Chapter 3
Acute Myeloid Leukemia with Myelodysplasia-Related Changes, Therapy-Related Myeloid Neoplasms, and Acute Myeloid Leukemia, Not Otherwise Specified

Peng Li and Robert S. Ohgami

Introduction

Acute Myeloid Leukemia with Myelodysplasia-Related Changes

In 2016, the updated World Health Organization (WHO) classification of hematopoietic neoplasms revised this entity minimally, and it remains a subcategory of acute myeloid leukemias (AMLs) entitled "acute myeloid leukemia with myelodysplasia-related changes (AML-MRC)." AML-MRC (Table 3.1) is defined as AML (≥20% blasts in peripheral blood or bone marrow) with a history of myelodysplastic syndrome (MDS) or myelodysplastic/myeloproliferative neoplasm (MDS/MPN), or specific MDS-related cytogenetic abnormalities (Table 3.2), or morphologic features of multilineage myelodysplasia (≥50% dysplastic cells in at least two cell lineages), in the absence of *NPM1* or biallelic *CEBPA* mutations, because the morphologic dysplasia in AML cases with *NPM1* or biallelic *CEBPA* mutations appears not to impact patient outcome [1–4]. AMLs with *NPM1* or biallelic *CEBPA* mutations have been upgraded from provisional entities in the 2008 WHO classification to full entities in the 2016 WHO classification and are now included amongst AMLs with recurrent genetic abnormalities.

Therapy-Related Myeloid Neoplasm

Therapy-related myeloid neoplasms (t-MNs), including AML, MDS, and MDS/MPN, occur after cytotoxic insults by chemotherapy or radiation therapy (Table 3.3) for a neoplastic or nonneoplastic disorder [5–7]. Although t-MNs can be further subclassified to t-MDS or t-AML based on blast counts, all therapy-related neoplasms are best considered as one clinical syndrome [4]. Associated cytogenetic and molecular abnormalities, independent of blast count, are better predictors of disease

Table 3.3 Cytotoxic agents inducing therapy-related myeloid neoplasms

Cytotoxic agents	Specific medication and therapy
Alkylating agents	Melphalan, cyclophosphamide, nitrogen mustard, chlorambucil, busulfan, carboplatin, cisplatin, dacarbazine, procarbazine, carmustine, mitomycin C, thiotepa, lomustine, etc.
Ionizing radiation therapy	Large fields including active bone marrow and for autologous bone marrow transplant modification
Topoisomerase II inhibitors	Etoposide, teniposide, doxorubicin, daunorubicin, mitoxantrone, amsacrine, actinomycin
Others	Antimetabolites: thiopurines, mycophenolate, fludarabine Antitubulin agents (usually in combination with other agents): vincristine, vinblastine, vindesine, paclitaxel, docetaxel

Modified from the WHO classification

prognosis and therapy response, and these abnormalities should be incorporated into the final diagnosis [4].

Acute Myeloid Leukemia, Not Otherwise Specified (AML, NOS)

All AML cases that do not fulfill the diagnostic criteria for AML with recurrent genetic abnormalities including *NPM1* and biallelic *CEBPA* mutations, AML-MRC, therapy-related myeloid neoplasm, or myeloid neoplasm with germline predisposition are classified as AML, not otherwise specified (NOS). The basis for subclassification within this category is primarily the morphologic features of blasts, although these morphologic subtypes lack clinical or biologic significance [8, 9]. In the updated 2016 WHO classification, the blast percentage of all AMLs including acute erythroid leukemia is based on total marrow nucleated cells, not nonerythroid cells. The attempt to achieve consistency in calculating blast percentage across all myeloid neoplasms can, at least in part, avoid overdiagnosis of AML primarily due to the low reproducibility of nonerythroid blasts counts. Further, cases previously subcategorized as acute erythroid leukemia, erythroid/myeloid type, share common clinical manifestations, morphologic, and cytogenetic features with cases of MDS [10–13]. Therefore, this subcategory of acute erythroid leukemia (defined as ≥50% BM erythroid precursors and ≥20% myeloblasts among nonerythroid cells) is removed from acute erythroid leukemia. The majority of such cases are now classified as MDS, especially MDS with excess blasts [4].

Epidemiology

AML-MRC is more common in older patients, with a median age of 68 years, and shows a slight male predominance [14]. The diagnosis of AML-MRC accounts for approximately 25–35% of adult AMLs [8, 15–17]. AML-MRC more commonly

Table 3.4 Cytotoxic agents inducing therapy-related myeloid neoplasms and their clinical manifestations

Cytotoxic agents	Latency	Cytogenetics	Dysplastic phase	Prognosis
Alkylating agents	Long, 5–7 years [7]	Deletions of chromosomes 5 and 7, complex karyotypes	Yes	Poor
Ionizing radiation	Long, 5–7 years [7]	Deletions of chromosomes 5 and 7, complex karyotypes	Yes	Poor
Topoisomerase II inhibitors	Short, 1–3 years	Abnormalities of *KMT2A* or *RUNX1*	Often no	Poor

occurs de novo [14] and may also arise from preexisting myelodysplasia (MDS or MDS/MPN). AML-MRC is generally associated with a worse prognosis and a lower rate of achieving complete remission in response to current chemotherapies compared to other types of AML. The prognosis for AML-MRC is also dependent on other individual factors, such as the patient's age, blast count [18], cytogenetic abnormalities [19, 20], specific molecular mutations [19, 20], and different therapies [5, 20, 21]. Patients with lower blast counts (20–29%) in the absence of MDS-related cytogenetic abnormalities, specifically in children, have relatively better clinical outcomes [21–23]. Recent studies also suggest that allogeneic hematopoietic stem cell transplantation may overcome the poor prognosis for AML-MRC, especially in patients who are 50 years old or younger [18].

Therapy-related myeloid neoplasms account for approximately 10% of AML and 20% of MDS, and are associated with a uniformly poor prognosis with a median survival of 6 months [5–7]. Overall, the median time to develop t-MDS/AML following cytotoxic therapy is approximately 3–5 years, with a marked risk reduction after the first decade [6, 7]. There are two types of t-MNs based on their causative therapeutic exposures (Table 3.4): a topoisomerase II inhibitor-related type and an alkylating agent/radiation-related type. Therapy-related myeloid neoplasms associated with chemotherapeutic administration of topoisomerase II inhibitors develop 1–3 years after exposure, and often show no morphologic dysplasia. Alkylating agent/radiation–related t-MNs occur 5–7 years after exposure to cytotoxic agents [6, 7]. Approximately two-thirds of these patients develop a myelodysplastic phase lasting months to years before overt AML. The remainder often presents with AML with myelodysplastic features [5, 6] in addition to myelodysplasia-related cytogenetic abnormalities involving chromosomes 5 (−5/del[5q]) and 7 (−7/del[7q]).

AML, NOS, encompasses a large heterogeneous group, representing 25–30% of adult AML. It occurs at a younger age than AML-MRC, and has an intermediate prognosis [14]. Generally, there are no common clinical features or consistent chromosomal abnormalities identified with this category, and this diagnosis is made by exclusion of other subcategories of AML.

Clinical Features

AML-MRC displays substantial heterogeneity in presentation and clinical course. Adults with AML-MRC often present with severe pancytopenia with a rapid increase in blasts. In contrast, children with a blast percentage between 20% and 29% and preexisting MDS (especially RAEB) experience relatively slow progression and stable blast counts for weeks to months [23]. Therapy-related myeloid neoplasms occurring with a short latency often show abnormalities of either *KMT2A* at 11q23 or *RUNX1* at 21q22, and are often associated with use of topoisomerase II inhibitors (Table 3.4). Longer latency t-MNs often have a prolonged MDS phase, multilineage dysplasia, and MDS-associated karyotypic abnormalities, and these features are more likely to be related to alkylating agents or ionizing radiation (Table 3.4). Patients with AML, NOS usually present with evidence of bone marrow failure and pancytopenias. Beyond medullary symptoms, extramedullary manifestations including soft tissue masses, cutaneous and gingival infiltration, and central nervous system (CNS) involvement are more common in acute monoblastic and monocytic leukemia. Patients with acute basophilic leukemia often have cutaneous involvement, organomegaly, lytic bone lesions associated with hyperhistaminemia, and bone marrow failure.

Morphology and Immunophenotype

Most cases of AML-MRC and t-MNs have morphologic evidence of multilineage dysplasia best evaluated with peripheral blood smears and bone marrow aspirates. Significant dysplastic features are defined as involving at least 50% of the cells of each particular lineage. Blood smears may be particularly useful in identifying myeloid dysplasia, while erythroid and megakaryocytic dysplasia are best evaluated with bone marrow aspirates and biopsies. Many of these dysplastic morphologic features in blood smears and bone marrow are nonspecific for AML-MRC/t-MNs and may be seen in a variety of other neoplastic and nonneoplastic hematologic disorders. Myeloid dysplasia is evidenced, for instance, by hypogranulation and abnormal nuclear segmentation. Dyserythropoiesis is the most common change seen in the bone marrow and includes bizarre erythroid precursors and ring sideroblasts. Dyserythropoiesis is also manifested by karyorrhexis, profound nuclear budding and irregularity, multinucleation, marked megaloblastoid maturation, and cytoplasmic vacuolization. Dysmegakaryopoiesis includes hypolobulated micromegakaryocytes, nonlobulated nuclei or odd numbers of nuclei, and widely spaced nuclei.

t-MN cases following alkylating agents/ionizing radiation often have increased blasts with associated multilineage dysplasia. Approximately 20–30% of t-MN cases, associated with topoisomerase II inhibitors and balanced recurrent chromosomal translocations involving 11q23 (*KMT2A*/*MLL*) or 21q22 (*RUNX1*), show

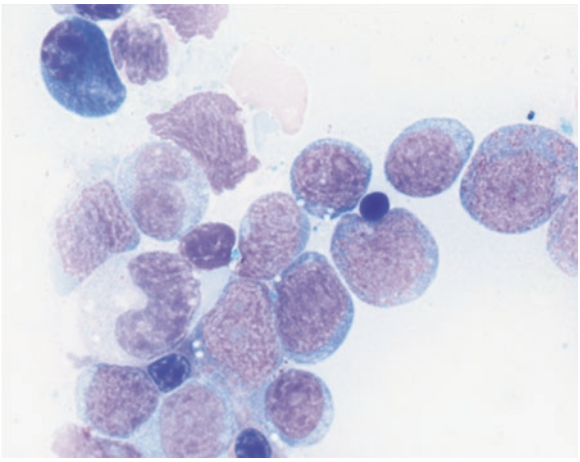

Fig. 3.1 Bone marrow aspirates in a patient with acute myelomonocytic leukemia. Bone marrow aspirates in a patient who is diagnosed with t-MN with *KMT2A* translocation

morphologic features similar to those identified in de novo acute monoblastic leukemia or myelomonocytic leukemia (Fig. 3.1).

No specific immunophenotypic feature typifies AML-MRC and t-MNs due to the heterogeneity of underlying causes and cytogenetic abnormalities [14]. Nonetheless, there is a general immunophenotypic overlap with AML-MRC and t-MNs, and blasts are CD34+ and CD117+ and express the pan-myeloid markers such as CD13 and CD33 [14, 24]. Aberrant expression of CD7, CD10, and CD56 in blasts is not uncommon. In secondary AMLs with monocytic differentiation, blasts often express CD4 and CD14 and lack CD34. Cases of AML-MRC and t-MNs with abnormalities of chromosomes 5 and 7 may show aberrant expression of TDT and CD7.

Most morphologic subtypes of AML, NOS, are defined by previous FAB criteria, and a 20% marrow blast cell count is sufficient for a diagnosis of acute leukemia [24]. This category includes many cases of AML with a normal karyotype, and mutation analysis, rather than morphologic or immunophenotypic features, and is probably the most predictive prognostic marker in this group.

Cytogenetic Abnormalities

Cytogenetic studies including conventional karyotyping remain a mainstream technology and are required in the evaluation of acute myeloid leukemia and other hematologic and nonhematologic disorders. The value of cytogenetic studies in AML can be divided into four main aspects: diagnosis, prognosis, prediction of therapeutic response, and monitoring minimal residual disease or early recurrence. Conventional karyotyping, although considered somewhat outdated compared to more specific and sensitive methods such as fluorescence in situ hybridization (FISH), provides a comprehensive view of the genome that cannot be obtained with

FISH or other more specific molecular studies, particularly in AMLs with a complex karyotype. Consequently, both conventional karyotyping and FISH remain the routine studies performed for AML diagnoses in clinical laboratories.

Cytogenetic Abnormalities in AML-MRC

The presence of MDS-related cytogenetic abnormalities is sufficient to make a diagnosis of AML with MRC (Table 3.1). A complex karyotype, seven unbalanced chromosomal abnormalities, and nine balanced chromosomal abnormalities are considered diagnostic of AML-MRC (Table 3.2).

Complex Karyotype

A complex karyotype (Fig. 3.2) is defined as three or more unrelated chromosomal abnormalities often leading to loss of genetic material at 5q, 14q33, 7q32q35, and 17p13, thus translating into decreased expression of genes at these chromosomal

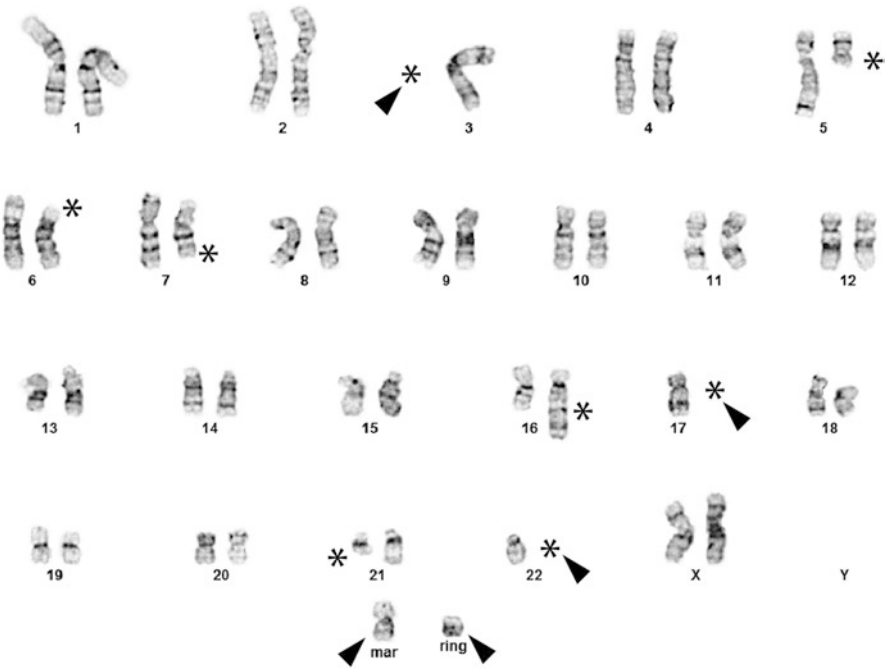

Fig. 3.2 Bone marrow karyotype from a patient with AML-MRC. Bone marrow from a patient shows a complex aberrant karyotype. A diagnosis of AML-MRC was made based on the cytogenetic findings in addition to morphologic features. *Indicates translocation; * with *arrow head* indicates absence of the chromosome; *arrowhead* indicates additional aberrant chromosomal materials

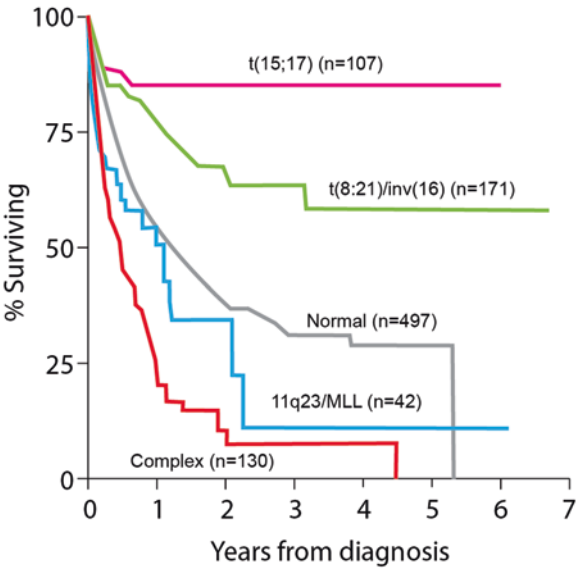

Fig. 3.3 Overall survival of patients with de novo AMLs. Patients with a complex karyotype (*red*) show a dismal clinical outcome indicated by overall survival in comparison to those with AML with balanced abnormalities or with a normal karyotype (Graph modified from [25])

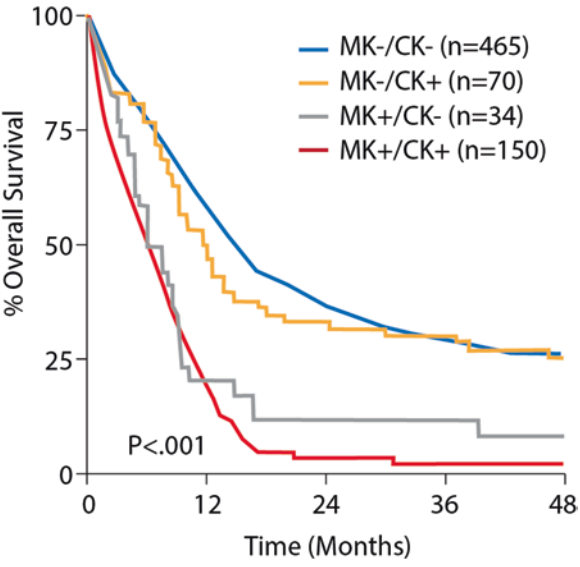

Fig. 3.4 Overall survival of patients with AMLs and noncore binding factor chromosomal abnormalities. Patients with a monosomal karyotype (MK+, −7, *gray* and *red*, 4 year OS 27% vs MK-, *yellow* and *blue*, 4-year OS 0–6%, $p < 0.001$) show a reduced overall survival regardless complex karyotypes (CK). Therefore, a single autosomal monosomy is a better predictor for very poor prognosis than a complex karyotype (Graph modified from [26])

loci. It is invariably associated with a poor prognosis [25] (Fig. 3.3). Recent studies demonstrated that autosomal monosomy, defined as the presence of two or more distinct autosomal chromosome monosomies or a single autosomal monosomy with one or more other chromosomal abnormalities, is a better predictor for poor prognosis than a complex karyotype in AML [26] (Fig. 3.4). A monosomal karyotype (Fig. 3.5), occurring in 5–10% of AMLs is associated with a dismal prognosis, with

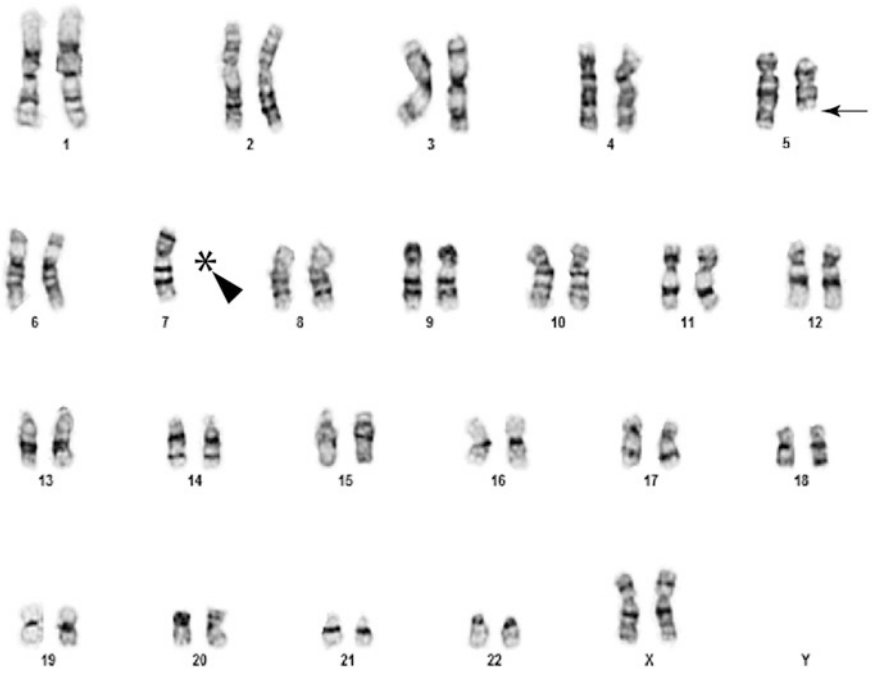

Fig. 3.5 Bone marrow karyotype from a patient with AML-MRC. Bone marrow karyotype from a patient shows a monosomy 7 (* and *arrowhead*) in addition to deletion 5q (*arrow*)

a 5-year overall survival of less than 5%. Monosomies 5 and 7, included by MDS-related cytogenetic abnormality and among the most frequent autosomal monosomies in AML, are associated with poor clinical outcomes, which appear to be independent for each specific monosomic chromosome [26].

Unbalanced Chromosomal Abnormalities

Unbalanced chromosomal abnormalities include, in order of decreasing frequency: deletion of 5q, loss of 7q, loss of 17p, loss of 13q, loss of 11q, and loss of 12p. They result in the loss of genomic integrity (Fig. 3.6). These lesions are the most common genetic aberrance in AML with MRC associated with poor clinical outcomes. In the updated WHO classification, del(9q) is no longer considered a defining MDS-related cytogenetic abnormality for AML-MRC [4]. Del(9q) is among the most frequent abnormalities associated with AML carrying *NPM1* or biallelic *CEBPA* mutations, and the presence of del(9q) is not an independent prognostic factor [2–4, 27]. Further, common recurring chromosomal abnormalities in MDS, such as trisomy 8, del(20q), and loss of chromosome Y, are not considered as defining abnormalities in AML-MRC, since they are also associated with AML carrying *NPM1* or biallelic *CEBPA* mutations and they lack prognostic significance in those settings [2–4, 27].

(**a**, **b**) Bone marrow karyotype (**a**) from a patient shows a deletion 5q (*) and this karyotypic finding is confirmed by FISH employing specific probes (*red* and *green*) targeting 5q (**b**, *a* a cell with normal karyotype; *b* a cell with del 5q)

Fig. 3.7 Bone marrow karyotype from a patient with AML-MRC. Bone marrow karyotype from a patient shows t(2;11)(p21;q23), indicated by *arrows*, in addition to del(5q)*

Balanced Chromosomal Abnormalities

Nine balanced chromosomal abnormalities diagnostic of AML-MRC include, in order of decreasing frequency: t(11;16), t(3;21), t(1;3), t(2;11), t(5;12), t(5;7), t(5;17), t(5;10), and t(3;5). Among these balanced gene rearrangements, t(11;16), t(3;21), and t(2;11) are also commonly seen in t-MNs (Fig. 3.7). A previous history of cytotoxic therapy including chemotherapy or radiation warrants a diagnosis of therapy-related myeloid neoplasm instead of AML-MRC. 5q33 is involved in four of the nine gene rearrangements and rearrangement of this locus leads to activation of the platelet-derived growth factor receptor-β (PDGFRB), a member of class III tyrosine kinase receptors (RTKIII) [28]. Two other rearrangements involve the *EVI1* locus at 3q26 and the *GATA2* and *RPN1* loci at 3q21 [26, 29–31]. Moreover, two other rearrangements involving a myeloid lymphoid leukemia (*MLL* or *KMT2A*) locus at 11q23 (Fig. 3.8), rather than AML with t(9;11), are also diagnostic of AML-MRC [4]. There are over 80 different chromosomal translocations involving *KMT2A*, and over 50 translocation partner genes have been characterized in adult and pediatric acute leukemias [32–36]. Translocations involving *MLLT3* (AF9), resulting predominantly in AML, are the most common. Other *KMT2A* translocations resulting in AML include *MLLT1* (*ENL*), *MLLT10* (*AF10*), *MLLT4* (*AF6*), and *ELL* as partner genes. Up to one-third of *KMT2A* translocations in AMLs are detectable by conventional karyotyping, and FISH or other molecular studies may be necessary to identify these variant translocations [32, 33]. The remaining t(3;5)(q25;q35) rearrangement is relatively unique in AML-MRC, and the overall

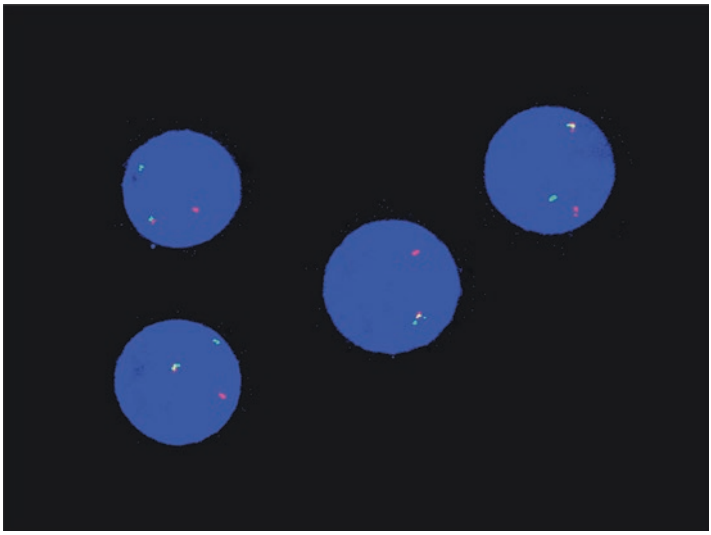

Fig. 3.8 Bone marrow fluorescence in situ hybridization from a patient with therapy related myeloid neoplasm (t-MNs). FISH study shows 11q23 rearrangement involving *KMT2A* gene with different translocations employing break-apart rearrangement probes. 11q23 rearrangement is revealed by segregation of *red* and *green* fluorescence labeled probes

incidence is less than 0.5% of AMLs [19, 20, 37]. This gene rearrangement leads to the fusion transcript *NPM1-MLF1* [38] and tends to occur in young adults. These patients may respond well to stem cell transplants [8, 39].

Cytogenetic Abnormalities in t-MNs

Therapy-induced AML secondary to alkylating agents is a prototypic AML, in which successive genetic hits occur and result in numerous genetic aberrations. t-MNs associated with alkylating cytotoxic agents/radiation and relatively long latency have abnormal cytogenetics most similar to those identified in AML-MRC [40]. As discussed earlier, these cytogenetic abnormalities are often associated with loss of chromosomes, particularly -5q or -7q, often in the setting of a complex karyotype [6, 7, 40].

In contrast, t-MNs associated with topoisomerase II inhibitors and short latency usually have balanced chromosomal abnormalities involving the *KMT2A* locus at 11q23 and the *RUNX1* locus at 21q22. Translocations involving the *KMT2A* locus at chromosome 11q23 are found in approximately 6% of t-MN cases.

Some patients with therapy-related AML have karyotypic changes identical to those of de novo AML, including types similar to those of the core binding factor leukemias, inv(16) or APL [41, 42]. In contrast to the dismal prognosis of most

Table 3.5 Cytogenetic abnormalities in patients with t-MNs

Cytogenetics		Frequency (%)
Karyotype	Normal	9.6
	Abnormal	90.4
Abnormal chromosome 5, 7, or both	Abnormal chromosome 5	20
	Abnormal chromosome 7	25
	Abnormal chromosome 5 and 7	22
Recurring balanced rearrangements	t(11q23)	3
	t(3;21) or t(8;21) or t(21q22)	3
	t(15;17)	2
	inv(16)	2
Others	+8, −13/del(13q), −Y, +11, del(11q), del(20q), +21, and others	18.5

Modified from [43]

therapy-related AMLs, some studies suggest that cases with t(15;17) or inv(16) may have good prognoses similar to their de novo counterparts [41]. A summary of cytogenetic abnormalities in patients with t-MNs is listed in Table 3.5 [43].

Somatic Mutations and Prognosis

The molecular dissection of many nonrandom recurrent gene rearrangements originally detected by conventional karyotyping and FISH has paved the way for the development of more specific and sensitive molecular tools in the diagnosis of AML. Compared to cytogenetic studies, these new approaches, particularly polymerase chain reaction (PCR) and sequencing-based methods, are more timely, sensitive, accurate, and quantitative, and overcome some of the limitations of karyotyping, such as the requirement of fresh material and viable dividing cells. Increasingly, next-generation sequencing (NGS) technologies, also known as high-throughput sequencing, have superseded traditional sequencing methods such as Sanger sequencing and pyrosequencing in clinical laboratories. NGS-based assays have numerous technical advantages over traditional methods, with the capacity to fully and rapidly sequence many genes in a single reaction that requires less DNA input. NGS can detect a large variety of genetic lesions in hematologic malignancies, including point mutations, small and intermediate-size deletions and insertions, copy number variants, and even translocations. The use of NGS-based assays in clinical and research laboratories has led to the discovery of a vast number of new mutations in myeloid neoplasms.

Common Mutations in Cytogenetically Normal Acute Myeloid Leukemia (CN-AML)

A large number of somatic, point, and insertion/deletion mutations have been identified, in addition to those cytogenetically detectable lesions described previously, and these mutations require distinct molecular genetic analyses beyond cytogenetic studies for sensitive and accurate detection. The genes likely to have clinical and prognostic significance in CN-AMLs include *FLT3* abnormalities; *KMT2A* partial tandem duplications (*KMT2A* PTD); *NPM1*, *CEBPA*, *RUNX1*, *ASXL1/2*, *IDH1/2*, *KIT*, *TET2*, *RAS, CBL, ND4*, and *DNMT3A* mutations; and overexpression of a large number of different genes (Table 3.6). Most, but not all, of these mutations are enriched in CN-AMLs and, to a lesser degree, in AML-MRC and t-MNs (Table 3.6). Indeed, almost all AMLs have mutations in one of the eight categories of genes that are highly relevant for myeloid tumorigenesis, including (1) myeloid transcription-factor fusions, (2) the gene encoding nucleophosmin (*NPM1*), (3) multifunctional tumor-suppressor genes, (4) DNA methylation-related genes, (5) signal transduction genes, (6) chromatin-modifying genes, (7) spliceosome-complex genes, and (8) cohesin-complex genes. Among these genes, some mutations are either cooperative or mutually exclusive, and these specific patterns suggest biologic relationships among many of the genes and categories [44–46]. For instance, mutations of *FLT3*, *DNMT3A*, and *NPM1* are often present simultaneously, while other mutations of *NPM1*, *RUNX1*, *CEBPA*, and *TP53* are almost always mutually exclusive both at diagnosis and at the time of disease transformation (Fig. 3.9) [47–50]. Further, the AML morphologic phenotype might be driven by a more complex pattern of concurrent mutations rather than individual genes.

A major new area of emphasis in the revised 2016 WHO classification is on molecular genetics in cytogenetically normal AML. The three genes with the mutations most commonly detected and clinically relevant in CN-AMLs are *FLT3*, *NPM1*, and *CEBPA* (Table 3.6). Unlike *FLT3* mutations, which can also be identified in AML with recurrent genetic abnormalities and many other AML subtypes, AML with mutations in either *NPM1* or biallelic *CEBPA* are defined as distinct biologic subtypes of AML, and they are considered full AML entities in the most updated WHO classification: AML with mutated *NPM1*, and AML with biallelic mutations of *CEBPA*. Mutations in *NPM1* and biallelic *CEBPA*, diagnostic for entities are discussed elsewhere.

Fms-Like Tyrosine Kinase 3 (FLT3)

FLT3 mutations are identified in many AML subtypes (including cases with karyotypic abnormalities), thus *FLT3* mutations alone do not define a distinct biologic subtype [46]. Interestingly, mutations in *FLT3* and in genes encoding other kinases including tyrosine kinases, serine–threonine kinases, protein tyrosine phosphatases, and RAS family proteins are mutually exclusive in AMLs [46]. FLT3 is a class III

Table 3.6 Examples of recurrent mutations in AML, NOS, and AML with MRC and t-MNs [19, 20, 46, 54, 55, 85, 87, 126, 143–146]

Genes	Locus	Mutations/effects	% in AML, NOS	% in AML-MRC	% in t-MNs	Prognosis	Putative biologic mechanism	Biology and genetic correlation
NPM1	5q35.1	Indel	25–35	–	3–16	Good	Cytoplasmic mislocalization; dysregulated P53	Cup-like nuclei

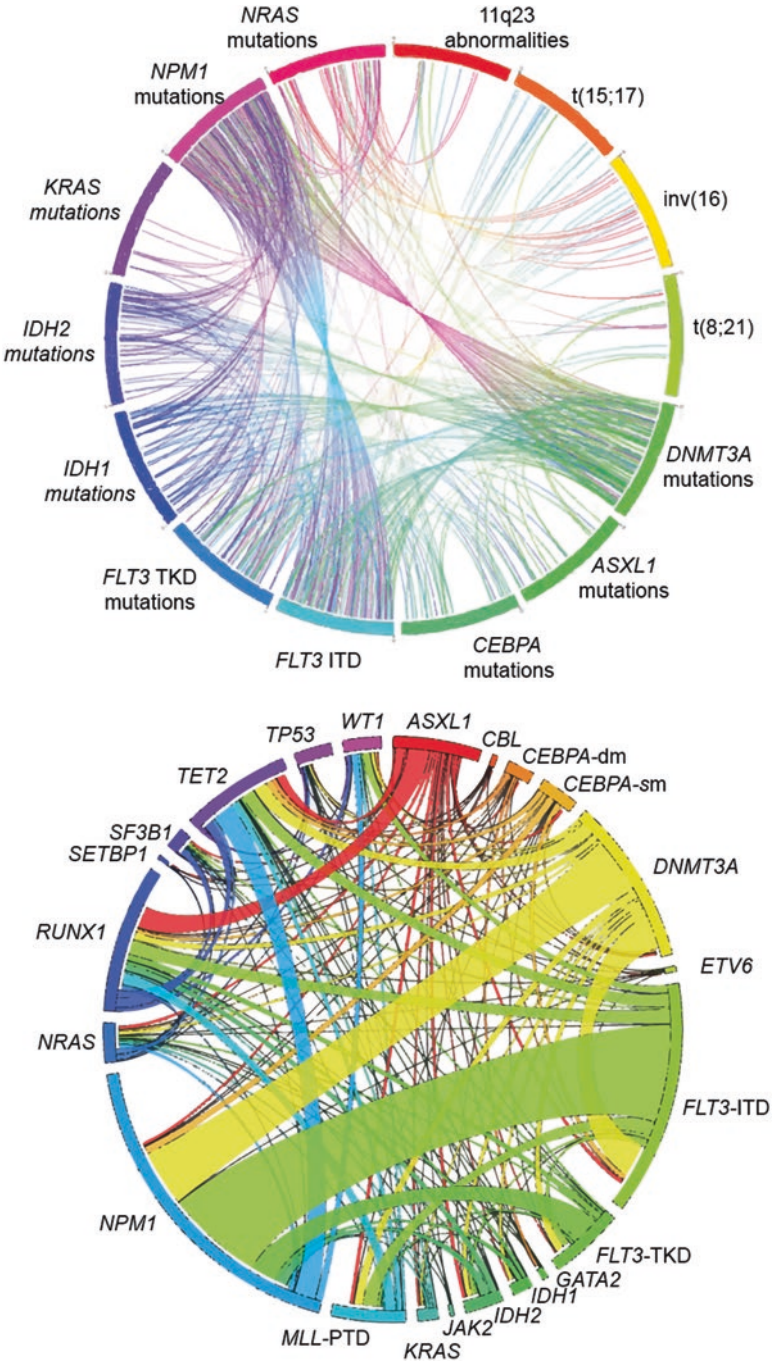

Fig. 3.9 Molecular heterogeneity and complexity of AML. (**a**) Circos plots demonstrate the molecular heterogeneity of de novo AMLs and the specific patterns of cooperation and mutual exclusivity. *Colored lines* indicate concurrent genetic abnormalities. (**b**) The *outer circular segments* indicate the particular molecular maturations and the length of each segment indicates their relative frequencies in AML. *Outer segments* indicate a particular subcohort being positive for the given marker. *Ribbon widths* indicate relative frequencies of co-occurrences (Graph modified from [50, 143])

receptor tyrosine kinase and Ig receptor superfamily member that is expressed by hematopoietic progenitor cells and downregulated during differentiation. Independent of ligand binding, phosphorylation of regions in the juxtamembranous (JM) domain of FLT3, resulting in a persistent "on" signal, leads to uncontrolled proliferation and inhibition of differentiation and apoptosis via STAT5 and mitogen-activated protein kinase (MAPK) signaling [51–53] in transformed leukemic cells. There are two fundamental types of *FLT3* abnormalities: internal tandem duplication (ITD) of the JM domain, and a missense mutation at Asp835 (TKD) [54, 55]. *FLT3*-ITD is relatively more common [54], and occurs in 12–28% of AML, NOS, approximately 8% of AML-MRC, and about 7% of t-MNs (Table 3.6). Point mutations of *FLT3*-TKD are reported in about 7% of all AML, NOS [54]. Overall, *FLT3* mutations, among the most commonly identified somatic abnormalities in AML, are seen in approximately 35% of all AMLs, and are enriched in up to 50% of AMLs with normal cytogenetics [54, 55]. Overactivation of the FLT3 signaling pathway appears to be the single most important prognostic factor for overall survival in AML patients younger than 60 years [53]. It is correlated with a poor prognosis, and this correlation appears to be independent of the karyotypically aberrant AML groups especially in AMLs with mutant *NPM1* and *DNMT3A* [53, 54, 56]. In addition, *FLT3*-TKD mutations with high allele fraction (>10%), similar to *KIT* mutations, are associated with a higher cumulative incidence of relapse in core binding factor AML patients [57].

KIT (CD117)

KIT is a member of a type III tyrosine kinase receptor (RTK) family. Mutations in RTKs and their associated pathways in AML result in constitutive activation of downstream signaling cascades. KIT activation is triggered by binding of its ligands, stem cell factors, and receptor dimerization, which in turn facilitates receptor autophosphorylation. Intracellular signal transduction is mediated through multiple signaling pathways, including RAS–RAF–MAPK, JAK-STAT, and PI3K-AKT pathways. Mutations in *KIT* result in either KIT overexpression or constitutively active tyrosine kinase receptors. This gain of function confers a proliferative and survival advantage to hematopoietic progenitors thus promoting malignant transformation in myeloid cells. Similar to KRAS and NRAS, the critical components of its downstream signaling pathways, *KIT* mutations can be seen in AMLs with normal cytogenetics (Table 3.6) but are particularly common in core binding factor AMLs, occurring in 7–46% of AMLs with t(8;21) or inv(16) [58]. These mutations tend to be associated with a poor prognosis in these cytogenetically favorable AMLs. In AML, *KIT* mutations are found in the extracellular domain (exon 8), kinase domain (exon 17, especially KIT D816V mutations), and rarely in transmembrane (exon 10) and juxtamembrane domains (exon 11) [59].

RAS

The *RAS* (rat sarcoma) gene family encodes approximately 50 structurally homologous proteins which contain a consensus guanosine triphosphate-binding motif, hence the name, small G-protein. RAS proteins, located on the cell surface, function as conduits for RTK signaling through downstream cascades to nuclear transcription factors regulating cell growth and cell-cycling proteins. Mutations in both *NRAS* (neuroblastoma RAS) and *KRAS* (Kirsten RAS) have been reported in CN-AML and AML with MRC (Table 3.6). Single-point mutations in RAS lead to constitutive activation by locking RAS into its active conformation or reducing its sensitivity to the GTPase-activating proteins (GAPs), thus resulting in overall gain-of-function effects [60, 61], and almost exclusively occur in "hot spot" codons 12, 13, and 61 [61]. *RAS* mutations are detected by PCR followed by pyrosequencing and NGS in most clinical laboratories.

Histone-Lysine N-Methyltransferase 2A (KMT2A or MLL)

Partial tandem duplication (PTD) of the *KMT2A* gene, also known as acute lymphoblastic leukemia 1 (*ALL-1*) or myeloid/lymphoid or mixed-lineage leukemia (*MLL*), is another example of a biologically relevant genetic abnormality in AML with normal karyotype. KMT2A is a histone methyltransferase mediating chromatin modification and, as a positive regulator of gene expression for known targets such as *HOX* genes, plays an essential role in regulating gene expression during embryonic development and hematopoiesis. *KMT2A* PTD, containing a varied number of exons 5–12 duplicated and inserted before exon 12 giving rise to an in-frame repetition and an elongated protein [62], is associated with an unfavorable outcome [63] in AMLs. Although ~90% of cases with trisomy 11 are associated with *KMT2A* PTD, it is also present in ~10% of AMLs with normal cytogenetics [62, 64]. This mutation is readily detected by RT-PCR amplifying exons 2–12 in most clinical laboratories [62].

Isocitrate Dehydrogenase 1 and 2 (IDH1/2)

IDH1 and IDH2 are key metabolic enzymes involved in the biosynthesis of central metabolites in the TCA cycle, the major pathway for cellular NADPH generation, and the pentose phosphate pathway. Loss of IDH1/2 function in malignancies impairs oxidative detoxification mechanisms, leading to DNA damage and genomic instability, and thus promoting tumorigenesis, especially in hypoxic setting [65, 66]. IDH converts αKG to (D)-2-hydroxyglutarate (2-HG) using NADPH as cofactors, and 2-HG in turns inhibits histone demethylation by suppressing αKG-dependent dioxygenases. Mutations in *IDH* are uniformly associated with elevated 2-HG in a vast number of cancers. Inhibition of histone demethylation (hypermethylated histone) and altered DNA methylation patterns can block the differentiation of non-transformed cells and facilitate myeloid neoplastic transformation [67]. The

prognostic value of *IDH* mutations in AML remains unknown since results vary across studies and a recent retrospective analysis found no impact of *IDH* mutation status on overall survival in patients with AMLs [68].

Additional Sex Combs Like 1 (ASXL1)

The *ASXL1* gene encodes a human homologue of the additional sex combs (Asx) gene of *Drosophila*, located on chromosome 20q11. ASXL1 protein function in human remains largely unknown, although recent studies suggest that ASXL1 may be involved in the regulation of histone methylation and that *ASXL1* mutations are an early event contributing to leukemogenesis [69, 70]. *ASXL1* mutations are found in 5–12% of CN-AML and are enriched in secondary AMLs (Table 3.6), especially in older patients [71, 72]. *ASXL1* mutations, including nonsense or frameshift mutations, are almost exclusively in the "hot spot," exon 12, leading to disruption of the carboxy-terminal plant homeodomain (PHD) finger domain. Indeed, the mutation c.1934dupG (G646WfsX12) represents half of all *ASXL1* mutations and can be easily detected by sequencing. *ASXL1* mutations are also closely associated with other cytogenetic and molecular lesions, such as isolated trisomy 8 and *RUNX1*, and appear to be an independent adverse prognostic factor [73, 74].

DNA Methyltransferases 3A (DNMT3A)

DNA methyltransferases (DNMTs) transfer a methyl group from the universal methyl donor, S-adenosyl-methionine (SAM), to carbon-5 (C5) of cytosine and are predominately responsible for the maintenance of genomic DNA methylation patterns. DNMT3A plays an important role in the maintenance of methylation patterns during primordial germ cell and early embryonic development [75]. Although *DNMT3A* was originally considered an oncogene in human tumorigenesis, recent studies identified several inactivating *DNMT3A* mutations and loss of DNMT3A activity in myeloid neoplasms, suggesting that DNMT3A may also behave as a tumor suppressor [76, 77]. Mutations include missense, nonsense, frameshift, and in-frame alterations throughout the gene across all functional domains, although mutations at arginine 882 (R882) in the catalytic domain resulting in impaired enzyme activity are the most common. However, most of the specific mutations identified in AMLs, presumably preleukemic lesions, have not been functionally characterized. *DNMT3A* mutations rarely occur alone in AMLs, and concurrent mutations in *FLT3*/ITD, *NPM1*, and *IDH* are common. These *DNMT3A* mutations show a negative correlation with AMLs with t(8;21), t(15;17), or inv(16). In addition, *DNMT3A* R882 mutations are associated with advanced age, high leukocyte and blast counts, and morphologic features of monocytic differentiation (FAB M4/M5) [78]. *DNMT3A* mutations also predict an adverse risk and poor outcome in AML patients [79] and can be detected by sequencing. Further, *DNMT3A* mutations at R882 can also be potential markers for minimal residual disease studies.

Tet Methylcytosine Dioxygenase 2 (TET2)

As a member of the TET family, TET2 proteins convert 5-methylcytosine to 5-hydroxymethylcytosine (5-hmC) in DNA, with ferrous iron and α-KG as cofactors. By regulating DNA methylation and gene expression of downstream targets, TET2 inhibits cell proliferation, self-renewal, and differentiation. *TET2* mutations were first identified in myeloid malignancies via single-nucleotide polymorphism array and comparative genomic-hybridization arrays and confirmed by NGS. Deletion of *TET2* on chromosome 4q24 is common in AMLs [80, 81]. *TET2* mutations, including frameshift, nonsense, and deletion mutations, are detected in 8–30% of patients with CN-AML, and lead to loss of function, resulting in uncontrolled myeloid proliferation and abnormal differentiation [80, 81] (Table 3.6). The presence of single or double allelic *TET2* mutations is positively correlated with mutations of *NPM1*, *DNMT3A*, *ASXL1*, and *RUNX1*, but virtually mutually exclusive with *IDH* mutations. *TET2* mutations are also closely associated with older age, higher leukocyte count, normal karyotype, intermediate-risk cytogenetics, and isolated trisomy 8. Although studies regarding the prognostic impact of *TET2* mutations in different AML subgroups showed inconsistent results, a meta-analysis of over 2500 patients with de novo, secondary, or therapy-related AML revealed that *TET2* mutations appear to be an adverse prognostic factor and independently predict the risk of relapse [82, 83].

Gene Mutations Enriched in AML-MRC and t-MNs

As previously mentioned, secondary AMLs, either AML secondary to a preexisting MDS or to cytogenetic toxic therapy, contain successive genetic hits and are characterized by numerous genetic aberrations. A subset of molecular mutations including *SRSF2*, *SF3B1*, *U2AF1*, *ZRSR2*, *ASXL1*, *EZH2*, *BCOR*, *STAG2*, and *TP53* are relatively specific for this group of secondary AMLs (Table 3.7) compared to those genes described above [19, 20, 40, 84–92]. These secondary AMLs have mutations in one of five categories of genes that are relevant for tumorigenesis and possibly for clinical prognosis, including (1) spliceosomes regulating mRNA splicing; (2) chromatin modifying genes; (3) transcription factors; (4) cohesin complex; and (5) *TP53*, which is a multifunctional tumor suppressor and particularly associated with t-MNs. Almost all of these mutations are detectable by sequencing. Among these genes, mutations in *ASXL1* are most common and their clinical significance has been discussed.

Mutations in Splicing Factors

Mutations in spliceosome factor genes are most common in myeloid neoplasms including MDS, AMLs, and chronic lymphocytic leukemia. They are also present in several solid tumors, although at lower frequencies. Dysregulation in alternative

Table 3.7 Gene mutations with clinical relevance in AML with myelodysplasia-related changes and therapy related myeloid neoplasm [19, 20, 40, 84–91]

Genes	Full name	Locus	Putative biologic mechanism	Mutations/effects	% in AML-MRC	% in t-MNs	Prognosis
SRSF2	Serine/arginine-rich splicing factor 2	17q25	mRNA splicing	Missense; DN or gain of function	20–30	0–7	Bad
SF3B1	Splicing factor 3b, subunit 1	2q33	mRNA splicing	Missense; DN or gain of function	11–20	0–3	Good
U2AF1	U2 small nuclear RNA splicing factor 1	21q22	mRNA splicing	Missense; DN or gain of function	16–30	3–5	Bad
ZRSR2	U2 small nuclear RNA splicing factor, subunit-related protein 2	Xp22	mRNA splicing	Nonsense/indel/splice sites; NF	8	1	Unclear
ASXL1	Additional sex combs like 1	20q11	Chromatin modification	Nonsense/indel; DN oractivation	32	3	Bad
EZH2	Enhancer of zeste homolog 2	7q35-q36	Chromatin modification	Missense/nonsense/indel; NF	7–9	3	Unclear
BCOR	BCL6 Co-repressor	Xp11	Transcription regulation	Missense/nonsense/frame shift; indel; splicing-site/NF	8–17	1	Bad
STAG2	Cohesin subunit SA-2	Xq25	Cohesin complex	Missense/Nonsense/frame shift; NF	14	5	Neutral
TP53	Tumor protein 53	17p13	DNA repair and tumor suppressor	Missense/indel; NF	15	35–40	Bad

DN dominant negative, *NF* nonfunctional

mRNA splicing, potentially impacting more than 20,000 human genes, results in malignant transformation and tumorigenesis in various cell types. Prototypic examples of genes with alternative splicing impaired by spliceosome mutations include *BCL2* and *BCL-X*, *CD44*, and *GSK3B* [93]. These mutations promote cell proliferation and inhibit apoptosis, thus promoting tumorigenesis. Recent studies demonstrated that somatic mutations in not only downstream targets but also the splicing machinery itself are common mutations driving myeloid neoplasms including AMLs. *SRSF2*, *SF3B1*, and *U2AF1* frequently acquire heterozygous missense mutations in specific codons leading to gain of function. In contrast, *ZRSR2* mutations largely include loss-of-function variants. Commonly identified in MDS and AML with MRC, mutations in one of four genes, which are mutually exclusive accounting for 5–10% of all AMLs [56]. The clinical or prognostic significance of mutations in each individual gene remains unknown. However, lesions in these genes as a group, particularly in combination with accumulated somatic mutations in chromatin regulators, are frequently associated with a low overall survival rate in AMLs. Further, AMLs with mutations in regulators of chromatin, splicing, and transcription show a distinct clinical presentation including dysplastic features in older age and dismal clinical outcome. Therefore, these common and clinically significant mutations should be considered for incorporation into diagnostic and prognostic classification guidelines [56] (Fig. 3.10).

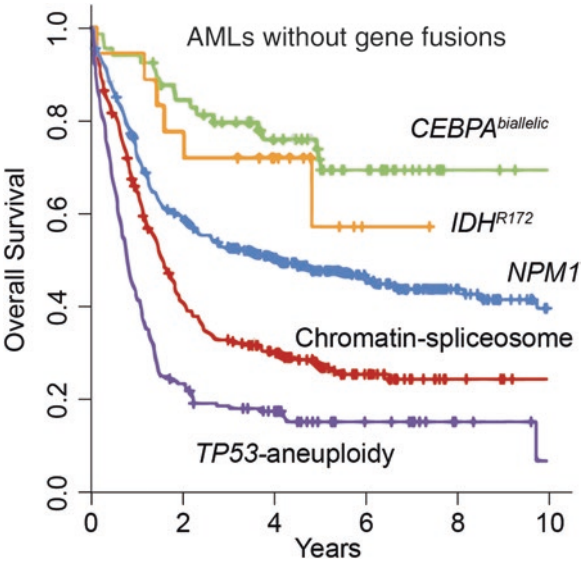

Fig. 3.10 Overall survival of patients with cytogenetic normal AMLs and following five driver mutations. Patients with AML and *NPM1* (*blue*) and biallelic *CEBPA* mutations (*green*) show optimal overall survival. A subgroup of AMLs with *TP53*-aneuploidy has a distinct dismal long term outcome (*purple*). As compared with other subgroups, patients in the subgroup with chromatin-spliceosome mutations show a poor overall survival (*red*) and the long term outlook in the *IDH2R172* subgroup is similar to that in patients with *NPM1*-mutated AML (Graph modified from [56])

Serine/Arginine-Rich Splicing Factor 2 Gene (SRSF2)

SRSF2 is an important component in the spliceosome, regulating many steps in RNA-related processes, including spliceosome assembly of the U1 snRNP, U2 snRNP binding at the branch point, and mRNA stabilization [94]. SRSF2 contains an RNA recognition motif and an RS domain rich in arginine and serine residues. Somatic mutations of *SRSF2* are predominantly missense mutations at a specific hotspot, codon Pro95. Proline at this codon is replaced by histidine, leucine, or arginine through missense mutations, or disrupted by in-frame insertions and deletions. Commonly identified in MDS (15%) and in chronic myelomonocytic leukemia (CMML, approximately 50%) [95], *SRSF2* mutations also preferentially occur in acute myeloid leukemia with preceding MDS or myelodysplastic morphology [90]. All patients with an initial mutation retain the same mutation after AML transformation, and approximately 15% of patients who are initially mutation-negative acquire this type mutation after AML progression. There appears to be no significant difference in the time to leukemic transformation between mutation-positive and -negative patients at the initial diagnosis of MDS [90].

Splicing Factor 3B1 (SF3B1)

This gene encodes subunit 1 of the splicing factor 3b protein complex, which is an essential member of the U2 small ribonucleoprotein complex responsible for branch site recognition near the 3′ end of premessenger RNA. *SF3B1* mutations are frequently identified in a specific MDS subtype with refractory anemia and ring sideroblasts (RARS), and in other subtypes of MDS or MDS/MPN overlap syndromes, such as MDS/MPN with ring sideroblasts and thrombocytosis, a new full entity in the updated WHO classification. Ring sideroblasts are a morphological feature especially associated with *SF3B1* mutations. Missense substitutions are concentrated at codon 700, in the middle of four contiguous HEAT domains, and result in a gain of function or dominant negative activity, in which the mutant protein suppresses its wild-type counterpart. *SF3B1* mutations are associated with a lower rate of transformation to AML and appear to predict an indolent disease in MDS, while the same mutations alone have no detectable prognostic impact in secondary AMLs [91, 96]. In contrast, mutations in splicing factors in combination with *SRSF2*, *ZRSR2*, and *U2AF1* mutations appear to predict unfavorable prognosis in patients with de novo acute myeloid leukemia [97].

U2-Complex Auxiliary Factor 1 (U2AF1)

U2AF1 encodes a subunit of the U2 spliceosome required for the binding of U2 snRNP to the pre-mRNA branch site. The encoded protein contains four major functional domains: two zinc-finger regions, an arginine-serine domain, and a U2AF homology domain. U2AF1 binds directly to several other splicing factors important for myeloid neoplastic transformation, including *U2AF2*, *SRSF2*, and

SF1. There are two hotspots at codons S34 and Q157 where several missense substitutions occur [95]. Small in-frame insertions and deletions around codon 157 have also been identified but at a much lower frequency. These mutations lead to oncogenic gain-of-function phenotypes and directly interfere with RNA binding, resulting in splicing changes [98]. As with other spliceosome components, *U2AF1* mutations are associated with AML-MRC and morphologic trilineage dysplasia. Further, *U2AF1* mutations alone are an independent prognostic factor and associated with poor clinical outcomes in patients with AMLs [99].

Zinc Finger, RNA-Binding Motif and Serine/Arginine Rich 2 Gene (ZRSR2)

ZRSR2, frequently mutated in myeloid malignancies, is located on the X chromosome and encodes a serine/arginine-rich splicing factor regulating the recognition of the 3′ splice acceptor site as a component of the U2 auxiliary factor heterodimer. In contrast to other splicing factors described above, *ZRSR2* mutations include out-of-frame insertions and deletions, splice-site mutations, and nonsense mutations, resulting in prematurely truncated proteins. Missense mutations across all exons also occur. These mutations result in loss of function, and occur in about 5% of patients with MDS, T-cell acute lymphoblastic leukemia, and plasmacytoid dendritic cell neoplasms [100–102]. Recent studies demonstrated no direct impact of *ZRSR2* mutations on clinical outcomes in patients with MDS, and the clinical relevance of *ZRSR2* mutations alone in patients with AMLs remains unknown.

Enhancer of Zeste Homolog 2 (EZH2)

The polycomb repressive complex 2 (PRC2) maintains transcriptional silencing through posttranslational histone modification and regulation of homeotic gene expression [103], and is essential for hematopoiesis and lymphopoiesis in human. Comprising the catalytic subunit of PRC2 is EZH2 or EZH1, which serves as a H3K27 methyltransferase in the complex [103]. Overexpression of EZH2 is frequently identified in solid tumors such as prostate, breast, and endometrial cancers. Gain-of-function mutations in the catalytic domain are also commonly detected in patients with follicular lymphoma and diffuse large B-cell lymphoma [104]. In contrast, loss-of-function mutations across all 20 exons of *EZH2* are commonly detected in myeloid malignancies, especially MDS and acute myeloid leukemia. Inactivation of EZH2 leading to loss of H3K27 trimethylation contributes to myeloid neoplasms including MDS, MPN, and MDS/MPN overlap syndrome, but appears to attenuate its predisposition to leukemic transformation secondary to MDS [105–107] in animal models. Although frequently found in other myeloid neoplasms associated with a poor prognosis and clinical outcome, the prognostic relevance of *EZH2* mutations remains largely unknown in AMLs due to the low detection rate [78, 108].

BCL6 Corepressor (BCOR)

The *BCOR* gene encodes a POZ/zinc finger transcriptional repressor, also known as an interacting corepressor of BCL6, which is required for germinal center formation and may influence apoptosis in lymphoid tissue. BCOR is a key component in the polycomb repressive complex 1 (PRC1) variant, which inhibits transcriptional activity and regulates early embryonic development, mesenchymal stem cell function, and hematopoiesis [89]. Recent studies demonstrated that *BCOR* mutations occur in 3.8% of unselected CN-AML patients and are enriched in a substantial fraction (17.1%) of CN-AML patients showing the same genotype as the AML index subjected to whole-exome sequencing. Disruptive somatic *BCOR* mutations include out-of-frame mutations, small insertions and deletions, nonsense mutations, and splice-site mutations along the *BCOR* coding exons and exon/intron junctions. *BCOR* mutations are associated with decreased *BCOR* mRNA levels, absence of full-length BCOR proteins, and low expression of a truncated BCOR protein. Further mutations in *BCOR* are closely associated with mutations in other histone modifiers such as *DNMT3A*, suggesting cooperativity among these genetic alterations, while *BCOR* mutations are virtually mutually exclusive with *NPM1* mutations. *BCOR* mutations are associated with an unfavorable outcome in patients with CN-AML [89].

Cohesin Complex

The cohesin complex forms a ring structure regulating appropriate chromosomal segregation during mitosis and cell division, double-stranded DNA repair, and transcription. Genes encoding the cohesin complex in somatic vertebrate cells are *SMC1A*, *SMC3*, *RAD21* (*SCC1*), *STAG2* (*SA-2*), and *STAG1* (*SA-1*) [109]. Mutations in *STAGs* or other components in this complex result in chromosomal instability and contribute to myeloid malignant transformation [88]. Indeed, disruptive mutations of the core cohesin subunit *STAG2* occurs in a variety of human tumors, including glioblastoma, Ewing sarcoma, melanoma, cervical carcinoma, and hematologic cancers, as *STAG2* mutations lead to aneuploidy in a variety of human cancer cells [110]. Mutations throughout all coding exons of *STAG2* are common in antecedent MDS, secondary AML with predominantly normal cytogenetics, and de novo AMLs. Concurrent mutations in *NPM1*, *FLT3*, *DNMT3A*, and *PTPN11* correlate with *STAG2* mutation status. Cohesin complex or *STAG2* mutations alone are not independent predictive factors for overall survival or remission rates in AMLs [88, 111].

Tumor Protein 53 (TP53)

The tumor protein 53 (TP53) is a transcription factor and prototypical tumor suppressor that arrests the cell cycle, promotes apoptosis, and coordinates DNA damage repair in response to various cellular stresses and cytotoxic insults. TP53 mutations result in resistance to protein degradation through MDM2, and in abnormal nuclear accumulation detectable by immunohistochemistry. TP53 mutations are found in up to 40% of therapy-related AML [40] and in over 50% of AML with complex cytogenetics. Somatic TP53 mutations are also detected in 10–15% of de novo AML and MDS [91]. A large variety of TP53 mutations have been identified to date, including the point mutations and loss of the TP53 locus at chromosome 17p commonly seen in AMLs. These TP53 mutations can be identified by cytogenetic studies and sequencing. It has been suggested that TP53 mutations are not directly induced by cytotoxic chemotherapy. Rather, they are likely to reflect rare age-related mutations that are resistant to chemotherapy and which expand preferentially following treatment. TP53 mutations are directly correlated with a poor prognosis in patients with MDS and AML, with resistance to chemotherapy and reductions in overall and disease-free survival, even in patients undergoing stem cell transplantation [91]. Moreover, TP53 mutations impart similarly poor prognoses in other malignancies as well. Recent studies suggest that a mutation in TP53 with aneuploidy may represent an acquired causative driver mutation involving discrete evolution pathways in the tumorigenesis of acute myeloid leukemia. AML patients with TP53 mutations and aneuploidy had dismal clinical outcomes, and beyond the current WHO classification, AML with TP53-aneuploidy may be defined as a distinct subtype [56, 87, 99].

Standard and Targeted Therapy

As the molecular landscape of AML becomes more detailed, and we understand how various cytogenetic abnormalities and somatic mutations affect the development of AML, the role of targeted therapies will become more critical. While standard therapies for AML include induction with cytarabine and an anthracycline drug such as daunorubicin followed by consolidation therapy with cytarabine and/or stem cell transplant, here we discuss mainly targeted therapies, again which are gaining momentum in use.

In the case of DNMT3A, which is commonly mutated in AML, nonspecific inhibitors of DNMT, are already commonly used, such as azacitidine and decitabine, and, in preliminary studies, provide better responses in older patients harboring mutations in epigenetic modifiers including *DNMT3A* [112, 113]. DNMT inhibitors may be a superior treatment option for older patients ineligible for intensive chemotherapy. Additional large-scale studies are warranted.

Many targeted therapies focus on mutations in kinase proteins (FLT3, KIT). For instance, FLT3 is considered a potentially important target for leukemia therapy [54]. Although no FLT3-specific inhibitor has been developed to date, many tyrosine

kinase inhibitors (TKIs) appear to inhibit FLT3, and several potential FLT3 inhibitors are being evaluated in clinical trials [54, 114–117]. Midostaurin (PKC412, Novartis Pharmaceuticals, East Hanover, NJ, USA), a benzoylstaurosporine, is a first-generation FLT3 inhibitor, and inhibits the kinase activities of both FLT3/ITDs and FLT3/KDMs, as well as wild-type FLT3 [118]. Phase 2 studies of PKC412, alone or in combination with conventional chemotherapeutic agents in patients with AML or MDS, have shown that patients with *FLT3* mutations but not previously exposed to other FLT3 inhibitors realize the greatest benefit, although the duration of remission was short in some patients [119–121]. United States Food and Drug Administration (FDA) granted Breakthrough Therapy designation to PKC412 (midostaurin) recently primarily based upon the positive results from the Phase III RATIFY (CALGB 10603) clinical trial. Patients who received PKC412 (midostaurin) and standard induction and consolidation chemotherapy experienced a significant improvement in overall survival (OS) (hazard ratio = 0.77, $P = 0.0074$) compared with those who received standard induction and consolidation chemotherapy alone. The median OS for patients in the PKC412 (midostaurin) treatment group was 74.7 months (95% confidence interval [CI]: 31.7, not attained), versus 25.6 months (95% CI: 18.6, 42.9) for patients in the placebo group. Unfortunately, PKC412 alone has insufficient activity in AML patients, and off-target effects such as pulmonary edema are concerning. CEP-701 (Cephalon, Frazer, PA, USA), another relatively-specific first-generation inhibitor targeting FLT3 kinases, showed a transient decrease in circulating blasts [122] in patients with relapsed or refractory acute myeloid leukemia without achieving a complete remission [122, 123]. In recent years, a new generation of more potent and specific FLT3 inhibitors has been developed, with AC220 [124] and G-749 [125] as leading examples. These newer agents have shown significant promise in early phases of clinical investigation including animal models and are currently in more advanced clinical trials [123–125].

TKIs have been used in combination with conventional chemotherapy in *KIT*-positive relapsed/refractory AML and are in clinical trials [126]. Imatinib combined with traditional chemotherapy reagents including mitoxantrone, etoposide, and cytarabine in patients with *KIT*-positive relapsed/refractory AML achieved a complete response in approximately 60% of patients [127, 128]. A multicenter phase 2 trial for older patients with *KIT*-positive AML, who are not optimal candidates for intensive induction therapy, showed that imatinib combined with low-dose cytarabine achieved an 11% hematologic response [129]. However, in most of these studies, the *KIT* mutation status was evaluated by flow cytometry rather than molecular studies. In contrast, dasatinib alone as a maintenance therapy in patients with high-risk AMLs who achieved complete remission 1 (CR1) showed a poor 2-year disease-free survival rate of 25% [130].

Other targeted therapies may be exquisitely protein specific such as IDH inhibitors [65, 66], which are currently being assessed in clinical trials. Other therapies may be somewhat indirect and target a step in the pathway involving the gene of interest. For instance, *RAS* is another gene mutated highly in AML and since RAS activity is dependent on posttranslational farnesylation, specific inhibitors targeting farnesyltransferase have been examined in clinical trials involving patients with

AML [131]. Overall, responses to farnesyltransferase inhibitors in AMLs have not been encouraging. In a trial of 348 elderly patients with AML (aged ≥70 years) who received tipifarnib, less than 20% achieved a complete remission [132–134]. RAS signaling also activates downstream targets, most notably mitogen-activated protein kinase (MAPK) and phosphoinositide 3-kinase (PI3K)–AKT through a variety of pathways to promote cell proliferation. Combination therapy with inhibitors targeting the downstream RAS effectors, MEK and AKT, is currently being investigated in clinical trials in AML patients with RAS mutations [135, 136].

In the case of *MLL/KMT2A*, it is known that DOT1L, a histone methyltransferase, is required for the development and maintenance of *KMT2A*-rearranged leukemias [137]. Preclinical studies have shown potential clinical utility of DOT1L inhibition in AMLs [137–139], and small-molecule and competitive inhibitors of DOT1L have been developed (EPZ-5676; Epizyme Inc., Cambridge, MA, USA) which preliminarily show some promising responses, including complete morphologic and cytogenetic remissions, and resolution of leukemia cutis and treatment-related increases in neutrophils and/or monocytes [140].

Finally, modulation of the spliceosome complex may provide a new therapeutic approach in patients with MDS or AML containing spliceosome gene mutations; but studies on specific inhibitors targeting splicing factors in AMLs remain in the preclinical stage. E7107, a structurally distinct splicing inhibitor, is the only compound that specifically inhibits SF3B1, and has been tested in clinical trials. Preliminary data suggest that SF3B1 inhibition has therapeutic potential for the treatment of solid tumors with *SF3B1* mutations. Additional clinical studies with new inhibitors targeting splicing factors for patients with myeloid neoplasms are needed [141, 142].

Conclusions

As our understanding of the molecular landscape of AML continues to grow, so too will our subclassification of this disease. Additionally, while such detailed understanding drives our diagnostic categorization of this disease, perhaps more importantly it also informs us of the mechanisms driving AML. Importantly, with an understanding of the mechanisms of this disease, continual development of specific targeted therapies is possible which will continue to positively change the course of this disease.
