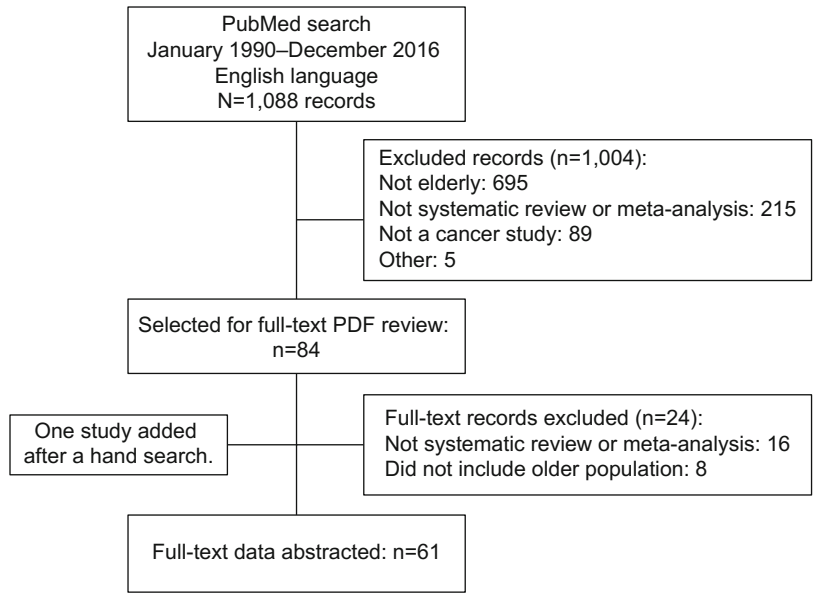

Fig. 2 PRISMA diagram: Flow of publications selected for data abstraction

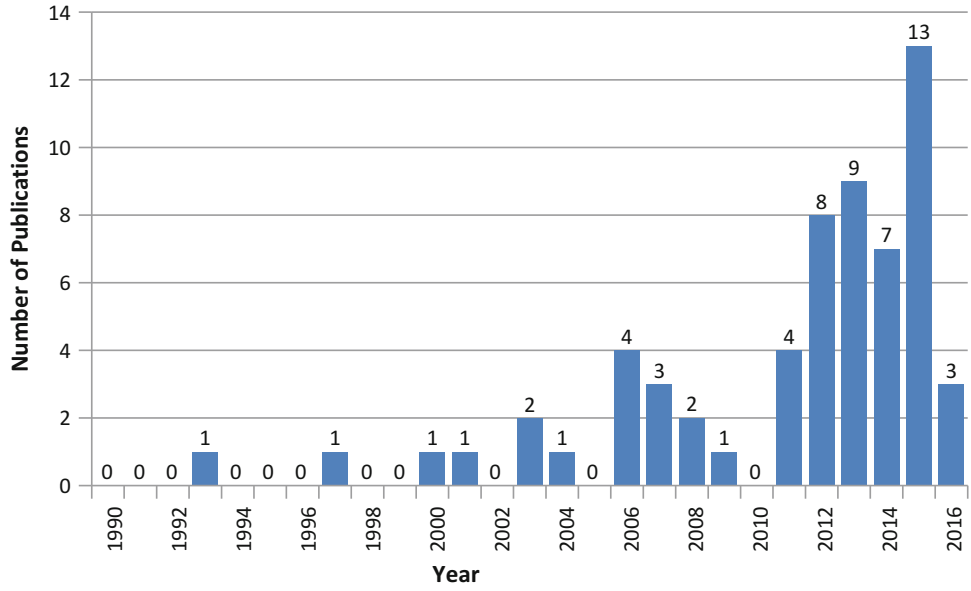

Fig. 3 Recent systematic review and meta-analyses publications, by year

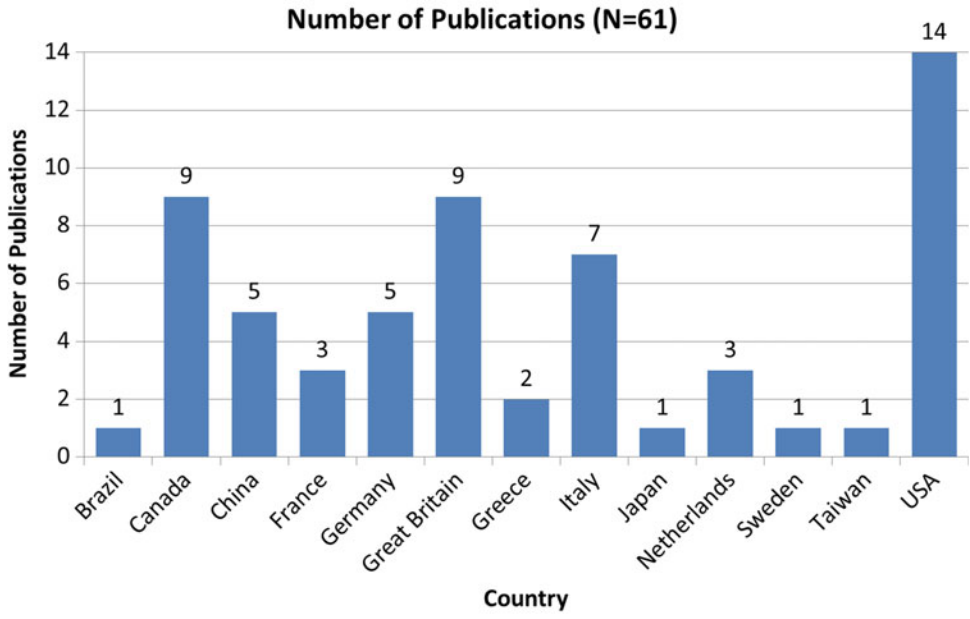

Fig. 4 Recent systematic review and meta-analyses publications, by country

cohorts. The age thresholds reported in the eligible studies included ≥60 (Buscemi et al. 2006), ≥65 (Whiting et al. 2003), ≥70 (Vandenbroucke et al. 2007), and ≥75 years (Fig. 5). Published systematic reviews and meta-analyses related to geriatric oncology included only RCTs (N = 37) or only non-RCTs (N = 9) while 16 permitted both types of studies. Depending on the topic of interest, the size of the evidence reviews identified differed considerably with the majority including 10 or fewer

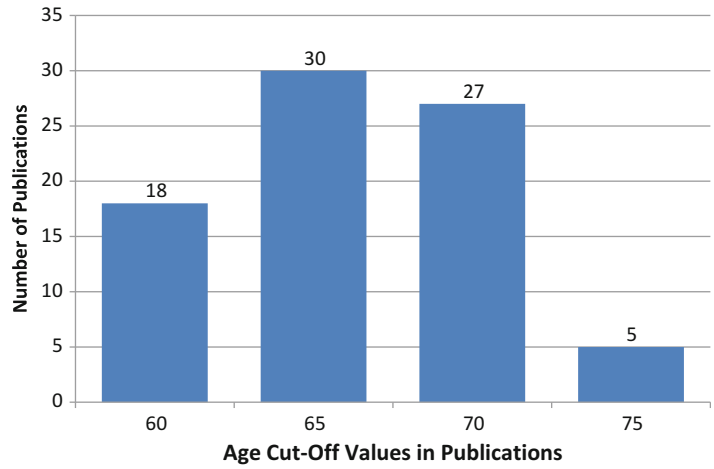

Fig. 5 Recent systematic review and meta-analyses publications, age cut-off values in publications

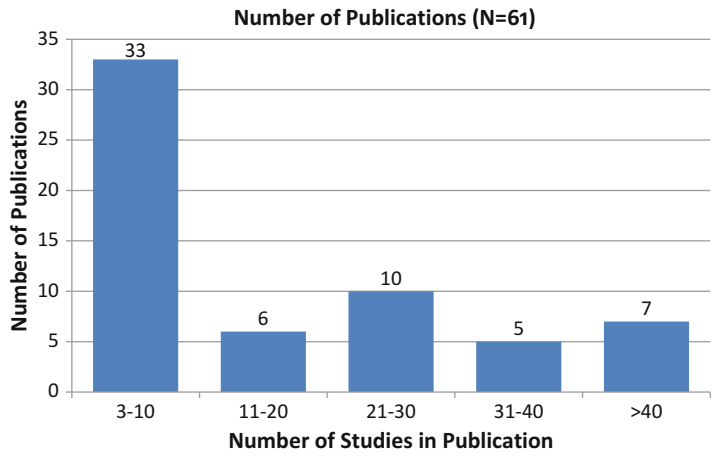

Fig. 6 Recent systematic review and meta-analyses publications, by number of included studies

studies (N = 33) while 16 included 11–30 studies and 12 included more than 30 studies (Fig. 6). Likewise, the number of subjects in the included trials of each systematic review ranged from 153 to over 15,000 whereas most reported fewer than 3000 subjects and 6 studies did not present the total numbers of subjects included. While 15 reviews looked at a range or multiple cancer types, 46 focused on patients with specific cancer types, most commonly non-small cell lung cancer (N = 9), colorectal cancer (N = 8), breast cancer (N = 7), multiple myeloma (N = 5), and lymphoma (N = 4) along with acute myeloid leukemia, chronic myelogenous leukemia, glioblastoma, ovarian cancer, and genitourinary and upper gastrointestinal malignancies. Of note, 19 studies (31%) utilized a limited subset or convenience sample of studies often based on access to individual patient data. These are included but may not represent true comprehensive systematic reviews.

Summary of Major Recommendations/ Guidelines for Quality Appraisal or Reporting of Systematic Reviews and Meta-analyses

As summarized earlier, systematic reviews and meta-analyses are formal, defined research methods for gathering, appraising, and summarizing evidence relating to specific defined clinical questions. The methods applied to systematic reviews and meta-analyses of geriatric oncology studies do not differ from those in other areas of

clinical medicine although the focus of the review may be, e.g., comprehensive geriatric assessment. The criteria for reporting and appraising results of systematic reviews have been detailed by several organizations, professional societies, and major medical journals (Moher et al. 1999, 2009; Bossuyt et al. 2003, 2004; Burdett and Stewart 2002; Steinberg et al. 1997; Earle et al. 2000; Bown and Sutton 2010; Buscemi et al. 2006; Elamin et al. 2009; Fleming et al. 2014; Horton et al. 2010; Kho et al. 2008; CEBM 2007; Shea et al. 2007; Sylvester et al. 2000; Vandenbroucke et al. 2007; Viswanathan et al. 2008; von Elm et al. 2007; Whiting et al. 2003, 2006, 2011; Willis and Quigley 2011; Zeng et al. 2015). The Institute of Medicine established standards for systematic reviews entitled "Finding What Works in Healthcare." (Eden et al. 2011) An excellent general source of information and tools for enhancing the quality and transparency of health research is found at the Equator Network (http://www.equator-network.org/). This site provides links to the PRISMA Statement, Checklist, and Protocol along with extended versions of PRISMA for (a) incorporating Network Meta-analyses, (b) Individual Patient Data Meta-analyses, and (c) reporting on health equity, and reporting in journal and conference abstracts along other resources. A PRISMA diagram is generally regarded as essential for displaying numbers and reasons for study exclusion along with the number of studies considered eligible for data extraction and analysis. The quality review should include the search strategy, study eligibility and selection, data extraction, outcome measures, data quality measures, and efforts to minimize bias. Appraisal of study quality and standards of reporting of diagnostic studies should consider the available QUADAS (Quality of Assessment of Studies of Diagnostic Accuracy for inclusion in Systematic reviews) and STARD (Standard for Reporting of Diagnostic Accuracy) (Whiting et al. 2003). Also available are links to the MOOSE (Meta-analysis of Observational Studies in Epidemiology) for reporting meta-analyses of such studies (Stroup et al. 2000). These initiatives outline the most important features to consider in assessing studies of diagnostic accuracy and the methods employed to reduce systematic error or bias in such studies.

Discussion

The rising incidence of cancer with age is paralleled by an increase in the number of major medical comorbid conditions that often complicate the disease and its treatment. Historically, cancer clinical trials have provided limited information on the management of older patients with cancer due to imposed eligibility restrictions on age and/or comorbidities. Geriatric Oncology has emerged as a clinical and scientific discipline within oncology directed at issues related to clinical management and specific research questions relevant to the elderly patient with cancer. Increasingly, systematic reviews and meta-analyses of randomized and nonrandomized trials related to cancer in the elderly have appeared addressing a range of fields including prevention and screening, diagnosis and staging, functional assessment including comprehensive geriatric assessment, cancer treatment, supportive care, and survivorship and end-of-life. Systematic reviews should specify a specific question and establish the target patient population and setting as well as the exposure prognostic factor or intervention of interest, and specify relevant comparison(s) and clinically important outcomes. A rigorous explicit and transparent process of identifying, appraising, and selecting or excluding the relevant evidence should be conducted. The results of a systematic review may then be summarized descriptively or as a formal meta-analysis. In this chapter, we have presented the general principles and specific steps recommended in the planning, conduct, analysis, and reporting of high quality systematic reviews and meta-analyses. We have presented and summarized reported systematic reviews and meta-analyses related to Geriatric Oncology published over the past two decades. Currently available tools for the conduct, analysis, quality appraisal, and reporting of systematic reviews and meta-analyses are provided and reviewed designed to enhance the quality and understanding of systematic evidence reviews and meta-analyses. Such rigorous and systematic evidence summaries and analyses are likely to continue to increase in number and quality as the field of Geriatric Oncology continues to mature.

Research Methods: Quality of Life and Patient-Reported Outcome Research in Geriatric Oncology

68

Ulrich Wedding

Contents

Abstract

Both clinical care for and clinical research in older patients with cancer need to define endpoints of treatment. Clinical research in geriatric oncology aims to improve the care for older adults with cancer. When asking older adults with cancer what they consider most important as aim of their treatment, some will focus more on lengths and others more on quality of life. Whereas it is easy to measure length of survival, it is more difficult to measure quality of life. As variety of quality of life assessment instruments is available, some of them are addressing health-related quality of life in general; some are developed in a disease-specific background, such as cancer; and others focus on special types of cancer or special kinds of cancer treatment. In the context of older adults

M. Extermann (ed.), *Geriatric Oncology*,
https://doi.org/10.1007/978-3-319-57415-8_4

with cancer, geriatric assessment is established to address areas of resources and limitations. Those items of geriatric assessment reported by the patient or demonstrated in performance test should be considered as patient-reported outcomes as well. Results of geriatric assessment and of health-related quality of life are closely related in older adults with cancer.

Introduction

Traditionally, the tumor was the main – if not exclusive – target of treatment in oncology, the removal of the tumor via surgery and the elimination or shrinkage via radiation or via chemotherapy. In the consequence, either cure (often reported as 5 years survival rates) or remission rates (complete or partial) were the focus of reports of success of oncological trials. However, cure is in any case temporary, as all lives end with the death and remissions seen in X-rays, CT or MRT scan, or ultrasound might not be of any meaningful benefit for the patient either, when they do not result in improved length and/or quality of life. This is especially true in the context of older adults with cancer, as their remaining average life expectancy is lower and the potential gain of years in life via cure less, compared to younger once. Therefore, the field of geriatric oncology is a paradigm to focus on patient-reported outcomes and quality of life.

What Are Patient-Reported Outcomes?

Patient-reported outcomes (PROs) are any reports coming directly from patients about a disease, health, or treatment without interpretation by a clinician or anyone else (Kyte et al. 2016). They include a range of outcomes, such as health-related quality of life (HRQoL), symptoms, functional status, and well-being (Acquadro et al. 2003). In the context of geriatric oncology, some items assessed within the geriatric assessment are patient-reported outcomes; others are physician-reported or performance-based.

Endpoints in Clinical Research in Geriatric Oncology

When the remaining length of survival becomes less achievable, as old itself, age-related and other health-related conditions limit the chance to gain more length of life, and the quality of life becomes more important. In cancer care, cancer treatment often affects quality of life in a negative way substantially. The best way to avoid these treatment-associated negative effects on quality of life would be not to treat a patient. However, that would result in the omission of the positive effects on length of life and quality of life as well. Therefore, treatment decision in geriatric oncology is always a balancing between positive and negative effects. This is summarized in Fig. 1.

Phase 3 clinical trials aim to improve clinical care in a way to establish new standards of care. When setting up phase 3 clinical trials, the most important question is: Will the results be able to set a new standard of care, if the primary endpoint is achieved? Therefore, there is no need to make a difference between endpoints in clinical care and in clinical research. Endpoints in clinical research, at least in big phase 3 trials, should be those the patient is most interested in to achieve.

The Task Force Elderly of the European Organization for Research and Treatment of Cancer (EORTC), the International Society of Geriatric Oncology (SIOG), and the Cancer-Alliance for Clinical Trials in Oncology published a recommendation on appropriate trial design and on selection of appropriate endpoints for clinical trials in older adults with cancer (Wildiers et al. 2013). Combined endpoints or composite endpoints, including efficacy and patient-reported outcomes, seem to be most appropriate for clinical trials in older adults with cancer. However, they are more difficult to plan and less established so far, and the number of patients might be higher than in trials just looking on a single endpoint. The advantage of combined endpoints or composite endpoints overweighs the disadvantage as these endpoints fit much better in the real world of the patients.

In randomized controlled trials, clinical research demonstrates group differences,

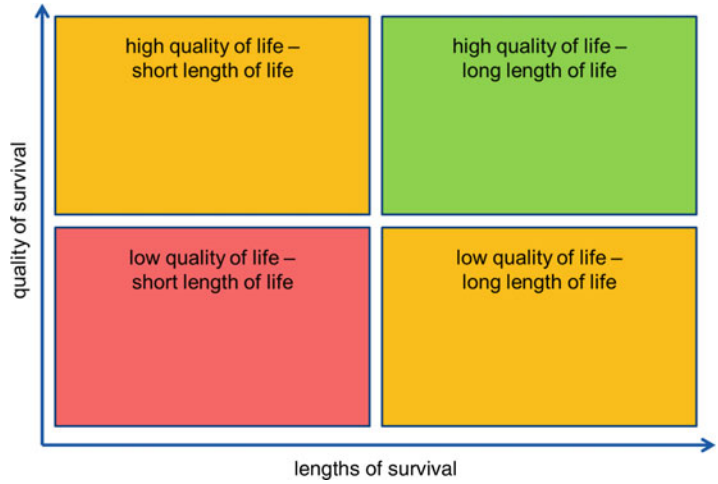

Fig. 1 Goal in treatment

comparing a group receiving standard treatment to a group receiving experimental treatment. In clinical care and in patients, the main comparison to judge the situation is, e.g., quality of life, before and after treatment. In clinical care, a much more individualized approach is possible to define each patient's most important aim of treatment. However, even in clinical care, a standardized approach is recommended in addition not to miss important areas of concern of the patient. Physicians and patients tend to consider different areas as important for the patient (Atkinson et al. 2012). In addition, cancer patients tend to underreport their symptoms to the physician (Nekolaichuk et al. 1999). The reasons may be diverse, e.g., reporting of symptoms related to the disease or the treatment might result in a physician's decision to withdraw treatment. However, the patient might be interested to carry on with the treatment, as it is part of his hope for further survival.

Instruments to Assess Patient-Reported Outcomes

Most instruments to measure PROs are developed in the field of health-related quality of life. A newer area within cancer treatment is patient-reported experience of toxicity of treatment, as patient-reported outcome. Health-related quality of life is a broad concept which can be defined as the patient's subjective perception of the impact of his/her disease and its treatment(s) on his/her daily life; physical, psychological, and social functioning; and well-being.

Health-Related Quality of Life Instruments

A broad variety of instruments to assess patient-reported outcomes exists. Some are general instruments, like the EUROQUAL or the SF-36; others are disease-specific, focusing, e.g., on cancer patients. In this chapter, we will focus on the description of disease-specific tools.

Within the disease-specific tools, often a general tool exists, which can be used in combination with tools for specific types of cancer, e.g., breast cancer or pancreatic cancer; specific types of treatment, e.g., high-dose chemotherapy; specific treatment situation, e.g., palliative care; specific symptoms, e.g., cachexia; or specific age groups, e.g., elderly.

In a systematic review, Fitzsimmons points out that within health outcome assessment, there has been less focus on the older person with cancer and provides a theoretical framework for the further focus (Fitzsimmons 2004). Later she together with others provided a systematic review on the use of quality of life instruments in older adults with cancer and concludes that the development, validation, and use of HRQOL instruments often ignore the specific needs of older people. This

review highlights the need for a HRQOL instrument specifically designed to capture the issues and concerns most relevant to older cancer patients (Fitzsimmons et al. 2009).

The European Perspective

In 1993, Aaronson et al. published the quality of life questionnaire (QLQ) of the European Organization for Research and Treatment of Cancer (EORTC) (Aaronson et al. 1993). The questionnaire contains 30 questions, covering 15 different areas, global health status/quality of life; 5 different functional roles, such as physical functioning, role functioning, emotional functioning, cognitive functioning, and social functioning; and 9 areas that cover different symptoms, such as fatigue, nausea and vomiting, pain, dyspnea, insomnia, appetite loss, constipation, diarrhea, and financial difficulties.

Within the European Medicines Agency (EMA), the Committee for Medicinal Products for Human Use (CHMP) and its Oncology Working Party (ONCWP) provide a new guidance with recommendations for the incorporation of PROs and HRQoL in the clinical development of anticancer medicines and advice on appropriate design, conduct, and analysis of PRO studies. The guidance was published in April 2016 and came into effect in November 2016. The guidance has a special focus on elderly patients, mentioning their special needs and on patients I a non-curative (palliative) treatment setting (http://www.ema.europa.eu/docs/en_GB/document_library/Other/2016/04/WC500205159.pdf).

The paper focuses mainly on the licensing process; however, it provides interesting insides, e.g., the use of time-dependent endpoints of patient-reported outcome measures, such as the time till deterioration of symptoms, e.g., pain (Gravanis et al. 2013). The EMA paper mentions the EORTC-QLQs and the FACT as possible instruments to assess PROs. They consider the PRO-CTCAE (see below) as not yet validated enough to recommend them for use. Regarding elderly patients, they point out: "In elderly patients, concomitant diseases are more frequent, affecting psychological status and general performance. It is important to consider that HRQL is affected by comorbidities, multiple medications (polypharmacy), functional status, ability to carry out activities of daily living, mental status (depression, cognitive functioning) and social support."

Members of a task force of the International Society for Quality of Life Research (ISOQOL) provided comments to the EMA-PRO guidance and point out steps for further development (Kyte et al. 2016).

The North American Perspective

Nearly in parallel in North America, the Functional Assessment of Cancer Therapy-General (FACT-G) was developed (Cella et al. 1993). It covers physical, social/family, emotional, and functional well-being of patients receiving cancer treatment. In addition, 21 cancer-specific measurement tools, 27 cancer-specific symptom indexes, 12 treatment-specific measures, 18 symptom-specific measures, 13 non-cancer measures, and 4 pediatric measures are available (Camuso et al. 2016).

The EORTC QLQ-ELD14

As written above, Fitzsimmons et al. pointed out the need of special quality of life instruments for older adults with cancer (Fitzsimmons et al. 2009). Johnson et al. performed phases 1 to 3 of the development of an elderly cancer patients specific quality of life module, initially called ELD15, after removal of one question, ELD14 (Johnson et al. 2010). This ELD14 module was tested in phase 4, and the results were published by Wheelwright et al. (Wheelwright et al. 2013). The following items are included and add relevant PROs in addition to the global EORTC-QLQ-C30 questionnaire: mobility (three questions), joint stiffness (one question), family support (one question), worries about others (two questions), future worries (three questions), maintaining purpose (two questions), and burden of illness (two questions).

Creation of New Quality of Life Instruments

If one considers the existing quality of life measurements as not suitable to catch the patient's

voice, a structured process exists to how to approach the development of a new quality of life questionnaire.

The stepwise process, as suggested by the EORTC Quality of Life Group, is described in details in a handbook (http://groups.eortc.be/qol/sites/default/files/archives/guidelines_for_developing_questionnaire-_final.pdf). The authors describe four phases/steps: Phase 1, generation of quality of life issues; Phase 2, construction of the item list; Phase 3, pretesting; and Phase 4, field-testing. The process is exemplary described by Johnson et al. in their report on the development of the EORTC QLQ-ELD14 (Johnson et al. 2010). In each step, it is important to involve the patients in the process (Camuso et al. 2016).

Patient-Reported Outcome and Toxicity

Traditionally, the toxicity of cancer treatment is reported within the Common Terminology Criteria for Adverse Events (CTCAE), a part of the Cancer Therapy Evaluation Program (CTEP) which coordinates the clinical therapeutics development program of the Division of Cancer Treatment and Diagnosis (DCTD) of the National Cancer Institute (NCI) of the USA.

Traditionally in clinical trials and in clinical practice, data on toxicity are not directly reported by the patient in the database, but it takes a long way from experience of symptoms, being asked for the symptoms with in a visit in clinic, interpretation of symptoms, writing them to the chart, and extracting them from the chart to a database by a data manager. Multiple steps between the patient and the database make it a process contains many possibilities to miss important parts of the symptoms the patients experience (Basch et al. 2014). In addition, Maio et al. analyzed the difference, when toxicity was reported by physicians and by the patients separately (Di Maio et al. 2015).

Therefore, a couple of years ago, an approach was suggested to let patients rate the toxicity they experience from chemotherapy or other cancer treatments they experience themselves, the so-called PRO-CTCAE (Reeve et al. 2014). With a structured process included different approaches of assessment of PROs and a formulized consensus process, they identified that following 12 items as important: fatigue, insomnia, pain, anorexia (appetite loss), dyspnea, cognitive problems, anxiety (includes worry), nausea, depression (includes sadness), sensory neuropathy, constipation, and diarrhea. These symptoms should belong to a core set of symptoms which should be included in all trials in cancer measuring PROs. Important criteria for the selection were:

- Rank ordered within the top 10 symptoms based on prevalence, severity, and/or importance ratings in at least two data sources
- Present across diverse cancer populations
- Attributable to either disease or to anticancer treatment
- Sensitive to change
- Measurable from the patient perspective

Further studies demonstrated that the preferred recall period for the PRO-CTCAE is the past 7 days (Mendoza et al. 2017). A comprehensive educational review is provided by Kluetz (Kluetz et al. 2016). A limitation of this approach is the focus on adverse event based on cancer treatment, which is of great important for drug approval, compared to a broader approach, where the overall situation, the cancer itself, and the treatment are considered all together, which reflects the situation of the patient in clinical practice better.

Patient-Reported Outcome/Health-Related Quality of Life and Geriatric Assessment

The content and meaning of a geriatric assessment within the care for older adults with cancer are reported in details at other chapters within this book (see ► Chap. 25, "Comprehensive Geriatric Assessment (CGA) for Cancer Patients"). Fitzsimmons points out that the focus on HRQoL only does not cover all areas that are important for older adults with cancer

Table 1 Items of geriatric assessment and their association with HRQoL (Wedding et al. 2007a)

Area	GA scale	HRQoL scale	Effect	Author
Functional status	ADL	EORTC-QLQ-C30	Dependence ADL – Reduced global HRQoL	Esbensen et al. 2004
	ADL	EORTC-QLQ-C30	Dependence ADL – Reduced global HRQoL	Thome et al. 2004
	IADL	EORTC-QLQ-C30	Dependence IADL – Reduced global HRQoL	Wedding et al. 2007b
Mobility/falls	6-minute walk test	Sf-36	Impaired mobility – Reduced HRQoL	Saad et al. 2006
Cognition	MMSE	EORTC-QLQ-C30	No association	Iconomou et al. 2004
Depression	BDI	EORTC-QLQ-C30	Depression – Reduced HRQoL	Wedding et al. 2008
Comorbidity	CIRS-G	EORTC-QLQ-C30	Comorbidity – Reduced HRQoL	Wedding et al. 2007c

GA geriatric assessment, *ADL* activities of daily living, *IADL* instrumental activities of daily living, *MMSE* mini-mental status examination, *BDI* beck depression inventory, *CIRS-G* cumulative illness rating scale geriatric version, *HRQoL* health-related quality of life

Table 2 Comparison of assessment: geriatric assessment vs. health-related quality of life assessment

Area	GA	HRQoL
Structured way to collect data in areas often missed by history taking and physical examination	√	√
Limitations in these areas occur more often in elderly patients	√	√
These areas are important for the patients, e.g., regarding their quality of life	√	√
Validated diagnostic tools exist	√	√
Regular follow-up is recommended	√	√
Diagnostic and therapeutic parts are performed by a multi-professional and multidisciplinary team	√	No
Validated therapeutic interventions exist	√	No
Improves quality of life	√	√

GA geriatric assessment, *HRQoL* health-related quality of life

(Fitzsimmons 2004). When asking older adults what is an important aim for them, they mention the maintenance of their ability to care for themselves and to stay independent as very important. Maintenance of independence or ability to care for oneself is not an established endpoint in clinical trials but part of geriatric assessment.

With a review on quality of life in older adults with cancer, Wedding et al. could point out that most items of geriatric assessment were closely associated with health-related quality of life (Wedding et al. 2007a) (see Table 1). In another table, we compared geriatric assessment and quality of life assessment for their use in clinical cancer research and care (see Table 2).

First trials including geriatric assessment and HRQoL come up. They could demonstrate

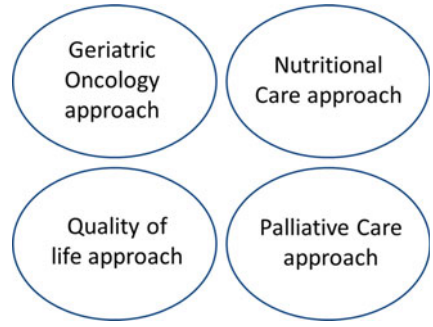

Fig. 2 Overlap between different approaches toward the patient

that limitations in geriatric assessment prior to treatment are associated with poor recovery of HRQoL in the course of treatment, e.g., in patients older than 65 years receiving radiotherapy

Table 3 Pro and contra arguments for the use of QoL measurement in older adults with cancer

Pro	Contra
QoL is one of two major endpoints patients are interested in	Filling in a QoL questionnaire does not contribute to QoL
QoL becomes more important when length of life becomes more limited	In an elderly cancer patient many assessment tools are already used
QoL summarizes a lot of different items	Even in a cognitive fit elderly population, the average time they are able to concentrate is less than 1 hour
Validated instrument exist	QoL measurement is mostly based on cognitive competence and excludes increasing number of elderly patients
QoL measurement improves QoL outcome	Results of geriatric assessment are closely related to QoL
	Interventions to results of geriatric assessment are more or less defined and interventions to poor quality of life not
	Many items of QLQs do not measure QoL but symptoms

for cancer of the lung or head and neck (VanderWalde et al. 2017).

Different approaches to the patient cover identical or similar areas, e.g., quality of life instruments contain a considerable number of symptoms, which are assessed within a palliative care approach as well, and geriatric assessment contains assessment of nutrition, which is covered in nutritional assessment as well. Future activities should address the overlap between the different approaches (Fig. 2). All areas belong to a holistic approach to the patient and cover the non-tumor-directed care/supportive care (Hui et al.). Table 3 provides pro and contra arguments for quality of life assessment compared to geriatric assessment as patient-reported outcome in the care for older adults with cancer.

Improving PRO by Using PROM

Finally, the focus on patient-reported outcome is to improve patient-reported outcomes. Thus the question arises: Does the use of patient-reported outcome measurement improve patient-reported outcome?

Velikova et al. randomized 286 patients treated by 28 different oncologists between three arms, one with no intervention (control group), one with measurement of EORTC-QLQ-C30 and the HADS questionnaire (attention control group), and one with the measurement of the questionnaire and recommendations of interventions regarding the results (intervention group). The effect was measured with the FACT questionnaire. Whereas quality of life deteriorated in 31% and improved in 14% of patients of the control group, the figures were 7% and 32% for the attention control group and 14% and 40% for the intervention group (Velikova et al. 2004). Thus even the reporting of quality of life data improves quality of life outcomes. A study in which cancer patients treated as outpatients self-reported their symptoms electronically and got advise when to contact their clinicians demonstrated improved symptom outcome compared to a control group (Berry et al. 2014a, b). This approach was further developed at the Sloan Memorial Cancer Center, where patients were asked to self-report their symptoms computed based on a weekly base; received a reminder via e-mail, when they missed it; and got a printed version for their routinely visit in the clinic and a contact to a nurse, when severe symptoms occurred. Compared to a control group, quality of life improved (Basch et al. 2016). Strasser et al. could demonstrate that such approaches are applicable on a multicenter setting as well (Strasser et al. 2016).

PRO-cision Medicine

In medicine in general and in oncology especially, the term personalized medicine or precision medicine is used to describe the selection of tumor-specific treatment based on characteristics of the tumor, especially when analyzing molecular targets. Nathan Cherny et al. pointed out that this is a rather small concept of personalized medicine and

further elements should be included, such as the social context, etc. (Cherny et al. 2014). The term PRO-cision Medicine, used by Jensen and Snyder, supports this approach (Jensen and Snyder 2016).

Conclusion

Patients are interested to live longer and better. With decreasing options regarding length of life, quality of life becomes more important. Better life in the context of medicine, oncology, and geriatric oncology should be addressed in an in-depth talk to the patient and his/her relatives. A use of tools can help to focus on topics important for the patients (PROs). Most areas of geriatric assessment are important regarding QoL.

Abstract

As the population is aging, and cancer treatment is advancing, the life span of significant proportion of older cancer survivors is increasing. In order to maintain wellbeing and functional independency of older cancer survivors, it is critical to appreciate the intersection of aging, cancer and cancer treatments, and its impact on older cancer patients' functional status. While the main focus of treatment of older cancer patients after the diagnosis is on the cancer, this should be broadened as active cancer treatment subsides and their transition to survivorship starts. While the best models of care for older cancer survivors are emerging, it is essential for the primary care providers and/or oncologists to be aware of unique challenges facing older cancer survivors. In this chapter, we will review challenges that are more common among older cancer survivors. We will assess the existing literature in this regard and explore the opportunities for further research in each section.

Keywords

Cancer survivorship · Functional activity · Cognitive impairment · Emotional wellbeing · Geriatric oncology

Introduction

With the advances in cancer treatment, the USA is facing an increasing number of cancer survivors. The number of cancer survivors in 2014 was estimated to be 14.5 million, and the number is expected to increase to 19 million by 2024. With the population aging, it is highly likely that the significant portion of cancer survivors will be age 65 or older (Desantis et al. 2014). Moreover, given the early diagnosis of cancer and advances in cancer treatment, the likelihood of long-term cancer survivors (those living beyond 5 years after cancer diagnosis) will increase (Siegel et al. 2014). As a result, it is critical to provide better care to older cancer survivors to fully assess the medical and physiological challenges pertinent to them. The models of care for older cancer survivors are still evolving. There is a difference in the attitudes of primary care providers and oncologists in the provision of care for cancer survivors. More than 1/3 of primary care providers prefer to provide care for cancer survivors in collaboration with the oncologists; however, only 1/6 oncologists agreed with this model. More than 50% of primary care providers felt confident in providing such care; however, only 23% of oncologists agreed with such statement (Potosky et al. 2011). As expected, the confident primary care providers had more intensity of care for cancer survivors (Klabunde et al. 2013).

It is critical for primary care providers and oncologists to be aware of the intersection between aging, cancer, cancer treatment, and their impact on cancer survivors' frailty status in order to provide more comprehensive care.

Interaction Between Aging, Cancer, Cancer Treatment, and Their Impact on Frailty

With a broad definition, frailty is "a state of decreased (or total lack of) reserve and resistance to physical and emotional stressors, due to continuous decline in various organ functions" (Rockwood 2005). While the correlation is not 100%, in general, patients tend to become more frail as they age (Schuurmans et al. 2004). Those with cancer tend to be more frail compared to noncancer patients (Mohile et al. 2009; Flood et al. 2006), and cancer treatment itself may lead to frailty.

Measuring Frailty of Older Cancer Survivors

Traditionally, geriatricians perform comprehensive geriatric assessment (CGA) in order to assess aging-related deficits of older cancer patients and survivors (Caplan et al. 2004; Vidán et al. 2005). CGA is a multidimensional assessment. While its specific domains and instruments vary among investigators, most agree that CGA

should include functional domain with assessment of Activities of Daily Living, Instrumental Activities of Daily living, comorbid conditions, cognition, nutritional status, and emotional well-being. Based on CGA, investigators have been able to develop models to predict chemotherapy toxicity (Hurria et al. 2011; Extermann et al. 2012). CGA has also been shown to be correlated with complications and outcome after cancer surgery (Kristjansson et al. 2010a, b) and to influence cancer treatment decision-making (Caillet et al. 2011; Chaïbi et al. 2011).

Older Cancer Survivors' Outcomes and Research

In the following sections, we will review the available literature on outcomes of older cancer survivors and potentials for future research and investigations.

Functional Decline

Disability among cancer survivors appears to be most pronounced in the area of physical functioning, with nearly one in six (16.8%) working-age cancer survivors reporting an inability to work and another 7.4% limited in their ability to work (Hewitt et al. 2003). Nearly one half of cancer survivors are aged 65 and older. They may have preexisting chronic diseases and functional limitations at the time of their cancer diagnosis. Functional dependence is associated with decreased survival (Reuben et al. 1992). In older women who are breast cancer survivors, though the ability to perform normal activities were most affected during the period 2 years after diagnosis, even more than 5 years after cancer diagnosis, survivors had 30–50% increased odds of reporting an inability to do activities requiring mobility and strength (Sweeney et al. 2006).

The assessment of function needs to include Activities of Daily Living (ADL) and Instrumental Activities of Daily Living (IADLs) in addition to performance status (PS). ADLs and IADLs bear a poor correlation with performance status (Extermann et al. 1998). While about 80% of older adults with cancer have an ECOG performance status of 0 or 1 at the time of diagnosis, more than 50% of these patients require assistance with instrumental activities of daily living such as driving, shopping, and managing finances (Schubert et al. 2008). These assessments are listed in Table 1.

In addition, asking about recent falls is important in the assessment of functional status. Older cancer survivors may be predisposed to falls because of the sequelae associated with cancer and its treatments (Huang et al. 2014). Falls are associated with lower health-related quality of life scores as well as with a significant prospective decline in these scores in older cancer survivors (Pandya et al. 2016).

Cancer-Related Functional Compromise

1. Fatigue is one of the most common symptoms of cancer and it can manifest as weakness and exercise intolerance (Gilliam and St. Clair 2011). Depending on the site, the tumors may

Table 1 Some commonly used functional assessment tools

	Performance status (PS) scales					
	Eastern Cooperative Oncology Group (ECOG)	Karnofsky (KPS) (Schag et al. 1984)	Activities of daily living	Instrumental activities of daily living	Gait speed (Studenski et al. 2011)	Timed get up and go (Shumway-Cook et al. 2000)
Scores	5 to 0	0–100	0–6	0–8	In meters/second	In seconds
Type of tool	Self-report	Self-report	Self-report	Self-report	Performance based	Performance based

directly impact physical functioning capability. Involvement of the spinal cord by cancer is seen in 5–10% of all patients with cancer (Chamberlain 2015). Neoplastic myelopathies are not infrequent. Spinal tumors may cause spinal cord compression and vascular compromise resulting in neurologic compromise. They may also alter the architecture of the spinal column, resulting in spinal instability (Ruppert 2017).

2. Adjuvant chemotherapy for breast cancer has been associated with deterioration of fine motor skill. Compared with a population-based reference group, cyclophosphamide methotrexate 5-fluorouracil chemotherapy-exposed breast cancer survivors demonstrated motor slowing while drawing an Archimedes spiral, on average 20 years after completion of primary treatment (Hoogendam et al. 2015). Chemotherapy-induced peripheral neuropathy (CIPN) is a major dose-limiting side effect that can lead to long-term morbidity. Approximately, one third of patients receiving chemotherapy with taxanes, Vinca alkaloids, platinum compounds, or proteasome inhibitors develop this toxic side effect (Podratz et al. 2016). Chemotherapy-induced neuropathies cannot be treated, and protective strategies have not been found to be effective. Neurotoxicity is usually dependent on cumulative dose. Severity of neuropathy increases with duration of treatment and progression stops once drug treatment is completed. The platinum compounds are an exception where sensory loss may progress for several months after cessation of treatment, called "coasting" (Windebank and Grisold 2008). Neurotoxicity from chemotherapy has shown declines as large as 50% in performance-based measures, persisting over 2 years, and with patient reported recurrent falls, cane use, and mobility-related disability (Hile et al. 2010). CIPN, primarily motor, is associated with falls and functional impairments (Gewandter et al. 2013).
3. Surgery is a major stressor to functional status, and functional decline is commonly noted after surgery. Memorial Sloan Kettering Cancer Study has shown that 51% of adults 75 years and older who underwent cancer surgery required skilled care at discharge (Alexander et al. 2016). Studies have shown that postoperative functional setbacks tend to persist in older patients (Lawrence et al. 2004). A significant proportion of older patients undergoing major surgery experienced functional decline at 1 month (45.3%), 3 months (30.1%), and 1 year (28.3%) (Kwon et al. 2012). This same study found that, though a higher preoperative functional status was related to a quicker recovery, no subgroups returned to baseline functional status.
4. Data on long-term functional compromise in older cancer patients treated with hormone therapy (HT) or radiation therapy is scant. There are, however, some studies that show their impact on health-related quality of life. Patients with low-risk prostate cancer who received external beam radiation therapy (EBRT) are significantly more likely to experience a decrease in more than one functional domain (urinary, sexual, bowel, or hormonal) at 1 year when compared with those on active surveillance – 60% versus 28% (Banerji et al. 2017). Bowel function significantly worsened with the addition of HT to EBRT (Brassell et al. 2013).

Oncologic management of spinal tumors varies according to the stability of the spine, neurologic status, and presence of pain. Treatment options include surgical intervention, radiation therapy, chemotherapy, and hormonal manipulation. When combined with this management, rehabilitation can serve to relieve symptoms, improve quality of life, and enhance function (Ruppert 2017). In patients with neuropathy, restorative approaches have not been well established. Symptomatic and other management are necessary to maintain and improve quality of life (Windebank and Grisold 2008). Enhancing fitness and functional capacity prior to surgery can accelerate postsurgery recovery. Presurgical exercise may benefit cancer patients through positive effects on function and physical capacity (Singh et al. 2013). Patient mobilization on postoperative day 0 provides better outcomes than later mobilization

Table 2 Tests to assess cognition

	Mini-Mental status examination (Kang et al. 1997)	Montreal cognitive assessment (Nasreddine et al. 2005)	Mini-Cog (Borson et al. 2000)
Year of creation	1975	1996	2000
Time to administer	7–8 min	10–12 min	3 min
Scoring	Maximum score of 30 Cut-off score of 24	Maximum score of 30 Cut-off score 26	Maximum score of 5 Cut-off score of 3
Domains assessed	Attention, visuospatial, memory, language	Attention, visuospatial, memory, executive, language	Executive, memory
Advantages/ disadvantages	Affected by educational level, language, and cultural barriers	Greater sensitivity to detect mild levels of cognitive impairment	Not influenced by education level or language abilities Fast and simple

with lower length of stay, need for opioids, and enhanced recovery (Ibrahim et al. 2013). In reducing fatigue among older cancer survivors, various interventions have been tested. A secondary analysis on patients age 60 or older, who completed cancer treatment between 2 and 24 months prior to enrollment into the study, showed that yoga might be helpful in reducing fatigue (Sprod et al. 2015). Another study on older prostate cancer survivors showed that Qigong intervention (meditative focus on breath, sitting exercises, and standing movements) experienced an improvement in their fatigue level (Campo et al. 2014). The majority of studies on cancer survivors have been focused on breast and prostate cancer survivors. As a result, American College of Sports Medicine encourages investigators to explore the impact of physical exercises in other cancer survivors and to assess the dose-response effect of the interventions (Panel 2010).

Cognitive Decline

Both cancer and cancer therapies can negatively affect cognition, and older adults with preexisting cognitive impairment may be more susceptible to cognitive decline with therapy than younger patients (Magnuson et al. 2016). A recent study in lymphoma patients showed that cognitive disturbance may be a significant survivorship issue. These patients had a higher frequency of impairment on both objective and subjective cognitive measures and these were in turn associated with other psychosocial factors such as fatigue, anxiety, and pain (Krolak et al. 2016). The common tests to assess cognition are listed in Table 2.

Cognitive screening tests commonly used in Oncogeriatrics are often not sensitive enough to detect subtle disorders. Hence, more detailed cognitive assessment batteries of neuropsychological tests may be necessary. Trained neuropsychologists are needed for formal neuropsychological testing. The data obtained are compared to normal population valuesand can be adjusted for the patient's baseline intelligence and previous educational level. It is composed of different tests, the exact constituents of which tend to vary between individual neuropsychologists and depending on the specific population or clinical question to be addressed. Typically, it will take 1–3 h to perform (Woodford and George 2007).

Cancer-Related Cognitive Deficits

1. The impact of cancer itself on cognitive functions, known as the "*cancer brain"* concept, could also play a role through increased inflammation, dysregulation of cytokines, or oxidative stresses (Lange et al. 2014). About 60–90% patients with intracranial tumors face cognitive impairments along with some emotional and behavioral changes (Dhandapani et al. 2016). In the intracranial tumors, the duration and location of the mass, brain edema, and associated neuroinflammation contribute to cognitive dysfunction.

2. Chemotherapy-related cognitive impairment (CRCI), or the "*chemobrain*" phenomenon, refers to the chemotherapy-induced impairment of memory, executive function, or information processing speed (Lange et al. 2014). CRCI has been reported in up to 12–75% of patients with cancer and is associated with cancer type, treatment, duration of follow-up, type of study design, and definition of cognitive impairment (Loh et al. 2016). It has been extensively described in breast cancer patients. Survivors of breast cancer treated with adjuvant CMF chemotherapy more than 20 years ago perform worse, on average, than random population controls on neuropsychological tests (Koppelmans et al. 2012). The epsilon 4 allele of APOE may be a potential genetic marker for increased vulnerability to chemotherapy-induced cognitive decline (Ahles et al. 2003).
3. Hormonal therapy could be associated with increased risk of cognitive changes as well. Different studies have shown possible immediate to longer term cognitive sequelae with the use of selective estrogen receptor modulators (SERMs) and aromatase inhibitors (AIs). Thousands of breast cancer patients have been enrolled on trials evaluating the efficacy of endocrine therapy, but there is a relative paucity of data addressing cognitive changes with these agents (Agrawal et al. 2010). There is a strong argument that androgen-ablation therapy is linked to subtle but significant cognitive declines in men with prostate cancer. Androgen deprivation therapy (ADT) patients are more vulnerable to experiencing specific cognitive and neurobehavioral symptoms than non-ADT patients, but these cognitive symptoms may not easily be detected using neuropsychological tests (Wu et al. 2016). Between 47% and 69% of men on ADT declined in at least one cognitive area, most commonly in visuospatial abilities and executive functioning (Nelson et al. 2008). Prostate cancer patients who received ADT performed significantly worse on visuomotor tasks compared to non-cancer control groups (Mcginty et al. 2014).
4. There are two main entities of postoperative cognitive decline: delirium and postoperative cognitive dysfunction (POCD). Both have multifactorial pathogenesis but differ in numerous other ways, with delirium being well defined and acute in onset and postoperative cognitive dysfunction being subtler and with longer duration (Krenk and Rasmussen 2011). POCD has been documented after cardiac and noncardiac surgery (Evered et al. 2011). Apart from the nature of the surgical procedure, advanced age is the most important risk factor for POCD. In patients older than 60 years, a POCD rate of 10% is detected 3 months after surgery (Coburn et al. 2010). The anesthetic technique is not a determinant of POCD, the risk appears to be similar after both general and regional anesthesia (Sauer et al. 2009). On the other hand, patients with intracranial tumors have substantial cognitive dysfunction with deficits in different domains based on tumor size and location, and this tends to show significant improvement beyond 6 months following surgery, especially among tumors which are extra-axial, benign, and non-irradiated (Dhandapani et al. 2016; Hendrix et al. 2016).
5. Cognitive deficits are common in people who have received cranial irradiation and have a serious impact on daily functioning and quality of life. Standard treatment of primary and metastatic brain tumors includes high-dose megavoltage-range radiation to the cranial vault. About half of patients survive >6 months. However, 50–90% of survivors exhibit disabling cognitive dysfunction (Makale et al. 2016). Low-grade glioma patients who received radiotherapy, followed long term (6–28 years), showed a progressive decline in attentional functioning, even those who received fraction doses that are regarded as safe (</=2 Gy) (Douw et al. 2009). Prophylactic cranial irradiation (PCI) in locally advanced NSCLC patients was associated with decline in tested and self-reported cognitive functioning both at 6 and 12 months post radiation (Gondi et al. 2013).

There is supportive evidence that memantine may help prevent cognitive deficits for adults with brain metastases receiving cranial irradiation and that donepezil may have a role in treating cognitive deficits in adults with primary or metastatic brain tumors who have been treated with cranial irradiation (Day et al. 2014). Sparing "radiosensitive" areas such as hippocampi could have a modest but measurable impact with regard to cognitive preservation, an effect that can possibly be enhanced when used in conjunction with memantine and/or donepezil (Dhermain and Barani 2016). There is no strong evidence to support any nonpharmacological interventions (medical or cognitive/behavioral) in the prevention or amelioration of cognitive deficits (Treanor et al. 2016.)

Older Cancer Survivors and Endocrine Abnormalities

Cancer is a major risk factor for both generalized and local bone loss. Bone loss assessed by bone mineral density (BMD) testing is substantially higher in cancer patients than in the general population, independent of cancer type (Drake 2013). Aging in both men and women is associated with increased rates of osteoporosis and fractures due to decline in sex steroids, primarily estrogen, and testosterone that occur in both sexes with aging; however, cancer survivors are at higher risk for osteoporosis and subsequent fractures compared with the general population. Breast cancer therapies can lead to bone loss and increased fracture risk. Although tamoxifen is associated with a decreased risk of osteoporosis if used in postmenopausal women, it may lead to an increase in the incidence of osteoporosis in premenopausal women (Shahrokni et al. 2016). Men who undergo long-term androgen deprivation for prostate cancer are at increased fracture risk due to severe suppression of testosterone levels. Men with prostate cancer were found to have a 1.9-fold relative risk of fracture with this risk being higher for those on androgen deprivation therapy (Tuck 2017). Bone health is a particular concern because androgen deprivation therapy causes a high annual rate of bone loss and this, combined with the preexisting high prevalence of osteoporosis in men with prostate cancer, results in a dramatic increase in fracture rates (Tuck 2017). Early bone loss can be seen in patients who have undergone bone marrow transplantation, and patients with multiple myeloma develop characteristic focal osteolytic lesions, generalized bone loss, and a fracture rate as high as 16-fold when compared to the general population (Drake 2013). Additionally, patients with gastric cancer who have had a gastrectomy are at an increased risk of developing osteoporosis thought to be secondary to the loss of gastric acidification necessary for optimal intestinal calcium absorption (Virik and Wilson 2016).

Epidemiologic studies have shown an increased risk of cancer as well as a higher mortality rate in patients with type 2 diabetes. Type 2 diabetes, obesity, and the metabolic syndrome are associated with an increased risk of cancer development. Although this correlation is not fully understood, proposed mechanisms include insulin resistance, hyperinsulinemia, and inflammatory cytokines. A meta-analysis of 221 datasets found that a 5 kg/m^2 increase in BMI was associated with an increased risk of developing esophageal, thyroid, colon, and renal carcinoma and multiple myeloma in men and women, in addition to hepatocellular and rectal cancer, and malignant melanoma in men, and endometrial, gallbladder, postmenopausal breast, and pancreatic cancer and leukemia in women (Zelenko and Gallagher 2014). Two known causes of the metabolic syndrome are testosterone deficiency and estrogen deficiency (Shahrokni et al. 2016). Patients with testicular cancer and hematological malignancies are considered to be at increased risk for the metabolic syndrome (de Haas 2010). Patients with prostate cancer receiving androgen-deprivation therapy had a higher prevalence of metabolic syndrome (55%) than patients treated with prostatectomy, radiotherapy, or both (22%) and healthy controls (20%) (Micucci et al. 2016). Metabolic syndrome can also represent a long-term complication after cancer treatment that

affects life expectancy and quality of life (Micucci et al. 2016). The presence of metabolic syndrome in cancer survivors is associated with signs of early atherosclerosis and may represent the connection between cancer treatment and its severe late effects like cardiovascular disease (Micucci et al. 2016).

Physical activity helps patients maintain a healthy weight and is beneficial for bone health. Physical activity has been shown to improve muscular strength and endurance, and improve fatigue (Campo et al. 2014). According to consensus, physical activity is safe during and after cancer treatment but "relationships related to specific cancer diagnoses, treatments, and underlying cardiometabolic mechanisms associated with survival has not been thoroughly examined in randomized controlled trials" (Tuck 2017). Clinicians should consider individual differences among cancer survivors and tailor physical activity programs to meet the individual needs of the patient.

The Psychosocial Aspects of Cancer Survivorship

Surviving cancer can be as much of a psychological battle as it is a physical one. Thirty-five to 38% of patients have significant emotional distress related to their cancer diagnosis (Faller et al. 2013), and at least 11.6% and 17.9% of long-term cancer survivors have depression and significant levels of anxiety, respectively (Shahrokni et al. 2016). Even years after a cancer is diagnosed and treated, a variety of practical, spiritual, and emotional challenges can be present. Cancer-related distress can include a wide continuum of emotions related to, among others, symptoms of depression, anxiety, and adjustment disorder. In the cancer population, distress is often reported to be above 30% (Jacobsen et al. 2005). Symptoms of anxiety and depression may also occur independently and progress quite differently after a cancer diagnosis (Paice et al. 2016). A meta-analysis showed that exercise training can reduce depressive symptoms of cancer survivors; however, the most showed benefit was for patients aging 47–62 (Brown et al. 2010). The studies on other types of interventions on reducing anxiety, depression, and adjustment disorder among older cancer survivors are very limited.

Post-cancer pain syndromes can be viewed as part of a cluster of symptoms, including fatigue, anxiety, depression, and sleep disturbance (Aaronson et al. 2014). Patients with neurologic cancers often report high levels of depression, fatigue, distress, and existential concerns, often exacerbated by aggressive treatment regimens and poor prognosis. These patients typically report lower quality of life, irrespective of the time since diagnosis or treatment (Bultz et al. 2013).

Estimates of the prevalence of pain in cancer survivors vary widely and have been reported to be as high as 40% (Paice et al. 2016). Risk factors for chronic pain in survivors include the type and invasiveness of the tumor, the treatment regimen used, the time since cancer treatment, and the efficacy of initial pain therapy. Management may include nonopioid medication options such as antidepressants, antiepileptic drugs, and topical agents. Interventional modalities may be considered, including nerve blocks, trigger point injections, spinal cord stimulators, or implanted intrathecal pumps.

Cardiotoxicity

In general, older cancer patients with preexisting cardiac conditions are more likely to develop cancer-treatment-related cardiotoxicity in the short term and long term (Schmitz et al. 2012). For example, the incidence of cardiotoxicity among breast cancer patients is 3–35% (Yeh and Bickford 2009), and the mortality risk due to cardiotoxicity may at times surpass the risk of mortality due to breast cancer (Patnaik et al. 2011). The cardiotoxicity of chemotherapy agents differs. For example, even low doses of anthracyclines, drugs commonly used in breast cancer patients, can cause cardiotoxicity in patients with preexisting cardiac disease (Ryberg et al. 2008). A systematic review showed that incidence of clinical and subclinical cardiotoxicity in patients who received anthracyclines

was 5.4 and 6.25 higher compared to those who did not receive anthracycline (Smith et al. 2010). These patients were also five times more likely to die because of cardiac disease than those who did not receive anthracycline. One study showed that for every 10 year increase in age, the risk of developing congestive heart failure in these patients is doubled (Pinder et al. 2007).

Among prostate cancer patients on ADT, the risk of cardiotoxicity is higher than those who are not on ADT (O'Farrell et al. 2015; Taylor et al. 2009). Once again, increasing age is associated with increasing likelihood of toxicity as each year increase in age, increased the risk of toxicity by 3% (Saigal et al. 2007). It is expected that 5.5% of patients on ADT following prostatectomy die within 5 years due cardiac causes, compared to 2% of patients who only underwent prostatectomy (Tsai et al. 2007).

Among other agents causing cardiac toxicity, 5-fluouracil (5-FU), a commonly used agent for a variety of cancers, should also be noted. Patients receiving 5-FU may experience cardiotoxicity with the incidence rate ranging from 1.2% to 18%. The toxicity usually occurs while the patient is receiving the treatment (Saif et al. 2009). Capecitabine, an oral derivative of 5-FU, is also responsible for causing ischemia in as high as 9% of patients (Curigliano et al. 2010). Similar to 5-FU, the cardiotoxicity from capecitabine is also short term.

The Future of Cancer Survivorship Research for Older Patients

Despite advances in exploring and improving physical and psychosocial problems of older cancer survivors, many questions have remained unanswered. These questions are in four broad levels of the patient, the healthcare provider, the caregiver, and the society. In the patient level, models based on geriatric assessment have been developed that can predict chemotherapy toxicity (Hurria et al. 2011; Extermann et al. 2012). There has been effort to utilize geriatric assessment in predicting surgical outcomes of older cancer patients (Kristjansson et al., 2010a). Moreover, efforts have been made to predict short- and long-term mortality of older cancer patients (Freyer et al. 2005). However, there is a significant gap between short-term outcomes (e.g., chemotherapy toxicity) and long-term outcomes (e.g., mortality). Are patients who are predicted to die after a certain amount of time, die suddenly? Or do they experience a gradual functional decline and then die? What role can the healthcare system and the society play to avoid gradual decline? Studies have shown that patients with more comorbid conditions are at higher risk for adverse short- and long-term outcomes (Patnaik et al. 2011). What is the interaction between comorbid conditions, cancer, and outcomes? Do more intensive follow-up and management of older cancer survivors and their comorbid conditions improve outcomes of these patients? While the survivorship guidelines have been developed for cancer survivors regardless of their age, there is a need for specific recommendations regarding the issues pertinent to older cancer survivors (e.g., bone health). As mentioned in the introduction, with the aging population and advances in cancer treatment, it is expected that more older cancer patients be diagnosed and treated properly and transition to the survivorship and many younger patients experience years of cancer free period and transition to become older cancer survivors. In order to provide more intense care and monitoring for these patients, the traditional healthcare system may reach its capacity soon. Can advances in the information technology in other fields be used in caring for older cancer survivors? Are older cancer survivors receptive to such interventions and assessments? Does it improve outcomes such as maintaining functional activity of older cancer survivors? Does it shift the care from more expensive emergency room visits and hospital admissions to more proactive outpatient clinics? Regardless of method of assessment (in person, over the phone, or using wireless technology) which healthcare provider should be responsible for responding to the findings? Outpatient primary care provider, oncologist, or a special older cancer survivorship clinic? What is the role of the caregiver and how we can empower the caregiver? Majority of older patients are receiving informal

care either through their spouses and/or their children. In the era with emphasis on caregiver empowerment, how could the caregivers, who might be old themselves, be educated, trained, and empowered to care for the older cancer survivor? How can supportive services be directed to those in need?

Methodological Challenges

Studies on older cancer patients' survivorship may pose methodological challenges unique to this population. It has been proposed that there could be an interaction between age, cancer, and cancer treatment on frailty (Shahrokni et al. 2016). As a result, in order to assess the impact of any of these three factors (age, cancer, cancer treatment), a control group with similar characteristics in the other two factors is needed. For example, if the question is to assess the impact of 5-year hormonal treatment on frailty of breast cancer survivors older than age 75 who have undergone lumpectomy and radiation, the optimal control group would be breast cancer survivors older than age 75 who have undergone lumpectomy and radiation but did not receive hormonal treatment. In addition, it is also important to assess, address, and control for timing of cancer diagnosis and treatment in relationship. In the example above, there might be differences between frailty levels of patients in the control group who had surgery a year ago compared to 6 years ago. As wellbeing and fitness of older cancer survivors may have direct correlation with their socioeconomic status, studies of older cancer survivors need to consider assessing factors such as socioeconomic status (e.g., income, insurance status, primary language, living condition, social support). Healthy selection bias is always a major challenge in any observational or interventional study (Hernán et al. 2004). One way of solving such problems is to use datasets that are collected as routine care via electronic medical records. This will significantly decrease the possibility of healthy selection bias. This also may solve a problem of accruing patients into clinical trials. Recruitment to clinical trials can be challenging, leading to 1 in 10 cancer trials registered on ClinicalTrials.gov between 2005 and 2011 being closed prematurely due to poor accrual and other trials taking longer than anticipated to complete recruitment. This is a major problem for oncologists, not only from a scientific perspective but also due to the implications of failing to meet recruitment targets (Moorcraft et al. 2016). Few adult cancer patients are treated on clinical trials; however, patients previously enrolled in these trials are an important source of information about treatment-related late effects. Retrospective recruitment has substantial limitations. In the future, mechanisms should be established for prospective long-term follow-up to identify and understand the frequency and type of late effects associated with cancer treatments (Ganz et al. 2009).

Conclusion

The advances in cancer treatment will lead to substantial increase in the number of older cancer survivors in the next decade. Collaborative clinical, research, and policy efforts need be made in order to preserve functional independency and maintain wellbeing of older cancer survivors.
