Numerous studies have searched for an environmental or occupational cause, with few consistent results. Most of the occupational studies have resulted in variable findings, with most of the positive findings being weak. One of the difficulties in interpreting such studies is that they make multiple comparisons between exposures and diseases. Case–control studies can look at associations with many occupations or exposures. Cohort (follow-up) studies of a particular occupation can evaluate many disease outcomes. Many of the observed disease–occupation associations in such studies are likely to be due to chance, given the large number of associations evaluated. Such chance observations probably underlie many of the reported associations of the lymphomas with occupational exposures. The lack of consistency of findings from one study to another suggests that most reports are indeed chance findings. The strongest suspected occupation is wood-working [6, 47, 48]. As for occupational chemical exposures, many studies have found slight excesses of risk that are not statistically significant [6, 47, 48]. Studies of occupational exposures to herbicides, particularly the phenoxy herbicides, have shown an association, but these results have been inconsistent [49]. On balance, it appears that few, if any, well-confirmed chemical or occupational exposures might cause Hodgkin lymphoma.

A multitude of other potential risk factors for Hodgkin lymphoma ranging from tobacco use to other medical conditions and religion have been studied over the years [5, 6, 13, 19, 48]. Results have been mixed and inconsistent across many studies. The strongest and most consistent risk factors for the disease are listed in Table 39.2.

Table 39.2 Summary of known risk factors for Hodgkin lymphoma

Risk factor	Strength of the association	Consistency of the association
Epstein–Barr virus in Reed–Sternberg cells	Strong	Consistent
History of infectious mononucleosis	Moderate	Consistent
Family history of Hodgkin lymphoma	Moderate to strong	Consistent
Childhood socioeconomic status	Moderate	Consistent
Immunodeficiency syndromes	Weak to moderate	Consistent
Occupational exposures	Weak	Inconsistent

Non-Hodgkin Lymphomas

Incidence

The non-Hodgkin lymphomas are much more common than Hodgkin lymphoma. The recent overall annual incidence in the United States is 19.5 cases/100,000 population (23.7/100,000 in males and 16.1 in females) [2]. As can be seen in Table 39.3, incidence rates are much higher in whites than in blacks and the incidence goes up with age. The incidence rate for males older than 65 years is 112.6/100,000 and for females of the same age group it is 75.4. The 5-year relative survival is 72.6% overall. This survival is much poorer than that of Hodgkin disease. A trend toward poorer survival in the older patient is seen that is not as marked as that observed for survival in Hodgkin lymphoma. As is observed in the latter disease, survival is better in whites than in blacks, but whites have much higher rates of both diseases than do blacks [2].

Table 39.3 Important statistics on non-Hodgkin lymphomas

Population	Incidence
US incidence per 100,000 population per year, 2009–2013	
Overall US rate	19.5
Males	28.7
Females	16.1
Whites	20.4
Blacks	14.6
0–14 years	1.0
<65 years	9.2
Males	10.9
Females	7.5
65+ years	90.9
Males	112.6
Females	76.4
Population	Survival (%)
US 5-year relative survival, 2006–2012	
Overall	72.6
Males	71.7
Females	78.7
Whites	73.6
Blacks	65.2
Survival by age at diagnosis	
0–14 years	90.8
<45 years	81.6
65+ years	62.4

Rates are adjusted to the 2000 US standard population
Based on SEER data, 2009–2013 and 2006–2012

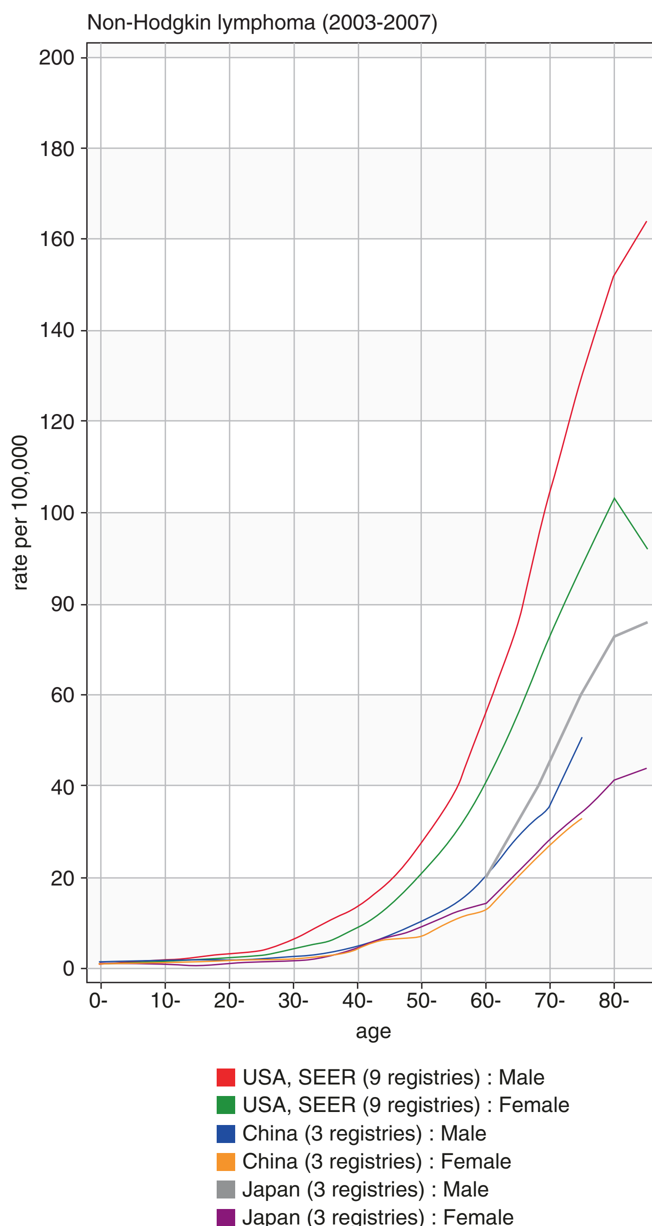

Fig. 39.7 Non-Hodgkin lymphoma, 2003–2007: Male. (Modified with permission from Ferley J, Parkin DM, Curado MP, Bray F, Edwards B, Shin HR, Forman D. Cancer Incidence in Five Continents, Volumes I to IX: IARC CancerBase No. 9 [Internet]. Lyon, France: International Agency for Research on Cancer; 2010. Available from: http://ci5.iarc.fr/)

International Variation

Figure 39.7 depicts non-Hodgkin lymphoma age–incidence patterns for males and females in the United States, China, and Japan [10]. In contrast to the age–incidence pattern for Hodgkin lymphoma that of non-Hodgkin lymphoma shows a unimodal pattern that rises steeply with age after age 30 years. Although the age–incidence plots are of similar shapes in the three countries illustrated, incidence rates consistently are much lower in the two Asian countries than in the US for both Hodgkin and non-Hodgkin lymphomas. In all three countries illustrated, non-Hodgkin lymphoma incidence is higher in males than in females.

Changing Incidence

A great deal of attention has been directed to gradually increasing non-Hodgkin lymphoma incidence rates in the US and developed countries in recent years. Since the early 1970s, US incidence rates have increased at the rate of 3–4% a year, which is more rapid than for all cancers other than melanoma and lung cancer among women [50]. These increasing rates are seen for all ages (except the very young), in whites and blacks, in the United States and internationally, and in both genders. During the 1980s, a further increase was seen in young and middle-aged men related to the AIDS epidemic, but this does not account for all the observed increase in incidence. Increases have been

more marked for extranodal disease, particularly for non-Hodgkin lymphomas arising in the brain, and for high-grade tumors. These observations have stimulated great interest, but no clear explanations have been found. The most recent data from the U.S. SEER program show that this increase has leveled off beginning about 1994 and that it has declined from this peak [2]. Figure 39.3 shows recent SEER data for incidence in the US. These data suggest that non-Hodgkin lymphoma incidence has leveled off and may now be declining. Figure 39.1 shows incidence trends over time for non-Hodgkin lymphoma in the US, China, and Japan. As can be seen, the increasing incidence of non-Hodgkin lymphoma has abated for men in the US since 1995, and only recently for women [10]. The incidence for China and Japan has increased at a slower rate and appears to be declining slightly recently. The comparable incidence data for Hodgkin lymphoma show a relatively stable pattern over the past 30 years (Fig. 39.2). Hodgkin lymphoma incidence rates in the US, China, and Japan have been relatively stable.

It should be kept in mind that the non-Hodgkin lymphomas are a diverse group of diseases. The observed overall increase in incidence may mask significantly more striking increases of individual entities within this overall rubric. Modern lymphoma classification systems such as the WHO classification of tumors of the hematopoietic and lymphoid tissues are based primarily on microscopic morphology and immunophenotypic features of tumors and to a lesser degree on clinical features [51]. Thus, the categories may not correlate with etiologic factors and may not represent distinct etiologic entities. The misclassification of non-Hodgkin lymphomas without regard for causal subgroups could lead to serious misclassification which would mask or artificially produce underestimates of risk in epidemiologic studies. Future classification of the non-Hodgkin lymphomas for epidemiologic research will require close cooperation between epidemiologists and expert pathologists, as well as molecular geneticists, to develop meaningful diagnostic and etiologic entities.

Immunodeficiency

No malignancy, with the possible exception of Kaposi's sarcoma, is more strongly associated with immunodeficiency than is non-Hodgkin lymphoma. The best established cause is impairment of immune function caused by either primary immunodeficiency syndromes, pharmacologic intervention (as used in transplantation), or human immunodeficiency virus (HIV) infection. Observation of this linkage between immunodeficiency and increased lymphoma risk derives originally from studies of cancer occurrence in primary immunodeficiency syndromes. A series of 500 cancers from the Immunodeficiency-Cancer Registry at the University of Minnesota reveals that overall 50.4% of all cancers in these subjects are non-Hodgkin lymphomas [52]. The second most frequent cancers in this registry are leukemias. Hodgkin lymphoma ranks fourth behind adenocarcinoma. The median age at diagnosis for lymphoma cases in this registry is 7.1 years. A 3:1 male/female ratio was seen, which may reflect the contribution of several X-linked disorders as well as the observation of a male excess in tumors of subjects with ataxia-telangiectasia, an autosomal recessive disorder. Most of the non-Hodgkin lymphomas in primary immunodeficiency patients are of B-cell origin. The association between EBV and non-Hodgkin lymphomas occurring in patients with primary immunodeficiencies has not been universal. In this regard, these lymphomas are more similar to those seen in AIDS patients. A high frequency of extranodal non-Hodgkin lymphoma in the primary immunodeficiencies is found, primarily of the central nervous system and gastrointestinal tract.

A second major immunodeficiency risk factor is that of therapeutic immunosuppression, such as in patients undergoing transplantation. The first observations to demonstrate this finding were studies of non-Hodgkin lymphoma risk in renal transplant recipients. It was observed that the disease developed 40–100 times more often than expected and that these tumors had a predilection for the central nervous system, primarily the brain, which was involved in almost half the cases [53, 54]. Most of this excess risk is evident within the first year following transplantation. The risk appears to be related to the intensity of the immunosuppressive therapy, which is reflected in the higher incidence of posttransplant non-Hodgkin lymphoma in heart and pancreas transplant patients, who receive an unusually intensive immunosuppressive regimen [55]. In the overwhelming majority of the lymphomas seen in posttransplant patients, EBV is found in the tumor samples [55]. It is also possible that non-Hodgkin lymphoma occurs with increased frequency in patients without transplantation who received immunosuppressive drugs for conditions such as collagen diseases. Kinlen [56] reported an 11-fold increased risk in patients without grafts who received immunosuppressive drugs for conditions such as rheumatoid arthritis. The increasing use of new pharmacologic and biologic immunosuppressive therapies in a variety of autoimmune diseases, such as psoriasis, rheumatoid arthritis, and Crohn's disease, raises concerns about long-term risks of non-Hodgkin lymphoma in treated patients.

In summary, inherited immunodeficiency syndromes or pharmacologic immunosuppression cause a very striking and large increase in risk. In both instances, the frequencies of both extranodal disease and an aggressive clinical course are high. Whereas posttransplantation non-Hodgkin lymphomas are largely EBV-associated, in a review of tumor

specimens from 13 cases in the University of Minnesota Immunodeficiency Registry only 31% were EBV positive [52]. Immunodeficiency, whether primary, secondary to therapy, or acquired, appears to be the best established and strongest risk factor for non-Hodgkin lymphoma.

AIDS-Related Disease

Non-Hodgkin lymphomas were found to occur remarkably frequently in AIDS patients, an observation that was made quite early in the AIDS epidemic [57]. Further documentation of the AIDS-non-Hodgkin lymphoma association led to the inclusion of non-Hodgkin lymphoma as a diagnostic criterion for AIDS when the criteria were changed in 1985 [58]. Based on epidemiologic surveys, it has been estimated that non-Hodgkin lymphomas occur 60 times more frequently in AIDS patients than do similar lymphomas in the general population [59]. It is estimated that non-Hodgkin lymphoma is the index AIDS diagnosis in about 3% of new AIDS cases, with some evidence suggesting that this frequency may be increasing [60]. AIDS-related non-Hodgkin lymphomas occur in all risk group categories for AIDS (i.e., intravenous drug users, heterosexual contacts of cases, transfusion recipients, and so forth). No differences between risk groups have been reported with regard to clinical manifestations, clinical course, or response to therapy [60]. The patterns of occurrence in HIV patients appear to be changing over time. Earlier in the AIDS epidemic, about 50% of the patients with AIDS-related non-Hodgkin lymphoma had a previous diagnosis of opportunistic infection or Kaposi's sarcoma (or both), and only 15% had no previous AIDS diagnosis. More recently the proportion of such patients with no preceding AIDS-related diagnosis has risen to approximately one-third to one-half.

The impact of HIV infection on incidence has been estimated by modeling techniques. About 2000 AIDS-related non-Hodgkin lymphoma cases occurred in the United States in 1990 [61]. Projections into the future suggest that between 8 and 27% of non-Hodgkin lymphoma cases diagnosed in the United States might be AIDS related. However, it must be remembered that the overall rising incidence of the non-Hodgkin lymphomas in the United States and other countries has clearly preceded the AIDS epidemic and is independent of the contribution of AIDS-related cases.

The clinical presentation of AIDS-related non-Hodgkin lymphoma is similar to that seen in primary, immune deficiency conditions, or other immunosuppressed patients. The non-Hodgkin lymphoma seen in HIV-infected individuals is of high-grade subtypes, with undifferentiated or immunoblastic lymphoma accounting for 60–80% of reported cases of AIDS-related non-Hodgkin lymphoma [61]. Burkitt lymphoma-like tumors account for approximately 20% of AIDS-related non-Hodgkin lymphomas in the United States and seem to occur most frequently in children and young adults between 10 and 19 years of age [62]. Interestingly, most of the Burkitt lymphoma-like AIDS-related non-Hodgkin lymphomas show no evidence of EBV in tumor tissues. Also, most of the AIDS-related Burkitt lymphoma-like lesions are similar to non-endemic Burkitt lymphomas in that they have a low frequency of the characteristic cytogenetic abnormalities seen in the endemic form. However, some AIDS-related Burkitt lymphoma-like tumors in AIDS patients have been found to have the characteristic cytogenetic abnormalities and EBV positivity seen in endemic Burkitt lymphoma.

In general, the AIDS-related non-Hodgkin lymphomas are primarily of B-cell origin, have a rapid progression and aggressive clinical picture with single or multiple tumors, and a predilection for extranodal sites. As in non-AIDS-related non-Hodgkin lymphomas, males are more frequently affected than females. Primary CNS non-Hodgkin lymphoma is a frequent AIDS-related type. Such CNS involvement is rare in non-immunocompromised groups, occurring in approximately 1% of non-Hodgkin lymphomas, but it has been reported to constitute about 20% of those associated with AIDS [59]. Again, it must be pointed out that the increasing incidence of primary CNS lymphoma in the general population appears to be independent of the increase of primary CNS lymphoma in HIV-infected persons [63]. Primary CNS lymphoma may account for up to one-fourth of all HIV-associated non-Hodgkin lymphomas, and involvement of the CNS occurs in 10–25% of patients presenting at other sites. Based on observations such as these, the case definition initially chosen for diagnosis of AIDS was changed to include HIV-positive patients with both high-grade B-cell lymphoma and primary brain lymphomas [56]. It should also be pointed out that the non-Hodgkin lymphomas seen in AIDS may be occult and may only be demonstrated at autopsy [64]. Unfortunately, the precise role of EBV in the AIDS-related non-Hodgkin lymphomas has not been elucidated and may very well differ in various subgroups.

The increasing incidence of AIDS-related non-Hodgkin lymphoma cannot account solely for the increasing incidence of non-Hodgkin lymphoma observed in the United States, and elsewhere. Nevertheless, it is an important contributor to the rise in incidence. It also further suggests that immunodeficiency, whether congenital, acquired, or pharmacologically induced, is a potent risk factor.

The epidemiology of AIDS-related lymphoma has evolved in recent years. The demographic characteristics of these cases have shifted to increasing incidence in Hispanic/Latinos, women, and persons with heterosexually acquired AIDS [65]. The introduction of highly active antiretroviral therapy (HAART) in 1996–1997 has also produced changes in the patterns and incidence of AIDS-related lymphoma.

A large study from France found a marked decrease in incidence of AIDS-related lymphomas in HIV-infected patients from 86.0 per 10,000 person-years in 1993–1994 to 42.9 in 1997–1998 [66]. They also found a greater decrease in primary brain lymphomas from 27.8/10,000 in 1993–1994 to 9.7 in 1997–1998. This may account in part for the recent decline in overall non-Hodgkin lymphoma incidence.

Familial Aggregation

Numerous case reports and series of interesting kindreds have documented the occurrence of more than one non-Hodgkin lymphoma in family members [67]. In comparing aggregation of cancers in Hodgkin lymphoma and non-Hodgkin lymphoma families, several differences are immediately apparent. The first is that for the non-Hodgkin lymphomas far more families are multiply affected (having larger proportions of affected relatives) than are seen in Hodgkin lymphoma. Second, in non-Hodgkin lymphoma, familial aggregation involves relatives with the same disease as well as other lymphoproliferative malignancies, whereas reports of familial aggregation of Hodgkin lymphoma primarily deal with multiple occurrences of the same disease. A third difference relates to reports of multiply affected preadolescent male sibships with extranodal non-Hodgkin lymphomas, primarily of the gastrointestinal tract. Such observations are reported primarily from Mediterranean countries. These may be related to the so-called Mediterranean lymphomas, which are associated with the production of abnormal immunoglobulins. Fourth is the observation that in many multiply affected families primary immunodeficiency syndromes such as ataxia-telangiectasia are also found [67].

Familial aggregation of non-Hodgkin lymphoma appears to be less marked than that observed for Hodgkin lymphoma. Goldin et al., in a large, population-based study from Sweden, found an odds ratio of 1.7 (95% confidence limit = 1.4–2.2) for the occurrence of a non-Hodgkin lymphoma in first-degree relatives of cases. In contrast to this, the same study found an odds ratio of 3.1 (1.8–5.3) for Hodgkin lymphoma in first-degree relatives of Hodgkin lymphoma cases [39, 40]. Interestingly, they also found a slightly increased risk of Hodgkin lymphoma in first-degree relatives of non-Hodgkin lymphoma probands (odds ratio = 1.4, 95% confidence interval = 1.0–2.0). Slight, nonsignificant increases in odds ratios were also found for the occurrence of chronic lymphocytic leukemia (odds ratio = 1.3) and multiple myeloma (1.1) in first-degree relatives of non-Hodgkin lymphoma cases.

Wiernik et al. observed that genetic anticipation occurs in familial non-Hodgkin lymphoma [68]. Genetic anticipation is the phenomenon in which a disease manifests itself at an earlier age or with increased severity in successive generations in a kindred. A significant difference was observed between the ages of onset in the children of cases' generation and the SEER population but not in the parent generation and the SEER population. More recent studies have confirmed this finding, observing genetic anticipation for combinations of Hodgkin and non-Hodgkin lymphomas and for all B-cell lymphomas [33, 34, 69]. If these findings are valid, they would strongly suggest a genetic basis for non-Hodgkin lymphomas and a common genetic basis for both Hodgkin and non-Hodgkin lymphomas. As discussed earlier for Hodgkin lymphoma, studies of anticipation for the combined group of hematologic malignancies could produce biased results due to different ages of onset for the different malignancies included.

A question about the validity of these findings has been raised by a study of anticipation in a large number of Hodgkin and non-Hodgkin lymphoma, chronic lymphocytic leukemia, and multiple myeloma cases from population-based registries in Denmark and Sweden [32]. This study found no anticipation for Hodgkin lymphoma, chronic lymphocytic leukemia, or myeloma. While they found significant anticipation in non-Hodgkin lymphoma families initially, analyses adjusted for the changing incidence rates of non-Hodgkin lymphoma over time led to the disappearance of the statistical difference in the ages of parents and their offspring. They concluded that secular trends in incidence of non-Hodgkin lymphoma could have biased previous observations of anticipation. Thus, there is need for further large, population-based studies to evaluate the validity of the observed genetic anticipation for this group of diseases and resolve the differences in study results.

Skin Cancer and Ultraviolet Exposure

A report by Adami et al. [70] suggests that ultraviolet exposure, as from sunlight, might be one of the factors underlying the increasing incidence of non-Hodgkin lymphoma. This finding fits with an earlier report of an excess of skin cancer in patients with non-Hodgkin lymphoma [71]. Additionally, melanoma and squamous cell cancers of the skin occur excessively, along with non-Hodgkin lymphoma, in renal transplant recipients [53, 54]. These observations, plus the increasing incidence of melanoma, led these investigators to pursue this hypothesis. They reported a fivefold increased risk of squamous cell skin cancer and a twofold increased risk of melanoma in non-Hodgkin lymphoma patients. Conversely, they found a twofold increased risk of the disease in squamous cell skin cancer patients. These findings stimulated much further research. Some subsequent studies found an inverse association between ultraviolet exposure and lymphoma risk [72–75], others a positive association [76], and still others found no association [77, 78].

At present the association remains equivocal, but increasingly appears unlikely to stand the test of time. In many ways, the example of ultraviolet radiation exposure epitomizes the nature of epidemiologic research on the causation of non-Hodgkin lymphoma.

Occupational Exposures

Although many studies of occupations and occupational exposures have been performed, few consistent or strong observations have been reported. One area of major investigation has been farming occupations: at least 21 cohort studies of farmers or occupational surveys of cancer that presented data on non-Hodgkin lymphoma and farming occupations had been done as of 1991 [79]. The risk ratios for the association between this disease and farming ranged from 0.6 to 2.6. Eleven of these 21 studies reported excess risks in farmers, but only three of these were statistically significantly in excess. One of the 21 surveys showed a significantly low relative risk, implying a protective effect. Even more studies of farmers have been done since with similarly inconsistent results [80].

The lesson to be learned from this and other arrays of occupational studies is that many studies have been done of numerous occupations and numerous cancers. Hundreds, if not thousands, of associations have been assessed, and it must be remembered that five of each 100 might be expected to deviate significantly from the null hypothesis just on the basis of chance. Thus, for an assumption of causality to be made for such associations, factors such as the consistency of the findings, the strength of the reported association, the biologic plausibility of the association, and observation of dose–response relationships need to be considered. Using such criteria, it would appear that a slightly increased risk is consistently found in farmers. In general, the magnitude of the increased risk is below twofold and could be due to unidentified confounding factors.

The observation of a possible increased risk in farmers led to studies of chemicals used by these farmers. From these studies have emerged observations that there appears to be an association between pesticide exposure and risk. Several studies have evaluated the potential etiologic role of phenoxy herbicides [81]. Although the results lack consistency, the findings are more consistent than are those from studies of farming occupation and other farming exposures. A dose–response relationship has been suggested in some of the studies as well. At present, no consistent association appears to exist between herbicide use (particularly phenoxy herbicides) and risk of NHL [49, 81]. Alexander et al. reviewed the phenoxy herbicide literature including farming and manufacturing exposures and found associations both positive and negative with the associations centered around the "no association" value of 1.0. [80] Thus, it is likely that there is no meaningful association between occupational exposure to phenoxy herbicides and risk of non-Hodgkin lymphoma. A similar set of results for other occupational pesticide exposures and lymphoma risk was also found in the Alexander et al. review.

Other occupational and environmental factors that have been considered include radiation, zoonotic viruses, exposure to wood, hair dyes, numerous chemicals, electromagnetic fields, tobacco use, and a variety of other exposures [80, 82–85]. In general, none of these exposures has been consistently associated with an increased risk. In summary, very large numbers of investigations of the potential etiologic role of environmental and occupational exposures in the non-Hodgkin lymphomas have been conducted; thus far, these exposures appear to play at most a slight role in the overall causation.

A review of the epidemiologic literature on the non-Hodgkin lymphomas published by Alexander et al. provides the most extensive current review on occupations and occupational exposures and non-Hodgkin lymphoma risks [80]. Their conclusion states, "Review and evaluation of the epidemiologic studies of occupational and environmental factors have identified no specific exposure that is consistently associated with NHL." Their review which was funded by a pesticide manufacturer, but which was peer-reviewed, provides a table on all the published studies of pesticide exposure and non-Hodgkin lymphoma that runs for 5¼ pages. What becomes apparent from review of this table are the numerous studies performed, the generally weak associations found and the tremendous inconsistency of the results. A similar table of occupational exposures and risk of non-Hodgkin lymphoma is presented by Scherr and Mueller in an earlier literature review [85]. Their table runs for 6½ pages and shows similar results—weak associations and lack of consistency of findings. These observations suggest that most of the observed associations reported in the literature are due to chance or bias. Despite a huge amount of epidemiologic research on potential occupational and environmental causes of non-Hodgkin lymphoma, no consistent or strong associations have been found. What this suggests is that no such strong or valid associations exist, or that studies of occupational exposures are subject to misclassification of exposures, or to misclassification of lymphomas as a single etiologic entity. It must be understood that the exposures of farmers, for example, entail a wide range of things ranging from fertilizer and pesticide use to animal infections and to diesel fuel and gasoline. A more serious potential limitation of this area of research may be that non-Hodgkin lymphoma may be composed of a group of similar diseases with different etiologies and studies of the overall group could mask specific exposure associations with component etiologic entities.

A recent, very large pooled analysis of ten international case–control studies from the InterLymph consortium assessed various occupations and risk of non-Hodgkin lymphoma and its subtypes [86]. They confirmed previously reported associations between non-Hodgkin lymphoma and farming occupations: field crop/vegetable farm works OR = 1.26, 95% confidence limit 1.05–1.51, and general farm workers OR = 1.19, 95% CI 1.03–1.37. Like other studies of farmers the ORs were very low and barely statistically significant despite the huge number of cases. Other weak associations were found for women hairdressers, charworkers/cleaners, spray painters, electrical wiremen, and carpenters. Specific lymphoma subtype associations were found for diffuse large B-cell lymphoma (DLBCL) and chronic lymphocytic/small lymphocytic lymphoma in women hairdressers, and for DLBCL and peripheral T-cell lymphoma in textile workers. The broad spectrum of associated occupations suggests that many of these findings are due to chance as might be expected in case–control studies. It was disappointing that few subtype-specific consistent associations were found. Yet again, no strong and consistent occupational risk factors were identified.

Epidemiologic approaches in part have proven unsuccessful to date because of inherent study design limitations. Non-Hodgkin lymphoma is not a common disease and most of the exposures studied as risk factors are relatively uncommon in the general population. The most efficient epidemiologic study design for assessing an uncommon exposure would be cohort studies. In such studies, occupational or other exposure groups can be assembled and followed for occurrence of lymphoma. Since lymphomas are relatively uncommon, particularly in younger individuals, only a few cases might be observed in the cohort leading to statistical instability of the results. Conversely, in a case–control study where relatively large numbers of cases can be assembled, any single environmental exposure would be most uncommon, thereby limiting the stability of the results. Factors such as these are likely explanations for the mixed bag of results obtained thus far and for the great variability of the results.

Burkitt Lymphoma

From an epidemiologist's viewpoint, one of the most interesting non-Hodgkin lymphomas is Burkitt lymphoma. Burkitt lymphoma has perhaps stirred up the greatest initial interest in the possible viral etiology of human lymphomas. Denis Burkitt [87] was an Irish surgeon who, while working in Uganda, first drew attention to a lymphoid malignancy primarily involving the jaw in children. This disease, which he called *African lymphoma,* had distinct clinical, pathologic, and epidemiologic features. Burkitt [88] went on what he termed "tumor safaris" throughout Africa to map the distribution of Burkitt lymphoma. He defined a lymphoma belt extending entirely across Africa, but in a manner corresponding to tropical areas of low altitude. Within his lymphoma belt, he found little Burkitt lymphoma in areas of high altitude [89]. Based on his observations, Burkitt concluded that the disease was defined by rainfall and altitude and corresponded closely to those areas in which malaria was endemic. Later it was found that Burkitt lymphoma appeared to be endemic in New Guinea, particularly in its lowland areas. He did not consider malaria itself as the cause since the disease occurred in countries other than Africa or New Guinea where there is no malaria. This led Burkitt to consider an arthropod-borne virus as the etiologic agent. Burkitt sent specimens of his African lymphoma to outside investigators for study. In 1964 Epstein, Achong, and Barr [90] were able to demonstrate a new herpes virus in cultured Burkitt lymphoma cells from one of Burkitt's patients. It was also observed that when this new virus infected cells it immortalized them in tissue culture.

One of the fascinating early findings in the study of Burkitt lymphoma was that of time–space clustering, a characteristic of many infectious diseases [91]. Several studies showed very clear-cut time–space clustering of Burkitt lymphoma in areas of Uganda. These occurrences appear to suggest epidemic behavior of the disease. However, it must be noted that time–space clustering, while characteristic of many infectious diseases can also be due to other noninfectious shared environmental exposures. Also, based on studies in Uganda, Burkitt lymphoma patients appeared to come from families of lower SES [92].

Based on the observed overlapping of malarious areas and the occurrence of Burkitt lymphoma in Africa, many hypotheses were developed that regarded malaria as an etiologic cofactor. While these notions suffice for endemic Burkitt lymphoma, they could not explain the etiology of the sporadic cases that occur in non-malarious developed countries.

EBV was subsequently shown to occur throughout the world and was identified as the causative agent of infectious mononucleosis by Henle et al. in 1968 [93]. EBV was later found to be associated with many other diseases such as nasopharyngeal carcinoma, sarcoidosis, and lupus erythematosus. It is also almost uniformly present in those lymphomas occurring posttransplantation. African Burkitt lymphoma cases have very much higher EBV antibody titers than do controls, particularly viral capsid antigen (VCA) antibody titers [94]. The high titers of EBV VCA antibodies in Burkitt lymphoma patients were found to antedate the occurrence of the tumor by months to years [95]. With the advent of newer molecular biologic techniques, EBV could be detected in Burkitt lymphoma tumor tissues. About 90% of endemic Burkitt lymphoma patients, but only 10–15% of the non-endemic cases, have been found to have EBV in their tumors [60].

Another characteristic of Burkitt lymphoma is a high frequency of chromosomal translocations that occur at specific breakpoints on chromosomes 8, 14, 2, and 22 [62]. t(8:14) is demonstrated in over 90% of endemic Burkitt lymphoma tumors. The remaining 10% of tumors equally show t(8:2) and t(8:22). These translocations appear to be unrelated to the presence or absence of EBV in the tumor tissues. The less common sporadic form of Burkitt lymphoma occurs in economically developed countries with a worldwide distribution. The sporadic form shows a bimodal age incidence pattern, with peaks in children older than in the endemic form and also in adults. Most of the sporadic Burkitt lymphomas are extranodal, with a high proportion of tumors affecting the gastrointestinal tract or CNS rather than the jaw, as seen in endemic disease. Only about 15% of sporadic Burkitt tumors are EBV-associated [62]. Both types represent clonal proliferations of B-cells and both exhibit the same chromosomal translocations. In AIDS-related Burkitt lymphoma, variability of the tumors exists, with some showing the findings of sporadic and others the findings of endemic Burkitt lymphomas. However, most of the tumors show no evidence of EBV [62].

In summary, Burkitt lymphoma appears to be intertwined with EBV. However, EBV is infrequently found in the sporadic form, which is seen in developed countries. Thus, the model developed to explain the occurrence of Burkitt lymphoma in endemic areas (an interplay of EBV infection, malaria, and some as yet unidentified third factor) cannot explain all cases. Nevertheless, the unusual descriptive epidemiologic features of the disease and the well-documented occurrence of time–space case clustering, plus the apparently major role that EBV plays in most of these cases, suggest that Burkitt lymphoma has a viral etiology. It is now widely accepted that EBV is a cause of Burkitt lymphoma although the causal mechanism is unknown [1, 24].

Infectious Agents

In addition to EBV, several other infectious agents have been evaluated and determined to be causes of some non-Hodgkin lymphomas [96]. The human T-lymphotropic virus-I (HTLV-I) has been found to be a cause of adult T-cell leukemia/lymphoma, an uncommon lymphoma with interesting geographic and epidemiologic patterns of distribution [1, 97]. The human herpes virus-8 (HHV-8), also known as the Kaposi sarcoma virus, has been found to be a cause of primary effusion lymphoma [1, 97, 98]. A bacterial agent, *H. pylori*, has been found to be a cause of mucosal-associated lymphoid tissue (MALT) lymphoma [1, 97, 99]. The hepatitis-C virus (HCV) has been determined to be a cause of all subtypes of non-Hodgkin lymphomas [1, 100].

These findings suggest that infectious agents play an important role in the etiology of some types of lymphoma. These lymphoma types tend to be uncommon, but their diversity suggest that the non-Hodgkin lymphomas are a heterogeneous group of diseases with different causes.

Other Causes

Numerous other potential environmental causes of non-Hodgkin lymphoma have been investigated and again the results of these studies have been weak and inconsistent [80, 84]. Factors ranging from cigarette smoking to radiation exposure to diet and body weight have been studied as risk factors for non-Hodgkin lymphoma with equivocal results. Several autoimmune disorders and medical conditions such as Sjögren's syndrome and type-2 diabetes have also been linked to an increased risk of lymphoma [40, 80, 84]. The reader is referred to the review articles cited here for greater detail on these other possible causes [40, 80, 83–85].

Summary

Both Hodgkin lymphoma and non-Hodgkin lymphoma are interesting diseases that have puzzled epidemiologists due to their many tantalizing epidemiologic findings. Until recently, the non-Hodgkin lymphomas had been gradually increasing in incidence, whereas Hodgkin lymphoma incidence has been either steady or slightly decreasing overall. The increasing incidence of non-Hodgkin lymphoma cannot be fully explained by AIDS-related cases. Both diseases have striking international variation in their occurrence, with some of the highest incidence rates occurring in the United States and other developed countries. Both diseases exhibit familial aggregation with an increased risk to relatives on the order of threefold for Hodgkin lymphoma and two- to threefold for non-Hodgkin lymphoma (Tables 39.2 and 39.4). Both diseases show evidence of genetic anticipation. Hodgkin lymphoma has a bimodal age–incidence pattern, whereas non-Hodgkin lymphoma has a unimodal pattern with its mode occurring in the elderly. The bimodality of Hodgkin lymphoma is constant in developed countries whereas in Asia there appears to be a shift toward bimodality that was previously absent. Whereas SES appears to be directly associated with risk of both diseases, far more data exist on this topic for Hodgkin lymphoma than for non-Hodgkin lymphoma. In fact, the SES findings related to Hodgkin lymphoma make a strong case for the importance of environmental factors in the etiology of the disease. However, for both diseases only a few associations between nonviral environmental exposures and risk have been reported consistently. The most intriguing commonality between the two diseases is their association

Table 39.4 Known risk factors for the non-Hodgkin lymphomas

Risk factor	Strength of the association	Consistency of the association
Immune deficiency		
Primary	Strong	Consistent
Posttransplantation	Very strong	Consistent
Other drug-induced	Strong	
Acquired (AIDS)	Moderate to strong	Consistent
Family history of non-Hodgkin lymphoma	Weak to moderate	Consistent
EBV infection	Moderate	Consistent mostly for Burkitt lymphoma
Other infectious agents (hepatitis-C virus, HTLV-1, HHV-8, *H. pylori*)	Weak to moderate	Consistent, mostly for uncommon lymphomas
Occupational exposures	Weak	Inconsistent

with EBV (Tables 39.2 and 39.4), although different patterns of association are seen. However no other infectious agents appear to be causally related to Hodgkin lymphoma, whereas several agents are associated with some uncommon non-Hodgkin lymphomas. The lymphomas represent some of the few human cancers in which a virus can be identified in tumor specimens with any degree of regularity.

For both diseases, the most likely etiologic mechanism is a complex interplay among genetic susceptibility, immune function, and perhaps viral infection (Tables 39.2 and 39.4). The difficulty in unraveling this complex knot is that abnormal immune function could be genetically determined or virally induced. Which virus may cause these diseases is not known. Although EBV is a sufficient cause in some cases, it is not a necessary cause, as evidenced by the many EBV-negative lymphomas. It appears that HIV is not a direct cause of either disease, rather it is more likely that the disturbed immune function caused by HIV infection leads to non-Hodgkin lymphoma and, less frequently, to Hodgkin lymphoma. On these grounds, both groups of diseases would appear to be fertile territory for uncovering important etiologic mechanisms in human cancer.

An important area for future epidemiologic research on the non-Hodgkin's lymphomas is the search for environmental risk factors for component lymphomas, since the rubric of non-Hodgkin lymphoma used in most previous research may well have encompassed several different diseases with different etiologies. It is likely that previous epidemiologic research has been stalemated by reliance on outdated classifications of these lymphomas. The disappointing results of prior epidemiologic research on non-Hodgkin lymphoma subtypes with weak and inconsistent findings may be a reflection of such misclassification of diagnostic entities. Future research will need to go beyond the established subtypes that have been determined largely by histology and immunophenotyping. Collection of patients' biologic specimens (tumor tissues and blood) will also be necessary. Molecular genetic biomarker approaches and newer statistical methods, such as medical informatics as used in cancer biomarker research, may have to be used. Studies searching for new categorizations of lymphomas will have to be of large size and may require multicenter studies to assure adequate numbers of patients with individual lymphoma subtypes. A feasible approach to mounting such studies would be to utilize cases from clinical trials to conduct case–control studies, as has been done for the relatively rare pediatric cancers [101]. Increasingly, cancer clinical trials are being done on highly specific molecular biologic classifications of subsets of cancers. Clinical trials of molecularly defined subtypes of lymphomas would provide carefully diagnosed cases in relatively large numbers for case–control studies of component lymphomas. Unlike prior case–control studies, definitions of cases can then go beyond simple light microscopy and immunophenotyping disease classifications.

40 Pathology of Non-Hodgkin and Hodgkin Lymphomas

Mariko Yabe and L. Jeffrey Medeiros

Introduction

Non-Hodgkin lymphomas (NHLs) are neoplasms that arise from lymphocytes of B-cell, T-cell, or NK-cell lineage or rarely from histiocytes. The anatomic location and many of the biologic features of various NHL types can be related to their normal counterparts. Normal B-cells are concentrated in the follicles and medullary cords of lymph nodes and in the follicles of the spleen [1]. The lymphoid follicles represent the proliferative site of the B-cell system. Upon antigen stimulation, secondary germinal centers develop in which rapid cell division of B-cells takes place. The medullary cord region of the lymph node represents the secretory component of the B-cell system. By contrast, T-cells are selectively concentrated in the paracortical regions of lymph nodes and within the periarterial lymphoid sheaths of the spleen. In addition, small numbers of T-cells are found within follicles where they help in the induction of B-cell differentiation (follicular helper T-cells) [2]. Histiocytes are preferentially found in the subcapsular and medullary sinuses of lymph nodes and the cords of Billroth in the splenic red pulp. Histiocytes are also a part of the reticuloendothelial system of the liver and lung. Tissue histiocytes have two broad categories of function. Most histiocytes are phagocytic, whereas a minority of specialized cells is involved in antigen processing and presentation to B- and T-cells [1, 2].

In general, the cell of origin or normal counterpart of NHLs is best understood for B-cell NHLs. For example, follicular lymphoma is known to be derived from B-cells within the germinal center of the lymphoid follicle. By contrast, the cell of origin of T-cell NHLs is much less well understood and there is also likely plasticity in cell differentiation in relation to the microenvironment and antigenic stimulation. Origin from a multipotential stem cell also may be relevant and could explain the occurrence of rare composite lymphomas, i.e., one site involved by two different histologic types of lymphoma, each of which shares the same molecular abnormality.

Physiological characteristics of B-cells, T-cells, NK-cells, and histiocytes are also retained in many NHLs and can be used for pathologic diagnosis. The best example is immunoglobulin (Ig) synthesis by B-cells. Since B-cells express either Igκ or Igλ light chain, but not both, immunophenotypic assessment for Ig light chain is a useful clonal marker because a neoplastic clone is derived from a single precursor cell. By contrast, a polyclonal proliferation of cells, derived from many different precursor cells, will express a mixture of Igκ- and Igλ-positive cells [1, 2]. T-cells, in contrast, do not express the equivalent of Ig light chains in B-cells, making the assessment of clonality more challenging by immunophenotypic methods, although polyclonal versus monoclonal patterns of T-cell receptor beta chain antibody expression can be assessed by flow cytometry [3]. For NK-cells, there are no rearrangements of the immunoglobulin and T-cell receptor genes. Skewed expression of killer cell immunoglobulin-like receptors (KIR) detected by flow cytometry can help in the assessment of clonality of a NK-cell population [4].

Numerous monoclonal antibodies reactive against B- and T-cell and histiocytes-associated antigens are also available and can be used, in part, for assigning a stage of differentiation or likely normal cell counterpart of an NHL. Histiocyte

subsets include follicular dendritic cells (located within the germinal center), interdigitating dendritic cells (located in the paracortex), fibroblastic reticular cells, and Langerhans cells (located primarily in skin).

Molecular studies have greatly contributed to the classification of NHLs and understanding of their pathogenesis. B- and T-cells normally undergo rearrangement of their antigen receptor genes which can be used as markers of clonality in the assessment of lymphoid neoplasms [5]. Distinctive chromosomal translocations also have been identified in certain types of NHL, many of which are related to mistakes in the physiologic antigen receptor gene rearrangement process or result from mistakes in repair of double-stranded DNA breaks result from mistakes in repair of [5–7].

Hodgkin lymphoma (HL) and NHL have been regarded traditionally as distinct diseases based on their differences in clinical features, response to therapy, pathology, and immunophenotype. The diagnosis of classical Hodgkin lymphoma (CHL) depends on the identification of large neoplastic cells with a distinctive immunophenotype (CD15 +/−, CD30+, PAX5 dim+, CD45-) in an appropriate cellular background of inflammatory cells. Nodular lymphocyte predominant Hodgkin lymphoma (NLPHL) is characterized by a nodular, or a nodular and diffuse proliferation of scattered large neoplastic cells with CD15-, CD20+, CD30-, CD45+ immunophenotype. In recent years, evidence has accumulated that the malignant cell in virtually all cases of HL is of B-cell origin [8], albeit a defective B-cell, and therefore the clinical and biologic overlap between HL and NHL becomes less surprising. This is especially true for NLPHL, and recent studies have shown extensive overlap between NLPHL and T-cell/histiocyte-rich large B-cell lymphoma [9].

Brief History of Classification of Non-Hodgkin Lymphomas

The era of modern classification of NHLs began in 1956 with a classification introduced by Henry Rappaport, who initially collaborated with Edward Gall, a coauthor of an earlier classification with Tracy Mallory [10]. The approach using the Rappaport classification was to first divide lymphomas by pattern, either nodular or diffuse, and then subclassify them further on the basis of cytologic features. Tumors composed of lymphocytes that closely resembled normal lymphocytes were termed well differentiated. Poorly differentiated tumors were composed of relatively small lymphoid cells with irregular nuclear contours that less closely resembled normal lymphocytes. Non-Hodgkin lymphomas composed of large cells were designated as histiocytic on the basis of their resemblance to normal histiocytes. Undifferentiated NHLs were composed of cells of intermediate size that failed to demonstrate cytologic features of either lymphoid or histiocytic origin. Mixed NHLs were composed of a mixture of poorly differentiated lymphocytes and histiocytes.

The Rappaport classification was popular with pathologists and clinicians at the time, but as our understanding of the normal immune system improved, scientific inaccuracies became apparent on the basis of the following observations. First, morphologically identical lymphocytes were found to be functionally heterogeneous. The principal classes of lymphocytes are B- and T-cells, but these are also multiple subpopulations as well as minor subclasses of lymphoid cells. Secondly, small lymphocytes are not an end-stage cell or the final product of a differentiation process. Thus, grading lymphocytes as either well or poorly differentiated does not necessarily relate to differentiation. Lastly, so-called histiocytic lymphoma of the Rappaport classification was usually not of histiocytic origin, but derived from transformed lymphocytes.

In an attempt to address these scientific inaccuracies, new classifications were proposed that attempted to relate lymphoid neoplasms more closely to their counterparts in the normal immune system. By the late 1970s, six lymphoma classifications were in use throughout the world. Of these, in retrospect, the classifications of Lukes and Collins [11] and particularly the Kiel classification [12] were most influential. Nevertheless, the plethora of classifications resulted in confusion and controversy. In an attempt to resolve these differences, the National Cancer Institute funded an international study to test each of the major classifications on 1175 NHLs staged and treated in a relatively consistent manner [13]. On the basis of this study, it was concluded that each of the systems was useful in separating large numbers of patients into subgroups with varying survivals and clinical features. Furthermore, no one scheme appeared to be superior to another. As a consequence of these findings, the investigators involved in the study jointly developed a Working Formulation [13]. In this formulation NHLs were divided into three groups based on clinical outcome: low grade, intermediate grade, and high grade. The authors also emphasized that the Working Formulation was not an alternative classification, but rather a common language that could be used to translate one classification scheme into another. The Working Formulation became

popular, and was principally used in the United States for the next decade. In Europe, the Kiel classification remained most popular, and was updated in 1988 [14]. It should be emphasized that the Working Formulation was based purely on histologic data; immunologic and molecular data were not included, and this was one of the principal reasons why the Kiel classification remained popular in Europe.

The application of newly developed immunophenotypic and molecular methods to the study of hematolymphoid neoplasms made it clear that the Working Formulation (and to a lesser extent the Kiel classification) were inadequate. The results of these studies showed that the categories of the Working Formulation were immunologically and molecularly heterogeneous. Pathologists in the US began to informally modify the Working Formulation by including immunophenotypic and molecular data. For example, the Working Formulation category of "malignant lymphoma, small lymphocytic" had CD5+ and CD5- subsets. Other categories such as "malignant lymphoma, diffuse mixed small and large cell" had B-cell and T-cell subsets. By the early 1990s, virtually all hematopathologists who used the Working Formulation were using a much improved, more complex version that included histologic, immunophenotypic, molecular, and cytogenetic data, but in a non-standardized fashion. In the meantime, most European hematopathologists continued to use the Kiel classification.

The International Lymphoma Study Group proposed a new lymphoma classification that was essentially a summary of the available literature, and was built upon many of the concepts of the Kiel classification. This classification, first published in the journal *Blood* in 1994, is known as the Revised European-American Classification of Lymphoid Neoplasms (REAL) [15]. After a very important validation study of this classification organized by Dennis Weisenburger and James Armitage at the University of Nebraska Medical Center [16], the REAL classification became the basis for a revised classification of lymphoid neoplasms by the World Health Organization (WHO), with the third edition in 2001, fourth edition in 2008, and recently an update of the fourth edition (Tables 40.1, 40.2, and 40.3) [17].

In this chapter, we emphasize the pathology of lymphoid neoplasms, most of which present as "lymphoma" as they are designated in the current WHO classification. Plasma cell neoplasms, myeloid neoplasms, and histiocytic processes are covered in other chapters.

Table 40.1 Revised 4th Edition of WHO classification of B-lymphoid neoplasms

Precursor B-cell neoplasms
B-lymphoblastic leukemia/lymphoma, not otherwise specified
B-lymphoblastic leukemia/lymphoma, with recurrent genetic abnormalities
B-lymphoblastic leukemia/lymphoma with t(9;22)(q34;q11,2); *BCR-ABL1*
B-lymphoblastic leukemia/lymphoma with t(v;11q23.3); *KMT2A* rearranged
B-lymphoblastic leukemia/lymphoma with t(12;21)(p13;q22); *ETV6-RUNX1*
B-lymphoblastic leukemia/lymphoma with hyperdiploidy
B-lymphoblastic leukemia/lymphoma with hypodiploidy
B-lymphoblastic leukemia/lymphoma with t(5;14)(q31.1;q32.3); *IL3-IGH*
B-lymphoblastic leukemia/lymphoma with t(1;19)(q23;p13.3); *TCF3-PBX1*
B-lymphoblastic leukemia/lymphoma, BCR-ABL1-like
B-lymphoblastic leukemia/lymphoma with iAMP21
Mature B-cell neoplasms
Chronic lymphocytic leukemia/small lymphocytic lymphoma
Monoclonal B-cell lymphocytosis
B-cell prolymphocytic leukemia
Splenic marginal zone B-cell lymphoma
Hairy cell leukemia
Splenic B-cell lymphoma/leukemia unclassifiable
Splenic diffuse red pulp small B-cell lymphoma
Hairy cell leukemia-variant
Lymphoplasmacytic lymphoma
Waldenstrom macroglobulinemia
Monoclonal gammopathy of undetermined significance (MGUS), IgM
Mu heavy chain disease
Gamma heavy chain disease
Alpha heavy chain disease
Monoclonal gammopathy of undetermined significance (MGUS), IgG/A
Plasma cell myeloma
Solitary plasmacytoma of bone
Extraosseous plasmacytoma
Monoclonal immunoglobulin deposition diseases
Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT)
Nodal marginal zone lymphoma
Pediatric nodal marginal zone lymphoma
Follicular lymphoma
In situ follicular neoplasia
Duodenal-type follicular lymphoma
Pediatric-type follicular lymphoma
Large B-cell lymphoma with IRF4 rearrangement

(continued)

Table 40.1 (continued)

Primary cutaneous follicle center lymphoma
Mantle cell lymphoma
In situ mantle cell neoplasia
Diffuse large B-cell lymphoma (DLBCL), not otherwise specified
Germinal center B-cell type
Activated B-cell type
T-cell/histiocyte-rich large B-cell lymphoma
Primary DLBCL of the central nervous system
Primary cutaneous DLBCL, leg type
EBV positive DLBCL, NOS
EBV+ Mucocutaneous ulcer
DLBCL associated with chronic inflammation
Lymphomatoid granulomatosis
Primary mediastinal (thymic) large B-cell lymphoma
Intravascular large B-cell lymphoma
ALK positive large B-cell lymphoma
Plasmablastic lymphoma
Primary effusion lymphoma
HHV8 positive DLBCL, NOS
Burkitt lymphoma
Burkitt lymphoma with 11q aberration
High-grade B-cell lymphoma, with *MYC* and *BCL2* and/or *BCL6* rearrangements
High-grade B-cell lymphoma, NOS
B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical
Hodgkin lymphoma
Provisional entities are listed in italics.

Table 40.2 Revised 4th Edition of WHO classification of T- and natural killer-cell neoplasms

Precursor T-cell neoplasm
T-lymphoblastic lymphoma/leukemia
Early T-cell precursor lymphoblastic leukemia
Natural killer (NK) cell lymphoblastic leukemia/lymphoma
Mature T-cell and NK-cell neoplasms
T-cell prolymphocytic leukemia
T-cell large granular lymphocytic leukemia
Chronic lymphoproliferative disorder of NK-cells
Aggressive NK-cell leukemia
Systemic EBV+ T-cell lymphoma of childhood
Hydroa vacciniforme-like lymphoproliferative disorder
Adult T-cell leukemia/lymphoma
Extranodal NK/T-cell lymphoma, nasal type
Enteropathy-associated T-cell lymphoma
Monomorphic epitheliotropic intestinal T-cell lymphoma
Indolent T-cell lymphoproliferative disorder of the GI tract
Hepatosplenic T-cell lymphoma
Subcutaneous panniculitis-like T-cell lymphoma
Mycosis fungoides
Sezary syndrome
Primary cutaneous CD30 positive T-cell lymphoproliferative disorders
Lymphomatoid papulosis
Primary cutaneous anaplastic large cell lymphoma
Primary cutaneous gamma-delta T-cell lymphoma
Primary cutaneous CD8 positive aggressive epidermotropic cytotoxic T-cell lymphoma
Primary cutaneous acral CD8 positive T-cell lymphoma
Primary cutaneous CD4 positive small/medium T-cell lymphoproliferative disorder
Peripheral T-cell lymphoma, not otherwise specified
Angioimmunoblastic T-cell lymphoma
Follicular T-cell lymphoma
Nodal peripheral T-cell lymphoma with TFH phenotype
Anaplastic large cell lymphoma, ALK positive
Anaplastic large cell lymphoma, ALK negative
Breast implant-associated anaplastic large cell lymphoma
Provisional entities are listed in italics

Table 40.3 Revised 4th Edition of WHO classification of Hodgkin lymphoma

Nodular lymphocyte-predominant Hodgkin lymphoma
Classical Hodgkin lymphoma
Nodular sclerosis classical Hodgkin lymphoma
Lymphocyte-rich classical Hodgkin lymphoma
Mixed cellularity classical Hodgkin lymphoma
Lymphocyte-depleted classical Hodgkin lymphoma

B-Cell Non-Hodgkin Lymphomas

B-Lymphoblastic Leukemia/Lymphoma, Not Otherwise Specified

B-lymphoblastic leukemia/lymphoma (B-ALL/LBL), not otherwise specified, is the most common type of B-ALL/LBL. Approximately 90% of B-ALL/LBLs present as leukemic neoplasms, better known as acute lymphoblastic leukemia (ALL). By contrast, B-LBL without leukemic involvement at the time of presentation is uncommon and represents no more than 10% of all B-ALL/LBLs [18].

Patients with B-ALL/LBL are most commonly young children, under the age of 6 years, who present with ALL. Extramedullary involvement is frequent, with a particular predilection for the central nervous system (CNS), lymph nodes, spleen, liver, and testis. Only a small subset of patients presents as lymphoma, with extranodal sites of involvement being most common, particularly skin, bone, and soft tissue, although a mediastinal mass is rare [19–21]. Regardless of stage, patients require aggressive chemotherapy regimens [22].

Histologically, the normal architecture of the lymph node is effaced by a diffuse, relatively uniform proliferation of cells

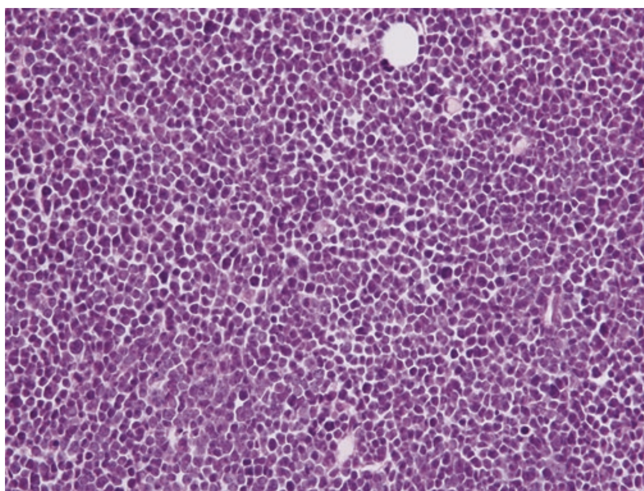

Fig. 40.1 B lymphoblastic leukemia/lymphoma involving adipose tissue. The neoplastic cells are small with blastic chromatin (hematoxylin-eosin, 400×)

that have a tendency to stream out into perinodal tissues [19, 23]. The neoplastic cells have scant cytoplasm, round or convoluted nuclei, and fine (blastic) chromatin (Fig. 40.1). Mitotic figures are numerous. Due to the high growth rate, a starry-sky pattern secondary to individual cell necrosis and scavenging by macrophages can be present in 10–20% of cases.

B-LBLs are neoplasms with immature B-cell immunophenotypes that appear to correspond to "frozen" stages of normal B-cell maturation. Normal B-cells initially express surface CD10 and CD19, followed by CD22, and then CD20. These antigens are detectable in the cell cytoplasm prior to expression on the cell surface. The tumor cells usually do not express Igs on their cell surface [2]. These stages in B-LBL have been referred to as pro-pro B-cell, pro-B-cell, and pre-B-cell, with the latter expressing cytoplasmic IgM in addition to other B-cell antigens. Rarely, surface IgM or Ig light chain (usually not both) can be expressed. An extremely useful marker in the diagnosis of both B-cell LBL is terminal deoxynucleotidyl transferase (TdT), a distinct type of DNA polymerase present normally only in immature lymphocytes [2]. TdT has a physiologic role as it is involved in the process of gene rearrangement, and is thought to add extra nucleotide bases between the variable (V), diversity (D), and joining (J) regions of the immunoglobulin (IG) and T-cell receptor (TCR) genes undergoing rearrangement. TdT is expressed in almost all cases of B-cell LBL.

Similar to surface antigen expression, the antigen receptor genes appear to rearrange sequentially in normal B-cells with a developmental hierarchy [24]. At the earliest stage of B-cell differentiation *IGH* undergoes rearrangement. Subsequently, the Igκ light chain gene rearranges. If neither *IGK* light chain gene allele is functionally rearranged, then the *IGL* light chain gene rearranges. This molecular mechanism allows a B-cell to express only one Ig light chain (the principle of allelic exclusion). The findings in B-LBLs mirror the normal state; all neoplasms carry monoclonal *IGH* rearrangements, but only more mature tumors carry light chain gene rearrangements [24]. Lineage infidelity is common in B-LBLs as T-cell receptor gene rearrangements are common (*TRD* > *TRG* > *TRB*).

B-Lymphoblastic Leukemia/Lymphoma with Recurrent Genetic Abnormalities

A number of nonrandom cytogenetic and molecular findings occur in B-ALL/LBL cases, and some of these abnormalities are sufficiently common that the WHO classification now considers these abnormalities as part of the definition of disease. In sum, there are nine types of B-ALL/LBL associated with specific molecular or cytogenetic abnormalities including two provisional entities (Table 40.1). Histologically, all of these neoplasms are indistinguishable from B-ALL/LBL not otherwise specified (NOS), and there are minor immunophenotypic correlations with specific abnormalities [25]. Details of each entity are discussed in other chapters.

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

Morphologically and immunophenotypically, the neoplastic cells of chronic lymphocytic leukemia (CLL) are identical to those of nodal-based small lymphocytic lymphoma (SLL), and the two entities are thought to represent different manifestations of the same disease. Many patients who present with nodal-based SLL also have subclinical peripheral blood involvement, and progression to overt CLL occurs frequently. Clinical data also suggest that patients with CLL or SLL can be treated similarly [26]. The designation SLL is now applied to patients who have tissue involvement by a lymphoma that morphologically and immunophenotypically represents CLL/SLL, but with no evidence of leukemia. In the absence of extramedullary tissue involvement, diagnosis of CLL requires $\geq 5 \times 10^9$/L monoclonal lymphocytes with a CLL phenotype in the peripheral blood. The designation of monoclonal B lymphocytosis (MBL) is used for patients who do not fulfill this criterion [27]. Progression to CLL occurs in approximately 1–2% of persons with MBL per year [27].

CLL/SLL represents approximately 12% of all B-cell lymphoid neoplasms. CLL/SLL occurs primarily in middle-aged and older patients with a peak incidence in the sixth to eighth decades. The ratio of male to female cases is approximately 1.5:1. Clinically, CLL/SLL is associated with generalized lymphadenopathy. Although patients frequently have

stage III or IV disease, CLL/SLL patients usually have an indolent clinical course with only vague symptoms such as weakness and anorexia; occasionally they have systemic symptoms [26].

When involved by CLL/SLL, the normal lymph node architecture is usually extensively effaced, but in some cases sinuses are patent. At low power, vaguely nodular, pale areas are usually present that can be small or prominent and represent proliferation centers, also known as pseudo-follicular growth centers or pseudofollicles (Fig. 40.2) [28, 29]. Cytologically, the neoplastic cells are predominantly small round lymphocytes with inconspicuous nucleoli, clumped chromatin, scanty cytoplasm, and infrequent mitoses. However, slightly larger lymphoid cells with irregular nuclear contours (known as prolymphocytes) and large cells with round vesicular nuclei and central nucleoli (known as paraimmunoblasts) are also found. These cells are most numerous in the proliferation centers. In some cases, these proliferation centers can surround residual benign germinal centers mimicking a marginal zone pattern [30].

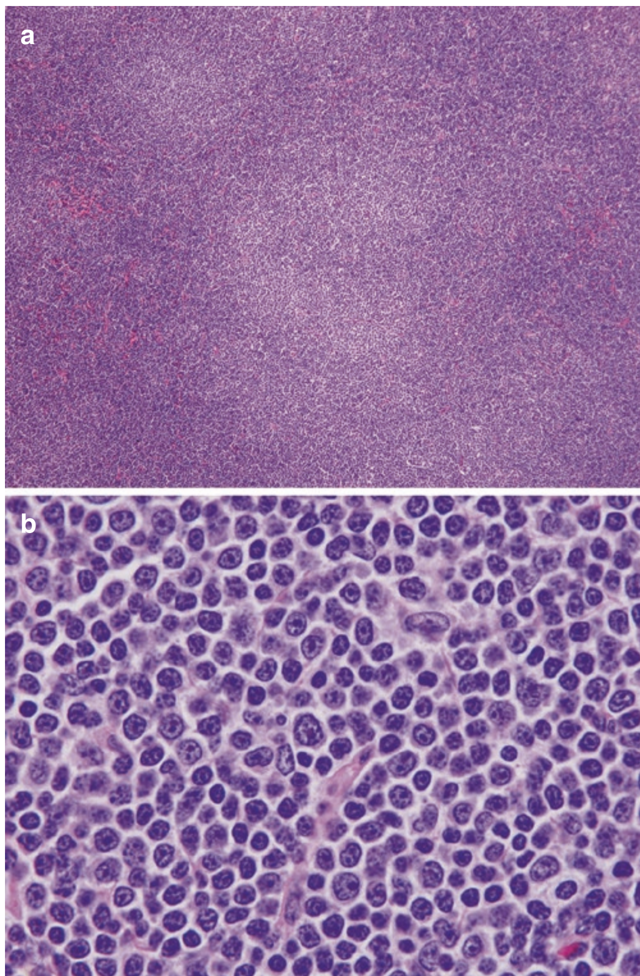

Fig. 40.2 Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) involving lymph node. (**a**) Pale nodules seen at low magnification represent proliferation centers characteristic of CLL/SLL. (**b**) High magnification of proliferation center shows small lymphocytes, prolymphocytes (slightly irregular nuclear contours), and fewer large paraimmunoblasts (with nucleoli). ((**a**) hematoxylin-eosin, 100×; (**b**) hematoxylin-eosin, 400×)

In tissue culture, CLL/SLL cells can be induced to secrete Ig, suggesting that these tumors are composed of cells at a presecretory stage [31]. Furthermore, a small subset of CLL/SLLs exhibit plasmacytoid differentiation. Morphologically, the neoplastic cells in these cases have more abundant cytoplasm and the nucleus may be eccentrically situated. Like plasma cells, these cells contain cytoplasmic Ig that may be secreted producing a monoclonal IgM paraprotein [32]. These patients typically have a low level of monoclonal paraprotein, less than 1.5 g/dL, and these neoplasms behave as do non-plasmacytoid cases of CLL/SLL.

Several studies have suggested that the earliest genetic and epigenetic alterations eventually leading to CLL may occur in pluripotent hematopoietic stem cells (HSCs) [33, 34]. Experiments in mice have shown that HSCs from patients with CLL can engraft efficiently in immunodeficient mice and cause clonal B-cell lymphoproliferations in vivo [33]. These data imply the presence of genetic and epigenetic lesions in HSCs from patients with CLL that skew the potential of HSCs towards the B-cell lineage [33].

Immunophenotypically, CLL/SLL are B-cell tumors that express monotypic Ig light chain (κ > λ), IgM, usually IgD, and pan-B-cell antigens such as CD19, CD20, CD22, CD79A, and PAX5 [35]. The density of Ig and CD20 antigen expression on the surface of CLL/SLL cells is characteristically low corresponding to “dim” immunofluorescence detected by flow cytometry. Bcl-2, CD21, and CD23 are usually positive, and CD79B and FMC7 are usually negative. These neoplasms also express the CD5 antigen, a pan-T-cell antigen that is not expressed on normal B-cells, but is expressed by CLL/SLL. Other T-cell antigens, CD10, Bcl-6, and cyclin D1 are negative. Recently, LEF1 was introduced as a new marker of CLL/SLL. LEF1 is a transcription factor involved in the wnt pathway that is expressed in most cases of CLL/SLL, but rarely in other small B-cell lymphomas [36]. However, it is reported that LEF1 is expressed in ~40% of cases of diffuse large B-cell lymphoma [36].

Chromosomal abnormalities have been shown in CLL/SLL, and are best detected by fluorescence in situ hybridization (FISH) as CLL/SLL cells grow poorly in cell culture [37]. Most FISH panels for CLL/SLL include probes to detect del(13q14), del(11q22) *ATM*, del (6q), del (17p13) *TP53*, and trisomy 12. Del (13q14) is most common (50–60% of patients) and is generally associated with a favorable prognosis, although a subset of patients with deletions involving the retinoblastoma 1 (*RB1*) tumor suppressor gene (−20% of CLL cases) have a less favorable outcome [38, 39]. Deletions of 11q22/*ATM* and (17p13) *TP53* are associated with poorer prognosis. The pathogenetic genes involved

in del(13q14), del(6q), and trisomy 12 are unknown. All together, approximately 75–80% of CLL/SLL cases have abnormalities detected using FISH panels.

A small subset of CLL/SLL cases carries chromosomal translocations further contributing to the molecular heterogeneity of CLL/SLL. Overall, these cases represent less than 10% of all CLL/SLL cases. Translocations involving the *BCL2* oncogene at 18q21 occur in <5% of cases. t(14;18)(q32;q21)/*IGH-BCL2* as well as t(2;18) or t(18;22) translocations involving the *IGK* (chromosome 2p13) or the *IGL* (chromosome 22q11) light chain genes occur. The *BCL3* oncogene, involved in t(14;19)(q32;q13), has been identified in a small subset of CLL/SLL, and correlates with a poorer prognosis and the presence of trisomy 12 [40]. The t(2;11) involving *BCL-11a* occurs in 1–2% of cases.

Genetic analysis of cases of CLL/SLL has shown that this disease has a number of molecular subsets. The variable region genes of the Ig heavy and light chain genes may be mutated (>2% change in germline sequence) or unmutated. Mutated cases of CLL/SLL are clinically indolent and patients have much longer median survival than patients with unmutated CLL/SLL [41, 42]. This may be attributable to defective B-cell receptor signaling in mutated CLL/SLL. As mutational analysis requires sequencing, a relatively labor-intensive procedure, surrogates of Ig mutational status have been sought. ZAP-70 and CD38 have been touted as reasonable surrogates, positive in unmutated cases of CLL/SLL. The correlation, however, is less than perfect.

Recent sequencing studies have shown recurrent mutations in CLL. Mutations in the coding portion of the *NOTCH1* have been reported in up to 10% of patients with CLL at diagnosis, mainly those with CLL of the *IGHV* unmutated subgroup [43–45]. This subgroup shows poorer outcome and increased risk of Richter transformation [46, 47]. Notably, up to 40% of *NOTCH1* mutated CLL patients carry trisomy 12, suggesting functional synergy between these two genetic lesions [48]. Mutations in the splicing factor 3b subunit 1 (*SF3B1*) are observed in up to 10% of the patients, mainly of the IGHV unmutated subgroup, and is associated fludarabine-refractoriness and poorer outcome [43, 49, 50]. Abnormalities of baculoviral IAP repeat containing 3 (*BIRC3)*, gene which regulates the ubiquitin-dependent pathways that modulate NF-κB activation, cause constitutive non-canonical NF-κB activation, and are reported to be associated with poor outcome in CLL/SLL [46]. An additive role of these molecular findings to the traditional FISH-based prognostic model have been proposed, leading to the following classification schema: high-risk CLL/SLL (*TP53* and/or *BIRC3* disrupted); intermediate-risk CLL/SLL (*NOTCH1* and/or *SF3B1* mutated and/or del11q); low-risk CLL/SLL (trisomy 12 or patients with normal karyotype); and very low-risk CLL/SLL (only 13q14 deleted) [51]. Importantly, up to 20% of patients belonging to the low-risk categories by FISH-based analysis were reclassified into higher-risk categories owing to the presence of *NOTCH1*, *SF3B1,* and *TP53* mutations and *BIRC3* disruption [50–52]. This integrated mutational and cytogenetic schema maintains its independent prognostic value during disease progression.

5–10% of cases of CLL/SLL appear to be run in families and there is also evidence for a familial predisposition to CLL/SLL [53, 54]. Several genome-wide association studies have led to the identification of multiple low-risk CLL/SLL susceptibility loci. The genetic basis of familial CLL/SLL, however, is poorly understood.

Approximately 5–10% of CLL/SLL patients develop high-grade lymphoma, also known as Richter syndrome (RS). Molecular findings in CLL/SLL cases that correlate with increased risk of progression to high-grade lymphoma include *NOTCH1* mutations, 8q24/*MYC* translocations, and del(17p13)/*TP53* gene mutations [55, 56]. The most common histologic type of high-grade lymphoma in CLL/SLL patients is diffuse large B-cell lymphoma (DLBCL). About 70–80% of RS-DLBCLs are clonally related to the underlying CLL/SLL and can have unmutated or mutated immunoglobulin heavy chain variable region (IGVH) sequences. Immune deficiency associated with CLL/SLL may be involved in the pathogenesis of clonally unrelated DLBCL. Other less common forms of Richter syndrome include the development of classical Hodgkin lymphoma, plasmablastic lymphoma, and rarely peripheral T-cell lymphoma[57, 58]. Prolymphocytoid transformation of CLL/SLL is also part of the RS spectrum. Approximately half of all cases once designated as B-cell prolymphocytic leukemia are currently better designated as prolymphocytoid transformation of CLL/SLL [59].

Lymphoplasmacytic Lymphoma and Waldenstrom Macroglobulinemia

The terms lymphoplasmacytic lymphoma (LPL) and Waldenstrom macroglobulinemia have evolved in their usage over the past decade, with major changes over the past 15 years. In the current WHO classification, LPL designates a lymphoma composed of small lymphocytes, plasmacytoid lymphocytes, and plasma cells that most often involves the bone marrow, but can involve lymph nodes, spleen, and uncommonly other extranodal sites [60]. A serum IgM paraprotein is very common in LPL. Patients with LPL also can have an IgG or IgA serum paraprotein.

Waldenstrom macroglobulinemia (WM) is considered to be the predominant subset within the LPL category [60–62]. WM is specifically defined as LPL involving the bone marrow that is associated with a serum IgM paraprotein [60]. In other words, WM is a disease of the bone marrow in which a subset of patients has extramedullary disease. Clinically, patients

with WM may present with a variety of symptoms and findings including mucous membrane bleeding, lymphadenopathy, hepatomegaly, peripheral neuropathy, and central nervous system abnormalities [60, 62, 63]. Clinical and laboratory abnormalities that correlate with a poorer prognosis include: age ≥ 65 years, albumin <40 g/L, hemoglobin <11.5 g/dL, platelet count <100 × 10^9/L, beta-2-microglobulin >3 mg/L, and serum monoclonal protein concentration > 7.0 g/dL. These features have been combined into a prognostic index [64]. The serum monoclonal IgM paraprotein concentration is highly variable, with most patients having a paraprotein level greater than 1 g/dL. In our experience, approximately 5–10% of patients present with signs and symptoms of a hyperviscosity syndrome [62]. Lymphadenopathy and hepatosplenomegaly occur in approximately 20% of patients with WM. Leukemic involvement is usually absent, and when present the leukocyte count is usually normal. Lymphadenopathy in WM patients is generalized, but is usually modest.

Histologically, lymph nodes involved by LPL/WM retain their general architecture. The pattern of LPL is diffuse and the cell population is predominantly small lymphocytes, with lesser plasmacytoid lymphocytes, and plasma cells. Intranuclear pseudoinclusions (Dutcher bodies) are common. The neoplastic cells respect sinuses and tend to home to the medullary cord regions [60, 62]. The capsule is extensively infiltrated, and perinodal adipose tissue is involved. It remains challenging to distinguish LPL/WM from nodal marginal zone B-cell lymphoma, particularly in the absence of bone marrow involvement and a serum paraprotein. Histologic evidence of other types of lymphoma that can be associated with a serum paraprotein, for example, proliferations centers as seen in CLL/SLL and monocytoid differentiation as seen in marginal zone B-cell lymphoma, are absent.

The bone marrow is usually replaced by WM in an interstitial or diffuse pattern, but nodular and rarely paratrabecular patterns of involvement occur. Amyloid deposition in the bone marrow or in extranodal sites occurs in small subset of WM patients.

The immunophenotype of LPL is B-cell, with the lymphocytic component expressing surface Ig and B-cell antigens and the plasmacytic component expressing CD19 and cytoplasmic Ig and plasma cell-associated antigens including CD38 and CD138. The Ig heavy chain is usually IgM, but LPL cells can express IgG or IgA. Bcl-2 is positive. The neoplastic cells are usually negative for CD5, CD10, CD23, CD103, and Bcl-6 [65]. CD20 is often expressed variably (dim to moderate or partial).

Next-generation sequencing studies have identified somatic *MYD88* mutations in up to 90% of cases [66, 67]. Although not specific for LPL/WM, *MYD88* mutations are rare or absent in other small B-cell tumors that can mimic LPL/WM, including splenic marginal zone lymphoma (SMZL) (~5%), CLL (~3%), and is very rare or absent in IgM multiple myeloma [67, 68]. Although many different *MYD88* mutations exist, the most prevalent is the L265P missense substitution. In particular, L265P is the sole *MYD88* variant observed in LPL/WM.

In addition to *MYD88*, several additional genes and pathways are concurrently mutated in LPL/WM patients. The chemokine receptor *CXCR4* is the second most commonly mutated gene in LPL/WM (up to 30% of cases) [69]. Nearly all patients with *CXCR4* mutations also carry the *MYD88* L265P mutation. Biologically, of *CXCR4* mutant LPL/WM cells have enhanced signaling downstream of CXCR4 (including BTK activation), as well as increased cell migration, adhesion, survival, and resistance to BTK or PI3Kδ inhibition.

The clinical course of patients with LPL/WM is indolent with median survival ranging from 5 to 10 years in various studies [60, 62]. Approximately 5–10% of patients can develop DLBCL, and, less commonly, LPL/WM patients can develop classical Hodgkin lymphoma. The presence of *CXCR4* mutations negatively affects responses to ibrutinib (BTK inhibitor) treatment in LPL/WM patients.

Follicular Lymphoma

Follicular lymphoma (FL) is a neoplasm of germinal center B-cells that usually exhibits a follicular pattern. Follicular lymphoma is a very common type of NHL in the United States [70]. The median patient age was 59 years in one study, with an age range from 23 to 90 years. Whites are affected more often than blacks. Unlike most other NHLs, women are affected equally or slightly more often than men [70]. Most patients have clinical stage III or IV disease at the time of diagnosis. Involvement of the lymph nodes, spleen, and liver is common. Bone marrow involvement occurs in approximately one-half of patients [70]. A small subset of patients with FL develop clinical evidence of leukemia. The characteristic cell in the peripheral blood has a deeply clefted nucleus and has been referred to as a buttock cell. Leukemic involvement only appears to influence prognosis when the leukocyte count is high. Subclinical involvement of peripheral blood by FL is detected commonly when assessed by molecular methods such as PCR. Rarely pediatric patients can develop FL. This patient subgroup has an excellent prognosis [71].

Histologically, the lymph node architecture is partially or completely effaced by neoplastic follicles, with a paucity of interfollicular tissue (Fig. 40.3). A large absolute number of follicles is the most reliable morphologic criterion for FL [72]. Unlike the lymphoid follicles in reactive hyperplasia, the follicles of FL are relatively uniform in size, lack a well-defined lymphoid cuff, and lack polarization. Histiocytes are usually

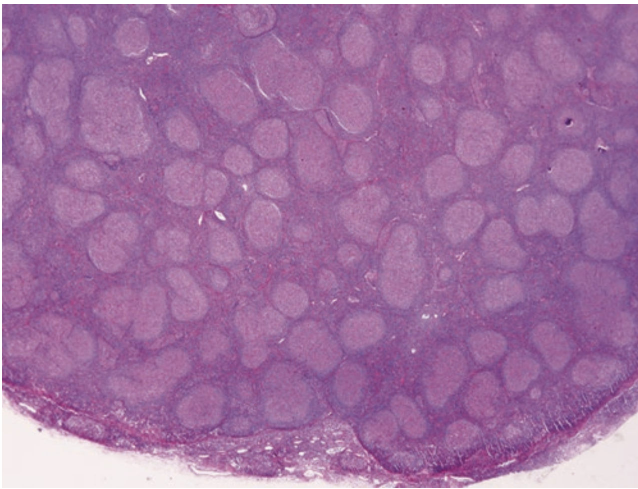

Fig. 40.3 Follicular lymphoma involving lymph node. The neoplasm forms follicles that are spread throughout the lymph node (hematoxylin-eosin, 20×)

less frequent in neoplastic follicles than in reactive follicles. Plasmacytoid differentiation can occur but is rare in FL.

Cytologically, FL cells closely mimic the cell types of normal germinal centers in reactive follicles [70, 72]. Centrocytes have irregular, cleaved nuclear contours and coarse, condensed chromatin. Centrocytes can be small or large (also known as small or large cleaved cells). Centroblasts (also known as large noncleaved cells) are two to three times the diameter of centrocytes with vesicular nuclei and one to three nucleoli. The centroblasts are the proliferating component and therefore the number of mitotic figures correlates with the number of these cells. A small subset of FL, approximately 10%, can exhibit marginal zone (also known as monocytoid) differentiation, manifested by a rim of monocytoid cells located peripheral to the neoplastic follicles. The presence of marginal zone differentiation has been shown to correlate with a poorer prognosis [73].

Grading cases of FL as grades 1, 2, and 3 is based on a count of the centroblasts. In grade 1 FL centroblasts are rare, <5/(high power) 400× microscopic field. Grade 2 tumors have ≥5 centroblasts/400× microscopic field and grade 3 tumors have >15/400× microscopic field. This system also has been modified by subdividing grade 3 FLs into two subsets, 3A and 3B [70, 74]. Grade 3B FL is composed of sheets of centroblasts without centrocytes in the background, and appears to be closely related to de novo DLBCL. The WHO classification suggests that grade 1 and 2 cases of FL can be combined into so-called "grade 1-2" as the clinical behavior of these two patient groups is similar [70]. Others suggest that grade 1, 2, and 3A are similar and can be considered as one group. These opinions will need to be confirmed with follow-up studies.

A component of diffuse pattern is common in biopsy specimens involved by FL, and in some cases the neoplasm can be entirely diffuse without a follicular component. Thus, the presence of neoplastic follicles is highly characteristic of FL, but is not required for diagnosis if the neoplastic cells otherwise have the cytologic, immunophenotypic, and molecular features of FL. Progression from a purely follicular to a follicular and diffuse pattern is common, and the presence of a diffuse component in patients with low-grade FL does not affect survival. A diffuse component, however, usually accompanies an increased number of large cells and therefore a diffuse component is more common in patients with grade 3 FL, particularly grade 3B. When a patient with FL develops a grade 3 tumor that is entirely diffuse, the neoplasm is designated as DLBCL. In biopsy specimens with both follicular and diffuse components, the WHO classification recommends that the components be semi-quantified, especially when the grade of the components is different, for example, follicular lymphoma, grade 1 (50%) with DLBCL (50%).

It is common for an individual patient with FL involving multiple sites to have discordant histologic findings. In this scenario one biopsy site may be involved by low-grade FL and a second biopsy site may be involved by grade 3 FL or DLBCL. This was shown in earlier decades when staging laparotomy was performed for patients with NHL [75]. Discordance is also common when comparing lymph node and bone marrow sites of disease. Lymph nodes may be involved by high-grade FL or DLBCL whereas the bone marrow is involved by grade 1 or 2 FL. In this scenario patient survival is much better than if the bone marrow is involved by grade 3 FL, and therefore bone marrow disease should be graded when possible [76].

Immunophenotypic studies have shown that most FLs express monotypic surface Ig and Igκ is expressed more often than Igλ [77]. Most tumors express IgM, but approximately 25% express IgG or IgA, an expected finding since normal follicular center lymphocytes commonly undergo Ig heavy chain switching following exposure to antigen. IgD is usually negative, since its presence is a feature of naive B cells in the mantle zone. Typically, FLs express Ig and B-cell antigens at high density (bright immunofluorescence). A subset of FLs, mostly grade 3, can be negative for surface Ig.

FLs express pan-B-cell markers, and most are positive for the germinal center B-cell associated antigens CD10, Bcl-6, germinal center B-cell expressed transcript-1 (GCET; also known as centerin), and human germinal center-associated lymphoma (HGAL), and are negative for T-cell antigens including CD5. Within the neoplastic follicles, meshworks of follicular dendritic cells can be appreciated that express CD21, CD23, or other follicular dendritic cell associated antigens. Bcl-2 is expressed in 80–90% of FL; as Bcl-2 is negative in reactive germinal centers, this marker is helpful in differential diagnosis. The centroblasts in FL commonly express activation and proliferation-associated (e.g., Ki-67) antigens. Koster and colleagues have suggested that prolif-

eration rate assessed by Ki-67 immunostaining is prognostically more predictive than grading [78].

The molecular hallmark of FL is the t(14;18)(q32;q21) [79]. Cytogenetic analysis has demonstrated t(14;18) in ~90% of cases. In this abnormality, the *BCL2* oncogene on chromosome 18q21 is juxtaposed with the joining region of the *IGH* gene on chromosome 14q32. The *BCL2* gene is deregulated, by being placed under the influence of *IGH* gene regulatory elements. The presence of t(14;18) alone does not appear sufficient for neoplastic transformation since this translocation has been identified in rare cells in the tonsils, lymph nodes, and blood of normal individuals without clinical evidence of lymphoma [80].

The Bcl-2 protein is a 25-kd molecule that is overexpressed in FLs and protects cells from programmed cell death (apoptosis). The inhibition of apoptosis prolongs cell life, resulting in an expanded compartment of B-cells at increased risk for additional molecular defects, presumably involved in neoplastic transformation. Fluorescence in situ hybridization (FISH) is an excellent way to demonstrate the t(14;18)(q32;q21) as the probes are large and cover most breakpoints [5]. There are at least three important breakpoint clusters in the *BCL2* gene for which PCR have been developed. The two most commonly assessed breakpoint regions are the major (MBR) and minor (MCR) breakpoint cluster regions, involved in 50–60% and 5–10% of cases, respectively [5]. An intermediate cluster region (ICR) also is involved in 10–20% of cases.

Gene expression profiling performed on cases of FL has shown that the host microenvironment has prognostic significance [81]. Molecular signatures corresponding to host T-cell subsets and macrophages are associated with better or worse survival [81, 82]. Another important finding is that gene expression patterns are different in tumors with the t(14;18)(q32;q21) versus tumors without this translocation. Recent advances in next generation sequencing have provided additional insights into the genetic basis of FL. Mutations in chromatin regulator/modifier genes, such as *CREBBP*, *EZH2,* and *KMT2D* (*MLL2*), are common early events, whereas mutations in *EBF1* and regulators of NF-κB signaling (*MYD88* and *TNFAIP3*) are later events and are often present at the time of transformation [83–85]. These genetic alterations can be used in prognostic scoring systems and are potential therapeutic targets [85].

In Situ Follicular Lymphoma

This term describes a specimen involved by FL in which the follicles are of normal size and not easily recognized as FL; however, some of the follicles strongly express CD10 and Bcl-2 (Fig. 40.4) and carry monoclonal *IGH* gene rearrangements and often *IGH-BCL2*/t(14;18)(q32;q21) [86]. Although the term is somewhat "catchy," it may be somewhat misleading as "in situ" in this context does not convey meaning similar to an in situ tumor at other anatomic sites (e.g., cervical carcinoma). A small subset of patients with in situ FL has simultaneous or subsequently develops morphologically obvious FL at other sites. The term in situ *follicular neoplasia* is suggested by the who classification for this lesion.

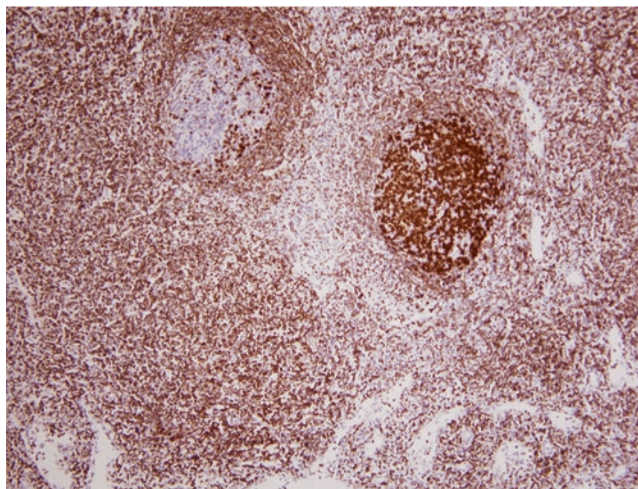

Fig. 40.4 Follicular lymphoma (FL) in situ involving lymph node. In routine histological sections this lymph node looked normal. Bcl-2 immunostaining of the two follicles in this field shows a mostly reactive follicle on the t (Bcl-2 negative) and in situ FL on the right (Bcl-2 strongly positive) (immunohistochemistry with hematoxylin counterstain, 100×)

Extranodal FL

Follicular lymphoma also can arise at extranodal sites. Although the morphologic features of FL at extranodal sites, in large part, resemble neoplasms in lymph nodes, there are important immunophenotypic and molecular differences [70]. Extranodal sites of FL are commonly Bcl-2 negative and lack the t(14;18)(q32;q21). The WHO classification emphasizes the distinctive nature of duodenal-type FL, which has features of a localized low-grade FL, but is distinct from other gastrointestinal tract FL, and has some features resembling in situ follicular FL or MALT lymphoma (see below). Patients with extranodal FL appear to have an excellent outcome, with some patients managed with a watch-and-wait strategy.

Pediatric-Type FL

Pediatric-type FL was recognized specifically in the 2016 update of the WHO classification [17]. These neoplasms preferentially affect boys, who typically present with localized peripheral lymphadenopathy, most often in the cervical region [87]. Pediatric FL typically presents with stage I disease with high histologic grade, expression of CD10 and Bcl-6, and a high proliferation index (Ki67 > 30%), but progression is uncommon and prognosis is excellent [87, 88]. These neoplasms lack *BCL2* or *BCL6* rearrangements, are usually negative for Bcl-2 expression, and often carry *MAP2k1 mutations*.

FL with 1p36 Deletion

A subtype of t(14;18)-negative follicular lymphoma with a predominantly diffuse growth pattern shows deletions in the chro-

mosomal region 1p36 [89]. Patients typically present with painless large lymphadenopathy often in the inguinal area. 75% of patients have localized (stage I or II) disease, and the lymphomas are histologically all low grade. CD23 is often positive. The prognosis is favorable.

Large B-Cell Lymphoma with *IRF4* Rearrangement

This lymphoma typically occurs in Waldeyer ring and/or cervical lymph nodes of children and young adults, and usually presents with low stage [90]. These tumors may have a follicular, follicular and diffuse or pure diffuse growth pattern resembling FL grade 3B or a DLBCL, and strong Irf-4/Mum-1 expression is seen usually with BCL-6 and a high Ki-67 proliferation index. CD10 is expressed in more than half of the cases, and they are most often of germinal center type, particularly based on gene expression profiling studies [90]. Most cases have *IRF4* translocations also involving immunoglobulin gene loci. These tumors uniformly lack *BCL2* rearrangements [90]. Patients with these tumors usually have a favorable prognosis.

Extranodal Marginal Zone B-Cell Lymphoma of Mucosa-Associated Lymphoid Tissue (MALT Lymphoma)

Prior to the advent of immunologic and gene rearrangement techniques, the diagnosis of extranodal low-grade B-cell lymphoma was established infrequently. Extranodal infiltrates composed of small round or slightly irregular lymphoid cells, often admixed with plasma cells, histiocytes, and lymphoid follicles were often classified as *pseudolymphomas*, since clinical studies showed that patients with these lesions pursued an indolent clinical course. Immunophenotypic and gene rearrangement studies have since shown that approximately 60–70% of pseudolymphomas express monotypic Ig light chain and contain immunoglobulin gene rearrangements [91, 92]. Thus, these tumors are now classified as low-grade B-cell lymphomas, and in most cases represent extranodal marginal zone B-cell lymphomas of MALT (MALT lymphoma).

MALT lymphoma was originally described by Isaacson and Wright [93] as a subset of gastrointestinal lymphomas in European patients that resembled immunoproliferative small intestinal disease (IPSID, also known as Mediterranean lymphoma). Subsequently, MALT lymphomas were identified in a variety of extranodal sites including the thyroid gland, thymus, breast, conjunctiva, gallbladder, cervix, larynx, trachea, dura, skin and kidney, as well as other sites [94]. Thus, the term MALT lymphoma, although it continues to be used, is somewhat misleading in the sense that not all MALT lymphomas arise in sites involving mucosal surfaces. Given this wide number of sites involved, the diversity of pathogenesis, and the varied molecular findings (see below), one can now make the argument that these neoplasms should no longer be grouped together as an "entity." However, these tumors do share morphologic and immunophenotypic similarities and are indolent clinically. MALT lymphomas represent approximately 7–8% of all NHL [94].

Patients with MALT lymphoma tend to have localized disease for prolonged intervals before disseminating. This is particularly true for patients with gastric MALT lymphoma whereas patients with non-gastric tumors more often present with stage III or IV disease or disseminate more often [95, 96]. Anatomic sites that are commonly involved by nodal low-grade B-cell NHLs, such as the bone marrow, liver, spleen, and peripheral blood, are infrequently involved by MALT lymphomas. With prolonged follow-up, patients with MALT lymphoma relapse frequently, and relapses often occur in other extranodal sites [94]. In a multivariate analysis at MD Anderson Cancer Center, factors that independently predicted overall survival included elevated serum beta-2 microglobulin level, presence of B symptoms, and male gender [97].

Histologically, four findings are present in most MALT lymphomas: a population of neoplastic small lymphoid (centrocyte-like) cells, occasional large lymphoid cells, reactive lymphoid follicles, and lymphoepithelial lesions when the MALT lymphoma involves a site that normally has glandular epithelium (Fig. 40.5) [94]. The neoplastic small lymphoid cells exhibit a range of cytologic appearances. In some neoplasms these cells closely resemble small lymphocytes, with or without plasmacytoid differentiation. In other neoplasms, the tumor appears biphasic: one component is characterized by small lymphoid cells with minimal cytoplasm, and the other component exhibits extensive plasmacytoid differentiation with many cells resembling mature plasma cells. Plasmacytoid differentiation tends to be more prominent in non-gastric tumors. In other tumors, the neoplastic cells have markedly irregular nuclear contours and resemble small cleaved lymphocytes (centrocyte-like cells). The lymphoma cells may have abundant pale cytoplasm with well-defined cytoplasmic membranes imparting a monocytoid appearance.

In most MALT-lymphomas, occasional large lymphoid cells are also present, which is not surprising since the natural history of a subset of low-grade lymphomas is to accumulate large cells and then progress to a high-grade lymphoma. When the large cells are numerous and form confluent sheets, the neoplasm has evolved to DLBCL. Use of the term *high-grade MALT-lymphoma* is not recommended [94].

Reactive lymphoid follicles are also usually present in MALT lymphomas, usually surrounded by neoplastic small lymphoid cells. These neoplastic cells may accumulate within these follicles (termed *colonization*), and the tumor acquires a nodular low-power appearance [98]. These neoplasms are not truly of follicle center cell origin. When MALT lymphomas involve a site that normally has epithelium (e.g., stomach), the neoplastic cells have a marked tendency to infiltrate epithelium, forming so-called lym-

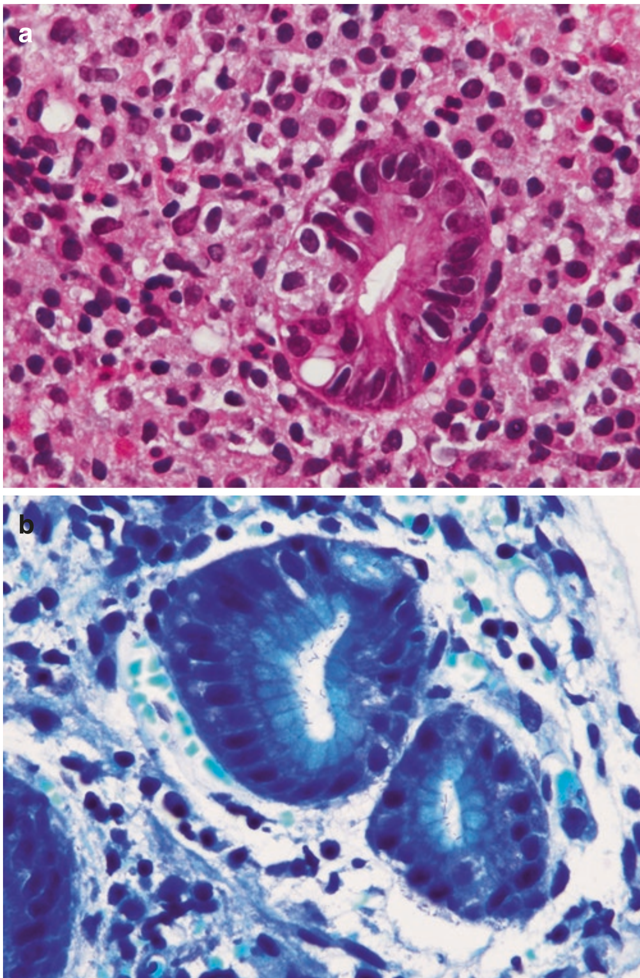

Fig. 40.5 MALT lymphoma involving the stomach. (**a**) Small lymphoma cells infiltrate a gland forming a lymphoepithelial lesion. (**b**) Giemsa stain highlights Helicobacter pylori species on surface of glandular epithelium ((**a**) hematoxylin-eosin, 1000×; (**b**) giemsa, 1000×)

phoepithelial lesions. In these lesions, three or more neoplastic B-cells are found within the epithelium, usually associated with evidence of epithelial damage. In addition to these common histologic findings in MALT lymphomas, there are also important site-specific differences.

In the stomach, normal lymphoid tissue is not present, however, benign MALT is acquired, often in response to *Helicobacter pylori* infection (Fig. 40.5) [94, 99]. Approximately 30% of cases of *H. pylori*-induced chronic gastritis are associated with lymphoid follicles; a smaller subset of cases also develops lymphoepithelial lesions. Conversely, over 75% of gastric MALT lymphomas are associated with *H. pylori* infection. Studies also have shown that benign MALT tissue and MALT lymphomas often regress following antibiotic therapy appropriate for *H. pylori* [100].

Gastric MALT lymphoma is indirectly influenced by *H. pylori* infection through T-cell stimulation, and recent studies have shown that *H. pylori*-triggering chemokines and their receptors, *H. pylori*-associated epigenetic changes, *H. pylori*-regulated miRNA expression, and tumor infiltration by CD4+/CD25+ regulatory T cells all contribute to lymphomagenesis of gastric MALT lymphoma [101–103]. It is also reported that the *H. pylori* protein CagA is incorporated into human B lymphocytes. Intracellular CagA coimmunoprecipitates with SHP-2, suggesting that it stimulates the proliferation of B cells by regulating intracellular signaling pathways, such as the activation of ERK and p38 MAP kinase and upregulation of expression of Bcl-2 [104].

Other associations between infectious agents and MALT lymphoma have been identified. *Chlamydia psittaci* has been associated with up to one-third of MALT lymphomas in the ocular adnexal region, *Borrelia burgdorferi* with a subset of cutaneous MALT lymphomas, and *Campylobacter jejuni* in MALT lymphoma involving the small intestine [105–107]. There are other studies, however, showing a low frequency of infectious organisms in patients with MALT lymphoma. Possibly geographic differences explain these discrepancies.

In the normal adult lung, MALT tissue is also poorly developed and inflammatory conditions usually precede the development of MALT lymphoma. Two inflammatory diseases are frequently associated with lung MALT lymphoma, Sjogren syndrome and lymphoid interstitial pneumonia [94]. Similarly, MALT lymphomas of the salivary gland are usually associated with Sjogren syndrome and Hashimoto thyroiditis frequently precedes MALT lymphoma of the thyroid gland. Patients with Sjogren syndrome have a 44-fold increased risk of developing lymphoma, most of which are MALT lymphomas [94]. Similarly, patients with Hashimoto thyroiditis have a 70-fold increased risk of lymphoma involving the thyroid gland, most of which are MALT lymphomas [108].

Immunophenotypic studies have shown that MALT lymphomas express monotypic Ig light chain, usually IgM, pan-B-cell antigens, and Bcl-2. IRTA1 and MNDA highlight a major subset of MALT lymphomas and appear to be helpful. These tumors typically do not express IgD, CD10, Bcl-6, cyclin D1, or T-cell antigens including CD5. There are no specific immunophenotypic markers for MALT lymphoma.

MALT lymphomas carry monoclonal immunoglobulin rearrangements. In a small study of four patients with multiple sites of disease, VDJ sequence analysis of the *IGH* gene showed that different sites of MALT lymphoma were not clonally related in 3 patients [109]. Approximately 10 chromosomal translocations have been characterized or partially characterized in MALT lymphomas [110]. These translocations, in aggregate, have been shown in approximately 30–40% of MALT lymphomas. These data indicate that MALT lymphoma is highly heterogeneous at the molecular level. Four translocations, to date, are relatively well characterized.

The t(11;18)(q21;q21) has been identified in 20–30% of MALT lymphomas [111, 112]. In this translocation (*BIRC3*) on 11q21 and *MALT1* on chromosome 18q21 are disrupted and recombine to form a novel *BIRC3-MALT1* fusion gene. *BIRC3* belongs to a protein family known as inhibitors of apoptosis proteins (IAP) that are evolutionary conserved and play a role in regulating apoptosis. *MALT1* is a novel gene that encodes a paracaspase that is critical to *BIRC3/API2* is critical to the function of API2-MALT1, which is known to activate NF-κB [113]. This translocation is common in stomach and lung MALT lymphomas.

The t(14;18)(q32;q21) occurs in 10–20% of MALT lymphomas, most often involving the ocular adnexal region, skin, and salivary glands [114]. This translocation juxtaposes *MALT1* at chromosome 18q21 with *IGH* on chromosome 14. This translocation has been implicated in NF-κB activation [113]. The t(3;14)(p14.1;q32) has been reported in up to 10% of MALT lymphomas and most commonly is found in tumors involving the ocular adnexal region, thyroid gland, and skin [115]. t(1;14)(p22;q32) is an uncommon translocation identified in less than 5% of MALT lymphomas that juxtaposes *BCL10* at 1p22 adjacent to *IGH* at 14q32 [116, 117]. The translocation truncates *BCL10* and thus Bcl-10 protein loses its pro-apoptosis function. The t(1;14) occurs most often in MALT lymphomas of the small intestine. *BCL10* mutations also occur outside the context of the t(1;14), in 7–10% of MALT lymphomas [117]. These mutations consist predominantly of deletions or insertions and are predicted to result in truncated proteins.

MALT lymphomas can be divided into translocation-positive and translocation-negative groups. For cases with translocations, the NF-κB pathway appears to be an important common pathway of activation [118]. Translocation-negative MALT lymphomas overexpress genes involved in inflammation and immune response, such as interleukin-8, CD28, and CD86, among others [118]. Other molecular abnormalities have been identified in MALT lymphomas. Trisomy 3 is present in approximately 20% of cases [119]. Trisomies 3 and 18 and del(6q23) occur at a similar frequency among different anatomical sites. Gains at 6p are more common among MALT lymphomas involving the orbital adnexa [120]. Gastric MALT lymphomas have a higher frequency of 8q gains [120]. *MYD88* is deregulated in a small subset of patients with MALT lymphoma (6%), and novel mutation and deletion were reported, in addition to L265P [121, 122].

Alpha Heavy Chain Disease

This disease is also known as immunoproliferative small intestinal disease and as Mediterranean lymphoma [94]. In alpha heavy chain disease the neoplastic cells secrete a form of truncated IgA that cannot bind to Ig light chain, as a result of deletions in the VH or CH1 regions of *IGH*. Morphologically and immunophenotypically alpha heavy chain disease resembles MALT lymphoma, most commonly with extreme plasmacytic differentiation. Patients who live in countries around the Mediterranean Sea or in South Africa are most commonly affected and the disease is associated with poor living conditions. Patients present with diarrhea or malabsorption as a result of disease involving the small intestine and mesenteric lymph nodes. Other gastrointestinal tract sites also can be involved. This disease may respond to antibiotic therapy.

Nodal Marginal Zone Lymphoma

These neoplasms were originally recognized by their cytologic resemblance to reactive monocytoid B-cells, hence the term *monocytoid B-cell lymphoma* was proposed by Sheibani and colleagues [123]. Subsequently, it became more clear that the neoplastic cells differ from reactive monocytoid cells in their location within the lymph node and immunophenotype. These tumors are currently thought to originate in the lymph node marginal zone and are designated as nodal marginal zone B-cell lymphoma (NMZL) in the WHO classification [124]. The designation as nodal (versus extranodal or splenic) in the WHO system is based on arbitrary clinical criteria. A MZL in lymph node is considered as nodal if there is no evidence of extranodal or splenic disease [124]. NMZL represents less than 2% of all NHLs.

Patients with NMZL are usually adults in the sixth or seventh decades with a slight female preponderance in some case series [125, 126]. The clinical course is indolent and B-type symptoms occur in approximately one-third of patients, similar to patients with other systemic low-grade B-cell NHL. Most patients present with peripheral lymphadenopathy, often initially detected as localized lymph nodes in the head and neck region, but widespread lymphadenopathy is also common. Bone marrow involvement is detected at a variable frequency in different studies, ranging from approximately 30 to 60%. Hepatitis C infection is associated with cases of NMZL mostly in Europe [125]. A serum paraprotein, usually at a low level, and composed of IgG, IgA, or IgM, has been reported in up to one-third of patients.

Histologically, lymph nodes involved by NMZL have a pale low power appearance as a result of the abundant cytoplasm of the neoplastic cells. These tumors can show a variety of patterns [124, 127, 128]. A diffuse pattern is most frequent, but NMZLs can colonize follicles imparting a nodular pattern that mimics FL. Uninvolved follicles often contain hyperplastic germinal centers. The cytologic features of NMZL are heterogeneous. The most distinctive cell type is the monocytoid lymphocyte which often predominates in cases of NMZL. The cytoplasm of monocytoid cells is relatively abundant, pale eosinophilic or clear, with well-

delineated cell borders. The tumor cell nuclei are small and cytologically bland. The tumor cell chromatin is relatively clumped and mitotic figures are infrequent. NMZLs also can be composed of centrocytes-like cells or cells with plasmacytoid differentiation. Large cells are also present in variable numbers, but if sheets of large cells are present the neoplasm has transformed to DLBCL. Bone marrow involvement is often observed in NMZL, ranging from 19% to 62% of cases reported in the literature [124, 128].

The diagnosis of nodal marginal zone lymphoma is one of the remaining problem areas in hematopathology, because no established positive markers exist for this lymphoma. Immunophenotypic studies have shown that NMZLs are mature B-cell neoplasms that express monotypic Ig light chain usually IgM, pan-B-cell antigens, CD11c, CD43, and Bcl-2 [124]. IRTA1 and MNDA are positive in a subset of NMZL and are rarely positive in FL [129]. These tumors usually do not express CD10, CD21, CD23, Bcl-6, cyclin D1, and T-cell antigens including CD5. Most cases are negative for IgD but approximately 15% of NMZLs are positive.

The molecular pathogenesis of NMZL is poorly understood. The immunoglobulin (IG) genes are rearranged and the IG variable regions commonly show somatic mutations. Recent gene expression studies have suggested deregulation of the NF-κB pathway [130]. Mutations in PTPRD, NOTCH2, KMT21) KLF2 occur in 20-35% of ases (131).

Multiple studies have investigated the cytogenetic features of NMZL using classical cytogenetics, comparative genomic hybridization, and FISH. No specific alterations have been identified. Gains of chromosome 1q, 2p, 3p, 3q, 6p, and 6q are most frequent, as are losses of 1q and 6q; chromosomes 3, 12, and 18 most often show trisomy, and monosomy is more rarely observed and most frequently involves chromosomes 9, 13, and 14 [121, 131, 132].

Translocations known to occur in MALT lymphoma do not occur in NMZL. Multiple translocations have been sporadically reported in NMZL, but they do not share a common breakpoint region. Some studies have shown translocations involving *BCL6* in a subset of NMZL.

Pediatric Nodal Marginal Zone Lymphoma

Nodal MZLs in children have distinctive clinical and morphological characteristics [17, 133]. There is a striking male predominance (M:F = 20:1), the median age is 16 years old, and 90% of patients present with Stage I lymphadenopathy, usually cervical [133]. Histologically, these tumors are similar to that seen in adults except that there are often features of progressive transformation of germinal center in which the outer border of follicles is disrupted and infiltrated by lymphoma cells [133]. The prognosis of patients with pediatric nodal MZL is excellent.

Splenic Marginal Zone B-Cell Lymphoma

Splenic marginal zone B-cell lymphoma (SMZL) was named by Schmid and colleagues [134] because these neoplasms were thought to arise from splenic marginal zone B-cells, and to be closely related to other marginal zone B-cell lymphomas. The cell of origin of SMZL, however, and its relationship to other marginal zone neoplasms is currently uncertain [135].

Patients with SMZL are adults, usually elderly, and have a characteristic disease distribution: spleen, splenic hilar and other abdominal lymph nodes, and bone marrow. Peripheral blood is often involved and the cells commonly have irregular or villous cytoplasmic projections, hence the older name splenic B-cell lymphoma with villous lymphocytes. Patients present with splenomegaly and laboratory abnormalities, usually anemia or thrombocytopenia, or both [136]. A subset of patients has an associated serum IgM paraprotein and levels can be high [137]. Systemic symptoms are usually absent. Splenomegaly is usually marked, but in a subset of cases the spleen is relatively small and these patients may have early, localized disease. A small subset of SMZL cases harbor hepatitis C virus (HCV), more frequently in southern Europe, and therapy for HCV seems to also affect the control of the tumoral load in these patients [138]. Recently, a high prevalence of SMZL among patients with acquired C1 inhibitor deficiency was reported, although the pathogenesis is not well understood [139].

Grossly, the spleen is usually massive. Histologically, SMZL preferentially involves the marginal zones surrounding lymphoid follicles of the white pulp and, if more extensive, also replaces lymphoid follicles and extends into red pulp [135, 140]. Cytologically, the neoplastic cells have relatively abundant clear cytoplasm and central round, bland nuclei. Plasmacytoid differentiation can be prominent. Mitotic figures are rare and occasional large lymphoid cells are present. Transformation to DLBCL can occur, detected as sheets of large B-cells, and often correlates with a more aggressive clinical course. Almost without exception, SMZL cases have bone marrow involvement. In the bone marrow, neoplasm often shows intrasinusoidal infiltration, and reactive germinal centers also can be present [140].

Immunophenotypic studies have shown that SMZLs are mature B-cell neoplasms that express monotypic Ig light chain, IgM, usually IgD, pan-B-cell antigens, CD11c and Bcl-2. SMZL cells are negative for pan-T-cell antigens, CD10, CD21, CD25, and CD103, and Bcl-6 [135]. Most cases of SMZL are negative for CD5 and CD23, but approximately 20% of cases can be positive for one or both markers. Patients with CD5+ SMZL often have leukemic involvement with high lymphocyte counts raising the differential diagnosis with CLL/SLL [141].

Conventional cytogenetic analysis has shown an abnormal karyotype in up to 75% of cases [135, 142]. Common abnormalities in SMZLs include gains of chromosome 3, more specifically 3q, gains of 12q, and deletions of 6q and 7q. The latter deletions are most often 7q31–32, present in up to 40% of cases. SMZLs contain IG gene rearrangements. The IG variable region genes are commonly mutated [143]. Stereotypes of the IG genes has been shown in approximately 10–30% of cases and are unrelated with the presence of HCV, suggesting a role for antigen drive involved in the pathogenesis of this subset [144]. No well-characterized chromosomal translocations occur in cases of SMZL.

Gene expression profiling of cases of SMZL has shown upregulation of genes involved in intracellular signaling (e.g., *AKT1*) and transcription as well as genes attributable to normal splenic tissue [145]. *MYD88* L265P was detected in up to 15% SMZL cases, and *NOTCH2* mutation has been found in up to 25% of SMZL [146, 147]. A recent study of whole exome sequencing identified novel recurrent inactivating mutations in Kruppel-like factor 2 (*KLF2*) in 42% of SMZLs, but rarely in other B-cell lymphomas [148]. Most *KLF2* mutations were frameshift indels or nonsense changes, with missense mutations clustered in the C-terminal zinc finger domains that suppress NF-κB activation [148]. IGHV1–2 rearrangement and 7q deletion are more common in SMZL with *KLF2* mutation, while *MYD88* and *TP53* mutations are found nearly exclusively in cases without *KLF2* mutation [148].

Splenic Diffuse Red Pulp B-Cell Lymphoma

These neoplasms are low-grade small B-cell neoplasms that diffusely replace the splenic red pulp, unlike SMZLs that preferentially replace splenic white pulp. Based on cytologic and immunophenotypic similarity, the term *splenic marginal zone lymphoma, diffuse variant* also has been used for these tumors. Splenic diffuse red pulp B-cell lymphoma is not well characterized and also resembles cases of so-called hairy cell leukemia variant. The current WHO classification considers splenic diffuse red pulp B-cell lymphoma and hairy cell leukemia variant to be closely related and groups these neoplasms into a provisional entity designated splenic B-cell lymphoma/leukemia, unclassifiable [149]. Recurrent chromosomal alterations frequent in SMZL are infrequent in splenic diffuse red pulp B-cell lymphoma, suggesting that these tumors are a different entity [150]. *NOTCH1*, *TP53*, and *MAP2K1* mutations in splenic diffuse red pulp small B-cell lymphoma are associated with disease progression [150].

Mantle Cell Lymphoma

Mantle cell lymphoma (MCL) is defined as follows: "a B-cell neoplasm generally composed of monomorphic small to medium-sized lymphoid cells with irregular nuclear contours and a *CCND1* translocation" [151]. The two constant components of this definition are B-cell lineage and a *CCND1* translocation, usually t(11;14)(q13;q32), whereas the morphologic appearance can be variable. Thus, the definition of MCL is essentially a molecular definition and this approach has lead to reclassification of a subset of small B-cell lymphomas that morphologically were considered other entities, but are now classified as MCL on the basis of the presence of t(11;14)(q13;q32). MCL represents approximately 6% of all NHLs.

It has been suggested that MCL develops along two pathways [152]. In one pathway, classical MCL is usually composed of *IGHV* unmutated or minimally mutated B cells that usually express the transcription factor SOX11. In the other pathway, MCL develops from *IGHV* mutated SOX11 negative B-cells which leads to leukemic non-nodal MCL, usually involving the peripheral blood, bone marrow, and often spleen [152]. These cases are more frequently clinically indolent. Acquisition of additional molecular/cytogenetic abnormalities, e.g., *TP53* mutation or *MYC* translocation, can lead to more aggressive variants of MCL.

Clinically, patients with MCL are usually elderly, and men are affected more often than women, with a male-to-female ratio of approximately 3 to 1 [153, 154]. B type symptoms occur in 30–40% of patients and 70–80% of patients have stage III or IV disease. Most patients present with generalized lymphadenopathy and bone marrow is commonly involved, approximately 60%. An absolute peripheral blood lymphocytosis of more than 4000/mm [3] is infrequent, but low-level involvement of the blood is common when carefully searched for morphologically or if sensitive molecular techniques are used. Relatively low levels of lymphocytosis probably do not influence survival significantly, but overt leukemia has been associated with a poorer prognosis in some studies [155]. Extranodal disease may occur, usually in association with nodal involvement. Patients may present with numerous polyps involving the gastroesophageal tract below the level of the gastrointestinal junction, also known in the literature as *multiple lymphomatous polyposis* of the intestine. Involvement of Waldeyer ring can occur.

During the CHOP therapy era, patients with MCL had a poor prognosis. R-CHOP generally results in a median PFS of 16–22 months [156, 157]. The importance of high-dose chemotherapy followed by autologous stem cell transplant has been established for patients younger than 65 years old [158]. For elderly patients, maintenance therapy with rituximab and bendamustine is reported to bring better outcome

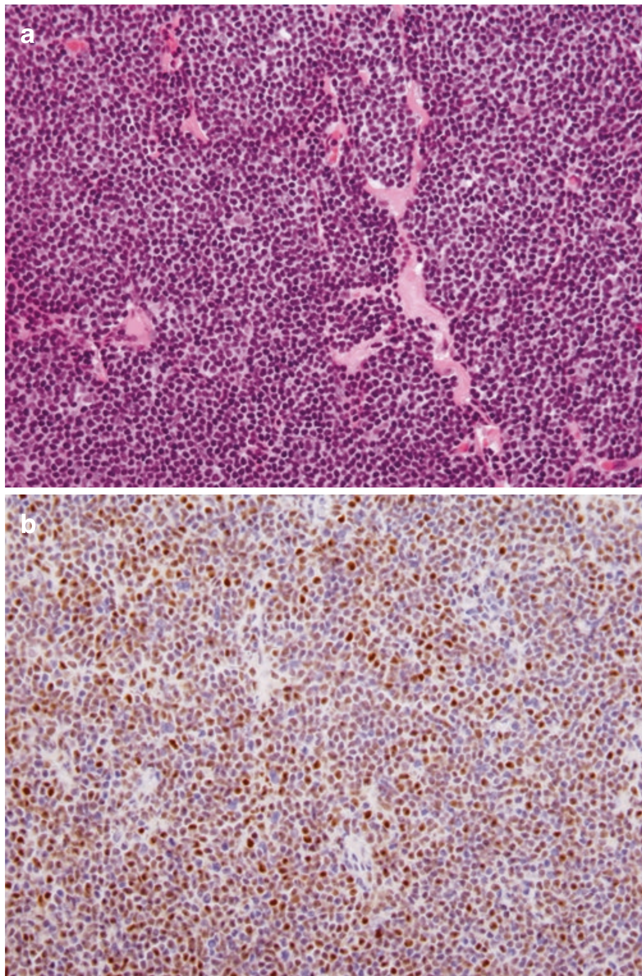

Fig. 40.6 Mantle cell lymphoma involving lymph node. (**a**) The neoplasm is composed of a monotonous population of small cells. Sclerotic blood vessels, common in mantle cell lymphoma, are also shown. (**b**) Cyclin D1 immunostain is positive supporting the diagnosis of mantle cell lymphoma (a. hematoxylin-eosin; b. immunohistochemistry with hematoxylin counterstain, 400×)

[158]. Recently, four agents have been received regulatory approval from FDA for patients with MCL: bortezomib (proteasome inhibitor), lenalidomide (immunomodulator), tensirolimus (mTOR inhibitor), and ibrutinib (Bruton tyrosine kinase inhibitor).

Histologically, MCL replaces the lymph node architecture in a diffuse, nodular, or mantle zone pattern. The mantle zone pattern is rare, occurring as a predominant pattern in less than 5% of cases, and results from the neoplasm selectively involving the follicle mantle zones surrounding germinal centers. Cytologically, typical cases of MCL are composed of a monotonous population of small lymphoid cells that can have slightly irregular or more pronounced irregular nuclear contours (Fig. 40.6) [159]. Large nucleolated lymphoid cells are rare. Other histologic findings common in MCL include numerous eosinophilic epithelioid histiocytes and germinal centers completely surrounded by tumor without a normal lymphoid cuff (so-called naked germinal centers). Plasmacytoid differentiation is rare but can occur in MCL.

Histologically aggressive variants of MCL occur and these can be divided into two types: blastoid and pleomorphic [151]. Blastoid MCLs are characterized by slightly larger lymphoid cells with finely dispersed nuclear chromatin and numerous mitotic features that resemble lymphoblastic lymphoma. Pleomorphic variants of MCL are composed of large cells that resemble, in part, DLBCL. In the blood, there is an aggressive variant of MCL that can resemble B-cell prolymphocytic leukemia. This variant is rare and probably fits within the spectrum of the pleomorphic variant. Histologically aggressive variants of MCL have a more aggressive clinical course, and are independent prognostic factors indicating shorter OS and PFS [160]. In patients who have both typical and pleomorphic variant MCL, either simultaneously of sequentially, clonal identity has been shown in most of the few cases analyzed [161].

Immunophenotypic studies have shown that typical cases of MCL express monotypic Ig light chain (more often Igλ), IgM, IgD, pan-B-cell antigens, Bcl-2, and CD5, and are negative for CD3, CD10, CD21, CD23, CD103, CD200, Irf-4/Mum-1, and Bcl-6 [151]. SOX11 expression has been demonstrated in more than 90% cases of MCL [162]. Using flow cytometry immunophenotyping, unlike cases of CLL/SLL, MCLs typically express brighter surface Ig and CD20, and are usually positive for CD79B and FMC-7. Although CD23 is usually negative in MCL, in 10% of tumors CD23 can be expressed, usually with dim intensity [163]. Cases of MCL can show variant immunophenotypes, but are still recognizable as MCL because they carry t(11;14) and overexpress cyclin D1. Approximately 5% of cases of MCL do not express CD5, or less often can be positive for CD10, Bcl-6, or Irf-4/Mum-1 [151]. In our experience, variant immunophenotypes are more common in histologically aggressive variants of MCL. Ki-67 index is an independent prognostic factor [160].

Conventional cytogenetic analysis of MCL cases has shown that the t(11;14)(q13;q32) involving *CCND1* and *IGH* is present in virtually all cases. This abnormality, however, is present as a sole cytogenetic abnormality in less than 10% of cases [164]. Usually a number of abnormalities are present in MCL and complex karyotypes (≥ 3 abnormalities) are very common. Most of these additional abnormalities include deletions and chromosome copy number changes. Deletions of loci at chromosome 9p21 (*CDK2Na/TPI6*) or 17p (*TP53*) occur relatively often, in up to 20% of cases, and are found mostly in histologically aggressive variants of MCL. Additional balanced chromosomal translocations are uncommon, but t(8;14)(q24;q32)/*MYC-IGH* occurs in a small subset of cases of blastoid variant MCL [165].

MCL has been a subject of intense molecular research in the past decade. A number of high throughput methods have been used to study MCL. These methods have shown that MCL cases have a characteristic, relatively homogeneous gene expression profile. Perhaps this is not unexpected since the definition of MCL is, in large part, based on the t(11;14). These studies also highlighted the importance of proliferation in MCL and how this signature can be used to predict prognosis [166, 167]. Subsequent immunohistochemical studies also have shown that Ki-67 cell counting (proliferating cells) also can be used to predict prognosis in MCL patients treated using a variety of therapeutic regimens [154, 168, 169]. Other methods have shown that there are numerous chromosomal gains and losses, specific deletions, and mutations in cases of MCL. As has been reviewed elsewhere, most of these changes impact the proliferation and cell cycle pathways in the neoplastic cells [170]. Apoptotic mechanisms are also dysregulated in MCL [171].

MCL has mutations affecting many different genes, with *ATM* (40–75%) and *CCND1* (35%) the most frequent [172, 173]. Other mutations are present less frequently, including as *NOTCH1*, *NOTCH2*, *KMT2D*, *WHSC1*, *RB1*, *POT1*, and *SMARCA4*.

Cyclin D1-Negative MCL

In the gene expression profiling study by Rosenwald and colleagues [166], a small subset of lymphomas were identified that morphologically and immunophenotypically resembled MCL, but lacked the t(11;14) as well as cyclin D1 expression. It was suggested these tumors were truly MCL in which aberrant cyclin D2 or cyclin D3 expression was fulfilling the usual role of cyclin D1, hence the designation as cyclin D1-negative MCL. It has become clear that cyclin D1 negative MCL is rare; about 50% of cases carry cyclin D2 translocations detected by FISH or overexpress cyclin D2 shown by RT-PCR [174].

Diffuse Large B-Cell Lymphoma

The diagnosis of DLBCL is based on histologic and immunophenotypic criteria; the tumor is composed of large B-cells with a diffuse growth pattern [175]. DLBCL is the most common type of NHL representing up to 40% of all cases worldwide [175].

In the WHO classification, attempts are made to tease out subgroups of DLBCL on the basis of unique histologic features, distinctive immunophenotypes, or relatively unique clinical presentations (e.g., primary mediastinal large B-cell lymphoma). Cases of DLBCL that cannot be further specified into one of these subgroups are designated as DLBCL not otherwise specified (NOS).

Diffuse Large B-Cell Lymphoma, NOS

DLBCL NOS (henceforth specified as DLBCL) occurs mainly in adults, with a median age in the seventh decade [175–177]. Men are affected slightly more often than women. Although less common in children, DLBCLs represent 15–20% of childhood NHLs. There are differences in immunophenotype and frequency of molecular alterations depending on the geographic region in which DLBCL is being studied. DLBCL can arise *de novo*, or as a transformation event in a patient with low-grade lymphoma, including CLL/SLL, follicular lymphoma, and marginal zone lymphoma.

Patients with DLBCL often have B type symptoms and present with a large, growing mass, often associated with necrosis. Nodal presentation is most common, but extranodal sites are frequently involved, and the disease may be restricted to extranodal sites in up to 40% of patients. A wide variety of extranodal sites can be involved by DLBCL. Approximately half of patients have stage I or II disease. Bone marrow involvement occurs in approximately 20–30% of patients [178]. Two main patterns of bone marrow involvement occur: bone marrow involvement may be concordant in which the cells infiltrating the marrow are large (large cell lymphoma), and this variant is generally associated with poorer OS and PFS [179]. In other cases the lymphoma cells infiltrating the marrow are small and characteristic of low-grade lymphoma (so-called discordant histology). Peripheral blood involvement by large neoplastic cells can be identified in a subset of patients, usually in those patients who have bone marrow disease [175].

If untreated, patients with DLBCL usually die of disease, often within 2 years, however approximately 60% of patients with DLBCL respond well to chemotherapy and can be cured. For years, the mainstay of chemotherapy was the CHOP regimen, but within the past decade rituximab (R) has been added to CHOP and R-CHOP is currently the preferred frontline therapy [180]. Predicting which patients will respond to therapy, however, remains challenging. To address prognostication of DLBCL patients, the International Prognostic Index (IPI) was established in 1993 [181]. The IPI employs five variables, each of which is worth one point: age > 60 years, poor performance status, stage III or IV disease, ≥2 extranodal sites of disease, and above normal serum LDH level. An IPI score of 0–1 indicates good prognosis whereas as an IPI score of 4–5 predicts a poor prognosis and a likely need for more aggressive therapy than the R-CHOP regimen. More recently, improvements to the IPI have seen suggested to further stratify patients. Although very helpful, the components of the IPI are essentially surrogates of DLBCL biology and it seems likely that in-depth knowledge of DLBCL pathogenesis will lead to better

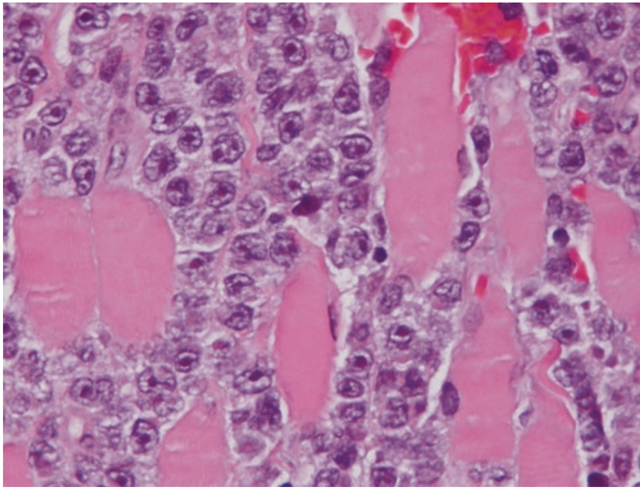

Fig. 40.7 Diffuse large B-cell lymphoma, immunoblastic variant, infiltrating skeletal muscle (hematoxylin-eosin, 1000×)

methods for predicting prognosis as well as identifying specific pathways or molecules for targeted therapy.

Histologically, DLBCLs partially or totally replace normal architecture in a diffuse pattern [175, 176]. Less commonly, DLBCL can partially replace organs, and in lymph nodes, DLBCL rarely can be confined to the interfollicular regions or sinuses. The definition of a large cell is based on nuclear size which needs to be greater than that of a benign histiocyte nucleus; histiocytes are virtually always present admixed within lymphomas. Mitotic figures are usually numerous.

Cytologically, the neoplastic cells in DLBCL can exhibit a spectrum of findings. The most common cytologic variants are centroblastic, immunoblastic (Fig. 40.7), and anaplastic [175]. Centroblasts are 20–30 μm in size and have round or oval vesicular nuclei with two to three nucleoli and more abundant amphophilic cytoplasm. Often one nucleolus is centrally located with one to three additional nucleoli opposed to the nuclear membrane. The term *immunoblast* refers to an activated lymphocyte. Neoplastic immunoblasts resemble transformed lymphocytes; they are larger than centroblasts with a centrally located vesicular round or oval nucleus containing a prominent target-like central nucleolus, and relatively abundant amphophilic cytoplasm. These cells commonly exhibit plasmacytoid differentiation. Anaplastic cells are often very large oval or polygonal cells with pleomorphic nuclei that can resemble, in part, Reed-Sternberg or Hodgkin cells.

Earlier studies of patients with DLBCL showed that patients with the immunoblastic variant had a worse prognosis [182]. However, problems in reproducibly subcategorizing cases of DLBCL lead the WHO classification to group these variants as DLBCL. A recent study has shown that the immunoblastic variant of DLBCL is associated with a poorer prognosis and a high frequency of *MYC* rearrangements, approximately 33% of cases [183, 184].

Approximately two-thirds of cases of DLBCL express monotypic surface Ig light chain, and IgM is the most common Ig heavy chain expressed [175]. Plasmacytoid DLBCLs commonly express monotypic cytoplasmic Ig. Approximately one-third of DLBCLs are Ig negative. DLBCLs express pan-B-cell antigens, 60–70% express Bcl-2, and a subset is positive for CD10, CD23, Bcl-6, or Ifr-4/Mum-1 [175]. DLBCLs are usually negative for T-cell antigens, but approximately 10% of cases can be CD5+. Patients with CD5+ DLBCL are reported to have more aggressive disease [185, 186]. Most cases of DLBCL express activation markers and have a substantial proliferation rate. Major histocompatibility complex (MHC) class I or II antigens can be absent in a subset of DLBCLs; these cases are reported to have a poorer prognosis [175]. CD30 is expressed by a subset of DLBCL and in most cases of the anaplastic variant. Approximately 2% of DLBCL express cyclin D1 [187]. Most cases of cyclin D1+ DLBCL have centroblastic morphology and a post germinal center phenotype positive for Irf-4/Mum-1 [187]. Overexpression of Myc can be detected by IHC in DLBCL cases without a *MYC* translocation [188]. Most studies use a cutoff of 40% or 50% Myc expressing cells to define these cases. In several studies, patients with DLBCL with overexpression of Myc and Bcl-2 protein, so-called double espressor DLBCL, have a poorer prognosis, but not as aggressive as double hit DLBCL with rearrangements of *MYC* and *BCL2* and/or *BCL6* [189].

Gene expression profiling using cDNA microarrays has made its greatest clinical impact in DLBCL. These studies have shown that DLBCL is heterogeneous and can be subdivided into prognostic subgroups [190, 191]. The most popular system divides DLBCL cases into germinal center B-cell like (GCB) and activated B-cell-like (ABC) groups [191]. Patients with GCB tumors have a better prognosis, independent of the IPI, in patients treated with either CHOP or R-CHOP chemotherapy regimens. Virtually all cases of DLBCL with t(14;18)(q32;q21) fall within the GCB group. NF-κB pathway activation has been found to be more prominent in the ABC type [192]. Chronic active B-cell receptor signaling also has been shown in the ABC type [193]. It should be noted, however, that a subset of DLBCLs cannot be classified as either GCB or ABC type, up to 30% in some studies. The GCB and ABC subgroups differ in their chromosomal alterations, activation of signaling pathways, and clinical outcome. Thus, the current WHO classification requires the identification of these two subtypes. As gene expression is not yet readily available for routine diagnosis, a number of groups have suggested various immunohistochemical staining algorithms to predict the GCB versus non-GCB types of DLBCL. One of the most widely accepted is known as the Hans classifier of DLBCL [194]. According to

this scheme cases that are CD10+ in more than 30% of the cells are of GCB type. Cases that are CD10 negative and BCL6+, Irf-4/Mum-1 negative are also in the GCB group. Cases that are Bcl-6-, CD10- or Bcl-6+ and Irf-4/Mum-1+ are in the non-GCB group. There are a number of other competing algorithms for immunohistochemical categorization of DLBCL into GBC or non-GCB types. Two of these systems use FOXP1; FOXP1 and GCET1 by Choi et al. and FOXP1 by Visco et al. [195, 196]. In a multi-center study performed by the Cancer and Leukemia Group B using dose-adjusted EPOCH-rituximab (R) for previously untreated DLBCL, significantly improved time to progression, event-free survival, and overall survival were noted in the GCB group as defined by the Hans method [197]. The efficacy of dose-adjusted EPOCH-R on GCB-DLBCL may relate to its effect on Bcl-6. Although most reports find that immunohistochemical algorithms correlate with prognosis in DLBCL, there are contrary papers arguing that these methods are not reliable surrogates for molecular testing.

Cytogenetics and molecular studies have shown that approximately 50% of DLBCLs carry chromosomal translocations. The most common translocation, in 20–30% of cases, involves chromosome 3q27, the site of the *BCL6* gene [175, 176]. The most common specific translocation is t(3;14)(q27;q32) but there are many others partners of *BCL6* that can be involved in translocations. Another subset of 10–20% of DLBCL cases carries the t(14;18)(q32;q21) involving the *BCL2* and *IGH* genes. The *MYC* oncogene is rearranged in approximately 10% of DLBCLs [175]. These cases are frequently associated with *BCL2*, or to a lesser extent, *BCL6* translocation. These tumors have been referred to as "double hit" or 'triple hit" lymphomas [198–200]. In the revised 2016 WHO classification, these tumors are placed in the new category of high-grade B-cell lymphoma with rearrangements of *MYC* and *BCL2* and/or *BCL6* [17]. In our experience, *MYC* rearrangements are more common in cases with evidence of high proliferation, such as a starry sky pattern or high numbers of Ki-67+ cells. *MYC* rearrangements may involve non-IG or IG partners, most often t(8;14)(q24;q32) involving *IGH*. IG partners convey a poorer prognosis [201]. *MYC* rearrangements are associated with high p53 expression and predict a poorer prognosis even without *BCL2/BCL6* translocation [202].

The IG are rearranged in DLBCL and the IG variable region genes are commonly mutated. *TP53* mutations occur in approximately 15% of DLBCLs and predict prognosis; mutations located specifically in the DNA binding domain of *TP53* are associated with the worst prognosis [203]. *BCL2* is amplified in approximately 20% of cases. Deletions in the *FAS* death domain are reported in approximately 20% of cases, resulting in defects in the extrinsic apoptotic pathway. Other genes that can be mutated in DLBCL with some frequency include *BCL6*, *MYC*, *PAX5*, *PIM1*, and *COK2NA* [204].

Recent molecular studies have identified common somatic mutations in DLBCL but a profile of alterations differentially represented in GCB and ABC subtypes [204]. Somatic mutations common in GCB and ABC DLBCL subtypes are inactivating mutations of *TP53* and genes involved in immunosurveillance (*B2M, CD58*), [204]. GCB-DLBCL carry frequent alterations in chronatin modulating ganes including *CREBBP/EP300, KMT2D/C MEF2* and *EZH2*, *BCL2* translocations, and mutations in the cell motility regulator *GNA13*. ABC-DLBCL have mutations in genes activating the B-cell receptor and Toll-like recepter and NF-κB pathways (*MYD88, CD79A, CARD11, TNFAIP3*) [204]. Mutations in *TP53, FOXO1, MLL3 (KMT2C), CCND3, NFKBIZ,* and *STAT6* have emerged as top candidate genes implicated in therapeutic resistance [205].

T-Cell/Histiocyte-Rich Large B-Cell Lymphoma

T-cell/histiocyte-rich large B-cell lymphoma (TCHRLBCL) is a histologically distinctive type of DLBCL in which the neoplastic large B-cells are few and are associated with numerous reactive T-cells and histiocytes in the biopsy specimen. No cutoff for the number of large B-cells is provided in the WHO classification but <10% is a helpful guideline; B-cells should not be present in aggregates or sheets [206].

Patients with TCHRLBCL tend to be adults with a slight male predominance [207, 208]. Patients often have B-type symptoms and advanced stage disease involving lymph nodes, bone marrow, liver, and spleen. Patients are often refractory to therapy and the disease can resemble DLBCL NOS in relapse biopsy specimens. Some cases of TCHRLBCL may arise from underlying nodular lymphocyte predominant Hodgkin lymphoma (NLPHL).

Histologically, TCHRLBCLs have a diffuse pattern and are composed predominantly of small reactive T-cells and benign non-epithelioid histiocytes [206, 208]. Granulocytes and plasma cells are absent. Usually <5–10% of all cells are singly scattered large, neoplastic B-cells than can appear as centroblasts, immunoblasts, pleomorphic Reed-Sternberg-like cells or lymphocyte predominant (LP)-like large cells. Immunohistochemical studies have shown that the large cells express pan-B-cell antigens, often express Bcl-2 and Bcl-6, and are negative for CD15 and CD138 [206]. The small lymphocytes and histiocytes express T-cell and histiocyte-associated markers, respectively. CD30 can be expressed in a subset of cases.

The large B-cells in TCHRLBCL carry IG gene rearrangements and the IG variable regions genes are commonly mutated. Comparative genomic hybridization has shown

some genetic imbalances, most commonly gains involving chromosome loci Xq, Xp21q11, 4q13q28, and 18q21, and loss of 17p [209]. Gene expression profiling studies have shown that these tumors have a host response signature, which is in keeping with the morphologic and immunophenotypic findings [210].

Differential Diagnosis from NLPHL

In contrast to the indolent clinical behavior of NLPHL, TCHRLBCL is often diagnosed in advanced clinical stages and has a poor prognosis. However, there are variants of NLPHL with histopathologic overlap with TCHRLBCL, especially THRLBCL-like NLPHL, and in small biopsies, it may not be possible to distinguish TCHRLBCL from NLPHL. Gene expression profiling of microdissected tumor cells of NLPHL, TCHRLBL-like NLPHL, and TCHRLBCL have not shown consistent differences in the gene expression profiles of these three entities. Array comparative genomic hybridization of these entities has shown several common and few unique genomic aberrations in NLPHL, TCHRLBL-like NLPHL, and TCHRLBCL, further supporting a close relationship of these entities [9]. Treetipsatit et al. [211] studied 195 cases of NLPHL and TCHRLBCL cases, and found five cases that were difficult to classify according to the current WHO criteria; these cases had a prominent nodular growth pattern with no FDC meshwork. Further refinement of diagnostic criteria is necessary for appropriate classification and clinical management [211].

Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis (LyG), originally described by Liebow and colleagues [212], was originally thought to have features that overlap with malignant lymphoma and Wegener's granulomatosis, leading to its name. LyG is now considered to be neoplastic at onset, is histologically distinctive, is associated with EBV infection, and therefore is included as a type of DLBCL in the WHO classification [213]. LyG is a rare disease.

Patients with LyG are usually middle aged adults (median age 46 years) and there is a male predominance (M:F = 2.2:1) [213]. There appears to be an increased frequency of LyG in immunodeficient patients. Patients present with pulmonary and systemic symptoms and chest radiographs typically show discrete, round masses, most often bilateral [213]. Clinically, all patients have lung involvement (100%), with the next common site being the central nervous system (38%). Other sites that can be involved frequently by LyG include the kidney, liver, and skin. The upper aerodigestive tract is rarely involved [213].

Histologically, LyG is characterized by an angiocentric and angiodestructive infiltrate of many small reactive T-cells with large atypical B-cells, plasma cells, and histiocytes [212, 213]. Granulocytes are rare. Necrosis can be prominent. The large lymphocytes, which represent the malignant cell population, express pan-B-cell antigens and commonly carry Epstein–Barr virus (EBV). The large B-cells can be CD30+, but are always CD15-. In the spectrum of DLBCL, both TCHRLBL and most LyG cases are characterized by the relative rarity of the neoplastic B-cell population with overwhelming background of non-neoplastic surrounding T-cells or histiocytes.

The grading of lymphomatoid granulomatosis relates to the proportion of EBV-positive B-cells relative to the reactive lymphocyte background [213]. It is graded as grade 1 (less than 5 EBV-positive cells/HPF); grade 2 (EBV-positive cells usually 5–20/HPF and occasionally up to 50/HPF); and grade 3 (large aggregates of EBV-positive cells). The natural history of LyG is to accrue large cells and evolve into a process that resembles DLBCL NOS [212].

Polymerase chain reaction studies have shown monoclonal immunoglobulin gene rearrangements and monoclonal EBV episomal DNA in high-grade LyG; demonstration of clonality in grade 1 cases is more inconsistent.

Primary Mediastinal Large B-Cell Lymphoma

The WHO classification defines primary mediastinal large B-cell lymphoma (PMLBL) as DLBCL arising in the mediastinum that is of putative thymic B-cell origin [214]. Applying this definition, however, is not always as easy as it seems clear. A major problem is the difficulty in determining whether a neoplasm arises in the mediastinum and/or the thymus versus mediastinal lymph nodes. Therefore, the category is somewhat "dirty" as it is difficult to exclude all cases of nodal DLBCL that present with a mediastinal mass from the category of PMLBL. The problem is further exacerbated by the increased use of fine needle aspiration and needle core biopsy for diagnosis of mediastinal masses. Although these specimens allow the diagnosis of DLBCL, their small size precludes or makes more difficult the observation of certain features highly suggestive of PMLBL. Despite these limitations, the category of PMLBL has unique clinicopathologic, immunophenotypic, and molecular features [214].

Patients with PMLBL are most often young adults, with onset in the fourth decade [215, 216]. There is a female predominance with a male/female ratio of 1 to 2. Patients typically present with a large, bulky (>10 cm) mass that causes local symptoms such as cough, chest pain, and shortness of breath. Approximately two-thirds of patients present with localized disease and approximately one-third of patients may develop superior vena cava syndrome. Patients typically have high serum LDH levels, but low serum levels of

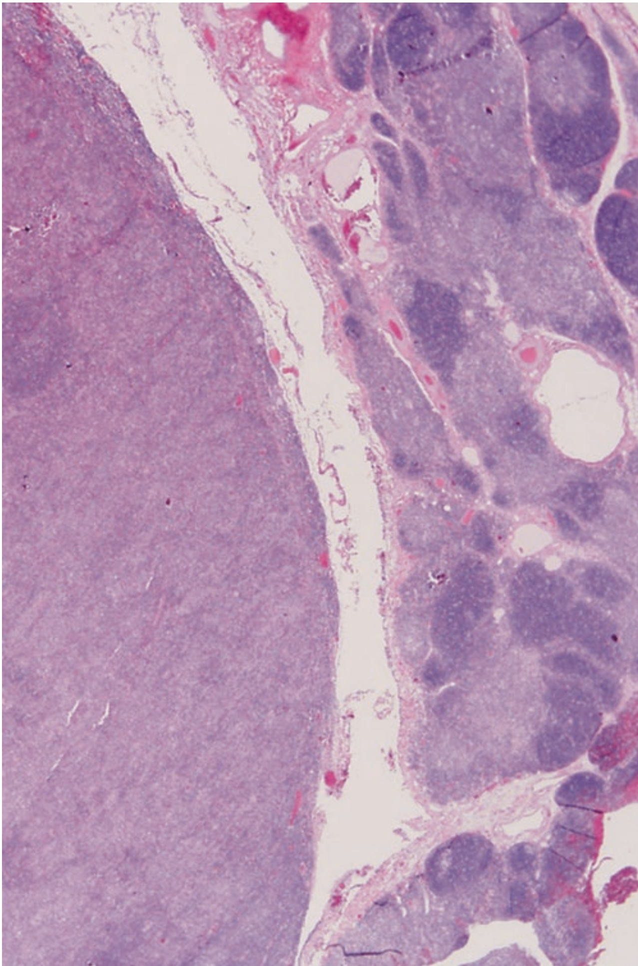

Fig. 40.8 Primary mediastinal (thymic) large B-cell lymphoma. Residual thymus gland is present at the right of the field (hematoxylin-eosin, 20×)

beta-2-microglobulin. Bone marrow involvement or dissemination of disease at the time of diagnosis is absent as, by definition, their presence supports systemic disease [214]. Admittedly, this is a clinical definition that is somewhat arbitrary as patients with PMLBL can theoretically disseminate before first diagnosis of disease. The optimal treatment of PMLBL has not been firmly established. R-CHOP, usually followed by radiotherapy, is the most widely used regimen, but 20–25% of patients still relapse or progress [217]. Better results have been reported with the dose-adjusted EPOCH-R [218]. Relapses commonly occur at extranodal sites, most commonly kidney, liver, adrenal gland, and brain [214].

Histologically, PMLBL diffusely replaces the thymus Fig. 40.8 and invades into contiguous structures including the lungs, pleura, pericardium, and can spread to regional lymph nodes. PMLBL is composed of large lymphoid cells that exhibit a spectrum of cytologic appearances: most commonly resembling centroblasts, and less often resembling immunoblasts, or Reed-Sternberg-like cells [214, 219]. The neoplastic cells often have abundant pale cytoplasm (so-called clear cells). Sclerosis is common and often compartmentalizes the neoplastic cells into groups. Mitotic figures are usually numerous.

Immunophenotypic studies have shown that the neoplastic cells express pan-B-cell antigens and B-cell transcription factors (PAX5, BOB.1, OCT-2, and PU.1) but are commonly negative for surface Ig [220, 221]. About 50% of all PMLBLs lack surface IG [222]. Cyclin E and MAL are commonly overexpressed [221, 223]. Approximately 75% of cases are weakly and/or heterogeneously positive for CD30 and large subsets of tumors are positive for Irf-4/Mum-1, CD23, Bcl-2, or Bcl-6 [214]. T-cell antigens including CD5 are negative as is CD21. PMLBLs show immunophenotypic evidence of NF-κB activation: TRAF1 and nuclear REL. A subset of cases lacks MHC class I or II antigens [214]. MYC does expression by IHC is present in most PMLBLs [224], but not correlate with genetic abnormalities by FISH [224]. CD200 exhibits staining specificity of 93%, similar to that of CD23 (93%) and MAL (97%), and greater than that of TRAF (77%) and REL (83%), suggesting that CD200 is a practical and useful marker for the diagnosis of PMLBLs [225].

PMLBLs carry IG rearrangements and the IG variable region genes are commonly mutated. Balanced chromosomal translocations are uncommon. Comparative genomic hybridization has shown gains at chromosomal loci 2p15, 9q24, Xp11.4–21, and Xq24–26, and losses at 1p13, 4q, 6 of, 7p, and 17p [226]. Recent study with FISH reported that the programmed death ligand (PDL) locus (9p24.1) is frequently and specifically rearranged in PMLBL (~20%) as compared with diffuse large B-cell lymphoma, follicular lymphoma, and Hodgkin lymphoma [227]. Rearrangement was significantly correlated with overexpression of program death ligands 1 and 2 (PDL1, PDL2) [227]. Rearrangements of *CIITA* (MHC class II transactivator) occur in about 25% of cases. A number of genes are amplified in subsets of PMLBL including *JAK2*, *REL*, *BCL11A*, and others. The *BCL6* or *SOCS1* genes are commonly mutated in PMLBL [220, 228]. Both the NF-κB and JAK-STAT pathways are activated in PMLBL, and these tumors also have a host response gene signature.

Gene expression profiling has shown that PMLBL has a signature distinct from GCB or ABC DLBCLs, sharing approximately one-third of its gene expression profile with classical Hodgkin lymphoma [229]. Recently, cases of DLBCL with features of PMLBL by gene expression signature but without detectable mediastinal involvement have been reported [230]. These patients are older, show more equal sex distribution, and show lower frequency of *CIITA* translocations as well as *PDL1/PDL2* abnormalities compared to the PMLBL in mediastinum.

Intravascular Large B-Cell Lymphoma

Intravascular large B-cell lymphoma (IVLBCL), also known as *angiotropic lymphoma* and originally described as malignant angioendotheliomatosis, is a rare variant of DLBCL in which the neoplastic cells grow selectively within blood vessels, especially capillaries [231]. Although the histologic pattern of IVLBCL is quite distinctive, the clinical presentation and immunophenotypes of IVLBCL are strikingly heterogeneous, suggesting that more than one etiology or more than one cell of origin is involved. Rare cases of IVLBCL of T-cell or natural killer cell lineage are also reported, but are not included in this category. The explanation for this pattern of infiltration in IVLBCL is unknown, but the neoplastic cells have been shown to express various chemokines (e.g., CXCR4) or to not express certain types of homing receptors [231, 232]. It has been hypothesized to be secondary to a defect in homing receptors on the neoplastic cells such as the lack of β1 integrin (CD29), and ICAM-1 (CD54) [233].

Patients with IVLBCL are typically middle-aged or elderly, with a slight male predominance, and most patients have B-type symptoms [231, 234]. There are differences in clinical presentation dependent on geographical location. Patients in Western countries tend to present with symptoms attributable to specific organs involved by lymphoma with signs and symptoms related to occlusion of small vessels in various organs, most often the central nervous system and skin. In Asian countries, by contrast, patients often present with widespread disease dissemination, hepatosplenomegaly, and can have cytopenias as a result of hemophagocytic syndrome [231, 234]. Organs commonly involved by IVLBCL include the central nervous system, skin, and kidney but any site may be involved. Standard radiographic studies often falsely do not detect disseminated disease, as no masses are present, but IVLBCL can be detected by FDG-PET scan [235]. Bone marrow involvement, although difficult to appreciate morphologically, is relatively common when the bone marrow is assessed using immunophenotypic or molecular methods [236, 237]. IVLBCL tends to not involve lymph nodes. The prognosis is often poor due to late detection of disease and poor response to chemotherapy [231].

Histologically, IVLBCL is characterized by the presence of large lymphoid cells filling and/or distending vascular lumina [231, 234]. The neoplastic cells are found primarily within capillaries or small blood vessels. Cytologically, the neoplastic cells can resemble centroblasts or immunoblasts. The tumor cells are often associated with tissue hemorrhage or necrosis and fibrin thrombi can be observed. Extravascular involvement can occur in patients with IVLBCL, and although not prominent clinically or radiologically, is not uncommon at autopsy.

With the advent of immunophenotypic studies, IVLBCL was conclusively shown to be a variant of large B-cell lymphoma, most often ABC phenotype. These tumors express pan-B-cell antigens and a subset express monotypic Ig [231, 234]. These tumors commonly express Irf-4/Mum-1, approximately 30–40% of cases are CD5+, and a smaller subset can express CD10. Bcl-6 is usually negative. Proliferation rate, as shown by Ki-67 immunostaining, is usually high.

Molecular studies have shown IG rearrangements in IVLBCL [237]. Rare cases assessed by conventional cytogenetics have shown a complex karyotype.

ALK+ Large B-Cell Lymphoma

This is a pathologically and immunophenotypically distinct type of LBCL in which the neoplastic cells resemble immunoblasts or plasmablasts and express anaplastic lymphoma kinase (ALK) [238]. ALK+ LBCL is a truly rare disease representing <1% of DLBCL cases.

ALK+ LBCL can affect patients of all ages with a male-to-female ratio of 3 to 1 [238, 239]. Lymph nodes are commonly involved and patients tend to present with advanced stage disease, often with involvement of extranodal sites. Histologically, ALK+ LBCL can replace lymph nodes diffusely or exhibit a sinusoidal pattern of involvement or both. The neoplastic cells are large with prominent central nucleoli and abundant cytoplasm resembling either immunoblasts or plasmablasts. The neoplastic cells are usually positive for plasma cell-associated markers (e.g., CD38, CD138), cytoplasmic IgA, and EMA, and can express CD4, CD43 (often focal), CD45 (usually dim if present), CD57, CD79a (often bright), PAX5 (often negative) and Irf-4/Mum-1, and are negative for CD10, CD20, CD30, Bcl-6, T-cell antigens, and EBV. The proliferation rate, shown by Ki-67, is often brisk.

The most characteristic feature of ALK+LBCL is the presence of ALK expression. ALK is expressed as a result of molecular abnormalities involving the *ALK* at chromosome 2p23. The most common abnormality is t(2;17)(p23;q23) involving the *ALK* and *CLTC* genes [238]. Less commonly the t(2;5)(p23;q35) is present in these tumors. The ALK immunostaining pattern correlates with these abnormalities, being cytoplasmic and flocculent in cases with t(2;17) and both nuclear and cytoplasmic in cases with t(2;5). This is attributable to the normal cellular location of the clathrin and nucleophosmin proteins, in cytoplasmic vesicles or the nucleus, respectively [238]. Rare cases are reported with other abnormalities of the *ALK* locus.

Valera and colleagues showed the relevance of the ALK/STAT3 pathway in the pathogenesis of ALK+ large B-cell lymphomas [240]. ALK rearranged receptor binds to ALK-wild type receptor, and triggers STAT3 homodi-

mer formation resulting in phosphorylation of its tyrosine residues. STAT3 dimer can then enter the nucleolus, where it promotes the activation of BLIMP1, a transcription factor that modulates plasma cell differentiation, and *MYC* [240]. BLIMP1, phosphorylated STAT3 and Myc are positive in most cases of ALK+ large B-cell lymphoma [240].

Plasmablastic Lymphoma

Plasmablastic lymphoma (PBL) is defined in the WHO classification as a diffuse, monomorphous proliferation of large neoplastic cells that resemble B-immunoblasts but have an immunophenotype of immature plasma cells [241]. This neoplasm was originally described by Delecluse and colleagues [242] in the oral cavity of patients with HIV infection, but it is now recognized that PBL can occur at virtually any site [241]. Extranodal sites are most often involved. These tumors have been reported in patients with other types of acquired, and congenital immunodeficiency, as well as patients without known immunodeficiency [243, 244]. Many patients have high stage disease and a high IPI score. The prognosis of patients with PBL is poor, despite therapy, with a median survival of approximately 1 year [241, 243].

Histologically, PBL is composed of large neoplastic cells arranged in a diffuse pattern. A starry-sky pattern and a high mitotic rate are common. The neoplastic cells have vesicular nuclei with solitary central nucleoli and abundant cytoplasm with variable plasmacytoid differentiation. Immunophenotypically, the neoplastic cells are positive for CD38, CD138, and Irf-4/Mum-1 and are usually negative for the CD20 and PAX5, although weak expression by a subset of cells can occur in a small subset of cases. The cells of PBL are also commonly positive for cytoplasmic Ig (usually IgG), CD79A, CD30, EMA, and p53, and can express CD10, and CD4. PBLs are usually negative for CD45/LCA, CD3, CD5, and HHV8. CD56 is usually absent and when present should raise the suspicion for plasmablastic myeloma. However in some cases a firm distinction cannot be made between plasmablastic lymphoma or anaplastic plasmacytoma [244]. BLIMP1 and XBP1 have been recently introduced as useful markers for the diagnosis of PBL. The use of a combination of PAX5, CD20, BLIMP1, and XBP1 enables the identification of a plasmablastic immunophenotype highly characteristic of plasmablastic lymphoma cases and associated with an aggressive clinical behavior [245]. The proliferation rate, assessed by Ki-67 expression, is usually high. Myc overexpression was seen in all cases assessed regardless of *MYC* rearrangement status [243]. EBV small encoded RNA (EBER) is detected in 70% of cases. EBV latent membrane protein is negative, consistent with EBV latency pattern 1.

PBL is characterized by acquisition of the transcriptional profile of plasma cells with overexpression of PRDM1/BLIMP1 and XBP1s, in concert with extinction of the B-cell differentiation program with downregulation of B-cell lineage transcription factors such as Pax5 [245]. PBLs carry monoclonal IG rearrangements and the IG variable region genes are often mutated [241]. *MYC* is rearranged in two-thirds of cases [243, 244, 246]. Gene expression analysis identified 645 genes as differentially expressed between PBL and DLBCL, with 257 highly expressed in PBL relative to DLBCL, and 388 lower in PBL [247]. Transcriptional factors *BCL6*, *BCL11A,* and *SPI-B* showed significantly lower mRNA expression in PBLs. A similar trend was observed for CXCR5 and IL4, which have a role in the germinal center (GC) microenvironment. These changes likely reflect post-GC-plasmablastic origin of these tumors. In contrast, mRNA levels of PRMT5, an important transcriptional repressor, were significantly higher in PBLs than in DLBCLs [247]. It seems that the classification of PBL, and its relationship with DLBCL, needs additional study although the clinically aggressive nature of PBL is not in doubt. It is reported that the acquisition of a partial plasmablastic phenotype (BLIMP1 expression) in DLBCL is associated with shorter survival in R-CHOP-treated patients [245].

Primary Effusion Lymphoma

Primary effusion lymphoma (PEL), also known as body cavity-based lymphoma, is a very rare neoplasm of large B-cells that usually involves one of the body cavities: pleural, pericardial, or peritoneal [248]. Usually, only one body cavity is involved. In a subset of patients, PEL also can involve tissue sites as a solid mass and rarely the tumor can initially present as an extracavitary mass. Extracavitary sites are usually extranodal, but we have seen cases of PEL initially diagnosed by lymph node biopsy. Almost all cases of PEL arise in the setting of immunodeficiency, most commonly HIV infection. Rarely, PEL has been reported in patients who have undergone organ transplantation or in elderly patients without obvious evidence of immunodeficiency [248]. HHV8 is universally associated with this lymphoma. In addition, most PEL patients also demonstrate coinfection with EBV, although there is limited expression of EBV-related genes and their role in pathogenesis remains unclear [249]. In 2004, extracavitary or solid variant was proposed for tumors without serous cavities involvement [250]. Classic and extracavitary PEL are similar with regard to morphology, immunophenotype, and molecular characteristics. The prognosis of this lymphoma is poor, with overall

survival commonly less than 1 year despite treatment with high-dose chemotherapy [251].

Morphologically, the neoplastic cells resemble immunoblasts or plasmablasts with prominent nucleoli and abundant basophilic cytoplasm [248, 252]. In some cases anaplastic or Reed-Sternberg-like cells are present. The tumor cells are found within body cavity fluids, but may adhere to and invade body cavity surfaces. In lymph nodes, PEL has a sinusoidal pattern of infiltration. Immunophenotypic studies have shown that PEL cells express CD30, CD38, CD138, EMA, and HLA-DR, and are usually negative for Ig (surface and cytoplasmic), pan-B-cell antigens (e.g., CD19 and CD20) and Bcl-6 [248]. All cases are positive for HHV8 and most cases are positive for EBER and CD45/LCA. A subset of PEL cases can express T-cell associated antigens. Rare cases of "PEL" are reported that lack evidence of HHV8; whether these cases are truly PEL or clinicopathologic mimics is uncertain. The WHO classification suggests that HHV8-negative effusion lymphoma is a distinct entity: lymphoma cells are HHV8 negative and express pan-B-cell antigens, patients are older, and are generally HIV negative, often hepatitis C positive, and often have an underlying medical condition leading to fluid overload [253]. Clinical outcomes and response to therapy in this subset are better than PEL patients. Underlying fluid overload status raises the possibility that these lymphomas are in fact secondary to chronic serosal stimulation [253].

Molecular studies have shown monoclonal IG rearrangements and a subset of cases also has TCR gene rearrangements (lineage infidelity) [248]. *MYC* translocations have been reported rarely. Comparative genomic hybridization has shown frequent gains of chromosome 12p [254]. One gene expression profiling study showed a common gene signature in PEL cases that was distinct from other types of NHL including HIV-associated NHLs. This signature shares features shared with EBV+ transformed lymphoblastoid and plasma cell myeloma cell lines [255].

Burkitt Lymphoma

Clinically, Burkitt lymphoma (BL) cases can be divided into three groups: endemic, sporadic, and immunodeficiency-associated. BL also can present in leukemic phase with preferential involvement of peripheral blood and bone marrow.

Endemic BL was first described by Denis Burkitt in equatorial Africa (Uganda) where it occurs within 15 degrees latitude north or south of the equator [256]. Other endemic areas include Papua New Guinea and Northern Brazil. Evidence of EBV infection is present in over 95% of patients. There are links with malaria and arbovirus infection [257]. The median age of patients with endemic BL is in the range of 4–7 years, with a boy/girl ratio of 2 to 1. The jaw is the most well-known site of disease, involving either the maxilla or mandible in 50–60% of patients, but large abdominal masses involving retroperitoneal structures, the gastrointestinal tract, or the gonads are also commonly present [256, 258].

Sporadic BL occurs in industrialized nations and represents approximately 1% of all NHLs in adults [258]. In children, sporadic BL is the most common type of NHL, up to 40–50% of all cases of NHL. Approximately 20% of patients have evidence of EBV infection. Patients are usually in the second or third decades of life, with a male/female ratio of 2–3 to 1. The jaw is infrequently involved and most patients present with large abdominal masses, frequently involving the ileocecal region of the gastrointestinal tract. Bone marrow and central nervous system involvement are uncommon at the time of presentation, in approximately 10–20% of cases, but are frequent sites of disease later in the clinical course.

Burkitt lymphoma also occurs in the clinical setting of immunodeficiency, most often HIV infection. Immunodeficiency-associated BL is associated with EBV infection in 30–40% of cases, and most often involves extranodal sites [258]. As is the case for all types of BL, EBV within tumor cells is episomal, consistent with latent infection, often present in multiple copies per cell, and monoclonal, indicating that the virus is present prior to neoplastic transformation. However, as is evident by the lower frequency of EBV in sporadic and immunodeficiency BL, EBV alone is not sufficient to cause BL, and neither EBV infection nor *MYC* translocation seems to be sufficient to initiate and maintain neoplastic proliferations in BL. Transforming genes, such as *LMP1*, which are associated with EBV latency, are not expressed in BL cells.

As BL is most often extranodal, and patients commonly present with a high tumor burden and bulky disease, traditional staging systems (e.g., Ann Arbor system) are of less prognostic value than schemes that assess tumor burden and amenability to surgical excision [259]. Patients with BL have a high risk of central nervous system involvement. Waldeyer ring and the mediastinum are involved uncommonly [258]. Since BL is often widely distributed at the time of presentation and has an extremely rapid clinical course, systemic chemotherapy is the treatment of choice. Improvements in diagnosis and combination chemotherapy with CNS prophylaxis have resulted in, more than 90% survival for all-stage children with BL, and for adults 60 years or younger with performance score 0–1 [260, 261]. Patients with immunodeficiency-associated BL also respond well to combination chemotherapy, providing their underlying immunodeficiency syndrome allows adequate therapy to be administered.

Histologically, the endemic, sporadic, and HIV-associated types of BL are very similar and are characterized by two essential features: the neoplastic cells have

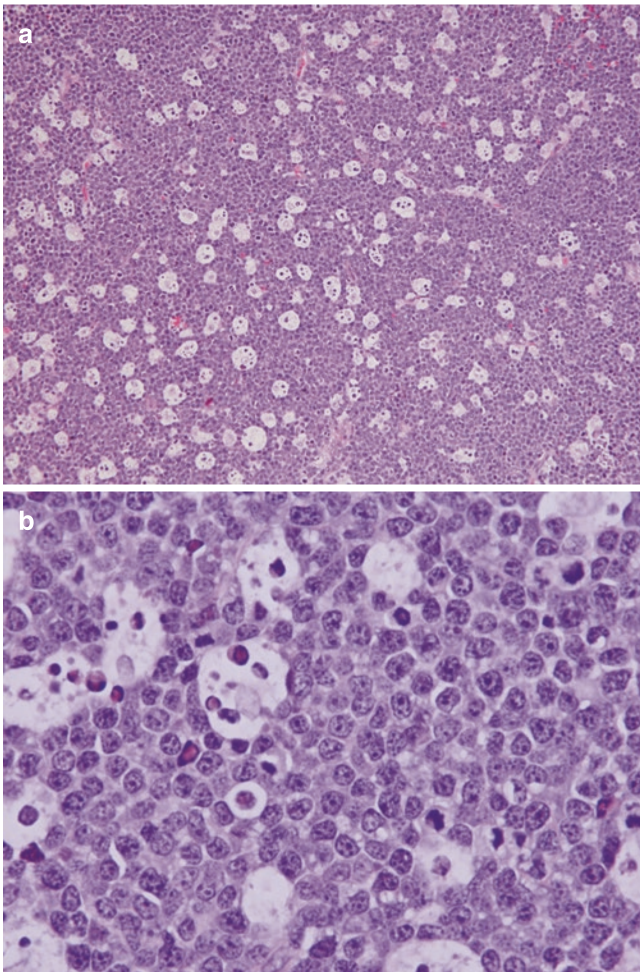

Fig. 40.9 Burkitt lymphoma. (**a**) Low-magnification shows the characteristic starry sky pattern with the histiocytes appearing as clear spaces or "stars" in a background "sky" of darker lymphoma cells. (**b**) The lymphoma cells are of intermediate size with multiple small nucleoli (hematoxylin-eosin, (**a**) 200×; (**b**) 1000×)

nuclei that approximate the size of the nuclei of benign histiocytes and the tumor has extraordinarily high mitotic and proliferation rates [258]. At low power, the neoplasms grow as expansile masses that diffusely infiltrate contiguous tissues. Reactive histiocytes are scattered throughout the tumor. The relatively clear cytoplasm of the histiocytes in a background of blue neoplastic cells imparts a "starry-sky" appearance (Fig. 40.9). This pattern results from rapid cell turnover with individual cell necrosis and scavenging of debris by macrophages. The neoplastic cells are round to ovoid, strikingly monotonous, and uniform in shape. The nuclear membrane is prominent, and the chromatin is coarse, with two to five prominent, basophilic nucleoli. Mitotic figures are numerous. Although the growth pattern of the tumor is usually diffuse, occasionally selective involvement of germinal centers in partially effaced lymph nodes imparts a nodular pattern.

Immunophenotypic studies of endemic, sporadic, and AIDS-associated BLs have shown similar findings. These tumors are of mature B-cell lineage and typically express monotypic Ig light chain, IgM, pan-B-cell antigens, CD10, CD38, Bcl-6, and SOX11. Ki67 proliferating index is 100% in nearly all cases. These tumors are usually negative for IgD, CD21, CD23, CD25, T-cell antigens, TdT and Bcl-2 [258]. Immunophenotypic variants have been reported, however, with a subset of cases Irf-4/Mum-1 and minor subsets negative for CD10, Bcl-6, or Ig, or weakly positive for Bcl-2 [262, 263].

Approximately 80% of cases carry the t(8;14)(q24;q32), with the remaining cases having one of two variant translocations: 15% carry t(2;8)(p11;q24) and 5% carry t(8;22)(q24;q11). Common to each of these translocations is involvement of chromosome region 8q24, the site of the *MYC*. Via these translocations, *MYC* is juxtaposed with the *IGH* on the derivative chromosome 14, or with the *IGK* and *IGL* juxtaposed with *MYC* on the derivative chromosome 8 [264]. *MYC* has a central role in normal cellular proliferation. This juxtaposition of *MYC* and immunoglobulin enhancers results in deregulation of the *MYC* gene, with increased Myc protein driving cell proliferation [265]. *MYC* mutations also occur in BL and may enhance tumorigenicity.

Burkitt lymphomas have IG rearrangements and the IG variable region genes are commonly mutated. Additional cytogenetic abnormalities also occur in BL. In one study, abnormalities of chromosome 13q and 22q were associated with worse prognosis in children, and abnormalities of chromosome 17 correlated with worse prognosis in adults [266]. There was no significant difference in karyotype complexity between children and adults with BL [266]. Frequent copy number abnormalities have also been detected by array-based single nucleotide polymorphism analysis [267]. In general, the karyotypes of BL are simpler than those observed in DLBCL or high-grade B-cell lymphomas (see below) [258].

The breakpoints of the t(8;14) are distinctive in endemic and sporadic BL [264]. In endemic BL, the breakpoint on chromosome 8 occurs far 5′ to the location of *MYC* whereas the breakpoint on chromosome 14 usually occurs within the joining region of *IGH*. By contrast, in sporadic BL, the breakpoint on chromosome 8 occurs within the *MYC* gene, usually in the first exon, or in adjacent flanking sequences. The breakpoint on chromosome 14 may occur within the *IGH* switch regions. These differences suggest endemic and sporadic BL arise at different stages of B-cell differentiation, and may involve mistakes that occur as a result of somatic mutation or *IGH* switching, respectively.

Two major studies of BL using gene expression profiling were published in 2006 [268, 269]. These studies, which focused on sporadic BL, showed that BL has a distinctive

gene expression profile, showing a high level of expression of Myc and germinal center B-cell genes, and a low level of NF-κB. This profile was also identified in a small subset of cases that lacked *MYC* translocations as well as a small subset of cases that resembled DLBCL. In the study by Hummel and colleagues [268], the authors emphasized that there is a spectrum of gene expression that occurs between DLBCL and BL. In both studies, rare lymphomas that carried both *MYC* translocations and t(14;18)(q32;q21)/*IGH-BCL2* translocations were identified that had a gene expression profile of BL and yet did not behave as do most patients with BL [268, 269]. In restrospect, these "double hit" lymphomas should not have been included in the BL category. *MYC* also regulates microRNA expression, including up to 60 microRNAs [265]. Despite differences in epidemiology, endemic, sporadic, and HIV-related BL have been shown to have identical miRNA profiles [270].

Recent molecular studies have improved our understanding of the pathogenesis of these tumors. Mutations in the transcription factor *TCF3* (*E2A*) or its negative regulator *ID3* occur in about 70% of sporadic and immunodeficiency-related BL and 40% of endemic BL [271, 272]. *ID3* mutations are more common than *TCF3* mutations (68% and 11%, respectively), and are also biallelic, suggesting a possible tumor suppressor function [271]. These proteins play an important role in germinal center B-cell differentiation, thus dysregulation of this signaling pathway seems important in Burkitt lymphomagenesis [273]. The interplay between EBV infection and Burkitt lymphomagenesis still remains unknown.

Burkitt-Like Lymphoma with 11q Aberration

Some recent studies have identified a subset of lymphomas that resemble BL morphologically, immunophenotypically, and by GEP, but which lack *MYC* rearrangements [274, 275]. Instead they have a chromosome 11q alteration characterized by proximal gains and telomeric losses. Further studies have identified candidate genes potentially affected by these imbalances: *PAFAH1B2*/11q23.3 (overexpressed), *FLI1* (downregulated), and *ETS1* (recurrently mutated) [274, 275]. Compared with classic BL, these lymphomas have more complex karyotypes, lower levels of Myc expression, occasionally a follicular pattern, and frequently present with nodal disease [274, 275]. The clinical course seems to be similar to BL, but the number of cases reported is still limited. These cases are considered as a provisional entity in the revised 2016 WHO classification [17].

High-Grade B-Cell Lymphomas

The terminology "B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and Burkitt lymphoma (BCLU)" was adopted by the 2008 WHO classification for aggressive B-cell lymphomas with morphologic, phenotypic, and genetic features which overlap between Burkitt Lymphoma and DLBCL [276]. The tumors in this category had great overlap with lymphomas designated previously in the International Working Formulation as small noncleaved cell lymphoma, non-Burkitt type, or in the REAL classification as high-grade B-cell lymphoma, Burkitt-like. Later, additional studies demonstrated that B-cell lymphomas with rearrangements of *MYC* and *BCL2* and/or *BCL6* had features intermediate between DLBCL and BL. *MYC* translocations were identified in 35–50% of cases in the entity of B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and Burkitt lymphoma. In WHO 2016 revision, BCLU is re-named and separated in two categories: high-grade B-cell lymphoma with *MYC* and *BCL2* and/or *BCL6* translocations, and high-grade B-cell lymphoma, NOS [17].

High-Grade B-Cell Lymphoma with MYC and BCL2 and/or BCL6 Translocations

This group includes so-called "double hit" or "triple hit" lymphomas, with simultaneous presence of *MYC* and *BCL2* translocations, *MYC* and *BCL6* translocations, or *MYC*, *BCL2*, and *BCL6* translocations. These lymphomas are typically composed of a diffuse proliferation of medium to large sized cells, with irregular nuclear contours, and relatively large nucleoli. Many mitotic figures, prominent apoptosis, and a starry-sky pattern are often present. All large B-cell lymphomas with *MYC* and *BCL2* and/or *BCL6* rearrangements are included in this category [17]. In about 60% of cases the *MYC* translocations involve an IG gene partner, and in 40% of the cases they involve non-IG partners. Immunoglobulin gene partners are associated with a poorer prognosis [201]. This lymphoma occurs in adults (median age 55) and are of GCB phenotype [277, 278]. Double-hit lymphomas with *BCL6* and *MYC* translocations are rare aggressive B-cell lymphomas, tend to occur in old women, are frequently extranodal in presentation, and have a poor prognosis. They can be either GCB or ABC phenotype [279]. Triple-hit lymphomas are rare and aggressive lymphoma. In one study of 11 cases of triple-hit lymphomas, all patients were men, with a median age of 64 years old [200]. All cases were positive for CD10, Bcl-2, and FOXP1, Bcl-6 and Irf-4/Mum-1 were positive in 73% and 55%, respectively. All cases belonged to GCB immunophenotype [200].

High-Grade B-Cell Lymphoma, NOS

Cases that have intermediate features between DLBCL and BL but which lack a *MYC* and *BCL2* and/or *BCL6* rearrangement

are placed in the category [17]. Histologically, these neoplasms are diffuse, often have a starry-sky pattern, and have a high proliferation (Ki-67) rate (>99%) with numerous mitotic figures. The neoplastic cells, however, are of intermediate size similar to BL cells, but with greater nuclear pleomorphism, or are larger with more vesicular nuclear chromatin somewhat similar to DLBCL cells, but not as large. Cases of this category can histologically resemble BL but have atypical immunophenotypic features [17]. For example, these tumors express pan-B-cell antigens, CD10, and Bcl-6 which have a high proliferation (Ki-67) rate, and yet also strongly positive for Bcl-2. Blastoid-appearing large B-cell lymphomas which lack *MYC* rearrangement are also included in this category [17].

B-Cell Lymphoma, Unclassifiable, with Features Intermediate Between Diffuse Large B-Cell Lymphoma and Classical Hodgkin Lymphoma

These neoplasms are defined as having "overlapping clinical, morphological, and/or immunophenotypic features between classical Hodgkin lymphoma and DLBCL" [280].

Most cases designated as B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and classical Hodgkin lymphoma CHL are tumors at the interface between primary mediastinal large B-cell lymphoma (PMLBL) and classical Hodgkin lymphoma (CHL). The median age of patients is 33 years, and about 50% of patients have a mediastinal masses greater than 10 cm [281]. The clinical course of affected patients is thought to be more aggressive than that of patients with either PMLBL or CHL, although recent study suggests that dose-adjusted EPOCH-R produces durable remissions in most patients [281].

Using histologic and immunophenotypic findings, there are essentially two types of B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and CHL. In one type, the neoplasm is composed of sheets of large neoplastic cells resembling PMLBL, but the immunophenotype has features more in keeping with CHL (e.g., CD15+ or EBV+). In the other type, the neoplasm resembles CHL, usually nodular sclerosis type, but the neoplastic cells have an immunophenotype more like DLBCL (e.g., CD45/LCA+, strong expression of B-cell antigens). A subset of these tumors expresses MAL, as is seen in PMLBL. Strong CD20 expression is acceptable in cases diagnosed as CHL, and by itself, is not a reason to classify the neoplasm as a gray zone tumor.

Gene expression profiling of cases of PMLBL and CHL have shown that these neoplasms share aspects of their gene expression profiles [229]. Approximately one-third of the genes expressed in PMLBL and CHL are shared. These data provide, in part, a rationale for the WHO proposal of this category of disease.

T-Cell Non-Hodgkin Lymphomas

The classification of T-cell lymphomas and leukemias is challenging because, unlike B-cell NHLs, T-cell NHLs do not seem to correspond to normal stages of differentiation nor are most tumors associated with chromosomal translocations. As a result, the classification of some types of T-cell lymphoma, particularly extranodal forms, currently incorporates clinical findings into the classification system [17]. Knowledge of T-cell function, likely to emerge over time, may be helpful to more specifically classify T-cell lymphomas and leukemias. In the following sections, the focus is placed on T-cell neoplasms that usually or commonly present as lymphoma.

T Lymphoblastic Leukemia/Lymphoma

T lymphoblastic leukemia/lymphoma can present in two fashions: (1) as acute lymphoblastic leukemia (T-ALL) with extensive involvement of bone marrow and blood; and (2) as lymphoma (T-LBL), most often as an anterior mediastinal mass or lymphadenopathy. Patients who present as T-LBL often convert to a T-ALL clinical picture over time, and many patients who present as T-ALL have an anterior mediastinal mass. This clinical overlap, as well as overlap in immunophenotypic and molecular features, led the authors of the WHO classification to combine T-ALL and T-LBL cases into one category [282]. There are some immunophenotypic and molecular differences between T-ALL and T-LBL; however, that may explain their different clinical presentations [283]. Here we focus on patients presenting as T-LBL.

Patients with T-LBL are most often adolescents and young adults with a male-to-female ratio of 2 to 1 [282, 283]. Patients commonly present with widespread, supradiaphragmatic lymphadenopathy and/or an anterior mediastinal mass. Patients with a mediastinal mass may have dyspnea, cough, stridor or superior vena cava syndrome. Pleural and pericardial effusions are common. Peripheral blood involvement is seen in approximately one-third of patients at the time of presentation. Compared with patients with T-ALL, patients with T-LBL have lower serum LDH levels, a lower frequency of hepatosplenomegaly, and a lesser risk of central nervous system involvement [283]. T-LBL grows rapidly and, unless effectively treated, patients have a rapidly progressive down-

hill course with widespread dissemination of disease. Patients with T-LBL respond favorably to therapeutic regimens designed after those used for ALL.

Histologically, T-LBL replaces the lymph node in a diffuse pattern and often spills through the capsule into perinodal tissues [282, 284]. In cases with partial involvement, lymphoid follicles may be spared. A starry-sky pattern is present in a subset of cases. Rarely the neoplasm is compartmentalized by fibrous tissue imparting a nodular low power pattern. Cytologically, T-LBL is composed of lymphoblasts that have “dusty” or granular chromatin and either round or convoluted nuclear contours. Mitoses are numerous.

Immunophenotypic studies have shown that T-LBLs appear to illustrate the concept that these neoplasms represent clonal expansions of cells “frozen” in a state of differentiation [282]. This phenomenon allows one to deduce that a variety of antigens are acquired in sequence, most likely reflecting the sequence of expression by non-neoplastic lymphoid cells during development. These stages of T-cell differentiation can be divided into early T-precursor, pro-T, pre-T, cortical T, and medullary T [282, 285, 286]. CD7 and cytoplasmic CD3 expression occur very early in this sequence and are expressed in the pro-T stage. The early T-precursor, pro-T, and pre-T stages are CD4-, CD8- and the cortical T stage is CD4+, CD8+ and CD1a+. T-LBLs also commonly express CD34, CD99, and Bcl-2. Myeloid-associated antigens are expressed in up to one-third of cases [282]. T-LBL are negative for Ig and pan-B-cell antigens, with the exception of CD79A which can be positive in a subset of T-LBLs, approximately 50% in one study [287].

Most cases of T-ALL/LBL show TCR gene rearrangement, and there is a hierarchy: *TRD* followed by *TRF*, *TRB* and *TRA*. These cases also exhibit lineage infidelity manifested by the presence of *IGH* gene rearrangements in approximately 20% of cases [282, 288].

Most cytogenetic and molecular studies performed on T-cell lymphoblastic neoplasms have been performed on cases of T-ALL, with relatively few cases of T-LBL assessed. Based on the available data, there is overlap between T-LBL and T-ALL, but it must be noted that the cytogenetic and molecular profile for T-LBL presented here is based primarily on T-ALL data. Conventional cytogenetic studies of T-ALL/LBL have shown abnormalities in approximately 50% of cases [283, 289, 290]. The most common translocations involve the TCR genes at chromosomal loci 14q11 (*TRA* and *TRD*), 7q35 (*TRB*), and 7p14-15 (*TRG*). The most frequent gene partners are *HOX11/TLX1* at 10q24 and *HOX11L2/TLX3* at 5q35, with many other partners including *TAL1* (1p32), *RBTN1/LMO1* (11p15), *RBTN2/LMO2* (11p13), *LYL1* (19p13), and *MYC* (8q24). These translocations are of two types: (1) intact oncogenes that are juxtaposed with TCR gene loci; (2) dysregulated genes that are fused, creating a novel, chimeric gene. Many additional cytogenetic or molecular alterations have been shown in T-ALL, most of which affect the cell cycle. *NOTCH1* mutations are common in T-ALL, in 40–50% of cases, and additional abnormalities in other genes in the *NOTCH1* pathway have been reported, such as loss of *PTEN* and *AKT* activation [291]. Additional somewhat common alterations in T-ALL include: deletions of chromosome 9p21 (30–40%), del6q (in 15–20%), *WT1* mutations (~10%), duplications/gains of chromosome 6q23/*MYB* (5–10%), rearrangements/amplification of *ABL1* (5%), protein tyrosine phosphatase 2 (*PTPN2*) mutations, and deletions of chromosome 13q14/*RB1* [292–295].

Gene expression profiling of T-ALL cases has shown distinct gene signatures that correlate with the known cytogenetic abnormalities [296]. These studies also have shown that T-ALL without identified cytogenetic abnormalities can be characterized by similar gene signatures suggesting the presence of cytogenetically undetectable abnormalities in these pathways. There are at least five gene signature groups that correlate, in part, with immunophenotype: HOX11/TLX1 (early cortical T), HOX11L2/TLX3 (early cortical T), TAL1 plus either LMO1 or LMO2 (late cortical T), LYL1 plus LMO2, and MLL-MLLT1 (pro-T). Comparisons of T-ALL and T-LBL have been few to date: T-LBL cases preferentially express genes encoding cell adhesion and extracellular matrix proteins [296].

Early T-Precursor Acute Lymphoblastic Leukemia (ETP-ALL)

Early T-precursor acute lymphoblastic leukemia (ETP-ALL) is a recently described subgroup of T-ALL with a poor prognosis, originating from a subset of thymocytes that retain stem-cell-like features [286, 297]. This leukemia is defined immunophenotypically by the absence of CD1a, CD4, and CD8 expression, low CD5 (<75% positive cells), and expression (>25% positive cells) of at least one or more of the following myeloid or stem cell markers: CD117, CD34, HLA-DR, CD13, CD33, CD11b, or CD65 [286]. ETP-ALL show unique genetic and transcriptional features that overlap both with T-ALL and AML, and show lower frequencies of prototypical T-ALL lesions such as activating mutations in *NOTCH1* [297]. Cases of ETP-ALL also have a high prevalence of mutations typically associated with the pathogenesis of acute myeloid leukemias including *IDH1, IDH2, DNMT3A, FLT3,* and *NRAS* [297, 298].

Adult T-Cell Lymphoma/Leukemia

Adult T-cell lymphoma/leukemia (ATLL) is a type of mature T-cell lymphoma that is caused by infection by the human

T-cell leukemia/lymphoma retrovirus (HTLV-1) [299]. ATLL accounts for the high incidence of T-cell lymphoma in Japan, particularly on the islands of Kyushu and Okinawa where up to 5–6% of the population are seropositive for HTLV-1. However, the prevalence of seropositivity has decreased from up to 30% of individuals being seropositive for HTLV-1 in the 1970s [300]. Other endemic regions for HLTV-1 infection include Brazil and Caribbean countries and cases are also reported, albeit infrequently, in Europe, and the United States.

HTLV-1 is a single-stranded RNA retrovirus that is lymphotropic for T-lymphocytes [301]. The virus is transmitted by sexual intercourse, breast milk, shared needles among intravenous drug users, and transfusion of blood products. Rare cases of vertical transmission without breastfeeding are also reported [302]. The virus, however, is insufficient to cause lymphoma by itself and therefore other abnormalities must occur. This sequence of events most likely takes years as the incubation period for development of ATLL in HTLV-1 individuals ranges from 20 to 40 years [301].

Patients with ATLL are usually adults, with a median age between 58 and 62 years and a male-to-female ratio ranging from 1.2–1.5 to 1 [299, 303]. Affected patients may present with one of four variants: acute, lymphomatous, chronic, and smoldering [304]. Patients with acute ATLL, the most common form of the disease, have generalized lymphadenopathy, hepatosplenomegaly, skin lesions, peripheral blood involvement with high leukocyte counts, lytic bone lesions, and hypercalcemia. Hypercalcemia also may develop in the absence of bone lesions. The lungs and central nervous system are commonly involved. Patients with the lymphomatous form of ATLL present with prominent lymphadenopathy and tumors in other organs without hepatosplenomegaly or hypercalcemia. Skin lesions are common. Many patients with the acute form of ATLL, and a lesser number with lymphomatous ATLL, have evidence of immunodeficiency and opportunistic infections. These patients respond to chemotherapy, but remissions are short and overall survival is usually poor [305].

Patients who present with chronic variant ATLL have an absolute lymphocytosis and cytologically abnormal cells in the blood. Skin lesions, lymphadenopathy, and involvement of other viscera may occur and survival is usually greater than 2 years [299, 304]. Patients who have the smoldering form of ATLL have chronic disease for years, usually skin lesions with minimal peripheral blood involvement; the viscera are usually spared. Patients with the chronic and smoldering variants of ATLL do not usually require therapy but should be carefully followed as approximately 25% of patients transform to acute or lymphomatous variant ATLL [299, 305].

The neoplastic cells in the peripheral blood smear in patients with acute or lymphomatous ATLL are characteristic [299]. The circulating neoplastic cells are medium-sized with basophilic cytoplasm and markedly irregular, multilobulated nuclei, including cloverleaf shapes, also known as *flower cells*. In lymph nodes and viscera, ATLL diffusely replaces lymph nodes or extranodal sites. Cytologically, ATLL exhibits a spectrum of cell sizes, including small, medium-sized, large, anaplastic, and Reed-Sternberg-like cells [299, 306]. Histologically, lymph nodes may exhibit classical Hodgkin lymphoma or angioimmunoblastic T-cell lymphoma like morphology [299]. Skin lesions are seen in more than 50% of patients with ATLL. Epidermal infiltration with Pautrier-like microabscess is common, which can mimic mycosis fungoides. Many cases are indistinguishable from other T-cell lymphoma subtypes without knowledge of HTLV-I infection.

Immunophenotypic studies have shown that ATLLs have a mature T-cell immunophenotype [299]. The neoplastic cells express the pan-T-cell antigens CD2, CD3, CD5, and the TCR αβ receptor, but are usually negative for CD7. Most cases of ATLL are CD4+ CD8-. The lymphoma cells intensely express the CD25, and approximately 40% of ATLLs are positive for CCR4 and FOXP3; markers of regulatory T-cells [307]. ATLL cells variably express CD30 in a subset of cases, and are negative for Ig and B-cell antigens.

Conventional cytogenetic studies have shown a wide range of abnormalities in cases of ATLL. Usually multiple abnormalities are identified per individual neoplasm, at least six in one study [308]. These results suggest a multistep pathogenesis for ATLL, and are consistent with the known long incubation period from the time of infection to onset of tumor. Several studies with array based comparative genomic hybridization show frequent losses at chromosomes 6q and 13q, frequent gains at chromosomes 14q, 7q, and 3p, as well as aneuploidy (+3, +7, +21, −X, −Y), and translocations involving 14q11 and 14q32 (*TRA* and *TRD*, respectively). Increased number of chromosomal imbalances are associated with a significantly shorter survival [309].

The hallmark for the diagnosis of ATLL is the demonstration of HTLV-1 infection. Molecular identification of HTLV-1 is ideal for this purpose as the virus clonally integrates into the host cell genome in a random fashion [301]. The site of HTLV-1 integration into the genome appears to be similar in most cases; unusual sites of viral integration may correlate with a poorer prognosis [310]. The mechanisms to explain how HTLV-1 is involved in lymphomagenesis are not well worked out. The TAX viral protein and HTLV-1 basic leucine zipper factor (HBZ) are thought to be involved. Another point worth mentioning is that use of serum testing for HTLV-1 infection as a surrogate for molecular evidence of HTLV-1 infection is imperfect. In

countries with a low prevalence of HLTV-1 infection, the presence of HTLV-1 antibody highly correlates with ATLL in a patient presenting with evidence of lymphoma. However, in Japan and other areas with a high prevalence of HTLV-1 infection, antibody testing yields a high false positive rate [311].

Acute and chronic variants of ATLL, differ in their gene expression profile and in chromosome copy number. Expression of MET is high in acute variant ATLL suggesting a potential therapeutic target [312]. Recent study of an integrated molecular analysis of a total of 426 ATLL cases identified alterations of NF-κB signaling [313]. Other notable features include a predominance of activating mutations (*PLCG1, PRKCB, CARD11, VAV1, IRF4, FYN, CCR4, CCR7*) and gene fusions (*CTLA4-CD28* and *ICOS-CD28*) [313]. Frequent intragenic deletions involving *IKZF2*, *CARD11*, and *TP73* and mutations in *GATA3*, *HNRNPA2B1*, *GPR183*, *CSNK2A1*, *CSNK2B*, and *CSNK1A1* were also observed [313].

Extranodal NK/T-Cell Lymphoma, Nasal-Type

Extranodal NK/T-cell lymphoma, nasal type (NK/T-cell lymphoma) was designated previously as lethal midline granuloma, polymorphic reticulosis, midline malignant reticulosis, and angiocentric lymphoma [314]. This neoplasm exhibits marked geographic variation, with a high frequency in Asia and native Americans in Central and South America.

Clinically, NK/T-cell lymphomas have a marked propensity for involving extranodal sites, most commonly the nasal cavity, nasopharynx, and palate [314, 315]. In a subset of patients, the disease involves non-aerodigestive tract sites (so-called non-nasal type) [315]. Extranodal NK/T-cell lymphomas involving the upper aerodigestive tract are predominantly localized processes at onset and may be present for years prior to diagnosis, but widespread dissemination can occur including lymph nodes and bone marrow [314].

Extranodal NK/T-cell lymphomas are commonly associated with a hemophagocytic syndrome, clinically characterized by fever, hepatosplenomegaly, pancytopenia, and laboratory evidence of hemolysis. Based on their extranodal distribution, traditional staging systems are less useful and a system based on the presence of local invasion and stage (localized versus disseminated) has been proposed [316]. The prognosis of patients with NK/T-cell lymphomas involving the aerodigestive tract has improved with chemotherapy and radiotherapy [317, 318]. The prognosis of patients with non-nasal NK/T-cell lymphomas is much poorer [315].

Histologically, NK/T-cell lymphomas are diffuse, destructive tumors that almost invariably are associated with necrosis and commonly exhibit angioinvasion and angiodestruction [314, 319]. The cytologic spectrum of NK/T-cell lymphomas is very wide and neoplasms can be composed of small or very large cells. A prominent inflammatory cell background is also usually present, but eosinophils and neutrophils are rare or absent. In the early stages of disease, relatively few neoplastic cells associated with inflammatory cells can be observed, particularly in a small biopsy specimen, leading to misinterpretation as a benign process [314, 319].

Immunophenotypic studies of NK/T-cell lymphomas have shown that most cases are of NK-cell origin, although a subset of cases are of T-cell lineage [314, 319]. Virtually all cases of NK/T-cell lymphoma are positive for EBER [314]. Most cases also express the NK-cell-associated antigen CD56, and NK/T-cell-associated antigens such as CD2, and CD7. All cases of NK/T-cell lymphomas express cytoplasmic CD3e; NK-cell tumors are negative for T-cell-specific antigens such as surface CD3, CD5, and TCRs, whereas T-cell tumors express these T-cell markers. Most NK/T-cell lymphomas express cytotoxic markers (e.g., perforin, TIA-1, and granzyme B) [314, 320]. The neoplastic cells, when of large size, can express p53, FAS, and FAS ligand [320]. Ki-67 rate correlates, in part, with cell size and prognosis in localized neoplasms [321]. CD16 and CD57 are usually negative, and Ig and B-cell antigens are negative.

Molecular studies of NK/T-cell lymphomas have shown an absence of TCR and IG rearrangements in NK cases, and TCR gene rearrangements in T-cell cases [314]. EBV genomes have been identified in the neoplastic cells using Southern blot, PCR, and in situ hybridization techniques. The virus also has been shown to be present in monoclonal form indicating that EBV is present prior to clonal expansion. Comparative genomic hybridization studies of these neoplasms have shown gains of chromosome 2q and many losses involving chromosomal 1p, 4q, 5q, 6q, 7q, 12q, and 15q [322]. Deletion of chromosome 6q (6q21-6q25) is found in 40–50% of NK/T-cell lymphoma cases. Several putative tumor suppressor genes (*HACE1*, *PRDM1*, *ATG5*, *AIM1*, *FOXO3*) were identified in the 6q21–q25 region, and their roles as a potential tumor suppressors were suggested [323–325]. Many other gene alterations are reported, involving angiogenic genes, platelet-derived growth factor alpha, tumor suppressor genes including *TP53*, and deregulation of the AKT, JAK-STAT, and NF-κB pathways. Among these, *TP53* mutations appear to correlate with large cell morphology and more advanced-stage disease [326].

Enteropathy-Associated T-Cell Lymphoma

Enteropathy-associated T-cell lymphoma (EATL) is a rare and clinically distinctive type of T-cell lymphoma that represents <1% of all NHLs. These tumors are thought to arise from intraepithelial T-cells normally present in the gastrointestinal tract, particularly the jejunum and ileum [327]. This lymphoma

is closely linked to celiac disease. As a result, EATL is more common in Northern Europe, where celiac disease is more common. Patients with EATL present with abdominal pain, weight loss, or complications of intestinal perforation [327, 328]. Most, but not all patients with EATL have a history of celiac disease, usually with onset in adulthood. Despite combination chemotherapy the survival of individuals with EATL is poor [327, 328]. Approximately half of patients initially respond to chemotherapy, but almost all relapse and death results from either disease progression or complications of therapy.

It also should be noted that patients with celiac disease have an increased risk of B-cell NHLs, both intestinal and non-intestinal, and B-cell NHLs are more common than EATL [329]. It seems inconsistent that EATL is recognized by the WHO classification whereas B-cell NHLs in patients with celiac disease are not specifically recognized in a similar manner.

Grossly, the involved intestine demonstrates an ulcerating mass than can be flat or exophytic. The ulcer(s) often extend deeply into the bowel wall resulting in perforation. The jejunum and ileum are the most common sites of involvement, but other sites in the gastrointestinal tract have been reported rarely [327]. Histologically, the contiguous, uninvolved intestine often exhibits blunting of villi, increased plasma cells and lymphocytes in the lamina propria, and crypt hyperplasia: evidence of celiac disease. Cases of EATL diffusely replace the intestinal wall and necrosis is common [327, 330]. The neoplastic cells show a wide cytologic spectrum: small, intermediate-sized, large, anaplastic, or Reed-Sternberg-like. Numerous histiocytes and eosinophils are present in the background.

Immunophenotypic studies have shown that EATL tends to be CD3+, CD5-, CD7+, CD56-, CD103+, TCR αβ, and CD4-. CD8 is expressed in 20% of cases [327]. These tumors often express CD30 variably and usually express cytotoxic molecules. Fifty to sixty percent of EATL are positive for EBV.

Cases of EATL show TCR rearrangements and the IG are in the germline configuration [327]. Molecular analysis of biopsy specimens from patients with refractory celiac disease or ulcerative jejunitis, without morphologic evidence of lymphoma, also has shown TCR gene rearrangements suggesting that these diseases are preneoplastic conditions [331]. Comparative genomic hybridization has shown gains of chromosome loci 1q32, 5q34-q35.2, 9q31.3, and 16q12.1 [327, 332].

Monomorphic Epitheliotropic Intestinal T-Cell Lymphoma (MEITL)

This category is newly recognized in the current WHO classification and includes lymphomas that were previously designated as type II EATL [17, 327]. These tumors show no association with celiac disease, and show geographic distribution with increased incidence in Asians and Hispanic populations [17, 333]. MEITL is composed of a monomorphous intermediately sized population of cells. Necrosis is uncommon and there are fewer admixed inflammatory cells in the background than EATL [17]. MEITL has a T-cell immunophenotype similar to EATL, but usually positive for CD8 and CD56 [17]. Gains in chromosome 8q24 which involves *MYC* are seen in high proportion of cases [333, 334]. Up to 80% of cases express TCR γδ, small subset expresses TCR αβ, and coexpression of TCR αβ and TCR γδ as well as TCR silent cases are also reported [335]. Recent study demonstrated *STAT5B* mutations in 36% of MEITL with TCR γδ expression. *STAT3* mutations which are also observed in other T-cell lymphomas with TCR γδ expression were not observed in MEITL [336].

Hepatosplenic T-Cell Lymphoma

Hepatosplenic T-cell lymphoma (HSTCL) is a rare tumor that represents <1% of all NHLs. These neoplasms most commonly affect young adult men, with a median age of up to 35 years, and a subset of cases, approximately 20%, arise in patients with a history of immunosuppression [337, 338]. Patients with HSTCL commonly present with systemic, B-type symptoms and the complete blood count commonly shows thrombocytopenia, often with anemia and leukopenia [337–339]. Leukemic involvement is uncommon at the time of initial diagnosis. Patients also have marked hepatosplenomegaly and minimal or absent lymphadenopathy. Affected patients have an aggressive clinical course with a high rate of relapse and median overall survival of 28 months. An elevated serum bilirubin level, αβ TCR expression, and trisomy 8 are reported to correlate with poorer outcome [337, 338]. Recently, stem cell transplant has been reported to result in long-term survival for a substantial proportion of patients with HSTCL [338, 340].

Histologically, HSTCL diffusely replaces the red pulp of the spleen and involves sinusoids in the liver and bone marrow [337, 341]. Neoplastic cells of HSTCL are predominantly intermediate in size, with pale cytoplasm and round nuclei with condensed chromatin and inconspicuous nucleoli; however, they also show some cytological spectrum ranging from small-sized cells with high N/C ratio and hyperchromatic nuclei to large cells with irregular nuclear contours [338, 341]. Bone marrow is involved in virtually all cases at the time of diagnosis, and mild dyspoietic changes in the background trilineage hematopoietic cells are often observed [342].

Immunophenotypic studies have shown that HSTCL cells are positive for CD3 and CD7, and negative for CD5 and B-cell antigens [337, 338]. Most cases of HSTCL are CD4-, CD8-, but a subset may be CD8+. CD56 is expressed in two-thirds of cases, and CD57 is usually negative. The neoplastic cells are positive for TIA-1 and granzyme M, but are usually negative for perforin, and granzyme B, supporting a mature, non-activated cytotoxic T-cell immunophenotype. Most cases of HSTCL are derived from γδ T-cells, hence the original name *hepatosplenic γδ lymphoma*. However, a subset of

cases, approximately 20%, can express the TCR αβ [338, 343], considered a variant of this disease. EBV is usually negative in these tumors.

Conventional cytogenetic analysis of HSTCL has shown a characteristic abnormality, isochromosome 7q [337, 338, 344]. Trisomy 8 is present in a subset of cases. In one study, isochromosome 7q and trisomy 8 were identified in approximately 42% and 33% of cases at the time of diagnosis, respectively, by conventional cytogenetic analysis and/or FISH [338]. The *TRG* and *TRI* genes in HSTCL are usually rearranged. The *TRB* gene also may be rearranged. Recently, mutations of *STAT5B* and *STAT3* were found in a subset of HSTCL cases [345].

Peripheral T-Cell Lymphoma, Not Otherwise Specified

The term peripheral T-cell lymphoma is used to describe lymphoid neoplasms of mature T-cell lineage (as opposed to tumors of thymic origin). The terms post-thymic and mature T-cell lymphoma also have been used to describe these tumors. Peripheral T-cell lymphoma not otherwise specified (henceforth abbreviated as PTCL) is, in part, a diagnosis of exclusion: a lymphoma of mature T-cell lineage that does not fit into other, more specific categories [346]. In an international collaborative study, PTCL represented approximately 15% of all NHLs worldwide, and 25% of all T-cell NHLs [347].

Most patients with PTCL are adults, with a median age ranging from 51 to 68 years in various studies, with a male predominance [346–348]. Patients usually present with lymphadenopathy but extranodal sites of disease are common including skin, liver, Waldeyer ring, and lung. Most patients have advanced stage disease and approximately 50% have B symptoms. A subset of patients can present with eosinophilia, pruritis or hemophagocytic syndrome [349]. Older age, performance status, high serum LDH, and bone marrow involvement are associated with poorer prognosis and have been proposed as components in a prognostic model [348]. Patients with PTCL have a poor overall prognosis; the 5-year survival in different studies has ranged from 25 to 50% [346, 347].

Histologically, in most cases of PTCL the lymph node architecture is diffusely effaced [346, 350]. Vascular proliferation (epithelioid venules) is common and often many inflammatory cells are admixed within the tumor. Cytologically, the neoplastic cells of PTCL exhibit a spectrum of cell sizes including small, medium-sized, and large and can have abundant clear cytoplasm. Anaplastic or Reed-Sternberg-like cells may be found. Mitotic figures are usually easily identified and are often numerous.

There are unusual morphologic variants of PTCL. A subset of these neoplasms can involve the lymph node in paracortical distribution, sparing lymphoid follicles, known as the T-zone variant [346]. Another subgroup has numerous epithelioid histiocytes often arranged in rows, known as the lymphoepithelioid variant of Lennert lymphoma [351]. Rare cases of PTCL can preferentially surround lymphoid follicles in a marginal zone distribution mimicking marginal zone lymphoma, and others preferentially involve the lymphoid follicles mimicking follicular lymphoma [352]. However, in the current WHO classification, follicular variant of PTCL that manifest a T follicular helper (TFH) phenotype is classified as a distinct entity, designated as *Follicular T-cell lymphoma,* which will be discussed later [17].

Immunophenotypic studies have shown that PTCLs are of mature T-cell lineage. Thus, the neoplastic cells express pan-T-cell antigens, usually TCR αβ, and most cases are CD4+, CD8-, (T-helper cell) or CD4- [346, 347]. Approximately 75% of cases of PTCL exhibit an aberrant T-cell immunophenotype which is useful for diagnosis. Cytotoxic proteins, SYK, and CD56/NCAM are expressed by subsets of cases. Attempts have been made to use the immunophenotype to subdivide cases of PTCL: CD4 versus CD8; cytotoxic versus non-cytotoxic, and Th1 (e.g., CXCR3, CD69, CD134, and T-bet) versus Th2 (CD30 and CXCR4). The cytotoxic or Th1 immunophenotypes have been suggested to correlate with worse prognosis [353]. Rare cases of PTCL have been reported to express B-cell antigens, either CD20 or CD79A, but most B-cell antigens and Ig are negative [346]. Proliferation is usually high and Ki-67 rates exceeding 80% are associated with a worse prognosis [347].

Conventional cytogenetic analysis of PTCL cases commonly shows an abnormal karyotype, with a high frequency of complex karyotypes, particularly in tumors composed of large cells [354]. The most common abnormalities, in general, are copy number changes, but structural rearrangements also occur. There are no consistent abnormalities in PTCL. Comparative genomic hybridization analysis of PTCLs has shown a number of gains and losses [355, 356]. Different studies show different regions of gain or loss. In a study by Nelson and colleagues, the most frequent chromosomal gains were 1q, 3p, 5p, 7q (possibly *CDK6*), and 8q24 (including *MYC*), and the most frequent sites of loss were 6q and 10p [356]. Single nucleotide polymorphism (SNP) analysis also has shown many recurrent gains and losses, with gains of 2p15-16/*REL* in approximately one quarter of cases assessed [357]. In these cases, NF-κB pathway activation is documented [357].

PTCLs show monoclonal TCR gene rearrangements [346]. The IG are usually in the germline configuration. The T-cell receptor gene loci are uncommonly involved in chromosomal translocations. Gene expression profiling of PTCL cases has

shown marked heterogeneity, not surprising based on the disease definition [358]. Genes involved in proliferation, apoptosis, matrix remodeling, and signal transduction are overexpressed in subsets of cases [358]. In one study, a subset of cases had a cytotoxic T-cell gene signature that correlated with poorer prognosis [358]. Two major subgroups of PTCL have been suggested, based on overexpression of *GATA3* or *TBX21/Tbet*, with poorer or better prognosis, respectively [359]. Another important finding of gene expression profiling studies is that there is some overlap between PTCL and angioimmunoblastic T-cell lymphoma (AITL) as well as PTCL and ALK-negative anaplastic large cell lymphoma (ALK-ALCL) [358]. These data suggest that the PTCL-NOS category includes subsets of cases of AITL and ALK- ALCL (by gene expression) that lack characteristic histologic or immunophenotypic features. A recent study with whole-exome sequencing identified a highly prevalent *RHOA* mutation encoding a p.Gly17Val alteration present in 18% of PTCL [360].

Follicular T-Cell Lymphoma

A prominent follicular growth pattern can be observed in rare cases of T-cell lymphoma. There is growing evidence that this lymphoma may be a unique clinicopathologic entity based on its morphologic features and derivation from follicular helper T-cells, although this lymphoma also shows overlapping clinical and/or morphologic features with AITL [361, 362]. Therefore, in the current WHO classification, follicular T-cell lymphoma (FTCL) is listed as a provisional entity, and unified under a common heading with AITL [17]. Recurrent mutations of *TET2, DNMT3A,* and *RHOA* that affect a significant proportion of cases of AITL are also observed in FTCL [363–365]. Patients with FTCL more often present with localized disease. Interestingly, mutations of *IDH2*, common recurrent mutations in AITL, are not observed in FTCL [364]. t(5;9)(q33; q22) which involves the *ITK* and *SYK* genes is reported in both FTCL and AITL [366, 367].

Angioimmunoblastic T-Cell Lymphoma

Angioimmunoblastic T-cell lymphoma (AITL) is one of the most common specific types of T-cell lymphoma in Western nations, representing 15–20% of all cases of PTCL [368].

Clinically, patients with AITL are elderly, with a median age in the seventh decade, and no sex preference [368, 369]. AITL is commonly a systemic disease at its onset characterized by advanced stage disease, immunodysregulation, and immunodeficiency. Many patients have constitutional symptoms such as fever, chills, night sweats, malaise, and arthralgias. Patients usually have peripheral lymphadenopathy, often generalized, and extranodal sites of disease are common including

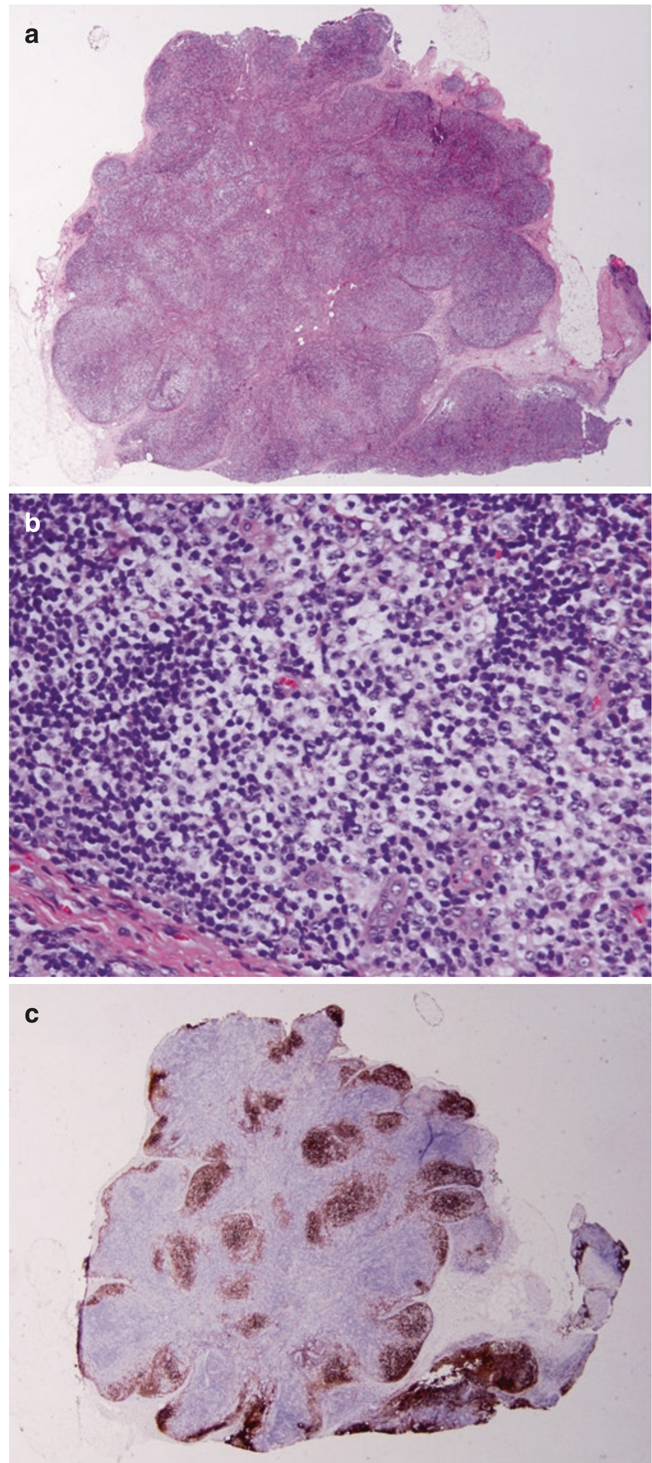

Fig. 40.10 Angioimmunoblastic T-cell lymphoma (AITL) involving lymph node. (**a**) At low magnification the normal nodal architecture can be seen to be replaced. (**b**) Many neoplastic cells with clear cytoplasm are present. (**c**) Immunostaining for CD21 shows many disordered aggregates of CD21+ follicular dendritic cells characteristic of AITL ((**a**) hematoxylin-eosin, 20×; (**b**) hematoxylin-eosin 400×; (**c**) immunohistochemistry with hematoxylin counterstain, 20×)

involvement of liver, spleen, skin, lungs, and bone marrow. Various laboratory abnormalities are common including polyclonal hypergammaglobulinemia, anemia (often hemolytic with positive direct Coombs test), cold agglutinins, circulating immune complexes, cryoglobulins, antinuclear antibodies, eosinophilia, and elevated serum levels of LDH and beta-2-microglobulin. Bone marrow involvement is common. The median survival for all patients with AITL is <3 years, but a subset of patients, approximately 25%, have a more indolent course with better long-term survival [368]. Infectious complications are a common cause of death. Immunomodulator and/or biologic therapeutic agents have been given to patients relatively recently with some promising results, including anti-VEGF (bevacizumab), thalidomide, and cyclosporine A [370, 371]. Age > 60 years, performance status >2, and the presentation with extranodal sites >1, B symptoms and platelet count $<150 \times 10^9$/L were reported to be poor prognostic factors [372].

In lymph nodes AITL can show three general, often overlapping patterns designated as types I, II, and III [368, 373]. In the type I pattern, the overall architecture is partially preserved and many hyperplastic lymphoid follicles are present. In types II and III, there is progressive or complete replacement, respectively, of the lymph node architecture, and small and atrophic (so-called burned-out) germinal centers can be present (Fig. 40.10). A mixture of patterns can occur at presentation, or patients may relapse with a different pattern [373]. The cytological features of AITL are broad, as there is usually an abundant and variable inflammatory infiltrate associated with the neoplastic cells [368, 373]. In fact, in many cases of AITL the neoplastic cells are a minority component in the biopsy specimen. As a result, the histologic appearance of AITL is polymorphous composed of neoplastic small and medium-sized lymphoid cells, often with clear cytoplasm, associated with reactive plasma cells, eosinophils, histiocytes, and B-immunoblasts. Some cases of AITL can have numerous epithelioid histiocytes (mimicking lymphoepithelioid variant of PTCL), as well as plasma cells. These plasma cells can be cytologically atypical and show monoclonal *IGH* rearrangement [374]. Arborizing small blood vessels corresponding to epithelioid venules are present and usually numerous in AITL.

Immunophenotypic studies of AITL have shown that these tumors are of mature T-cell lineage, expressing a variety of pan-T-cell antigens and negative for Ig and B-cell antigens [368]. In addition, most cases of AITL have an immunophenotype closely akin to that of normal follicular T-helper cells [375]. Therefore, the neoplastic cells are CD4+, CD8-, and are often positive for CXCL13, CD10, Bcl-6, PD-1, or CXCR5, as well as other antigens [368, 376]. Normal follicular T-helper cells are located in the light zones of germinal centers and are involved in normal germinal center B-cell differentiation. Their neoplastic transformation in AITL, or the interplay between the neoplastic T-cells and the microenvironment, may explain the presence of abundant non-neoplastic cells in biopsy specimens of AITL including the characteristic proliferation of follicular dendritic cells (CD21+, CD23+). The immunodysregulation and immunodeficiency associated with AITL also may explain the common presence of EBV in non-neoplastic B-immunoblasts in many AITL biopsy specimens. EBV load in tissue biopsy specimens correlates with histologic evidence of progression [377].

Conventional cytogenetic studies have shown a wide variety of numerical and structural abnormalities in approximately 75% of cases of AITL. Trisomies of chromosomes 3, 5, 21, and X and loss of 6q are most common [378]. The presence of a complex karyotype correlates with a poorer prognosis. Comparative genomic hybridization studies have further increased the frequency of detection of chromosomal alterations, identified in up to 90% of AITL cases. EBV is commonly associated with AITLs, as shown by a variety of molecular methods, and is monoclonal in a subset of cases [379]. EBV infection is most likely a secondary event in pathogenesis, as we have observed patients with AITL in which the initial biopsy specimen did not have evidence of EBV, but the virus was abundant at the time of relapse. Gene rearrangement studies have demonstrated that most AITL cases have T-cell receptor gene rearrangements. *IGH* is rearranged in 10–20% of cases [368]. Gene expression profiling studies of AITL have further confirmed the concept that AITL is a neoplasm of follicular T-helper cells [380]. In addition, approximately 90% of the gene signature in AITL is contributed by reactive cells in these lesions, particularly B-cells.

Recently, additional discoveries of the genetic basis for AITL were made. Mutations in the epigenetic regulators *TET2*, *DNMT3A*, and *IDH2* frequently occur in AITL, but are not specific [381, 382]. Most specific to AITL is a point mutation in the Ras homolog gene family member A (*RHOA* G17 V) in almost 70% of AITL samples, resulting in a disruption of RHOA signaling [364]. However, this was also present in PTCL with a TFH-immunophenotype. These studies suggest that these mutations may be acquired in a multistep manner, because all the *RHOA*-mutated samples are *TET2* mutated, and the smaller percentage of *IDH2*-mutated tumors harbored both *TET2* and *RHOA* mutations [364].

Patients with AITL are at risk for developing B-cell lymphomas, particularly DLBCL, and less frequently classical Hodgkin lymphoma or plasmacytoma [368, 383]. A subset of cases of DLBCL and most classical Hodgkin lymphoma arising in this setting are EBV+. One possible explanation for this phenomenon is that EBV infection prolongs B-cell lifespan, increasing the likelihood of secondary molecular aberrations that result in lymphoma. In some patients, the diagnosis of DLBCL can precede the diagnosis of AITL.

Anaplastic Large Cell Lymphoma, ALK-Positive

In 1985, Stein and colleagues [384] identified a subset of NHLs characterized by anaplastic large lymphoid cells, and originally named Ki-1 lymphoma. This neoplasm was subsequently designated as anaplastic large cell lymphoma (ALCL). In the current WHO classification, there are four categories of disease that include the term ALCL: ALK+ ALCL and ALK-ALCL which are their own entities, Breast implant-associated ALCL which is currently considered a provisional entity, and cutaneous ALCL, the latter being a well-established, separate category of disease [17]. ALK+ ALCL is defined as a T-cell lymphoma, usually composed of anaplastic cells, associated with molecular alterations of the *ALK* gene, ALK overexpression, and uniform expression of CD30 [385].

ALK+ ALCL affects children and adults, with a wide age range, but is most common in the first three decades of life [385–387]. There is a male predominance, 1.5 to 1. B symptoms are common in ALK+ ALCL patients, particularly high fever, and approximately 75% of patients have advanced stage disease. Many patients have a high IPI and serum levels of LDH or beta-2 microglobulin are often high. Lymph nodes are the most common site of involvement, but extranodal sites are commonly involved, most often skin, soft tissue, bones, and lungs. Bone marrow is involved in approximately 20% of patients with ALK+ ALCL if searched for diligently using immunohistochemical analysis. Leukemic involvement is uncommon in patients with ALK+ ALCL, but very high leukocyte counts can occur. ALK+ ALCL is clinically aggressive and patients require combination chemotherapy, however, prognosis is favorable. The overall 5-year survival ranges from 60 to 80%.

Histologically, ALK+ ALCL can partially or completely replace lymph node architecture [385–387]. In partially involved lymph nodes, the tumor tends to infiltrate sinuses, or preferentially replaces the paracortex (T-cell region). Necrosis is common and there are high numbers of apoptotic cells and mitotic figures. A starry-sky pattern occurs in a subset of cases. Cytologically, ALK+ ALCL can exhibit a remarkably wide spectrum. The WHO classification recognizes five variants: common or typical (60%) (Fig. 40.11), lymphohistiocytic (10%), small cell (5–10%), Hodgkin-like (3%), and composite or mixed (15%) [385]. The lymphohistiocytic variant is composed of relatively few neoplastic cells associated with numerous lymphocytes and histiocytes. In the small cell variant, large anaplastic neoplastic cells are infrequent and many small lymphoma cells are present. Small cell and lymphohistiocytic components are reported to be associated with poorer response to therapy in the pediatric population [388]. There are also other morphologic variants that are less common including: monomorphic (resembling DLBCL or plasmacytoma), sarcomatoid, eosinophil-rich, neutrophil-rich, and myxoid. In most

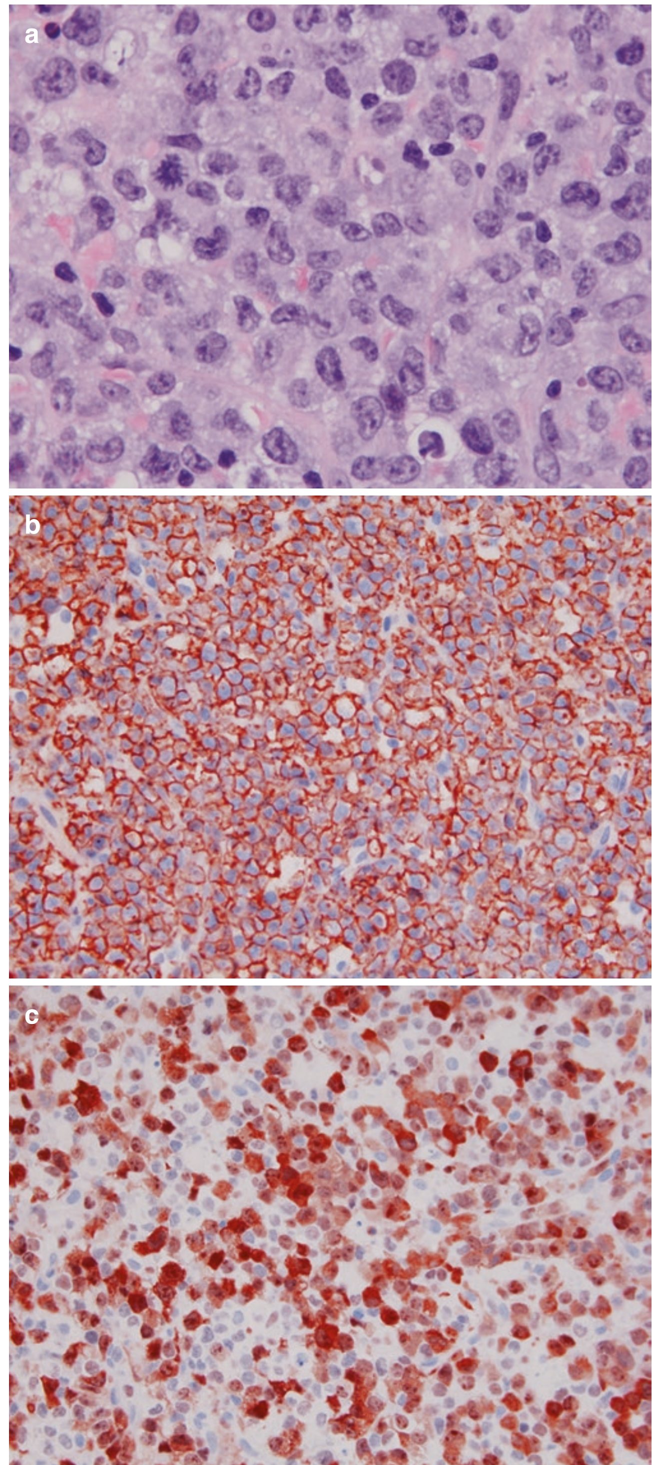

Fig. 40.11 Anaplastic lymphoma kinase (ALK) + anaplastic large cell lymphoma involving lymph node. (**a**) The lymphoma cells are large and a subset has horseshoe-shaped nuclei consistent with so-called hallmark cells. (**b**) The lymphoma cells uniformly and strongly express CD30. (**c**) The lymphoma cells express ALK in a nuclear and cytoplasmic pattern consistent with t(2;5)(p23;q35)/NPM-ALK. ((**a**) hematoxylin-eosin, 1000×; (**b**, **c**) immunohistochemistry with hematoxylin counterstain, 400×)

cases of ALK+ ALCL, irrespective of the variant, at least some hallmark cells are present. These are large cells with a horseshoe- or kidney-shaped nucleus with vesicular chromatin and prominent nucleoli, abundant and basophilic cytoplasm, and a paranuclear clear area or hof [385].

Immunophenotypic studies have shown that all cases of ALK+ ALCL express CD30, with a membranous and paranuclear pattern, as well as ALK [385–387]. Virtually all cases of ALK+ ALCL strongly express CD25, and most cases express EMA/MUC1, T-cell antigens (most often CD2, CD4, CD5, CD43, or CD45RO), cytotoxic antigens (granzyme B and TIA-1), and CD45/LCA (often dim and best detected by flow cytometry). Other molecules often expressed in ALK+ ALCL include: AP-1 transcription factors, phosphorylated (active) STAT3, Bcl-3, cyclin D3, clusterin, fascin, serpin A1, MCL-1, and BAX [368, 389–391]. P53 is commonly expressed but rarely mutated [392]. Ki-67 immunostaining shows a variable but usually high proliferation rate. Bcl-2 is virtually always absent, as is EBV (either EBER or LMP1) and CD117/KIT, and CD15 is very rarely expressed [385, 393]. ALK+ ALCLs are negative for Ig and B-cell antigens. Approximately 10–20% of cases of ALK+ ALCL are immunophenotypically "null cell" without any T-cell antigens being expressed. This occurs more often when only immunohistochemical analysis is used, as a lesser number of antibodies is available, and this method is less sensitive than flow cytometry.

Conventional cytogenetics studies initially showed the t(2;5)(p23;q35) translocation in a subset of cases initially designated as malignant histiocytosis and subsequently as ALCL [394]. The breakpoints of this translocation were then cloned, showing *ALK* at chromosome 2p23 and the nucleophosmin (*NPM1*) at chromosome 5q35 [395]. These genes are disrupted to create a novel *NPM1-ALK* fusion gene [395]. There are many additional molecular alterations of *ALK* including reciprocal translocations and one inversion [387]. These *ALK* gene abnormalities are now known to be characteristic of ALK+ ALCL and are included in the definition of this neoplasm. The t(2;5)(p23;q35) is most common, identified in approximately 80% of cases of ALK+ ALCL. The t(1;2)(q25;p23) involving *TPM3* occurs in approximately 10% of ALK+ ALCLs, and all other known translocations are uncommon, in the range of <1 to approximately 2% [385]. A study by Feldman and colleagues identified a novel *TRAF1-ALK* fusion using deep RNA sequencing [396]. The discovery of this *TRAF1-ALK* fusion expands the diversity of known ALK fusion partners and highlights the power of deep sequencing for fusion transcript discovery [396].

The pattern of ALK expression, as shown by immunohistochemical analysis, correlates with the molecular abnormalities present [385, 387]. Tumors carrying the t(2;5) have a nuclear and cytoplasmic pattern of ALK expression (Fig. 40.11c). This is because NPM1 can migrate from the cytoplasm into the nucleus. The rare t(2;X)(p23;q11–12) involves *moesin* (*MSN*). Tumors with this translocation have a membranous pattern of ALK expression, because *MSN* is located in the membrane. All other translocations result in a cytoplasmic pattern of ALK expression. The t(2;17)(p23;q23) involving *clathrin* (*CLTC*) is distinctive because the ALK expression pattern appears flocculent. This is true because CLTC is normally located in the membranes of cytoplasmic vesicles.

ALK+ ALCLs usually carry TCR gene rearrangements. Most of the "null cell' cases also carry TCR gene rearrangements but approximately 10% do not. Perhaps this subset of tumors arises from an early T-cell progenitor, at a stage of differentiation prior to gene rearrangement. The *perforin* gene is reported to be mutated in a subset of cases [397]. The *SHP1* and *RB* genes are commonly inactivated or deleted [398]. Comparative genomic hybridization analysis has shown areas of chromosomal gain or loss in approximately 60% of ALK+ ALCLs, including gains of chromosome 7, 17p, or 17q24, and losses of 4q13–21, 11q14, or 13q [399]. Gene expression profiling has shown that ALK+ ALCL has a different signature than ALK- ALCL, with overexpression of over 100 genes [400]. The top four genes are *BCL6*, *PTPN12*, *CEBPbeta*, and *serpin A1*. A number of studies have elucidated pathways that are active in ALK+ ALCL including pathways involved globally in proliferation, ribosome synthesis, survival, apoptosis evasion, angiogenesis, and cytoarchitectural organization.

The NPM-ALK fusion protein activates various signaling pathways in ALK+ ALCL cells, including the JAK/STAT3, PI3K/AKT/mTOR, RAS/ERK, and PLCγ pathways. Rearrangements of *MYC* have been reported in ALK+ ALCL. All these patients with dual *ALK* and *MYC* rearrangements demonstrated an aggressive clinical course, with systemic and extranodal presentation, early tumor relapse, and bone marrow involvement during the course of the disease [401, 402].

Anaplastic Large Cell Lymphoma, ALK-Negative

This disease is defined in the WHO classification as a CD30+ T-cell lymphoma "not reproducibly distinguishable on morphological grounds from ALK-positive ALCL, but lacks ALK protein" [403]. Recent clinical, pathologic, and genetic data have revealed significant heterogeneity in ALK- ALCL [404].

Patients with ALK- ALCL can be any age, but most patients are adults 40–65 years old. The male-to-female ratio is 1.5 to 1 [403]. Lymph nodes are most commonly involved but extranodal sites can be involved, most often skin, soft tissues, and bones. Patients often have B symptoms, advanced stage disease, and an aggressive clinical course requiring combination chemotherapy [403].

Histologically, most cases of ALK- ALCL resemble the common variant of ALK+ ALCL [386, 403, 404]. The neoplasm has a tendency to infiltrate lymph node sinuses. The lymphoma cells are large and often more pleomorphic, with a higher nucleus-to-cytoplasm ratio than observed in ALK+ ALCL. Hallmark cells, however, are present. Immunophenotypic studies show uniform expression of CD30 in a membranous and paranuclear pattern and absence of ALK [403]. ALK- ALCLs express T-cell antigens and most cases are positive for cytotoxic molecules and clusterin [386, 387, 403]. Many cases of ALK- ALCL express Bcl-2 and approximately 50% of cases express survivin. A subset of cases can express EMA or CD15, and all cases are negative for Ig and B-cell antigens.

Until recently, the genetics of ALK- ALCL has been unknown. A recent study by Parrilla and colleagues identified *DUSP22* and *TP63* rearrangements in 30% and 8% of systemic ALK-negative ALCLs, respectively [404]. The former involves the *DUSP22-IRF4* locus on 6p25.3, and is most commonly present as t(6;7)(p25.3;q32.3) [405]. *DUSP22* is a dual-specificity phosphatase that inhibits T-cell receptor signaling by inactivating MAP/ERK [406]. Most frequent partner gene of *TP63* is *TBL1XR1* [407]. *TP63* encodes the p53 family member, p63, and the gene rearrangements encode p63 fusion proteins which have putative oncogenic function [407]. These rearrangements are mutually exclusive, and are uniformly absent in ALK+ ALCL. *DUSP22* rearranged cases have favorable outcomes similar to ALK+ ALCL. *TP63* rearranged ALCLs have a poor prognosis.

Breast Implant-Associated Anaplastic Large Cell Lymphoma

Breast implant-associated ALCL is included as a provisional entity in current WHO classification [17]. Both saline and silicone filled implants have been implicated, with a median interval from the time of the implant to the lymphoma of about 10 years [408]. Histologically, breast implant-associated ALCLs are composed of large pleomorphic cells that are usually confined to serous fluid or the capsule surrounding the implant [408–410]. Immunophenotypic studies have shown strong and uniform expression of CD30 and T-cell antigens, with absence of ALK in all cases [410]. Many breast implant-associated ALCLs also express cytotoxic proteins, clusterin, and EMA. These neoplasms carry monoclonal TCR gene rearrangements.

In most cases the neoplastic cells are confined to the seroma fluid, without invasion of the capsule. In such cases conservative management is recommended, with removal of the implant and capsule [411]. If there is invasion through the capsule, there is a risk of lymph node involvement and systemic spread, warranting systemic chemotherapy [411]. The risk factors to develop this lymphoma have not yet been established.

Hodgkin Lymphoma

Hodgkin lymphoma (HL) represents approximately 10–15% of all lymphomas. The older classification of Jackson and Parker [412] divided HL into three groups: paragranuloma, granuloma, and sarcoma (Table 40.4). Although this classification recognized the excellent prognosis of patients with paragranuloma and the poor prognosis of patients with sarcoma, most cases fit within the granuloma group. This category was very heterogeneous in terms of clinical presentation, histologic findings, and prognosis thereby limiting the utility of the Jackson and Parker system. In 1966, Lukes and Butler [413] developed another HL classification in which six categories were recognized: lymphocytic and/or histiocytic (L&H) nodular, L&H diffuse, nodular sclerosis, mixed, diffuse fibrosis, and reticular. These categories recognized the distinctive neoplastic cells and the composition of the reactive cells found in the different types of HL. Subsequently, at an international symposium in Rye, New York, the Lukes and Butler classification was consolidated into four groups: lymphocytic predominance, nodular sclerosis, mixed cellularity, and lymphocytic depletion

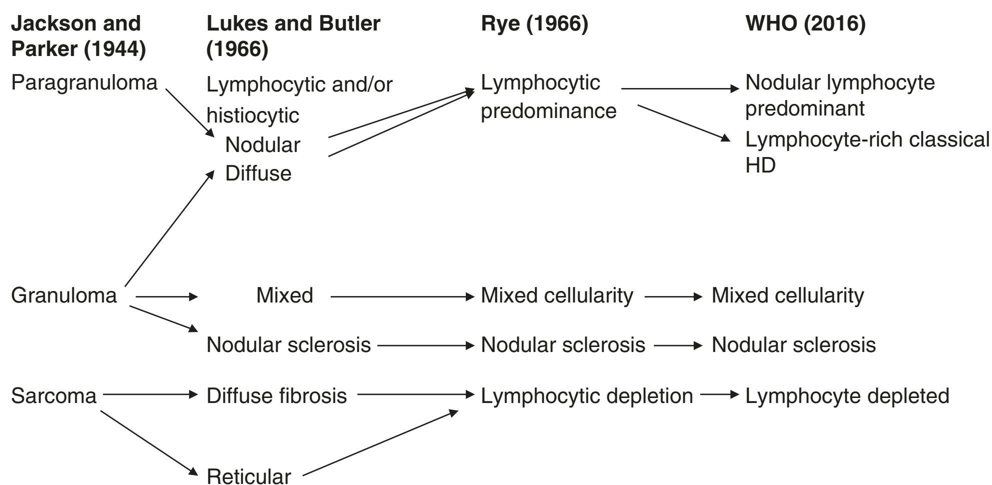

Table 40.4 Hodgkin lymphoma classification: historical and present

[414]. The L&H nodular and diffuse groups were combined into the lymphocytic predominance category and the diffuse fibrosis and reticular groups were consolidated into the lymphocytic depletion category. The Rye classification gained universal acceptance, was easy to use, and the categories correlated with clinical parameters. Nevertheless, some useful information was lost in the consolidation of the Lukes and Butler classification. This information was subsequently recaptured and in the 1980s and 1990s. In the WHO classification, two broad categories of HL are recognized: nodular lymphocyte predominant and classical HL. The latter group is composed of four types: nodular sclerosis, mixed cellularity, lymphocyte-rich classical, and lymphocyte depleted [17].

Hodgkin lymphomas share a number of clinical and pathologic features that distinguish them from NHLs. Hodgkin lymphomas tend to occur in children and younger adults, and arise in lymph nodes. Extranodal sites of origin are rare. Classical HLs begin in the interfollicular region of lymph node and progressively efface the architecture of that lymph node, and then usually spread in an orderly fashion to contiguous lymph node groups. This pattern of spread is quite different from many types of NHL. Another distinctive feature is the cellular composition of HLs. The neoplastic cells in a biopsy specimen involved by HL are usually only a minor component, often less than 1% of all cells in the specimen. The neoplastic cells are known as lymphocyte predominant (LP) cells in nodular lymphocyte predominant HL and as Reed-Sternberg and Hodgkin (RS + H) cells in the classical HL types. The remaining cells in biopsy specimens are reactive inflammatory cells.

Approximately 75% of HL patients can be cured with appropriate therapy and all histologic types are responsive to standard therapy. The major findings that correlate with response to therapy include patient age, presence or absence of systemic symptoms, stage, tumor bulk, and laboratory findings such as a high serum LDH level [415]. Although histologic type does not correlate with response to therapy, classification remains useful. In nodular lymphocyte predominant, the LP cells strongly express CD20, and rituximab has been used in therapeutic protocols [416]. For classical HL, brentuximab vedotin (antitubulin agent monomethyl auristatin E conjugated to CD30-specific monoclonal antibody) induces durable responses for relapsed or refractory cases [417, 418]. The HL type also correlates, in part, with patient age, sites of involvement, stage at presentation, and the presence of systemic symptoms [419].

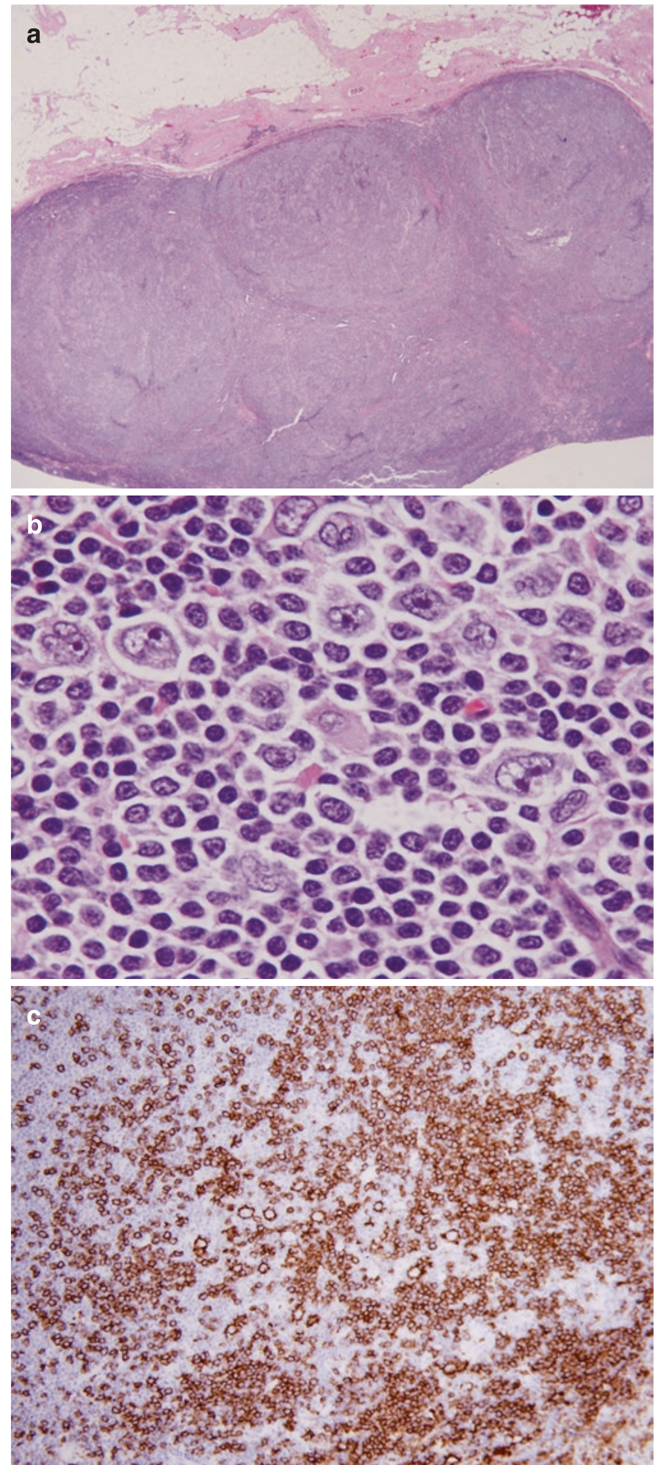

Fig. 40.12 Nodular lymphocyte predominant Hodgkin lymphoma involving lymph node. (**a**) Nodular pattern is obvious at low magnification. (**b**) High magnification of one nodule shows many large neoplastic lymphocyte predominant (LP) cells in a background of reactive small lymphocytes and histiocytes. (**c**) Immunostaining for CD20 shows that LP cells and many small reactive lymphocytes are CD20+ B-cells ((**a**, **b**) Hematoxylin-eosin, (**a**) 20× and (**b**) 1000×; (**c**) immunohistochemistry with hematoxylin counterstain, 200×)

Nodular Lymphocyte Predominant HL

Approximately 5% of patients with HL have the nodular lymphocyte predominant (NLP) type, which is usually localized and most involves cervical or axillary lymph nodes [420, 421].

Spleen, liver, and bone marrow are rarely involved (unless transformation to DLBCL has occurred). The disease can affect patients of all ages, but most patients are younger adults, between 30 and 50 years of age. There is a marked male predominance, with a male-to-female ratio up to 3 to 1 in some studies. Systemic symptoms, such as fever, weight loss, and night sweats are infrequent. This disease is clinically indolent. In an epidemiologic study from the NCI Statistics, Epidemiology, and End Results (SEER) program, the 5-year overall survival rate of patients with NLPHL was 83.9% [422].

Histologically, NLPHL is characterized by effacement of nodal architecture by variably sized, vague nodules composed of numerous small lymphocytes, histiocytes, and characteristic neoplastic LP (previously known as L&H) cells (Fig. 40.12) [420]. These cells are large with pale cytoplasm and polyploid, vesicular nuclei containing inconspicuous, basophilic nucleoli. LP cells resemble kernels of popped corn, hence the nickname *popcorn cells*. Eosinophils, neutrophils, and plasma cells are usually absent. Cells resembling Reed-Sternberg cells are rare. There is no associated necrosis or sclerosis, but sclerosis can be present at the time of relapse. It has long been recognized that NLPHL can have varied growth patterns, including some with diffuse areas and/or numerous T-cells. Fan and colleagues designated six histologic patterns; "classic" (B-cell-rich) nodular, serpiginous/interconnected nodular, nodular with prominent extranodular LP cells, T-cell-rich nodular, T-cell-rich diffuse large B-cell like, and a (diffuse) B-cell-rich pattern [423]. Among these, the typical histopathologic growth patterns in NLPHL include "classic" (B-cell-rich) nodular, and serpiginous/interconnected nodular subtype, and these comprise 75% of NLPHL cases. Twenty-five percent of NLPHL cases show one of the variant patterns, and these have been reported to be associated with advanced disease and a higher relapse rate [424].

Immunohistochemical studies have shown that NLPHL is distinct from other types of HL [420]. The LP cells express CD45, Ig J chain, pan-B-cell antigens (bright expression), and Bcl-6. The LP cells can express EMA or IgD in approximately 50% and 25% of all cases, respectively, and LP cells are almost always negative for CD15 and CD30. The neoplastic nodules can be observed to be centered in follicles. The nodules have a prominent network of follicular dendritic cells (CD21+, CD23+, and/or CD35+) and many intrafollicular T-cells (follicular helper T-cells) are present that often express CD4, CD10, CD57, Bcl-6, and PD-1. These T-cells can surround and form rosettes around the LP cells. The combination of histologic and immunophenotypic findings also allows one to appreciate the spectrum of patterns in cases of NLPHL.

Single cell PCR analysis of LP cells in NLPHL have shown monoclonal *IGH* gene rearrangements and a high number of somatic mutations in the variable regions, with evidence of ongoing mutations, consistent with a germinal center-derived B-cell tumor [425, 426]. These rearrangements are usually functional and Ig mRNA transcripts can be identified in most LP cells. Mutations of B-cell genes (e.g., *PAX5*) have been reported in a subset of cases and approximately 50% of tumors carry *BCL6* rearrangements [427]. Comparative genomic hybridization analysis of NLPHL revealed a high number of genomic imbalances in LP cells [209]. The chromosomes most often involved in that study were gains of chromosomes 1, 2q, 3, 4q, 5q, 6, 8q, 11q, 12q, and X, and loss of chromosome 17. A gene expression profiling study of microdissected LP cells showed that these cells have a gene signature corresponding to a transitional stage between germinal center B-cells and memory B-cells. LP cells further show a partial loss or defective B-cell phenotype with upregulation of genes in the NF-κB pathway and dysregulation of apoptosis [428]. Both NLPHL and CHL are characterized by constitutive activity of the NF-κB pathway, however, the mechanisms of underlying activation of NF-κB pathway are different between these two [428, 429]. The inactivating mutations found in genes such as *NFKBIA* and *TNFAIP3* in CHL are not present in most cases of NLPHL [429]. EBV infection, which is known to drive NF-κB activation in some cases of CHL, is rare in NLPHL.

Classical Hodgkin Lymphoma

Lymphocyte-Rich Classical HL

In the past decade, cases of classical HL were recognized that histologically resemble NLPHL, in either a nodular or diffuse pattern, but immunophenotypically resemble the classical types of HL [430]. In the WHO classification, these neoplasms are designated as *lymphocyte-rich classical HL* [431]. Others have questioned whether lymphocyte-rich classical (LRC) HL should be designated as a distinct type, or is more simply an early or transitional form of either nodular sclerosis or mixed cellularity HL.

In the largest study of LRCHL, including 145 patients as part of the German Hodgkin's Study Group, LRCHL represented 5% of all cases of HL [432]. The median age of affected patients is 38 years and there is a male predominance. B symptoms are uncommon and patients usually present with either stage I or II disease, most often involving cervical, supraclavicular, or axillary lymph nodes. The prognosis of patients with LRCHL is good, similar to patients with NLPHL [432].

The neoplastic RS + H cells in LRCHL have the immunophenotype of classical HL, being positive for CD15, CD30, PAX5 (dim), and negative for CD45/LCA [431]. In addition, the neoplastic cells seem to have intermediate features

between the LP cells of NLPHL and RS + H cells of classical HL [433]. In LRCHL the neoplastic cells more frequently express Bcl-6 and B-cell transcription factors than the RS + H cells of classical HL [433]. The background inflammatory cells in LRCHL are closer to that of follicles, more similar to NLPHL than classical HL, and lack eosinophils and neutrophils. In addition, a follicular T-cell microenvironment was identified in 50% of lymphocyte-rich classical Hodgkin's lymphoma cases [433]. Following these findings, LRCHL appears to occupy an intermediate position between classical HL and NLPHL, nevertheless, molecular studies of the neoplastic cells in LRCHL have shown *IGH* gene rearrangements with variable region mutations, without evidence of ongoing mutations, more in keeping with classical HL [434].

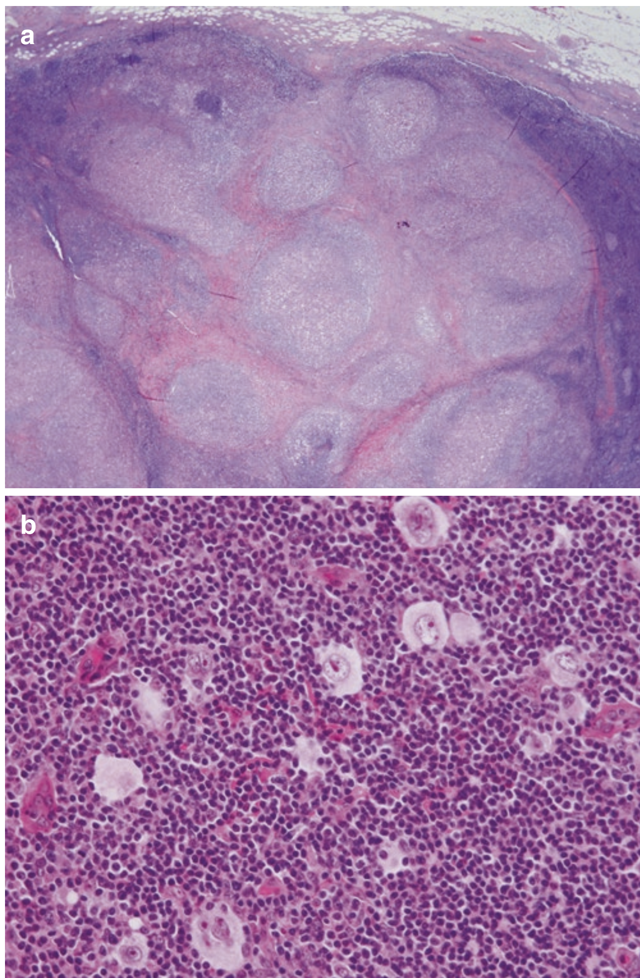

Fig. 40.13 Nodular sclerosis Hodgkin lymphoma. (**a**) Low magnification shows nodules of tumor surrounded by dense fibrous (sclerotic) bands. (**b**) Large, neoplastic lacunar cells in a background of predominantly small reactive lymphocytes (hematoxylin-eosin, (**a**) 20×; (**b**) 400×)

Nodular Sclerosis HL

Nodular sclerosis (NS) is the most common form of HL, representing approximately 70% of all cases [422, 435]. It is the most common type of HL below the age of 50 years, with the peak age range being between 15 and 35 years. The age-adjusted incidence rate of NS has increased in the United States over the past three decades [422]. This increase was greatest in adolescents and young adults. The disease affects men and women with equal frequency. Whites are affected more often than blacks and Hispanics. There is a correlation between overall economic resources and the frequency of disease, with wealthy countries and individuals of higher socioeconomic status having a higher incidence of NSHL.

NSHL has a marked predilection for involving cervical, supraclavicular, and mediastinal lymph nodes and the thymus can be involved [435]. B symptoms occur in up to 30–40% of patients. Approximately 80% of patients have a mediastinal mass, which often is bulky, and therefore most patients present with stage II disease. The disease can invade into the lungs. The bone marrow is involved in less than 5% of patients at the time of diagnosis. According to an NCI SEER study, the 5-year survival rate was 82.2% [422].

Histologically, NS is characterized by a triad of findings: (1) a nodular pattern, (2) broad bands of fibrosis that surround nodules, and (3) a characteristic mononuclear cell variant known as a lacunar cell (Fig. 40.13) [435]. According to the WHO classification definition of NSHL, at least one nodule must be surrounded by fibrous bands [435]. A lacunar cell has abundant clear cytoplasm with a sharply demarcated cell membrane. In formalin-fixed tissue the cell cytoplasm retracts leaving a clear space or lacuna surrounding the cell, which led to its name. The lacunar cell nucleus may be hyperlobulated or may contain multiple small nucleoli. The nucleoli are usually smaller than those seen in classic RS + H cells. A heterogeneous inflammatory cell background can be seen in NSHL, including small lymphocytes, histiocytes, eosinophils, neutrophils, and plasma cells in a variable mixture. Cases of NSHL with sheets of lacunar cells, often associated with necrosis and lymphocyte depletion, have been designated as syncytial variant of NSHL, and are reported to have a poorer prognosis [436]. Efforts have been made to grade cases of NSHL based on the numbers of neoplastic cells and reactive cells. British National Lymphoma Investigation (BNLI) proposed a grading system to subclassify into NS I and NS II, based on the number of RS + H cells, atypia, and quality and quantity of fibrosis. However, prognostic significance is controversial. Later, The German Hodgkin Lymphoma Study Group (GHSG) proposed a grading system based on the three risk factors (eosinophilia, lymphocyte depletion, and atypia of the RS + H cells). Cases with one or more risk factors are subclassified as high risk, and have poorer prognosis [437].

Mixed Cellularity HL

Mixed cellularity (MC) is the second common type of HL, representing approximately 25% of cases in wealthy countries, and is more frequent in poorer countries and in patients with HIV infection [422, 438]. This type is the most common form of HL in patients older than 40 years. Males are affected more often than females, with a ratio of approximately 2 to 1. In African-Americans and Hispanics, MCHL is relatively more common than in whites. Most patients present with peripheral lymphadenopathy. The mediastinum is rarely involved. B symptoms are common, in approximately 50–60% of patients, and most patients have clinical stage III or IV disease. According to NCI SEER data, the 5-year overall survival rate of patients with MCHL is 68.1% [422].

Histologically, MCHL is characterized by a large number of classic Reed-Sternberg cells and mononuclear (Hodgkin) cell variants. The lymph node architecture is usually diffusely replaced, but partially involved lymph nodes show selective paracortical infiltration. Rarely, a purely interfollicular pattern is present. Focal necrosis may be found, but the necrosis is usually not prominent. The reactive cell component is commonly composed of eosinophils, plasma cells, histiocytes, and small lymphocytes in variable proportions. In some cases histiocytes can predominate, often in clusters and with epithelioid features, making it difficult to identify the neoplastic cells. EBER is more frequently positive (approximately 75% of cases) than in nodular sclerosis and lymphocyte-rich classical HL [438].

Lymphocyte-Depleted HL

Lymphocyte-depleted (LD) is the least common type of HL, representing less than 1% of cases [439]. The median age of patients with LDHL occurs in the fourth or fifth decades, and the male-to-female ratio is approximately 2 to 1. Whites and blacks are equally affected [422]. Patients with LDHL are older, and present more often with advanced disease, and more frequent B symptoms than patients with other subtypes of HL [440, 441]. Patients with LDHL have the poorest prognosis of all types of HL, with a 5-year survival rate of 36.4% in a NCI SEER study [422].

Karube et al. reported that LD type represents an independent prognostic factor among classical Hodgkin lymphoma by multivariate analysis [441].

Grossly, the extent of tumor is often greater in LDHL than in other types of HL, and patients commonly have a large contiguous mass of matted lymph nodes or diffuse visceral involvement. In patients with LDHL, the incidence of non-contiguous lung involvement is high, suggesting vascular spread.

The age-adjusted incidence rate for LDHL in the NCI SEER database has decreased over the past decades [422]. This decrease is most likely explained by the recognition by pathologists that many tumors previously classified as LDHL are, in fact, NHLs [422, 442]. Improved classification is the result of application of immunohistochemical and molecular methods to the study of lymphoid neoplasms.

Histologically, LDHL can be subdivided into diffuse fibrosis and reticular variants as defined by Lukes and Butler. In the diffuse fibrosis variant, the tumor is characterized by an extensive proliferation of disordered, hypocellular fibrosis [439–441]. Reed-Sternberg and Hodgkin cells are usually numerous and may be spindled within dense collagen. Reactive inflammatory cells are relatively few. In the reticular variant, there are numerous RS + H cells and bizarre variants that have been termed pleomorphic variants. These cells may exhibit extreme variations in nuclear number and shape, often with giant nucleoli. Necrosis is common and may be extensive. Mitotic figures are usually numerous. EBV infection is common in LDHL.

Immunophenotypic Findings of Classical HL

In general, analysis of tissues involved by classical HL using flow cytometry is not helpful. The RS + H cells are typically infrequent in involved tissues and thus are difficult to assess [443]. Immunohistochemical methods are more helpful because this technique allows direct observation of RS + H cells as well as reactive cells. Thus, most pathologists currently assess HL cases using fixed tissue sections [443]. Reed-Sternberg and Hodgkin cells express CD15 (60–70%) and CD30 (>95%), and are negative for CD45/LCA. The B-cell differentiation program of RS + H cells is highly defective, and therefore these cells express pan-B-cell antigens such as CD20 variably, and in only a subset of cases, approximately 20%. A number of B-cell transcription factors are either weakly expressed by RS + H cells (e.g., PAX5), or are expressed in only subsets of cases (e.g., OCT2, BOB.1) [443]. Ki-67 immunostaining shows that most RS + H cells are positive and therefore proliferating. Bcl-2 is positive in up to half of classical HLs and has been correlated with poorer prognosis. NF-κB is expressed by RS + H cells in most cases of HL [443]. T-cell antigens can be aberrantly expressed by RS + H cells in approximately 10% of classical HL cases, but almost all of these tumors carry *IGH* rearrangements and are of B-cell origin [444]. The background lymphocytes in classical HL are a mixture of polytypic B-cell and T-cells, and histiocytes are also present. It is clear that the tumor microenvironment is very important. Expression levels of FOXP3, CD68, and CD20 in a background cells are also reported to be associated with prognosis [445].

EBV is present in the RS + H cells of classical HL in over two-thirds of cases of MCHL and LDHL, and in approximately 20% of NS [422, 443, 446]. Most cases of HL arising in the setting of HIV infection are EBV+. When present, EBV is present in monoclonal, episomal form and viral proteins are expressed with a type II latency pattern [446].

Molecular Genetic Findings of Classical HL

Conventional cytogenetic studies have revealed non-random complex abnormalities in up to half of HL cases. Chromosomal breakpoints have been reported to involve 6q15-16, 7q31-35, 8q22-24, 11q32, 12p11-13, 13p11-13, and 14q32 [447]. Comparative genomic hybridization methods also have shown a wide, variable number of chromosomal copy number changes occurring in subset of cases of classical HL [448].

For years the origin of the RS + H cells in classical HL was in doubt. However, with the onset of single-cell PCR methods it is now clear that almost all (if not all) cases of classical HL are of B-cell lineage [425, 426, 443]. The RS + H cells have *IGH* gene rearrangements and variable regions carry a high load of somatic mutations, and sometimes crippling mutations. In addition, a number of proteins are aberrantly expressed in classical HL (e.g., ID2) that, in combination with the molecular findings, may explain the defective B-cell differentiation that is characteristic of RS + H cells. Gene expression profiling and other methods have shown that a number of pathways are important in the pathogenesis of classical HL, with the NF-κB and JAK-STAT pathways being prominently involved, but genes involved in angiogenesis, apoptosis, extracellular matrix remodeling, proliferation, and cytokines also involved [449, 450]. Several studies have gone on to further implicate activation of the NF-κB pathway, via mutations in a number of genes including *NFKBIA, NFKBIE, TNFAIP3, REL*. Of note, these mutations are far less frequent in EBV-positive CHL, suggesting that the virus may replace the role of mutations in NF-κB pathway activation. Hypermethylation, a well-established modality of tumor suppressor gene inactivation, has been shown to be consistently present in the promoter regions of several key B-cell–specific transcription factors such as BOB.1 and PU.1 [451]. Furthermore, aberrant expression of *NOTCH1* and *ID2* involved in T-cell and NK-cell differentiation may cooperate with the aforementioned mechanisms to mask the B-cell gene signature of these cells. In conjunction with downregulation of the B-cell gene signature, several other pathways including the MAP/ERK and JAK/STAT pathways also promote survival and proliferation in CHL [452, 453].

Hodgkin Lymphoma and the Two-Disease Hypothesis

For many years epidemiologists have suggested that HL is heterogeneous and represents more than one disease [454]. This two-disease hypothesis suggested NSHL and MCHL as two different diseases. The epidemiologic, clinical, and pathologic findings support this hypothesis.

The age-adjusted incidence rates of NSHL and MCHL are distinctive. NSHL preferentially affects adolescents and young adults. Males and females are affected almost equally. Mediastinal lymph nodes and low clinical stage disease are the rule. The following social factors correlate with an increased risk of NSHL: small family size, early birth order, a single-family home, fewer neighborhood playmates, higher maternal education, and higher paternal social class [455, 456]. These epidemiologic findings suggest that NSHL is the result of relatively late exposure to an infectious agent, analogous to the paralytic polio model. By contrast, MCHL is relatively more common in young children and older adults. Males are affected more often than females. The mediastinum is involved less often and advanced stage of disease is more frequent. Social factors that correlate with increased risk of MCHL are the converse of NSHL: large family size, late birth order, more neighborhood playmates, lower maternal education, and lower paternal social class [455, 456]. These findings suggest that early exposure to an infectious agent may play a role in causing MCHL.

EBV, commonly identified in MCHL, may help to explain some of these epidemiologic features. Children <5 years of age rarely develop HL. Perhaps in this age group children are exposed to EBV, particularly in poor socioeconomic conditions, but a latency period is needed prior to the development of HL as a result of primary infection. Cases of MCHL in adults and the elderly population may be the result of reactivation of EBV, perhaps secondary to immunodeficiency that occurs as a result of aging or other causes. The relatively low prevalence of EBV in NSHL suggests that EBV is not necessary for NSHL to develop and that another infectious agent or other factors may be responsible. The marked heterogeneity of the pathologic and clinical findings within NSHL also raises the possibility that this disease may result from more than one infectious agent.

It also now seems clear that the two-disease hypothesis was too simple. Nodular lymphocyte predominant disease is a third disease included under the rubric of HL. The independent status of NLPHL as a third disease is supported by its unique immunophenotype, molecular features, and distinctive clinical behavior, characterized by late relapses. It seems likely that LDHL is an end stage of other types of HL. The place of LRCHL is not clear, as it has features intermediate between classical HL and NLPHL.

41 Immunology of the Lymphomas

Christopher Sequeira and Howard Ozer

Introduction

In the past 50 years, important discoveries have helped our current understanding of the immune system and its neoplasms. Early investigations led to the identification of distinct subpopulations of lymphocytes, the T (thymic-derived), B (bursa-equivalent), and natural killer (NK) lymphocytes which were not necessarily discernible by morphology and had differing functions [1, 2]. Cell-mediated immunity was found to be a function of T lymphocytes, while antibody responses (humoral immunity) were found to be a function of B lymphocytes. T and B cells were differentiated by the presence of certain antigens or proteins on their cell surfaces, specifically erythrocyte-rosette receptors (T) and surface immunoglobulins (B). It was later noted that different stages of lymphocyte maturation could be distinguished by the combination of particular antigens, generally glycoproteins, present on the cell surface, termed differentiation antigens. These antigens may be identified by specific, pure hybridoma antibodies (monoclonal antibodies) raised against them. The discovery of surface antigens on lymphocytes revolutionized the study of lymphoma. The combination of surface antigens (now termed cluster designation or CD group) present on a particular cell was designated its immunophenotype. The use of immunophenotypes has been helpful in classifying lymphomas into groups of B- or T-cell types and has provided insight into lymphocyte maturation. The result has been the development of new schemas of lymphocyte differentiation and new histologic classification systems attempting to correlate histology with phenotype. The progress in technology at the molecular level now permits detection of the earliest commitment to B- and T-lymphoid differentiation and serves to confirm immunophenotypic data.

As more has become known about lymphocyte differentiation and function, the role of abnormal immune responses in the development and perpetuation of lymphomas has been exploited for therapeutic potential. The efficacy of therapy with biologic agents that are employed to improve or restore abnormal immune function continues to be an area of intense ongoing investigation.

Immunologic Phenotyping

The phenotypic analysis of lymphomas has yielded practical applications for diagnosis and furthered our knowledge of lymphocyte differentiation. Understanding the development of lymphocytes from stem cells to mature, immunocompetent T and B cells is made easier by the demonstration of lineage-specific differentiation antigens. However, the critical initial step is to subclassify lymphoproliferative neoplasms within the T- and B-cell category because several of these differentiation antigens, for example, immune-associated antigen (Ia) determinants, are not necessarily T- or B-specific. The ability to detect the commitment to B- or T-cell lineage at an earlier stage is now possible through analysis of immunoglobulin gene or T-cell receptor (TCR) gene rearrangements.

In 1832, Thomas Hodgkin provided what is thought to be the first description of a patient with lymphoma [6]. More descriptions into the twentieth century of patients with enlarged lymph nodes and pathologic lymphoid follicle proliferation eventually led to a classification of approximately 600 patients by Gall and Mallory in the early 1940s [7]. They described follicular lymphoma (FL) as a distinct entity based on morphologic and clinical characteristics and described its ability to progress by histology in a series of 63 cases reported in 1941 [8]. The advent of the Rappaport classification in 1956 brought a novel approach to the description of lymphomas categorizing them as either “nodular” or “diffuse,” the latter noted to have a worse prognosis [9, 10].

Emerging techniques in immunophenotyping were applied to these entities within the Rappaport classification identifying their cell of origin as a follicular B cell [11]. The propensity of sheep erythrocytes to form rosettes around human T lymphocytes was utilized to identify Sezary cells and a proportion of lymphoblastic lymphomas to be of T-cell origin [12, 13]. This "E-rosette receptor" was eventually identified as CD2, a differentiation antigen found on nearly all T cells [14, 15]. The criteria utilized to establish the B-cell nature of a particular lymphoma are highly accurate but complicated. Any cell capable of synthesizing immunoglobulin, even by genetic criteria, is considered of B-cell origin. This can be rigorously demonstrated by removing all existing surface immunoglobulin. In lieu of this time-consuming procedure, with its limitations of cell viability, the demonstration of surface or cytoplasmic immunoglobulin showing restriction of the light chain (only κ or λ) is considered sufficient to conclude that a malignant cell is of B origin [16]. The demonstration of surface immunoglobulin alone is not sufficient to identify B cells conclusively because adsorption or uptake by Fc receptors of exogenous immunoglobulin in the serum will give a false-positive result, although in these cases there will be no light chain restriction [17, 18]. Conversely, adsorption of exogenous cytophilic immunoglobulin may give a falsely polyclonal finding for malignant monoclonal B cells that also express Fc receptors. In both these instances, the demonstration of J chains, present only in cells that synthesize immunoglobulin, may clarify the nature of the cell in question [19, 20]. The development of monoclonal antibodies through the use of hybridomas in 1975 [21] helped revolutionize the approach to lymphocyte and lymphoma immunophenotyping. The first monoclonal antibody targeting a human lymphocyte differentiation antigen was developed in 1979 [22]. The antigen was expressed on normal thymocytes and was later identified as CD1a in the human leukocyte differentiation antigen system [23]. In an effort to organize the evolving discoveries of cell membrane antigens, the CD or "clusters of differentiation" nomenclature was developed. To date, 350 CD designations have been determined and now include not only those found on the cell membrane, but also those that reside in the nucleus or cytoplasm [24].

Aside from distinguishing between T- and B-cell lymphomas, phenotyping also appears to shed light on the differentiation of normal lymphocytes and the malignant transformation of lymphomas. Phenotyping typically shows persistence of the major phenotype (T- or B-cell type) with few changes in surface receptors and identical heavy and light chain type in histologically transformed specimens [25–29]. The occasional patient in whom the heavy chain changes on subsequent biopsies may be a result of natural maturation, processes similar to those observed in B-cell cultures where μ/γ progresses to γ/α alone or switches to a γ/α heavy chain [30]. The prevailing theory is that the development of lymphoma cells parallels that of normal lymphoid tissue, with blocks occurring at various stages of development. This results in the heterogeneity of immunologic phenotypes in non-Hodgkin's lymphoma [27]. Thus, comparison of phenotypes from normal thymus, tonsils, and peripheral blood with lymphomatous tissue should be similar at equivalent stages of development. This theory fails to account for cells for which no normal counterpart has clearly been identified, as with hairy cell leukemia. The Lukes–Collins schema of B-cell maturation would place small, well-differentiated lymphocytes as early B cells with progressive development through follicular center cells (small cleaved to large cleaved to small noncleaved to large noncleaved) to immunoblastic lymphoma or multiple myeloma [31]. The T cells would mature from pre-T to convoluted thymic cells to mature T cells to functionally active effector cells (i.e., Sezary cells). The transformation from CLL to Richter's could thus be considered progression to a more mature cell type via a "switched on" transformation process, while conversion of MM to an immunoblastic cell type would result from dedifferentiation [32, 33]. The B schema of development differs little from previous convention except in the classification of CLL as an immature cell as opposed to a very mature cell. In this ordering, the intermediately mature forms are more virulent than the least and most differentiated forms. Habeshaw, using the Kiel classification, proposed a very similar sequence to that of Lukes. The B-cell schema he proposes begins with the pre-B-cell ALL cells progressing to CLL lymphocytes, then to germinal center cells (centroblastic/centrocytic), and finally immunoblastic cells or plasma cells. T-cell differentiation progresses from prethymic to thymic to mature T and finally to functional peripheral T cells. The maturation and proliferation schema constructed by Minowada et al. [27] from 55 long-term cell lines concurred with that of Lukes and Habeshaw.

The phenotypic maturation begins with the progenitor B cell, which possesses terminal deoxynucleotidyl transferase (TdT) activity, has Ia positivity, and may have immunoglobulin heavy chain gene rearrangement [34]. As the B cell matures to the pre-B stage, it retains TdT activity and sequentially acquires the CD10, CD19, and CD20 antigens and genotypically rearranges the immunoglobulin heavy chain gene and then the light chain gene. The early B-cell stage is characterized by loss of TdT activity and the CD10 antigen and acquisition of the mouse-rosette receptor and small amounts of surface immunoglobulin. Intermediate B cells express receptors for complement and Fc. These latter two stages correspond to the arrested developmental stages of CLL and small lymphocytic lymphomas. Mature B cells show variable expression of CD10 and CD21 and loss of the mouse erythrocyte receptor. These antigens (CD10, CD21) are lost in the plasmacytoid B-cell stage, at which point PC-1

and PCA-1 begin to appear. The terminal stage of B-cell maturation, the plasma cell, expresses PC-1 and PCA-1 and may express Ia but loses complement and Fc receptors and the pan-B antigens CD19 and CD20.

T-cell maturation progresses through three stages of thymocyte differentiation: (1) the early thymocyte (group I), which expresses CD5 and CD7 with or without CD2; (2) the common thymocyte (group II), which is CD2, CD5, and CD7-positive and now expresses CD1, CD4, and CD8 with variable CD3 positivity; and (3) the mature thymocyte (group III), which no longer expresses CD1 nor coexpresses CD4 and CD8. The mature thymocyte expresses the pan-T antigens CD2, CD5, and CD7 and the CD3 antigen. Mature T cells also express pan-T antigens CD2, CD5, and CD7 and CD3 with variable Fc receptor positivity. As with mature thymocytes, they should express either CD4 or CD8 [34].

The use of a panel of monoclonal antibodies to identify immunophenotypic patterns, not simply light chain restriction or E-rosette formation, has redefined the approach to lymphoma designation. Flow cytometry, which allows the immunophenotyping of individual cells in suspension for the presence or absence of antigens of interest, has helped us to improve diagnosis, classification, prognostication, and therapeutic decision-making. Antigens to be evaluated from a particular specimen depend on the type of specimen, the clinical history, as well as results of prior flow cytometric testing. Specific recommendations regarding flow cytometry indications and applications were formulated in 2006 after international experts convened in Bethesda, Maryland [35].

Non-Hodgkin's Lymphoma, B-Cell Types

Immunoglobulin light chain restriction and aberrant antigen expression distinguish neoplastic mature B-lymphoid cells from normal cells. Ault [36] first described the use of cytofluorographic techniques to rapidly screen large numbers of cells for κ and λ immunofluorescent staining. The sensitivity of the original technique permitted detection of a monoclonal B-cell population constituting less than 10% of the cells screened. A comparison of healthy normal volunteers, hospitalized patients without neoplasms, patients with non-Hodgkin's lymphomas in complete remission, and those with active non-Hodgkin's lymphomas without and with a leukemic phase yielded the following data. The hospitalized patients had relative increases of both κ- and λ-positive cells, but the κ/λ ratios were not significantly different in either light chain type to indicate the presence of a monoclonal population. Four of eight patients in complete remission and 44% of patients with active disease but without a leukemic phase had abnormal ratios of κ to λ but in only 32% of active nonleukemic non-Hodgkin's lymphoma patients was a distinct monoclonal pattern seen. All of the patients with leukemic non-Hodgkin's lymphoma had monoclonal patterns, that is, a distinct clonal excess. Other series utilizing more sensitive techniques subsequently confirmed clonal excess in up to 100% of B-cell non-Hodgkin's lymphoma patients with leukemia, CLL, multiple myeloma (MM), and Waldenström's macroglobulinemia (WM). Approximately 30% of B-cell non-Hodgkin's lymphoma without identifiable circulating leukemic cells revealed clonal excess [26, 37, 38]. The same techniques have also demonstrated clonal excess in pleural effusions with and without positive malignant cytology and in bone marrow biopsy specimens with no evidence or equivocal evidence of malignant involvement. In all instances, there was concordance among peripheral blood, bone marrow, lymph node, and pleural fluid as to light chain type [37, 39]. Clonal excess occurs more frequently in diffuse than follicular lymphomas, and more often in advanced stages of disease and in active or progressing disease [40].

While light chain restriction has typically been utilized as a marker of clonality, its presence has been detected in polyclonal B-cell populations [41]. Lambda immunoglobulin light chain restriction has been detected in tonsillar specimens of children as well as in patients with multicentric Castleman's disease [42, 43]. Similarly, monoclonal light chain class-restricted populations have been detected in follicular hyperplasia, such as that seen in patients with HIV, without neoplasia [44]. The presence of immunoglobulin light chain restriction is not universally indicative of monoclonality, and monoclonality of some lymphoid populations may not be synonymous with a neoplastic process. The importance of interpreting immunophenotyping in the context of other clinical and morphological findings cannot be overemphasized.

When the population of light chain-restricted B lymphocytes is large, abnormalities in the kappa–lambda ratio are found. However, small populations of clonal cells that are part of a polyclonal B-cell population may not be reflected in the kappa–lambda ratio. Evaluating those cells with a particular phenotype may more accurately detect a monoclonal population. Further complicating staining interpretation is the potential for nonspecific or cytophilic binding of antibodies. This is particularly evident in antibody binding to damaged or apoptotic cells. Cytophilic binding can be circumvented through the selective evaluation of only those cells expressing B-cell-associated antigens. Incubation of cells with a blocking reagent prior to anti-light chain antibody staining can minimize nonspecific staining.

Another potential pitfall of flow cytometric analysis is the possibility of not detecting an abnormal B-cell population in a tumor sample. False-negative results may occur secondary to sampling error, particularly in the case of tissue specimens in which the area of interest must be evaluated to appropriately identify areas for testing. Loss of cells during processing can vary depending on technique and cell type. Evaluating

more than one B-cell antigen and performing a cursory evaluation of all cells in the sample can avoid missed detection of abnormal B cells. Prior therapeutic treatment with the anti-CD20 antibody rituximab may yield neoplastic B cells devoid of CD20 [45]. B cells rarely may not demonstrate any surface immunoglobulin and complete absence by flow cytometry has been associated with a diagnosis of B-cell lymphoma in one series [46].

The use of flow cytometry has changed the approach to diagnosis in the modern era and, while not used in the World Health Organization (WHO) classification, does allow us to categorize lymphomas based on their immunophenotypic characteristics [47]. The determination of CD5 and CD10 expression can assist diagnostic efforts in combination with morphologic characteristics.

CD5−/CD10− Lymphomas

Those B-cell neoplasms positive for CD5 and negative for CD10 primarily encompass chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) and mantle cell lymphoma [48]. Marginal zone lymphoma (MZL) and diffuse large B-cell lymphoma (DLBCL) are associated with this phenotype, though in only a minority. Less commonly, the phenotype has been noted in patients with lymphoplasmacytic lymphoma. CLL/SLL has a characteristic phenotype with weak CD20, CD22, CD79a, and surface immunoglobulin expression. It typically demonstrates a strong CD23 intensity and is usually negative for FMC-7 [49]. FMC-7 is a 105-kDa protein expressed on most normal B cells and has been shown to be of significant diagnostic value in distinguishing CLL from other B-cell neoplasms [50]. Despite this characteristic phenotype, other entities such as prolymphocytic leukemia and DLBCL must be excluded. Further immunophenotypic information in the setting of CLL/SLL including CD38 and ZAP-70 expression may be helpful for prognostication [51]. CD38 expression has been thought to be a marker of poor prognosis in patients with CLL. While initially touted as a surrogate marker of immunoglobulin heavy-chain variable region (IgV(H)) mutation status, the two appear to be independent prognostic indicators [52]. In one series, the median survival of CLL patients with unmutated IgV(H) genes and expressed CD38 was 8 years, compared with 26 years in those patients with cells that had mutated IgV(H) genes and negative CD38 expression. The median survival in samples with discordant results was 15 years [52]. Zeta-chain-associated protein (ZAP-70) is a 70-kDa tyrosine kinase that plays a role in T-cell receptor signaling [53]. Gene expression profiling of CLL cells determined that those cells with unmutated IgV(H) genes had differential expression of select proteins, one of which included ZAP-70 [53]. Measurement of this protein by flow cytometry has been utilized as a surrogate marker of IgV(H) mutational status [53–58].

Mantle cell lymphoma (MCL), which also demonstrates a CD5+/CD10− phenotype, typically expresses CD20 and surface immunoglobulin with moderate to bright intensity. In contrast to CLL/SLL, CD23 expression is usually absent or weak and FMC-7 is typically detected. However, its phenotype can be variable, so additional studies are usually required for appropriate identification. Cyclin D1, a key regulatory protein of the cell cycle, appears to play an important role in the pathogenesis of MCL as evidenced by the presence of translocations leading to its overexpression [58]. Reliable detection of cyclin D1 expression by flow cytometry to distinguish MCL from other B-cell neoplasms has not been possible despite a variety of technical approaches [59].

A minority of samples from patients with DLBCL will demonstrate CD5 expression. The morphology of the cells allows distinction from small CD5+ lymphoid malignancies, though exclusion of the blastoid variant of MCL should be undertaken. DLBCL expressing CD5 may signify transformation from CLL/SLL [60] or may have developed de novo [61]. The latter would include the extremely rare entity of intravascular large-cell lymphoma. In a series of 120 patients with de novo CD5+ DLBCL, a higher rate of CNS recurrence was noted with a more aggressive clinical course [62]. The association of CD5 expression with a worse prognosis may be due to its proposed ability to promote IL-10 production and its effect on B-cell receptor signaling with resultant apoptosis avoidance [63].

Marginal zone lymphoma expresses CD5 in approximately 5% of cases. It may present a diagnostic challenge when trying to distinguish it from CLL/SLL and other CD5-positive lymphoid tumors [64]. Lack of CD23 expression in most cases of marginal zone lymphoma may also complicate diagnostic efforts. The presence of CD138 and CD38 expression suggests plasmacytic differentiation, although this finding is not specific to marginal zone lymphoma and serves more to distinguish it from CLL/SLL [48]. Genotypic studies may help establish the diagnosis, though a unique genotype does not appear to exist in marginal zone lymphoma [65]. Extranodal marginal zone lymphoma involving mucosa-associated lymphoid tissue, known as MALT lymphoma, can arise in a number of sites including the stomach, the salivary glands, or the thyroid gland [66–68]. Over two-thirds of MALT lymphomas arise in the stomach; thus it is the site most commonly studied. That gastric MALT lymphomas reproduce features of small intestinal Peyer's patches eventually led to the discovery that its development, at least initially, is antigen-dependent [69, 70]. Histologic features suggesting a role of the immune system in this disease include the invasion of lymphoma cells into germinal centers of normal B-cell follicles and the presence of plasma cell differentiation [71]. The association between gastric MALT

lymphoma and *H. pylori* infection was first proposed by Isaacson and colleagues when they demonstrated the bacteria in the majority of samples they studied [72]. Their work was later confirmed by others [69, 73, 74]. An immunological response playing a role in the development of MALT lymphoma was initially suggested again by the work of Isaacson and others [75]. Their key finding that the death of lymphoma-associated cells (T and B cells, macrophages) in culture could be abrogated by exposure of these cells to *H. pylori* preparations provided preliminary evidence of a causal relationship beyond the mere presence of the bacteria in tumor samples. Hussell and colleagues made the important observation that *H. pylori* was able to stimulate proliferation of tumor-infiltrating T cells and not lymphoma cells such that development of lymphoma appeared to be dependent on the recognition of *H. pylori* by T cells resulting in B-cell activation [76]. This supported the observations that MALT lymphomas of the stomach are usually not disseminated and that treatment of the infection results in tumor regression in about 75% of patients with early stage disease [77, 78]. The infiltration by CD4+ T cells expressing CD28 and CD69 and demonstrating interleukin-4 production and not interferon-γ suggests a Th-2-driven B-cell proliferation [79, 80]. Antigenic stimulation of the B-cell receptor may lead to NF-B activation with subsequent cell proliferation as supported by the observation that MALT lymphoma cells demonstrate somatically mutated surface immunoglobulin [81, 82]. Sequencing of rearranged immunoglobulin heavy chain genes in MALT lymphoma samples by Du and colleagues demonstrated intraclonal variation suggestive of ongoing mutation [83]. The identification of a target antigen has been elusive, although recent results demonstrate that recombinantly expressed MALT lymphoma antibodies are polyreactive and bind with some affinity to both self- and nonself antigens [84].

CD5−/CD10+

The most commonly encountered neoplasms expressing CD10 without CD5 expression include DLBCL and follicular lymphoma. Burkitt's lymphoma is also included in this immunophenotypic entity.

Diffuse Large B-Cell Lymphoma

Classification of DLBCL by gene expression profiling has identified two subgroups: germinal center (GC-DLBCL) and activated B-cell (ABC-DLBCL) diffuse large B-cell lymphoma [85]. A heterogeneous third subtype, termed type 3, was identified with genes in common with neither GC- or ABC-DLBCL [86]. In a series of 274 patients, germinal center DLBCL cases were associated with a greater rate of 5-year survival than both ABC-DLBCL and type 3 subgroups [86]. GC-DLBCLs appear to arise from B lymphocytes derived from germinal centers, while ABC-DLBCLs are thought to develop from postgerminal center-activated B cells [85–87]. Another distinct molecular subtype of DLBCL, primary mediastinal B-cell lymphoma (PMBL), has been noted to have significant similarity to Hodgkin's lymphoma (HL). The higher expression of over one-third of characteristic genes that distinguished PMBL from other DLBCLs was detected in HL cell lines [86]. Clinical parallels found in PMBL and HL including prevalence in young women with a predilection for mediastinal or thoracic involvement as well as their genotypic similarities suggesting a possible relation are yet to be molecularly defined [86].

In GC-DLBCLs, translocations involving the transcription factor BCL-6 are characteristic, and were originally identified due to their association with DLBCL [88]. BCL-6 is a regulator of GC B-cell development and is expressed by GC B cells, centroblasts, and centrocytes [89]. Aberrant BCL-6 expression appears to promote centroblast differentiation resulting in a proliferative phenotype [89].

ABC-DLBCL has been associated with aberrant NF-κB signaling as well as with constitutive activation of STAT3 [90, 91]. BCL-6 is thought to repress STAT3 expression in normally functioning B lymphocytes [90]. ABC-DLBCLs demonstrate decreased BCL-6 expression with resultant increase in STAT3 levels. Using siRNA, Ding et al. demonstrated that inactivation of STAT3 inhibited lymphoma cell proliferation and promoted apoptosis [90]. Increased NF-κB activity in ABC-DLBCL cells results in increased IL-6 and IL-10 secretion that can lead to constitutive STAT3 activation [90, 91]. BCL-6 is thought to repress STAT3 expression in normally functioning B lymphocytes [90]. Increased NF-κB activity in ABC-DLBCL cells results in increased IL-6 and IL-10 secretion which can lead to constitutive STAT3 activation [91].

ETS proteins are transcription factors that control the expression of genes involved in mechanisms such as cellular proliferation, differentiation, and apoptosis [92]. In the study of immunoglobulin class switch recombination (CSR) as a potential mechanism of chromosomal translocation in DLBCL, it has been suggested that ABC-DLBCLs have changes in the regulation of CSR leading to chromosomal translocations involving *BCL-6*, *MYC*, as well as *SPIB* (SPI-B transcription factor) [93].

SPIB belongs to the ETS family of transcription factors and is found in mature B cells, T-cell progenitors, and plasmacytoid dendritic cells [94, 95]. *SPIB* is integral to B-cell receptor signaling and appears to play a central role in germinal center reaction as evidenced by the smaller size, shorter duration, and greater proportion of apoptotic cells of germinal centers in *SPIB*-deficient mice [96]. The importance

of *SPIB* as a regulator of mature B-cell function is supported by its Blimp-1-mediated repression during plasmacytic differentiation [97]. That *SPIB* demonstrates much higher expression in ABC DLBCLs than in GCB DLBCLs and its translocation in the ABC DLBCL cell line OCI-Ly3 support a potential role in this DLBCL subtype [93].

Follicular Lymphoma

The clinical course of follicular lymphoma (FL) is typically indolent with median survival on the order of 8–10 years though there appears to be variability [98, 99]. BCL-2 overexpression noted in the majority of FL samples leads to impaired intrinsic and mitochondrial apoptotic pathways [100]. Dysregulation of BCL-2 arising from the characteristic (t14;18)(q32;q21) translocation does not appear to be in and of itself sufficient for transformation to malignancy. In a *BCL-2/Ig* transgenic mouse model, the development of lymphoma occurred in only a small portion of animals [101]. Follicular hyperplasia preceded the transformation to large-cell lymphoma with progression from a polyclonal population to one that was monoclonal before the change in histology to a large-cell phenotype. This progression with a long latency suggested the necessity of additional changes for lymphoma development, not just the presence of BCL-2 overexpression. In fact, the translocation promoting BCL-2 production has been noted in 55% of peripheral B lymphocytes from patients without lymphoma and appears to increase in incidence with age [102]. Over half of lymph nodes and tonsillar specimens with follicular hyperplasia demonstrated bcl-2/JH rearrangements in patients with no evidence of FL [103]. The lack of lymphoma development in BCL-2 transgenic mice with the observation of the characteristic translocation in normal populations supports the notion that additional changes are necessary in the pathophysiology of FL.

In vitro, FL cells have a short survival on the order of 24 h. Exposure of FL cells to cytokines can prolong cell survival to 1 week and beyond [104]. The microenvironment appears to play a crucial role in FL genesis, particularly in light of prior work demonstrating the inability of genetic changes alone to bring about disease. The germinal center where antigen-activated B cells differentiate to produce plasma cells and memory B cells may be a source of FL genesis. Follicular dendritic cells (FDC), traditionally known to function as antigen-presenting cells, also appear to inhibit germinal center B-cell death and promote cellular interaction and proliferation [105]. FDCs demonstrate expression of the complement receptors CD21 and CD35 and the immunoglobulin receptor CD23. Production of the chemokine CXCL3 by FDCs is high [106]. Expression of these markers by mature FDCs supports a surrounding network of T cells. Loss of CD21 receptor in FDCs appears to be related to large-cell lymphoma transformation associated with a poor prognosis [107]. Poor prognosis FL characterized as resistant to anti-CD20 treatment and early transformation to DLBCL possess genotypes demonstrating activation of mediators of cellular response including macrophages, dendritic cells, and activated T cells [108–110]. Unlike other B-cell lymphomas, FL does not appear to derive from antigenic stimulation. Rather, the overexpression of BCL-2 confers a growth advantage. Additional cytogenetic mutations (for example −6q and +1q) result in eventual activation of FDC and T cells and the development of an aggressive phenotype [111]. In this model, B-cell localization may be defective with tumor cell deposition within follicles. Clonal evolution may proceed at an increased rate resulting in early transformation. The microenvironment in better prognosis FL patients is more consistent with an inactive follicle and maintains CD21/CD35 and CD23 expression with greater reliance on anti-apoptotic signals for its malignant phenotype. In contrast to its more aggressively behaving counterpart, the genome in good prognosis patients appears to remain more stable until transformation [112]. This effect of the tumor microenvironment on FL pathogenesis has been supported by gene expression profiling of immune bystander cells. In a series of nearly 200 FL samples at diagnosis, two subsets of patients with differing gene expression signatures were discovered possessing distinct clinical behaviors [109]. As the differing genotypes were derived from bystander cells, they were termed immune response (IR) 1 and 2. IR1 consisted of increased expression of T-cell markers including *CD7, CD8B1, ITK, LEF1*, and *STAT4* and macrophage-derived genes including *CTN1* and *TNFSF13B*. The IR1 gene signature was associated with an improved overall survival. The IR2 signature consisted of macrophage and FDC-associated genes including *TLR5, FCGR1A, SEPT10, LGMN*, and *C3AR1*. Those patients whose tumors displayed the IR2 signature demonstrated a worse clinical outcome. In another series of 99 FL advanced stage patients, those with more than 15 CD68+ macrophages per high power field had a median survival of 5.0 years compared with 16.3 years in those patients with less than 15 CD68+ cells/hpf [113]. These results were confirmed by PCR and immunohistochemical analysis by Byers and colleagues [114] demonstrating an association of high numbers of CD68+ macrophages with worse outcomes. Increased CD7+ T cells were equated with longer survival. The presence of CCR1, a chemokine receptor indicative of monocyte activation during inflammation, predicted for a worse prognosis as well as transformation to DLBCL [110, 114]. The results of these analyses supported the developing notion that the host immune response plays a part in FL pathogenesis.

Burkitt's Lymphoma

Burkitt's lymphoma (BL), though more consistently so in its childhood form, is also among the category of CD5−/CD10+ lymphoma immunophenotypes. It is considered a highly aggressive lymphoma subtype and almost always demonstrates a Ki-67 index of 100%, a marker of cell proliferation. The BL variants include endemic, sporadic, and those associated with immunodeficient states. Like DLBCL, BL is also associated with a germinal center phenotype demonstrating CD77, a marker of the highly proliferative centroblast [115]. Within normal germinal centers, antigen-stimulated B cells proliferate. Their immunoglobulin genes are subject to somatic gene rearrangement and class switch recombination [116]. These processes are initiated by deamination mediated by activation-induced cytidine deaminase (AID) [117, 118]. Aberrant somatic hypermutation [119] can result in deregulated B-cell proliferation through characteristic translocations such as that of the *c-myc* gene into the Ig locus of BL [120]. The targets of c-myc are several and include regulation of cell proliferation, cell cycle control, and cell metabolism [121, 122]. Transgenic c-myc murine models have demonstrated its importance in the development of lymphoma, although those that develop are not of the germinal center phenotype [123–125]. Scheller and colleagues set out to elucidate the constitutive GC phenotype of BL cells and somatic hypermutation [126]. They were able to demonstrate that *c-myc* overexpression induces the cells to behave like centroblasts, results in expression of the key GC factors Bcl-6, E2A, and AID and also promotes ongoing somatic hypermutation in the cells. These features of human BL cells may thus be indicative of the high activity of the oncogenic transcription factor c-Myc, rather than a marker of differentiation stage of the cell of origin.

Though the association between Epstein–Barr virus (EBV) and BL has long been established, the mechanism of the infectious agent's capability to promote lymphomagenesis is still being elucidated. The overexpression of c-myc appears to be independent of EBV infection, though a potential relationship has been proposed as a means of pathogenesis [127]. Those areas of the world with endemic BL demonstrate *P. falciparum* malaria as a cofactor for EBV-mediated lymphoma development [128]. The immunosuppressive effect of malarial infection [129–131] appears to be the reason why children in endemic areas have extremely high EBV loads in their blood that increase during acute malarial infection [131–133]. *P. falciparum* also appears to have a proliferative effect on germinal centers. C-myc translocations in these germinal centers resulting in aberrant immunoglobulin gene rearrangements would normally be censored, but may be rescued by the growth advantage conferred by EBV infection. While HIV-infected patients do not demonstrate as high EBV levels as in patients with a malarial infection, a similar mechanism of B-cell activation is hypothesized [134].

The immune mechanisms involved in BL development in the setting of EBV infection have been postulated for quite some time. Important observations that EBV-infected cells can develop varying latent states in which cells are infected but viral particles are not replicating has resulted in a better understanding of why EBV infections results in lymphoproliferative disease in only a proportion of patients [135–137]. Resistance to HLA class I restricted cytotoxic lymphocytes by EBV-infected BL cells has suggested an escape from immune surveillance [138–141]. BL cells express reduced levels of adhesion molecules such that recognition by CD8+ T cells is impaired [135, 140, 142]. Enhanced antigen presentation in some long-term carriers allows EBV persistence without the development of lymphoproliferative disease [127]. The ability of BL cells to evade apoptosis by the promotion of certain viral latent genes appears to be crucial to its B-cell growth-transforming capacity. Latent membrane protein 1 (*LMP1*), the first of these latent genes to be identified, promotes the production of Bcl-2, Mcl-1, and bfl-1 with resultant apoptosis circumvention [143–146]. The development of BL in the setting of EBV infection appears to rely on a variety of viral properties providing a growth advantage in transformed cells, the mechanisms of which are slowly being elucidated.

Non-Hodgkin's Lymphomas, T-Cell/NK-Cell Types

The T-cell non-Hodgkin's lymphomas comprise several distinct clinical and pathologic entities that are now also found, in most cases, to be immunologically distinct as well. The differentiation stages of T-cell lymphomas parallel leukemic forms closely and incorporate neoplasms from all stages of T-cell development, thymic to immunocompetent T-cell types. Despite the capacity to distinguish T-cell neoplasms phenotypically and functionally, the classification of T-cell neoplasms is difficult to establish and frequently requires genotypic (T-cell receptor or TCR rearrangement) confirmation. The WHO 2008 classification of lymphomas has retained the classification of peripheral T-cell lymphoma, not otherwise specified (PTCL-NOS) to describe some T-cell lymphomas for which distinctive genetic or biologic features have not yet been discerned [147–149].

Peripheral T-Cell Lymphomas

The normal cell of origin giving rise to peripheral T-cell lymphomas (PTCL) has not been definitively described [149]. PTCLs are thought to be derived from T cells expressing the

αβ form of the TCR [150]. Cells from PTCL-NOS samples demonstrate CD4 expression more commonly than CD8, though CD4+CD8+ and less commonly CD4–CD8− phenotypes can be found [151–153]. PTCLs comprise just over 10% of all lymphomas and generally include the three subtypes of angioimmunoblastic T-cell lymphomas (AITL), anaplastic large-cell lymphoma (ALCL), and peripheral T-cell lymphoma, not otherwise specified (PTCL-NOS). While the molecular profiling of B-cell lymphomas has enabled us to develop a better understanding of their heterogeneity and etiology, the genetic signatures of T-cell lymphomas are being slowly being elucidated.

Angioimmunoblastic Lymphoma

Also known as angioimmunoblastic lymphoma with dysproteinemia (AILD), AITL is characterized by cells with abundant cytoplasm, significant blood vessel formation, proliferation of follicular dendritic cells, and EBV-infected B lymphoblasts [154]. AITLs appear to have arisen from mature CD4+CD8− helper T cells [155]. Expression of the chemokine receptors CXCR3 and OX40/CD134 supports a Th1 cell of origin [156, 157]. Additionally there may be expression of a variety of markers including the transcription factor BCL-6 and the chemokines CXCL13 and CXCR5 derived from a subset of T-helper cells found in germinal centers known as follicular helper T cells (T_{FH}) [158–162]. Comparison of gene expression profiles of AITL and other PTCLs has demonstrated a significant amount of similarity suggesting a common pathogenesis [163]. In an analysis by Piccaluga and colleagues, genes characteristic for varying subpopulations of T cells were evaluated. AITL demonstrated a molecular signature most characteristic of T_{FH}, a finding confirmed by others [150, 163]. In concordance with other groups, Piccaluga demonstrated the relationship of PTCL-NOS and ALCL to T-central memory cells and T-effector cells, respectively [163, 164]. Overexpression of VEGF and VEGFR-2 in AILT samples suggests that derangement of angiogenesis is part of its pathophysiology and may explain the [163, 165]anecdotal responses reported with bevacizumab therapy. In an effort to develop a molecular classification approach to PTCLs to aid in diagnosis, one series analyzed over 140 tumor samples [166]. The classifier that was derived for AITL included genes associated with germinal B centers (including CD10 and Bcl-6), B-cell receptor-associated signaling and members of the immunoglobulin family as well as follicular dendritic cell (FDC) markers, cytokines, and their receptors. These findings demonstrated consistent involvement of FDCs and B cells in the AITL microenvironment with support of malignant T-cell growth as well as angiogenesis and immunosuppression stemming from cytokine signaling. When compared to the gene expression profiling results of de Leval et al. [150], Piccaluga identified significant overlap between the molecular signature of a series of PTCL cases and AITL enabling reclassification of 18% of PTCL-NOS as AITL [167]. While the proposed cell of origin in AITL is the T_{FH} cell, differences from normal T_{FH} cells including high CD10 expression and low CD57 expression have been noted [168]. SLAM-associated protein (SAP) is expressed by the gene *SH2D1A* (*SAP/DSHP*) [169]. Expressed in CD4 and CD8 T cells as well as NK cells and a proportion of B cells, SAP appears to play an essential role in Ag-specific CD4 T cells to develop appropriate follicular helper CD4 T-cell functions [170]. Despite the elevated expression of SAP and SLAM in AITL samples, follicles are underdeveloped and not populated with neoplastic T cells, suggesting that the lymphoma cells may be at a prefollicular stage of development [166]. Secretion of IL-6 and IL-21 by malignant T_{FH} cells may promote B-cell differentiation resulting in the plasma cell infiltrate seen in AITL [166, 171] with resultant hypergammaglobulinemia and autoimmune features characteristic of the disease.

Anaplastic Large-Cell Lymphoma

Anaplastic large-cell lymphomas (ALCL) make up about 12% of all T-cell lymphomas [172]. The heterogeneity of ALCL has resulted in much speculation regarding its etiology [173, 174]. The strong expression of CD30 in ALCLs and the distinction of the disease into subsets based on chromosomal translocations involving the anaplastic lymphoma kinase (ALK) gene significantly helped diagnosis [175–177]. Differing genetic aberrations in ALK+ and ALK− ALCLs resulted in their consideration as different entities in the WHO's most recent classification [47, 163, 178–180]. Currently, no immunophenotypic or molecular profiles exist to differentiate ALK-negative ALCL, leading to the proposal that it may be more accurately described as belonging to the PTCL-NOS category [181, 182]. However, work published by Piva and colleagues demonstrates that all ALCL may be genetically differentiated from PTCL-NOS, and they have reported a molecular signature distinct to ALCL ALK-positive neoplasms [183]. The discovery of differential expression of 30 genes in both ALK-positive and ALK-negative ALCLs of which only a few are associated with ALK signaling also suggests a possible common precursor for both subtypes of ALCL. Defective expression of T-cell receptors is found in all subtypes of ALCL also supporting the notion that ALK-positive and ALK-negative subsets, though with distinctive characteristics, may share similar etiology [184]. Furthermore, some ALK-negative ALCLs express proteins such as phosphor-STAT-3 typically associated with ALK-positive tumors [183]. The distinction of

ALK-negative ALCLs from PTCL-NOS may become more feasible with molecular signatures thus allowing improved therapeutic approaches. In the gene classifiers derived by Iqbal and colleagues, although a signature to distinguish ALK-positive from ALK-negative subsets was not determined, the latter was distinguishable from PTCL-NOS [166]. Expression of TCR signaling associated genes was lower in ALK-negative samples compared with PTCL-NOS, and the genes for the cytokines IL-20 and IL-9, involved in angiogenesis and Jak3 activation, respectively, demonstrated higher expression. In the ALK-positive subset of samples, the expected ALK mRNA was preferentially detected as well as IL-26 and IL-31RA, which can activate STAT3. STAT3 expression promotes the expression of IL-17A, IL-17F, and IL-22 via the retinoic acid receptor-related orphan receptor (RORγ). The expression of IL-17A and IL-17-F, both T_H17-associated molecules, may signal deranged activation of T_H17-cell differentiation by abnormal cytokine secretion [166].

Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma (ATLL) has long been associated with the human T-lymphotropic virus type-1 (HTLV-1), a delta retrovirus that is estimated to infect 15–20 million people, globally [185, 186]. Approximately 2–5% of viral carriers will eventually develop ATLL [187]. ATLL manifests four to seven decades after infection supporting the notion that genetic or epigenetic events are necessary in the lymphoma's pathogenesis [188]. HTLV-1 expresses multiple gene products, one of which (TAX) appears to play a particularly important role in the promotion of infected cells and has been shown to complex with over 100 cellular proteins [189]. Multiple cellular pathways are stimulated by TAX including CREB/ATF, NF-κB, and AP1, all of which are intimately involved in T-cell proliferation and transformation [189]. In cellular models with defective TAX, lymphoma generation in vitro and in vivo is impaired [190]. Gene expression analysis of HTLV-1-infected and TAX-expressing cells has enabled identification of HTLV-1/TAX-regulated genes [191–194]. Included among these genes were those that regulate T-cell proliferation such as IL-2, IL-15, granulocyte-macrophage colony stimulating factor (GM-CSF), and tumor necrosis factor-α (TNF-α) [185, 186, 195].

A foxhead box protein 3 (Foxp3) represents a T-cell marker of Treg cells. It is a master gene regulating development and differentiation of CD4+/CD25+ Treg cells [196–199]. Adult T-cell leukemia cells, thought to represent post-thymic T cells, demonstrate CD4 and CD25 expression [200]. Foxp3 is present in adult T-cell leukemic cells as well as in HTLV-1-infected cells in asymptomatic carriers [201, 202]. Furthermore, infection of Treg cells by HTLV-1 has been shown to affect Foxp3 expression and thus suggests a potential role in the pathogenesis of adult T-cell leukemia [203–205]. Interestingly, in the development of a gene expression classifier to distinguish PTCLs, Iqbal and colleagues did not demonstrate an upregulation of Foxp3 mRNA, although overexpression of CD25 was seen [166]. In this series, when their classifier was applied to PTCL-NOS, three cases were reclassified as ATLL and were confirmed as arising from regions endemic for HTLV-1. Viral transcripts encoding the TAX protein were detected in these tumor samples and all three patients demonstrated a survival of less than 3 years, consistent with ATLL.

Cutaneous T-Cell Lymphoma

Of the heterogeneous cutaneous T-cell lymphomas (CTCLs), mycosis fungoides (MF) and Sezary syndrome (SS) are the most common entities. Clinically, MF is characterized by skin patches and plaques, whereas SS manifests as leukemic T cells and erythroderma [206, 207]. Although both MF and SS are clonally derived T-cell malignancies and demonstrate CD4+, CD45RO+, CLA+ (cutaneous lymphocyte antigen) expression, genomic differences exist suggesting a variable pathogenesis for the two conditions [208]. The etiology of CTCL has not yet been defined. Early stage disease is characterized by an inflammatory patch or plaque of the skin and demonstrates an infiltrate of reactive, nonmalignant T cells [209]. This T-cell infiltrate expresses CLA and CCR-4 [210, 211]. With progression of disease, the malignant T cells outnumber reactive cells in the dermis with increased atypia [211]. In a series of 62 CTCL samples, gene expression profiling revealed three "clusters" with divergent clinical behaviors [212]. Cluster 1 samples, associated with poorer prognosis, demonstrated lymphocyte clonal expansion with changes consistent with decreased T-cell receptor heterogeneity. Longer follow-up confirmed the accurate prognostic information derived from the three clusters [213]. Among the patients with stage I disease, those with cluster 1 or cluster 3 genes demonstrated a statistically significantly worse prognosis while those with a cluster 2 profile did not progress during the 6 years of follow-up. Analysis of select genes in this series revealed expression of genes associated with Th-17, a recently identified CD4+ T-helper cell with pro-inflammatory capabilities [214]. Others have shown malignant cells that share common features with T_{reg} cells as defined by expression of Foxp3 and CTLA-4 [215, 216]. Although these cells are thought to be dysfunctional [217], analysis of peripheral blood mononuclear cells (PBMC) from patients at varying stages of CTCL/MF has shed some light on potential pathogenic mechanisms [218]. Cytokine expression appears to diminish with advancing disease stage

suggesting defective immune response associated with disease progression. It remains unclear whether the cell of origin in CTCL is the T_{reg} cell or CD4+ T cells that adopt characteristics of T_{reg} cells [219].

While the cell of origin remains to be determined, also of interest is the mechanism by which malignant T cells localize to the skin to cause disease characteristic of CTCL. Chemokines, which are chemotactic, are thought to play an important role in the pathophysiology of CTCL [219]. Their receptors are cell-surface, G-protein-coupled receptors, of which there are reported to be 19. Varying expression of chemokine receptors on T-cell subsets results in differential responses to chemokine-stimulated T-cell migration such that expression of chemokines by epidermal keratinocytes can result in epidermal T-cell infiltration [220]. Chemokines, such as CCR-4 ligand produced by dendritic cells, may also play a role as malignant T-cell chemoattractants as suggested by the conjugation of dendritic cells with malignant T cells in Pautrier's microabscesses, characteristic of MF [221]. Expressed on about 25% of normal CD3+,CD4+ T cells, CCR-4 demonstrates much higher expression on malignant cells in MF and SS [219, 222, 223]. A ligand of CCR-4, CCL-17 is produced by keratinocytes, endothelial cells, and dendritic cells and is overexpressed in the dermis of patients with MF [224]. Similarly, CCL-27, a CCR-10 ligand, is less frequently expressed on normal circulating T cells but is increased in CTCL cells [222, 223]. The expression of CCL27 in normal keratinocytes suggests it may play a tropic role in bringing malignant cells to the dermis.

The dipeptidylpeptidase, CD26, is downregulated in MF and SS cells [225]. Inactivation of CXCL-12 by CD26 is thus impaired. CXCL-12 is a ligand of CXCR-4 and is produced by stromal cells and fibroblasts located in the dermis. In cell lines derived from patients with SS, absence of CD26 promoted chemotaxis that was mediated by unimpaired CXCL-12 [224]. Introduction of soluble CD26 inhibited migration via CXCR-4, suggesting a role of the CXCR-4/CXCL-12 axis in the epidermotropism of SS as regulated by CD26.

Natural Killer/T-Cell Lymphoma

Natural killer/T-cell lymphoma (NK/T) is a rare neoplasm of NK and NK/T cells. The WHO classification includes three subtypes of NK malignancies: extranodal NK/T-cell lymphoma, NK leukemia, and a blastic variant [226]. Extranodal NK/T-cell lymphoma (ENKL) is typically found in the nasal cavity or adjacent structures and is characterized by an aggressive disease course in advanced stages with chemotherapy resistance. It appears to be related to EBV infection as evidenced by geographic patterns of incidence.

It is thought that EBV infection is not merely associated with ENKL but plays a role in its pathogenesis. Normal nasopharyngeal cells in patients with ENKL demonstrate EBV infection; however, comparative genomic analysis reveals heterogeneity in the viral genome in contrast to the single strain detected in malignant cells from the nasopharynx [226]. Furthermore, the EBV genome within ENKL cells demonstrates deletion of *LMP-1* in nearly 100% of cases studied while normal cells carried the wild type. The level of circulating EBV DNA in patients with ENKL appears to be prognostic with high titers indicating a worse survival with treatment resistance.

The mechanisms of disease in ENKL remain largely unknown. Recent attempts to delineate genetic alterations as a means of understanding the biology of the disease have been undertaken, although the rarity of the disease and the predominance of necrosis in biopsy samples have been a hindrance. Huang and colleagues performed genomic analysis of nine samples of tissue from patients with ENKL and compared results with analysis of normal NK cells and cells from PTCL-NOS [227]. Comparison of ENKL cells with those from PTCL-NOS samples demonstrated in the former increased expression of genes related to NK-cell cytotoxic function. Granzymes (gzm), a family of serine proteases found in cytotoxic granules of NK cells, induce apoptosis in target cells [228]. The greatest increase in expression was noted in gzm H, which is constitutively expressed in NK cells and elicits apoptosis through the caspase-independent pathway [228, 229]. The predilection of ENKL for extranodal sites is corroborated by the findings of Huang in which downregulation of the chemokine receptor CCR7 and the upregulation of the chemokine ligands CCL27 and CXCL12 were noted, consistent with their roles in homing of cells to peripheral lymph nodes and to skin/intestine/bone marrow by CCR7 and CCL27/CXCL12, respectively. Other pathways implicated by the work of Huang and colleagues include deregulation of PDGFRα with resultant effects on AKT and Jak-STAT pathways, activation of NF-κB possibly through EBV infection, as well as increased expression of genes resulting in vascular invasion [227].

Hodgkin Lymphoma

The incidence of Hodgkin lymphoma (HL) in the United States is estimated to be 7400 cases per year [230]. Classical HL, comprised of nodular sclerosis, mixed cellularity, lymphocyte-depleted and lymphocyte-rich subtypes, represents 95% of HL cases with the remaining 5% made up of nodular lymphocyte predominant HL (NPHL) [47]. The tumor cells in classical HL (cHL) are termed Hodgkin and Reed–Sternberg (HRS) cells and in NPHL are known as lymphocyte predominant (LP) cells [47]. Aside from differing histologies, the cells of origin in cHL and NPHL are also distinct. In cHL, tumor cells are most likely derived from GC

B cells that have evaded apoptosis despite abnormal immunoglobulin V gene mutations in contrast to NPHL cells which result from antigen-selected GC B cells [231]. Although HRS and LP cells typically comprise less than 10% of cells in a tumor sample, efforts to analyze their molecular markers have been pursued in an effort to elucidate pathogenic mechanisms.

Somatic hypermutation of immunoglobulin V (IgV) heavy and light chains in HRS cells confirmed their origin from mature B cells that were of GC or post-GC differentiation [232]. Unlike most B-cell lymphomas that retain phenotypic characteristics of their cell of origin, HRS cells displayed characteristics of a multitude of hematopoietic cells [233]. Classic B-cell antigens such as the B-cell receptor (BCR), CD19, and CD20 are rarely expressed by HRS cells [234, 235]. Transcription factors that regulate certain B-cell-specific genes such as Oct-2, Pu.1, Bob1, and early B-cell factor (EBF) are also rarely seen [235–238]. Some transcription factors such as the helix–loop–helix transcription factors E12 and E47 are expressed, but concomitant expression of their inhibitors limits their function [236, 239, 240]. However, HRS cells express Pax5, a signal of commitment to B-cell lineage, although many of its target genes are not found [241].

Cases of HL in which T-cell markers are expressed have been reported and have been demonstrated as lacking Ig gene rearrangements and instead displayed T-cell receptor rearrangements suggesting T-cell origin [242–246]. In one series, gene expression analysis of cell lines from T-cell-derived HL, B-cell HL, and other B- and T-cell lymphomas (including CD30+ ALCL) demonstrated a gene expression profile in the T-cell HL similar to other HL cells supporting a common transformation pathway despite differing cells of origin [247].

Notch1, usually expressed in T cells, is also expressed in HRS cells and acts as a transcription factor favoring T-cell development over B-cell development in lymphoid precursors [248]. Its inhibitory effects on B-cell development center on its downregulation of the B-cell transcription factors E2A and EBF as well as promotion of ABF1 expression, a B-cell transcription factor inhibitor [248]. Jagged1, the activating ligand of Notch1, is found in cells from HL tumor samples supporting its role in HL biology [248].

The connection between LP cells in NLPHL and GC B cells was drawn with the identification in LP cells of classic GC B-cell markers including BCL-6 and cytidine deaminase. Furthermore, the association of LP cells in follicles with follicular dendritic cells and GC-type Th cells was also consistent with germinal center cell structure [232]. Gene expression profiling of LP cells in comparison with normal B cells and B-cell lymphomas suggested genetic similarity to late GC B cells that have adopted memory B-cell characteristics [249]. Though LP cells resemble follicular lymphoma cells in histology and in immunophenotype, gene expression profiling suggests a closer relationship with HRS cells than with FL cells [249]. Among the molecular similarities noted between HRS and LP cells is activation of the NF-κB pathway [249].

The role of EBV in the pathogenesis of a proportion of classical HL cases is well established. Approximately 40% of HRS cells have an EBV latent infection [232]. In EBV + HL cases, all HRS cells carry the virus. Expression of viral proteins including EBNA1, which is essential for viral replication, and LMP-1 and LMP-2a, which mimic CD40 and BCR, respectively, appears to be vital to lymphomagenesis in EBV-related cases [250, 251]. An important finding supporting the role of EBV in HL pathogenesis is the apparent requirement for EBV infection in those HL cases with loss of the BCR. It is postulated that EBV through LMP-2a expression can rescue from apoptosis B cells that have lost BCR. This rescue has been reproduced in vitro [251–253].

Constitutive activation of the transcription factor NF-κB appears to be required for survival of HL cells [254]. CD40, a member of the tumor necrosis factor family, is expressed by HRS cells and its ligand is expressed by T cells found in NHL tumors [255]. Activation of CD40 results in NF-κB activation. Other receptors expressed by HRS and potentially activating NF-κB include CD30, RANK, and Notch 1 [248, 256, 257]. Nearly half of classic HL tumors show amplification of the REL gene, which codes for a NF-κB factor [258, 259]. Mutations in the genes of NF-κB inhibitors IκBα (in about 15–20% of classic HL cases) and IκBε may also contribute to pathway activation. A recently identified tumor suppressor gene, *TNFAIP3*, is often mutated resulting in inactivation [260, 261]. The protein expressed by *TNFAIP3*, identified as A20, acts as an upstream inhibitor of the NF-κB pathway. Inactivating mutations have been identified in 30–40% of HL tumors studied [260, 261]. In vitro, restored expression of A20 in A20-silenced HL cell lines diminished expression of NF-κB pathway targets with a resultant decrease in cell survival [260, 261]. This phenomenon was also demonstrated in a murine model [260]. A similar analysis was undertaken to identify the role of NF-κB in LP cells but revealed only rare mutations in *NFKBIA* and *TNFAIP3* [232].

The microenvironment appears to play a crucial role in the pathogenesis of HL as evidenced by the difficulty in propagating HL cells in vitro and in vivo models. Secretion of chemokines and cytokines such as CCL5, CCL17, and CCL22 attract Th2 cells and IL-5, IL-9, CCL5, and CCL28 attract T_{reg} cells [232].

As described previously, the proportion of HRS cells in a given tumor is very small with the majority of cells represented by inflammatory lymphocytes, predominantly CD4+ T cells [262]. The pathogenic role of these infiltrating lymphocytes has been the subject of much investigation, and has been postulated to have a role in the suppression of effector

immune responses [263]. Suppression of immune response in HL has long been recognized and dates back to the recognition in 1902 by Dorothy Reed of diminished hypersensitivity response to intradermal purified protein derivative [264]. The propensity for graft rejection and the increased incidence of graft-versus-host disease after blood transfusion corroborated the immune suppression hypothesis [265–267].

The discovery of T_{reg} cells has sparked much interest in their potential role in many subtypes of lymphoma, including HL. T_{reg} cells are thought to mediate immune responses and control the body's response to foreign antigen such as in transplantation [268]. There are thought to exist two subtypes of T_{reg} cells, one which mediates its effects through cytokine release (IL-10 secretion) and the other through direct cell contact (CD4+CD25+) [269, 270]. Analysis of HL patient samples by Marshall and colleagues revealed the predominant cell populations in the HL infiltrating lymphocytes to be IL-10 secreting (or Tr1) and CD4+CD25+ T_{reg} cells (which were later found to express foxp3). The oft detected expression of CTLA-4 on HL lymphocytes also supports a T_{reg} infiltrate as it is a costimulatory molecule found on Tr1 and CD4+CD25+ T cells [271–273].

In a recent series published by Steidl and colleagues [274], gene expression profiling revealed the presence of CD68+ macrophages in the tumor infiltrate of classic HL samples to be associated with a worse survival. In fact, median survival in samples with the lowest quantity of CD68+ macrophages was not reached after over 16 years of follow-up compared with 2.7 years in those samples with the highest display of CD68+ macrophages. The exact role of macrophages in the pathogenesis of HL remains to be determined. This study also confirmed the favorable prognostic effect of CD20+ B cells in tumor samples, confirming the work of others [275].

Immunotherapy

The association of impaired immunity and neoplastic disease of the lymphoproliferative system is exemplified by clinical abnormalities, laboratory evidence of decreased immune responses in HD and non-Hodgkin's lymphoma, and the increased frequency of lymphomas in immunosuppressed states, congenital or acquired. This association suggests a link between the development and/or propagation of a neoplastic clone and abnormal immune function. By this reasoning, the prevention or abolition of lymphomas could presumably be altered by restoration of the host immune system.

Rituximab

Rituximab was first approved in 1997 by the Food and Drug Administration (FDA) for the treatment of relapsed/refractory follicular or low-grade NHL. In the registration trial, 166 patients with relapsed, indolent NHL were treated with 375 mg/m [2] of rituximab once a week for 4 weeks [276]. Almost half of the patients demonstrated a response with a complete response rate of 6%. Several other trials confirmed its activity in both treatment-naïve and previously treated cohorts [276–281]. In combination with standard chemotherapeutic regimens, the addition of rituximab has resulted in overall survival prolongation in both DLBCL and FL settings [282–292].

Ofatumumab

Ofatumumab is a human IgGκ monoclonal antibody directed against a novel epitope of the small extracellular loop of CD20 [293]. Its pharmacologic properties suggest a slower disassociation rate and greater stability in vitro in B-cell binding than rituximab. It appears capable of B-cell binding even with low expression of CD20 [294]. In a phase I/II study of 40 patients with relapsed/refractory grade 1 or 2 follicular lymphoma, 4 weekly doses resulted in an overall response rate of over 40% [294]. In a pivotal trial of ofatumumab in patients with CLL refractory to fludarabine and alemtuzumab, an overall response rate of 42% resulted in its approval by the FDA in 2009 for this indication [295]. In a phase III study of 447 adults with treatment naïve CLL who were not considered eligible for treatment with fludarabine, the addition of ofatumumab to chlorambucil vs. chlorambucil alone resulted in higher ORR (82% vs. 69%) and CR rates (12% vs. 1%) [296]. This data led to FDA approval of ofatumumab plus chlorambucil as first line treatment of patients with CLL. Ofatumumab was also studied as monotherapy in phase II trials for relapsed/refractory mantle cell lymphoma and DLBCL with good tolerability but only marginal efficacy [297, 298]. Ofatumumab was also investigated with CHOP in treatment naïve patients with follicular lymphoma. The combination proved to be effective with ORR rates of 90–100% and CR rate of 62% which is comparable to response rates with R-CHOP with a similar safety profile [299].

Obinutuzumab

Obinutuzumab is a glycoengineered type II humanized anti-CD20 mAb that does not require lipid rafts and allows CD20 to remain distributed across the surface of the B cell. Compared to Type I mAbs (rituximab), Type II anti-CD20 mAbs also bind complement at a much lower level which results in higher ADCC and apoptosis [300]. Obinutuzumab in combination with chlorambucil was FDA approved as first line treatment in CLL patient in based off of a randomized

phase III trial of 781 adults which showed superior ORR (78% vs. 65%) and CR (21% vs. 7%) when compared to rituximab plus chlorambucil [301]. In a phase III trial investigating obinutuzumab plus bendamustine (followed by 2y maintenance obinutuzumab) vs. bendamustine alone in patients with rituximab-refractory indolent non-Hodgkin's lymphomas showed almost double the median PFS (29.2 mos vs. 14 mos) for the obinutuzumab plus bendamustine arm with equivalent safety profiles [302].These results led to FDA approval of obinutuzumab plus bendamustine for rituximab-refractory follicular lymphoma in 2016.

Epratuzumab

CD22 is a sialoglycoprotein that is expressed on pre-B and mature B cells that acts as a signaling molecule in cellular adhesion, regulation of B-cell homing, and modulation of B-cell activation [303]. Epratuzumab is a humanized IgG1 mAB targeting CD22 once bound CD22 is internalized and although mechanism of action is unknown, it likely triggers BCR signaling and caspase-dependent apoptosis [304, 305]. Phase I/II studies investigating epraztuzumab as monotherapy in heavily pre-treated indolent and aggressive lymphomas showed that it had antitumoral effects with ORR of 24% in follicular lymphomas and 15% in DLBCL [306, 307]. The combination of epratuzumab and rituximab in relapsed/refractory FL patients resulted in ORR of 54% and CR rate of 24% [308]. In treatment naïve patient with FL, epratuzumab plus rituximab showed a high response rate of 82% with 42.4% CRs and a durage length of response with 60% remaining in remission at 3 years follow-up [309]. In a phase II study of previously untreated patients with CD22+ DLBCL, epratuzumab plus R-CHOP showed a response rate of 96% with 3 year EFS of 70% which compared favorably to traditional R-CHOP chemotherapy although OS was not affected [310].

Alemtuzumab

Alemtuzumab is a humanized monoclonal antibody directed against CD52 and was approved by the FDA for relapsed/refractory CLL/SLL in 2001. This approval was based on the results of a trial reported by Keating and colleagues in which 93 patients with disease refractory to fludarabine and an alkylating agent were treated with alemtuzumab [311]. The median survival was 16 months. It was subsequently approved for treatment-naïve patients in 2007 after the results of a randomized trial in which 292 untreated patients were given alemtuzumab or chlorambucil. Those patients in the alemtuzumab arm benefited with significantly longer progression-free survival at 14.6 months vs. 11.7 months ($p = 0.0001$). The complete response rate was 24% vs. 2% in the alemtuzumab- and chlorambucil-treated patients, respectively [312]. The results of a phase II study of 14 patients with relapsed/refractory peripheral T-cell lymphomas (PTCL) showed an ORR of 36% and three patients achieved CRs although treatment was associated with significant hematologic toxicity and infectious complications [313]. Another phase II study of alemtuzumab in 22 patients with relapsed/refractory mycosis fungoides (MF) and Sezary syndrome (SS) showed a 55% ORR with 32% CRs although again infectious complications were seen in 50% of study patients [314]. Adverse effects secondary to alemtuzumab include cytopenias, infusion reactions, cytomegalovirus reactivation, and other opportunistic infections.

Mogamulizumab

CCR4 is a marker for type 2 helper T cells and regulatory T cells (Treg) expressed on the surface of many patients with CTCL and PTCL [315, 316]. Ligands for CCR4, CCL17, and CCL22 are produced by tumor cells and cells in the tumoral microenvironment attracting CCR4+ Tregs to the tumor where they act to suppress the host immune response thereby allowing tumor immune evasion [317, 318]. Mogalizumab is a defucosylated humanized antibody to CCR4 allowing antibody-dependent cellular cytotoxicity [319] that is currently being investigated in PTCL and CTCL. A phase I/II study of mogalizumab in 41 patients with relapsed/refractory CTCL resulted in ORR of 26.8% with only few grade III/IV toxicities [320]. A phase II study of 38 patients with relapsed/refractory CTCL and PTCL showed mogalizumab achieved an ORR of 35% and CR rate of 14%. Most common adverse effects included cytopenias, infusion reactions, fevers, and skin toxicity [321].

Dacetuzumab and Lucatumumab

Belonging to the tumor necrosis factor receptor super family, CD40 is found on the surface of normal B cells and in most B-cell neoplasms. It appears to elicit ADCC, but not CDC [318]. Dacetuzumab is an agonistic chimeric murine–human monoclonal antibody against CD40. Xenograft studies in lymphoma have suggested a synergistic effect of dacetuzumab with rituximab and gemcitabine [322]. A phase II study of single agent dacetuzumab in relapsed DLBCL showed just modest activity with an ORR of 9% [323]. A phase Ib trial studying dacetuzumab with gemcitabine and rituximab in 33 patients with relapsed/refractory DLBCL observed an ORR of 47% although this is comparable to the efficacy of R-GemOx (rituximab, gemcitabine, and oxaliplatin) in the second line setting [324].

Lucatumumab is a human IgG1 CD40 antagonist that blocks signaling mediated by CD40 and its ligand. In vitro, it demonstrates enhanced ADCC when compared with rituximab [325]. In a Phase IA/II trial of lucatumumab in 111 patients with relapsed/refractory lymphomas, ORR was highest in FL (33.3%) and in marginal zone lymphoma (42.9%) [326].

Immune Checkpoint Blockade

Tumors have developed multiple means by which to evade the host immune response allowing their proliferation. PD-1 (programmed cell death) in an inhibitory transmembrane protein that binds to PD-L1 (programmed cell death ligand). The PD-1/PD-L1 pathway has been revealed as an important regulatory pathway that tumors hijack to directly inhibit apoptosis and cause T-cell exhaustion [327]. PD-1 and PD-L1 are frequently overexpressed in lymphoid malignancies including Hodgkin's lymphoma, FL and DLBCL [328–334]. Blockage of the PD-1/PD-L1 interaction has been shown to reactivatate previously anergic T cells [335]. These discoveries have led to intense ongoing investigation into the utility of targeting this pathway in the management of lymphomas.

Ipilimumab

Ipilimumab is a fully human IgG1κ monoclonal antibody against cytotoxic T-lymphocyte antigen 4 (CTLA-4). CTLA-4 is expressed on the cell surface of CD4+ and CD8+ T-cells and has a higher affinity for the costimulatory receptors CD80 and CD86 on APCs than the T-cell co-stimulatory receptor CD28 thereby terminating CD28 co-stimulation and T-cell activation [336, 337]. Ipilimumab has shown some antitumor effect in relapsed/refractory B-cell lymphomas with a favorable toxicity profile [338–340]. Adverse effects included diarrhea, headache, cytopenias, fatigue, and anorexia. Studies are currently ongoing utilizing ipilimumab in combination with other forms of immunotherapy.

PD-1 Inhibition

Three PD-1 inhibitors have been studied in clinical trials for patients with lymphomas: nivolumab, pembrolizumab, and pidilizumab. Pidilizumab is a humanized IgG monoclonal anti-PD-1 antibody. MD Anderson Cancer Center published results of a phase II trial using pidilizumab plus rituximab for patient with relapse FL. The study found that pidilizumab induced an ORR of 66% with a CR rate of 52% which is favorable when compared to historic controls for single-agent rituximab [341]. Nivolumab is a fully human monoclonal IgG4 antibody to PD-1. In a phase I trial of nivolumab in 23 patients with relapsed/refractory lymphoid malignancies, nivolumab was shown to have good tolerability with ORR highest in DLBCL (36% with 1 CR) and FL (40% with 1 CR) leading to phase II studies in these subtypes [342].

Results from PD-1 blockade in classical Hodgkin's lymphoma have shown promising results. PD-1 is highly upregulated in Reed–Sternberg cells due to gene amplification and EBV infection [331, 334]. As such inhibition of PD-1 has become an attractive strategy in patients with relapsed/refractory classical Hodgkin's lymphoma. A phase 1 study nivolumab in 23 patients with r/r cHL (with 78% post-autologous stem cell transplant and 78% relapsed after brentuximab vedotin) showed an objective response in 87% of participants and an overall acceptable safety profile [343]. This data led to FDA approval of HL for relapse post-autologous stem cell transplant with posttransplant brentuximab vedotin. Pembrolizumab is a humanized IgG4 monoclonal antibody targeting PD-1. In a phase 1b trial, 31 patients with r/r cHL that progressed on or after brentuximab vedotin were given pembrolizumab every 2 weeks. The ORR was 65% with CR rate of 16% in this heavily pre-treated group with 70% of those responses lasting at least 24 months [344]. This data led to breakthrough therapy designation and FDA approval of pembrolizumab in *r/r* cHL.

Brentuximab Vedotin

Brentuximab vedotin (BV) is a antibody-drug conjugate with a CD30 directed antibody linked to auristatin (a microtubule disrupting agent) [345]. BV has been shown in vitro to selectively induce apoptosis in cells bearing the CD30 receptor which is expressed on HRS cells [346]. The FDA initially approved BV in HL relapsed after autologous transplant based on the results of a phase II study in 102 heavily pretreated patients with HL that showed an ORR of 75% and CR rate of 34% with good tolerability. Most common adverse effects were peripheral neuropathy, nausea, fatigue, neutropenia, and diarrhea [347]. A phase 3 trial later evaluated BV as maintenance post-autologous stem cell transplant. The group that received BV as maintenance had an improved median PFS of 42.9 months vs. 24.1 months in the placebo group. These findings allowed for FDA approval of BV as maintenance therapy in the post-autologous stem cell transplant setting [348]. Studies are currently underway attempting to move BV to frontline therapy in combination with doxorubicin, vinblastine, and decarbazine (AVD).

Engineered Chimeric Antigen Receptor T-Cells

Chimeric antigen receptor T cells are autologous T lymphocytes that are genetically modified to express the binding site

of specific antibodies allowing autologous polyclonal T cells to bind a specific tumor associated antigen independent of MHC presentation [349]. The construct usually is composed of a single-chain fragment variable (scFv) fused to the activating intracellular signaling domain of the T-cell receptor, typically the zeta chain [350]. Transduction of the DNA encoding the construct is done ex vivo using retroviral or lentiviral vectors [351–353]. Most clinical experience with CD19 CAR T cells is in acute lymphoblastic leukemia but this is quickly translating to use in other CD19 positive lymphoid malignancies such as non-Hodgkin's lymphoma and CLL.

Researchers at MSKCC initially used CD19 CAR T cells for heavily pre-treated patients with CLL with no preconditioning chemotherapy and found no significant response. The protocol was modified to allow preconditioning fludarabine and cyclophosphamide with a 100% response rate (2 SD, 1 CR, 1 PR) [354, 355]. University of Pennsylvania investigators used the CTL019 CAR T-cell construct in patients with r/r CLL after lymphodepleting chemotherapy and realized a ORR of 57% in a pilot study [356]. In a follow-up phase II trial of 23 patients the ORR was slightly lower at 35% [357]. A team at the NCI tested it's CAR T-cell therapy in a small group of four patients with *r/r* CLL with conditioning fludarabine and cyclophosphamide but added IL-2 with an ORR of 75% [358]. They later dropped the IL-2 from the protocol and realized an ORR of 100% in a second cohort of four patients with three CRs [359].

Data from CAR T-cell therapy in B-cell NHLs is now becoming mature and available. The NCI team evaluated nine patients with DLBCL and indolent B-NHL using fludarabine and cyclophosphamide conditioning followed by their CAR T-cell construct. There was good efficacy in patients with DLBCL with four CRs, two PRs, and one SD. On patient with indolent B-NHL achieved a CR [359]. The UPenn investigators used their CD019 CAR T-cell construct in patients with *r/r* NHL h = who received varying lymphodepleting conditioning chemotherapies. Out of 22 evaluable patients with NHL (DLBCL 13, FL 7, MCL 2) ORR at 3 months was 68% (DLBCL 54%, FL 100% and MCL 50%) [360]. Investigators at the Fred Hutchinson Cancer Center treated 32 patients with r/r B-NHL with conditioning chemotherapy followed by CAR T cells with an objective response of 63%. Patients in this group that received fludarabin and cyclophosphamide had a higher response rate of 72% when compared to those that got cyclophosphamide alone or in combination with etoposide [361].

Despite the positive results from trials employing CAR T cells, their toxicities cannot be ignored. These adverse effects are not usually associated with the dose or timing of infusion but to the expansion or persistence of cells [362, 363]. Most common toxicities are cytokine release syndrome (which can be life-threatening), encephalopathy, and B-cell aplasia. Steroids and IL-6 blocking monoclonal antibody tocilizumab have been utilized for life-threatening CRS with some efficacy [362, 364].

Radioimmunotherapy

Radioisotopes coupled to a monoclonal antibody enable binding of the antibody to the target cell bringing the radioactive portion of the molecule in close proximity to act not only on the cell with the antigen of interest but also on cells that the antibody itself cannot reach. The two most studied radioimmunotherapeutic agents are yttrium-90-ibritumomab tiuxetan (Zevalin) and tositumomab/iodine-131 (Bexxar)

^{90}Y-ibritumomab was approved by the FDA for treatment of relapsed/refractory FL and low-grade NHL. In rituximab-treated patients, the overall repose rate in low-grade lymphomas with ^{90}Y-ibritumomab tiuxetan was 74% with a complete response rate of 15% [365]. In rituximab-naïve patients with relapse/refractory low-grade lymphomas, the overall response rate was 80% in ^{90}Y-ibritumomab tiuxetan-treated patients compared with 56% in the rituximab group. Complete responses were also higher in the radioimmunotherapy arm at 30% compared with 16% in the rituximab-treated patients [366]. In the First Line Indolent Trial (FIT), approximately 400 patients in a complete or partial response after induction therapy (most without rituximab) were randomized to either further therapy with radioimmunotherapy or no treatment [367]. Consolidation with ^{90}Y-ibritumomab tiuxetan resulted in a statistically significant increase in median progression-free survival at 36.5 months vs. 13.3 months without treatment ($p < 0.0001$). Interestingly, 78% of the 101 patients who had a partial response after initial therapy went on to have a complete response after consolidation. ^{90}Y-ibritumomab tiuxetan has been FDA-approved as consolidation treatment for patients with FL who achieve a complete or partial response after induction therapy.

^{90}Y-ibritumomab tiuxetan produces response rates of over 50% in rituximab-untreated patients and 19% in rituximab-exposed patients with refractory DLBCL [368]. A phase III trial investigating ^{90}Y-ibritumomab tiuxetan as maintenance treatment in DLBCL patients in complete remission after R-CHOP has been initiated.

^{131}I–tositumomab has been approved by the FDA for the treatment of CD20 expressing rituximab and chemotherapy refractory lymphoma. In rituximab-untreated patients who have previously been treated with chemotherapy, ^{131}I–tositumomab yields a response rate of 65% with a complete response rate of 20% [369]. In a phase II study of upfront therapy in patients with FL, the overall response rate was 95% and a complete response rate was 75% [370]. The 5-year progression-free survival was 59%. A phase II trial conducted by the Southwest Oncology Group investigated

the use of ^{131}I–tositumomab after six cycles of CHOP in previously untreated FL patients who achieved complete or partial response after chemotherapy [371]. Treatment with ^{131}I–tositumomab was accomplished in 84 of the 90 eligible patients and yielded an overall response rate of 98% and a complete response rate of 74%. Results from a phase III trial comparing CHOP followed by ^{131}I–tositumomab with R-CHOP in treatment-naïve FL patients are awaited.

Delayed myelosuppression appearing approximately 6–8 weeks after treatment remains the most significant adverse event secondary to radioimmunotherapy. Patients with preexisting cytopenias are not candidates for this treatment modality. They include those with absolute neutrophil counts $<1.5 \times 10^3$, platelets <100,000, hemoglobin <9 g/dL, over 25% marrow involvement or prior radiotherapy involving greater than 25% of bone marrow. The possibility of delayed leukemia or myelodysplastic syndromes is debated.

Conclusion

Our understanding and knowledge of the specific immunologic traits of the lymphomas over the past two decades has allowed vast development of immune-directed therapies that have been shown to improve survival in the lymphoid malignancies. The more recent clinical advances in targeting the PD-1/PD-L1 axis and utilizing CAR T-cell therapies has opened the door to a new era in the treatment of lymphomas where we are able to harness ones own immune system to target malignancies. The results of these preliminary clinical trials is encouraging but these therapies are still in their infancy and there is much to learn about the best strategy to utilize them. Still the future for immune therapy of the lymphoid malignancies is promising with multiple treatment options on the horizon.

42 Cytogenetics of Lymphomas

Meaghan Wall and Lynda J. Campbell

Introduction

Cytogenetic analysis relies on the production of banded metaphase chromosomes for analysis but chronic lymphoid malignancies have proved notoriously difficult to karyotype as they have extremely variable rates of growth in culture. The highest number of proliferating cells have been identified in diffuse large B-cell lymphomas (DLBCL) and Burkitt lymphomas (BL) whilst follicular lymphomas (FL) and lymphoplasmacytic lymphomas show decreased proliferation when compared with normal mature B lymphocytes [1]. Therefore, it has been necessary to use a range of tests to determine the genetics of lymphomas, including fluorescence in situ hybridisation (FISH) applied to interphase cells (i-FISH) and metaphase spreads, multicoloured FISH, chromosome comparative genomic hybridisation (CGH) and array-based strategies: array CGH (aCGH) and SNP array (SNP-A) analysis.

The first cytogenetic abnormality to have its genetic secrets unlocked was the 8;14 translocation which characterises Burkitt lymphoma. Researchers identified that the translocation caused two genes, *MYC* on 8q24 and the immunoglobulin heavy chain gene, *1GH* on 14q32, to come together. It is now known that two classes of translocations are found in malignancies. The first type is epitomised by the t(8;14) in Burkitt lymphoma; one gene which is already actively transcribed in the cell type, such as *IGH* in B lymphocytes, is juxtaposed to a gene such as *MYC* which is, by virtue of its resulting proximity to *IGH*, upregulated. Other translocations such as the t(9;22) in chronic myeloid leukaemia form fusion genes with a "new" gene product which incorporates part of the normal genes broken at the sites of translocation. The Burkitt type of translocation is the most common variety observed in chronic lymphoid malignancies as most reciprocal translocations identified in lymphomas involve either the immunoglobulin genes or the T-cell receptor genes in B-cell and T-cell lymphomas, respectively.

Mature B-Cell Neoplasms

Chronic Lymphocytic Leukaemia/Small Lymphocytic Lymphoma

Chronic lymphocytic leukaemia (CLL), or its non-leukemic counterpart small lymphocytic lymphoma (SLL), is a chronic B-cell lymphoid neoplasm. Cytogenetic studies in CLL have been complicated by the particular difficulty in inducing the malignant cells to divide in culture. Early studies reported normal karyotypes for most cases of CLL, almost certainly because the metaphase spreads obtained in these cases originated from normal cells present in the blood or bone marrow cultures. The addition of B-cell mitogens such as TPA enabled the detection of cytogenetic abnormalities in approximately 35–45% CLL cases. Abnormalities of 11q and 13q were shown to be the most common findings in classical CLL [2] and trisomy 12 to be associated with atypical morphology [2, 3].

In 2006, Dicker and colleagues published a method of culturing CLL/SLL cells using a mixture of CpG oligonucleotide and interleukin-2 enabling abnormal karyotypes to be identified in more than 80% CLLs by conventional cytogenetics [4]. The ability to visualise the karyotype of most CLL cases has confirmed that CLL is characterised by genomic imbalances, with the most common addition being trisomy 12 and the most common deletions being loss of 13q14 and 11q22 [5]. It has also identified a subgroup of patients with a complex aberrant karyotype (≥3 clonal chromosome aberrations) that are more likely to show deletion of 17p, an unmutated *IGHV* status and CD38 expression [5].

FISH applied to interphase cells has shown genetic abnormalities in most cases studied. A FISH study of 325 CLL cases by Döhner et al. identified abnormalities in 82% cases with deletions of 13q14 (55%) and 11q22 (18%), trisomy 12q (16%) and deletions of 17p13 (7%) and 6q (6%) being the commonest aberrations [6]. None of these aberrations was specific for CLL and so did not provide diagnostic information. However, FISH results correlated with outcome in this cohort. Patients with del(17p) and del(11q) had more advanced disease. Moreover, patients with del(17p) had the shortest median survival and those with del(13q) the longest. A large 2016 study, utilising the CLL Research Consortium database, validated the prognostic utility of the Döhner FISH hierarchy [7]. Median overall survival for patients with del(17p), del(11q), trisomy 12 and del(13q) was 5, 7, 11 and over 12 years, respectively. FISH studies of 18 patients followed for more than 10 years and never requiring treatment showed that none of them had deletions of 17p (*TP53*) or 11q (*ATM*), two had trisomy 12, three had a deletion of 13q. In thirteen patients, none of the studied abnormalities was detected. Thus, in a group of patients with demonstrated indolent disease, the absence of genomic aberrations as demonstrated by FISH correlated with good prognosis [8].

Many studies have shown deletions of 17p13 and 11q22 to be prognostically significant in CLL [6, 7, 9–11]. 11q22 deletions have an association with *ATM* and *BIRC3* mutations, unmutated *IGHV* status, complex karyotype and advanced clinical stage. A study of 118 treatment-naïve patients found that biallelic *ATM* alterations (deletion of one allele with mutation of the second allele) were mutually exclusive of 17p13 deletion and complex karyotype [12]. Biallelic *ATM* abnormalities were an independent predictor of poor overall survival with a hazard ratio similar to that for deletion of 17p13. Deletions of 17p13 have been shown to correlate with the presence of *TP53* mutations, complex cytogenetic abnormalities [13] and with amplification of 2p and deletion of 6q [14]. Del(17p) may be acquired as a secondary event during the course of the disease, particularly in patients with unmutated *IGHV* genes. The proportion of cells with a 17p13 deletion may also be an important prognostic factor. The UKCLL4 trial indicated that 17p deletion in >20% of cells was associated with a dismal complete response rate and a 100% progression rate within 3 years [15]. In the CRC study, patients with del(17p) in <20% nuclei had a substantially longer time to first treatment (TTFT) [7] and Tam et al. reported improved survival in 17p patients with a deletion present in <25% nuclei [16]. However, other groups have shown prognostic significance of 17p deletion using cut-off values of <20% based on the level of aberrant signal patterns identified in normal controls [17, 18] and Rossi et al. reported equivalent outcomes for patients harbouring large and small clones with a mutation in the *TP53* gene [19].

Loss of 13q14 is the commonest finding by FISH. The focus of the deletion has been identified as two microRNAs, *MIR15A* and *MIR16-1,* located in the fourth intron of the *DLEU2* gene [20]. It has been noted that both alleles may be lost and one study of 30 patients suggested that loss of both copies of 13q14 might be a marker for more aggressive disease [21]. Van Dyke et al. grouped 323 patients with a deletion of 13q as a sole abnormality according to locus dosage. TTFT and survival were equivalent for patients who were heterozygous, homozygous or mosaic for 13q deletion, suggesting that it is the presence or absence of a deletion rather than the mono- or biallelic nature of the deletion that dictates clinical behaviour [22]. These findings have been reproduced subsequently in other studies [11, 23]. The number of nuclei found to contain the deletion may have prognostic significance but there is no consensus on the cut-off value, with studies finding statistical significance at >60% [24], >70% [25], and >85% [7] cells, respectively. Accurate mapping of 13q14 deletions using DNA microarray technology has also enabled small lesions (without *RB1* gene deletion) to be distinguished readily from larger deletions (where *RB1* is deleted in addition to *MIR16-1/MIR15A*) [26]. There are conflicting data regarding the impact of larger deletions, with inferior outcomes reported in most [25, 27–29] but not all studies [24].

The significance of abnormalities detected by conventional cytogenetics is an area of active investigation, with a focus on the clinical impact of translocations and karyotypic complexity. In an early study by Mayr et al. translocations, either balanced or more commonly unbalanced, were associated with a significantly shorter TTFT [30]. However, Baliakis and colleagues found that karyotypic complexity but not translocations retained independent prognostic power in multivariate analysis [31]. Complex karyotypes were associated with unmutated *IGHV* status, CD38 expression and abnormalities involving 17p and 11q. Amongst those with complex karyotypes (>3 abnormalities), outcomes were worse in patients with five or more abnormalities. Translocations did have an association with karyotypic complexity, deletion of 17p and the presence of unmutated *IGHV* genes, but this relationship was confined to the unbalanced translocation group [31]. Although the presence of a translocation per se has not been confirmed as an independent prognostic variable, karyotypic complexity has been consistently associated with a poor prognosis [32, 33].

With respect to specific translocation breakpoints, apparently balanced reciprocal translocations involving 13q14 have been observed in CLL but FISH has shown that more than 90% demonstrated a 13q14 deletion at the translocation breakpoint [5]. Moreover, the favourable effect of del(13q) as a sole abnormality detected by FISH is undermined by the presence of translocations, leading to a significantly shorter TTFT [30, 31]. Patients with del(11q) detected by FISH plus translocations also showed significantly shorter treatment free survival when compared with patients with del(11q) without translocations. Most cases of del(17p) detected by FISH were associated with the presence of translocations [30, 34]. A recurrent dicentric unbalanced 17;18 translocation was observed in 16/1213 (1.3%) CLL

cases, resulting in loss of much of 17p and 18p, and associated with early age at diagnosis and disease progression [35].

Reciprocal translocations are uncommon in CLL [5]. Immunoglobulin (IG) translocations have been reported in 5–15% cases [5, 32, 36–38]. Although the majority of these (77%) involve *IGH* at 14q32, variant translocations involving *IGL* (20%) and *IGK* (3%) have also been described. Recurrent partner genes include *BCL2* at 18q21, *BCL3* at 19q13, *MYC* at 8q24, *CDK6* at 7q21, *BCL11A* at 2p16, *BMI1* at 10p12, *FGFR3/MMSET* at 4p16 and *PAX5* at 9p13 [38]. As all of these translocations have been described in a variety of other mature B-cell neoplasms, they lack specificity for CLL.

FISH studies have shown that the presence of an *IGH* translocation predicts a significantly shorter overall survival [32]. The exception to this rule appears to be translocations involving *BCL2* where the prognostic significance is more controversial. The t(14;18) has an association with trisomy 12 and atypical or plasmacytoid morphology in CLL. An adverse impact on prognosis of the t(14;18) was reported in one 2008 study [36], but this has not been confirmed in more recent studies. Put et al. studied 40 patients with CLL and the t(14;18) or a variant translocation. The TTFT in this cohort was 48 months, the estimated median overall survival was 182 months and the t(14;18) was not associated with advanced disease [39]. In a study by Baseggio and colleagues, t(14;18) cases had an intermediate prognosis [40]. In addition, TTFT was statistically superior to that of cases with *BCL3* translocations in the cohort of 64 patients studied by Nguyen-Khac et al. [41] and Davids et al. reported that TTFT was significantly longer in patients with the t(14;18) than in those with other *IGH* translocations [11].

The t(14;19)(q32;q13), has been observed in a variety of B-cell lymphoid malignancies, including CLL, marginal zone lymphoma (MZL) and lymphoplasmacytic lymphoma (LPL). The translocation results in juxtaposition of *BCL3* to *IGH*, resulting in overexpression of BCL3 [42]. The t(14;19) in CLL has been most commonly associated with atypical morphology and immunophenotype, a younger age group with a high proportion of patients diagnosed at less than 40 years of age, the presence of trisomy 12 and deletion of 6q, unmutated *IGHV* genes, rapidly progressive disease and a poor prognosis [41–44]. The t(2;14)(p16;q32) is rare but recurrent in CLL and has an association with atypical or plasmacytoid morphology and unmutated *IGHV* genes [38, 45]. *MYC* translocations are also rare in CLL but have been reported in association with increased prolymphocytes, complex cytogenetic abnormalities, del(11q) or del(17p) and a poor prognosis [46, 47]. *CDK6* translocations are unusual in that they are more likely to involve *IGK* than *IGH,* manifesting as the t(2;7)(p11.2;q21) (see Fig. 42.1); most cases reported to date have had a diagnosis of splenic marginal zone lymphoma or CLL [48, 49].

A recurrent translocation in CLL that does not involve an IG locus is the t(1;6)(p35.3;p25.3) involving the *IRF4/DUSP22* locus at 6p25.3 and an unknown partner gene at 1p35.3 (see Fig. 42.1). This translocation is more common in men than women and has an association with unmutated

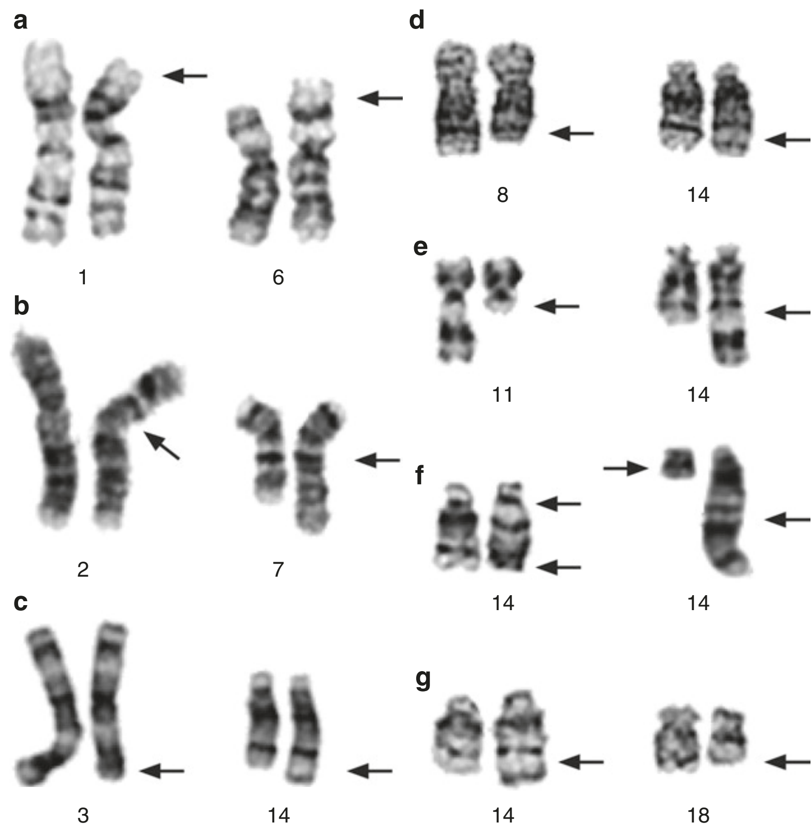

Fig. 42.1 Partial karyotypes of chromosome abnormalities observed in lymphoid malignancies. The abnormal chromosomes are situated on the *right* side of each pair with the normal homologue on the *left*. (**a**) t(1;6)(p35;p25) involving the *IRF4* gene on 6p25 and an unknown partner gene on 1p35; (**b**) t(2;7)(p11.2;q21) involving *IGK* on 2p11.2 and *CDK6* on 7q21; (**c**) t(3;14)(q27;q32) involving the *BCL6* gene on 3q27 and *IGH* gene on 14q32; (**d**) t(8;14)(q24;q32) involving the *MYC* gene on 8q24 and *IGH* gene; (**e**) t(11;14)(q13;q32) involving the *CCND1* gene on 11q13 and the *IGH* gene; (**f**) inversion of chromosome 14 involving the *TRA/TRD* locus on 14q11.2 and the *TCL1A* gene at 14q32 (*left panel*) and the variant t(14;14)(q11.2;q32) (*right panel*); (**g**) t(14;18)(q32;q21) involving the *IGH* gene and the *BCL2* gene on 18q21

IGHV, advanced clinical stage, a requirement for therapy and transformation to high-grade lymphoma [50].

Interstitial deletions of 14q are a recurrent abnormality in CLL. The breakpoints of the del(14)(q24.1q32.33) have been mapped to within the *IGH* locus and in a region of 14q24.1 containing the *ZFP36L1* gene [51]. One gene located within the deleted region is the candidate tumour suppressor gene (TSG) *TRAF3* which has been shown to be homozygously deleted in CLL, or heterozygously deleted with a loss of function mutation in the remaining allele and associated lower expression of TRAF3 mRNA [52]. Deletion of *TRAF3* is one of many genetic events predicted to perturb nuclear factor-KB (NFKB) signalling in mature B-cell lymphomas. FISH studies have also identified patients with deletions of *IGH*. In a series of 291 CLL cases, FISH identified loss of the telomeric 5′ segment of *IGH* (using a 900 kb probe covering the entire variable *IGH* segment) in 82% cases and found the deletion to be associated with good prognosis markers, including del(13q), normal karyotype and lack of CD38 and ZAP-70 expression [37]. However, it appears that these V_H deletions are not oncogenic but rather reflect the physiological events accompanying somatic *V-D-J* assembly [53].

A prognostic scoring system for CLL has been proposed that incorporates age (≥65 years), white blood cell count (≥20 × 10^9/L), unmutated *IGHV* status, *TP53* deletion, the presence of an *IGH* translocation and the number of chromosome aberrations identified by conventional cytogenetics [32]. Using these parameters, patients could be classified into favourable, intermediate and unfavourable risk groups. Genetic factors appear capable of predicting response to therapy. The response to rituximab therapy is significantly lower in CLL patients with del(17)(p13) when compared to patients with other genetic abnormalities identified by FISH [54], possibly due in part to significantly lower CD20 expression [55–57]. Absence of 11q and 17p deletion together with a mutated *IGHV* status is a predictor of favourable response to first-line fludarabine, cyclophosphamide, rituximab (FCR) therapy [58]. Karyotypic complexity was a predictor of event-free and overall survival in relapsed/refractory CLL patients treated with ibrutinib [59]. Complex karyotypes were an independent predictor of outcome after treatment with chlorambucil-based regimens, with the subgroup with karyotypic complexity plus a *TP53* abnormality (deletion or mutation) having a particularly poor prognosis [60].

SNP-A studies have identified the common abnormalities routinely detected by FISH (trisomy 12, deletion of *TP53*, deletion of *ATM* and deletion of 13q14) in the majority of CLL samples [61]. In addition, numerous other copy number changes and regions of copy-neutral loss of heterozygosity (CN-LOH) have been detected. CN-LOH involving the entire length of chromosome 13 and resulting in homozygous deletion of *MIR15A* and *MIR16-1* in the minimally deleted region of 13q14 has been reported [61], together with gain of *MYC* at 8q24, deletion of 8p (*TNFRSF10A/B*) and gain of 2p [62]. The region of gain of 2p in 8–28% CLL cases and up to 39% of CLLs with del(17p) includes the oncogenes, *MYCN, BCL11A* and *REL* [63]. Genomic complexity, as measured by the number of copy number changes identified by DNA microarray platforms, has emerged as an independent risk factor with increased complexity correlating with shortened TTFT [64–67] possibly due in part to the association of del(17p) with higher numbers of copy number aberrations [14, 68]. Array CGH of del(17p) CLLs showed deletions of 18p and/or 20p to be exclusively associated with *TP53* deletion and the higher the percentage of *TP53* deleted cells, the greater the number of additional cytogenetic abnormalities [14]. Regions involved in recurrent abnormalities have also been narrowed by aCGH to a minimal region of 11q encompassing *ATM*, a minimal deletion of 13q encompassing *MIR15A* and *MIR16-1* and a minimal gained region of 2p16 covering the *REL* and *BCL11A* genes [69].

Finally, given the median age of onset of CLL/SLL, the question must be asked as to whether it is cost effective and likely to impact on the choice of therapies to apply a wide battery of tests to older patients. Shanafelt et al. divided a cohort of 2487 CLL patients into those aged <55 years, 55–64, 65–74 and ≥75 years at diagnosis and determined that those aged ≥75 years did not show a reduced life expectancy when compared with age-matched controls and that prognostic testing in this age group had little utility for predicting overall survival [70].

B-Cell Prolymphocytic Leukaemia

B-cell prolymphocytic leukaemia (B-PLL) is a rare neoplasm of B prolymphocytes; it is differentiated from CLL by prolymphocytes representing 55% or more of lymphoid cells in the peripheral blood. Few studies of the cytogenetics of B-PLL have been reported and a retrospective analysis of eight cases of B-prolymphocytic leukaemia (B-PLL) with t(11;14) suggested that these cases represented a splenomegalic form of mantle cell lymphoma (MCL) evolving to leukaemia [71]. Prolymphocytoid transformation of splenic marginal zone lymphoma or splenic diffuse red pulp small B-cell lymphoma can also mimic B-PLL and should be suspected where deletion of 7q is present, especially if there are co-existing deletions of 8p and 17p [72, 73]. Whilst trisomy 12 appears rare, deletions and mutations of *TP53*, and deletions of 11q22.3-q23.1 and 13q14 have been observed in 53%, 39% and 27–55% cases, respectively [74, 75]. The frequency of *TP53* deletions and mutations may explain the aggressive course usually seen in B-PLL. The Burkitt 8;14 translocation and variant 8;22 and 2;8 translocations have

been reported in a handful of cases of B-PLL [47, 76–78] and copy number gain of MYC has also been described [79]. Gene expression analysis comparing B-PLL with CLL showed the two disorders to be biologically distinct with *MYC* one of the genes significantly overexpressed in B-PLL in comparison with CLL [80].

Splenic Marginal Zone Lymphoma

Splenic Marginal Zone Lymphoma (SMZL) is an uncommon low-grade B-cell disorder, which usually presents with a CD5-negative lymphocytosis. Complex chromosomal aberrations are seen in more than 50% cases. The oligonucleotide/IL-2 culture method pioneered by Dicker and colleagues [4] to increase the mitotic index in CLL has also been reported to improve the abnormality rate in SMZL [81].

The commonest abnormalities are gains of 3/3q (15–32%), trisomy 18 (8–12%), trisomy 12 (5–20%) and deletion of 7q32 (21–44%) [82–85]. CN-LOH of 7q has also been reported [86]. The deletion breakpoints at 7q appear heterogeneous with the common area of loss localised using aCGH to 7q32.1-7q32.2 including the *IRF5* gene and a cluster of microRNAs [86–88]. *KLF2* mutations are common in SMZL and deletions of 7q are enriched for in *KLF2* mutant tumours [89]. Arribas and colleagues described a high methylation promoter group in SMZL that was associated with adverse outcomes and had an association with 7q deletion and *NOTCH2* mutation [90]. The presence of two or more chromosomal aberrations may correlate with a shorter survival but the previous reports of an adverse outcome in patients with del(7q) do not appear to be substantiated in larger series [91, 92]. The smallest overlapping region of gain of chromosome 3 was narrowed down to 3q26.33q29 [69]. Rinaldi and colleagues performed DNA microarray studies and identified frequent 7q and 8p deletions in SMZL [72]. Deletions of 8p often co-occurred with 17p deletions and combined deletion of both these regions was associated with a poor prognosis. A second microarray study by Fresquet and colleagues found genomic complexity, deletion of 17p13/*TP53* and gain of 8q/*MYC* to be adverse prognostic factors [86].

Immunoglobulin (*IGH, IGK, IGL*) translocations have been observed in 7%–21% SMZL with a variety of partner chromosomes, resulting in translocations including t(9;14)(p13;q32) (*IGH-PAX5*), t(3;14)(q27;q32) (*IGH-BCL6*), t(14;19)(q32;p13) (*IGH-MUM1*), t(14;19)(q32;q13) (*IGH-BCL3*), t(6;14)(p21;q32) (*IGH-CCND3*) and t(2;7)(p11.2;q21) (*IGK-CDK6*). Numerous other *IG* translocations have been observed but the partner genes have not been identified [92, 93]. Translocations involving *BCL2* and *MALT1* have not been seen in SMZL and although the t(11;14) that is considered characteristic of mantle cell lymphoma has been described in cases of splenic MZBCL, these were reclassified subsequently as mantle cell lymphoma. Most cases of SMZL with *IG* translocations have been shown to contain complex cytogenetic abnormalities in addition to the translocation, but del(7q) and *IG* translocations rarely co-exist [82].

Hairy Cell Leukaemia

With the exception of mutations in the *BRAF* gene, which are present in virtually all cases, recognised recurrent genetic abnormalities are infrequent. Hairy cell leukaemia (HCL) has proven difficult to analyse cytogenetically as the bone marrow aspirate is frequently unsuccessful due to marrow fibrosis. A study using IL4 and anti-CD40 monoclonal antibodies to induce proliferation was able to successfully karyotype 42/43 patients tested but the abnormality rate was only 19% with trisomy of chromosome 5, abnormalities of chromosome 7 and structural rearrangements of 14q being the most frequent abnormalities [94].

A study of splenic tissue from 14 patients with HCL, using CGH and FISH, identified chromosomal gains and losses in only 4/14 cases [95] and a conventional cytogenetics study by Sambani et al. also only found an abnormal karyotype in 8/18 evaluable patients with the commonest abnormality identified being rearrangements of 14q [96]. Further aCGH and SNP arrays also reported few recurrent abnormalities but identified trisomy 5, deletion of 7q and abnormalities of 14q22-32 in a minority of cases [97, 98]. The association of trisomy 5 with HCL was called into question by in the microarray study of Hockley et al. in which trisomy 5 and gain of 5q were more common in HCL-variant than HCL [98]. Nuclear expression of SOX11 has been observed in a subset of HCL associated with upregulation of cyclin D1, but these cases did not contain the t(11;14) that is responsible for overexpression of cyclin D1 in MCL [99].

Lymphoplasmacytic Lymphoma

LPL is a malignant B-cell lymphoma characterised by proliferation of pleomorphic lymphoplasmacytoid lymphocytes and monoclonal IgM production. Mutations involving the *MYD88* gene at 3p22.2 are present in approximately 90% cases of LPL. Accordingly, *MYD88* mutations testing can be useful to distinguish LPL from other B-cell lymphoid neoplasms that may show some plasmacytoid differentiation, such as CLL/SLL, follicular lymphoma and marginal zone lymphoma where *MYD88* mutations are infrequent. LPL has not been shown to harbour the t(11;18), t(1;14) or t(14;18) translocations that are frequently observed in MALT lymphomas and this can be helpful in differentiating between LPL and mucosa-associated lymphoid tissue (MALT) lymphoma [100, 101]. Culture with CpG oligonucleotide and IL-2

achieves abnormality rates up to 80% in LPL [102]. Cytogenetic studies of LPL have shown the most common chromosome abnormalities to be del(6q), observed in 7–55% cases, and trisomy 4; trisomy 12 and *IGH* rearrangements are rarely observed [102, 103]. However, FISH studies found the del(6q) to be an uncommon finding in patients with nodal LPL [104, 105]. An association between trisomy 4 and trisomy 18 has been reported [102, 106]. Trisomy 3 or 3q, resulting from an isochromosome of 3q, has also been associated with B-cell chronic lymphoproliferative disorders with plasmacytoid differentiation [107, 108]. Array CGH applied to LPL cases have also shown del(6q) to be common and an isochromosome 6p pattern where 6q loss is accompanied by gain of 6p is seen in up to 50% of del(6q) cases [109]. CN-LOH of 3p may occur in association with *MYD88* mutation [110]. Frequent regions of gain identified by microarray studies include 3q, 4, 7, 8q, 12q, 18 and Xq. Recurrent regions of loss were 6q, 11q, 13q and 17p [85, 106, 109, 111].

The t(9;14)(p13;q32) involving the *PAX5* and *IGH* genes has been reported in a subset of nodal-based small cell lymphomas with plasmacytoid differentiation [112] but has not been observed in other series of patients with Waldenstrom's macroglobulinemia [113–115]. Moreover, the t(9;14) has been observed in a number of other lymphoma subtypes, including CLL, T-cell rich B-cell lymphomas and diffuse large B-cell lymphomas [116], and so does not appear to be specific to this condition.

Extranodal Marginal Zone Lymphoma of Mucosa-Associated Lymphoid Tissue (MALT Lymphoma)

The MALT lymphomas are common low-grade B-cell lymphomas that arise on a background of chronic inflammation at various mucosal sites. The gastric MALT lymphomas are linked to *Helicobacter pylori* (*H. pylori*) infection and small intestine, skin and ocular adnexal disease have been linked to *Campylobacter jejuni*, *Borrelia burgdorderi* and *Chlamydia psittaci* infections, respectively. MALT lymphomas are characterised by trisomies of chromosomes 3, 12 and/or 18 and a series of reciprocal translocations: t(11;18)(q21;q21), t(1;14)(p22;q32), t(14;18)(q32;q21) and t(3;14)(p14.1;q32) involving *BIRC3-MALT1*, *IGH-BCL10*, *IGH-MALT1* and *IGH-FOXP1,* respectively. The incidence of these translocations varies according to the anatomical site of the lymphoma (see Table 42.1). The t(11;18) is seen predominantly in stomach and lung, the t(14;18) in liver, ocular adnexa/orbit, skin and salivary glands and the trisomies in intestinal and salivary gland lymphomas [117, 118]. The oncogenic products of the t(11;18)(q21;q21), t(1;14)(p22;q32) and t(14;18)(q32;q21) all target the NFKB pathway, which is considered critical to malignant B-cell transformation and lymphoma progression.

Table 42.1 Frequency of translocations in MALT lymphomas

Site of MALT lymphoma	Translocation	Frequency (%)
Stomach	t(11;18)(q21;q21)	57/256 (22%)
	t(1;14)(p11;q32)	8/256 (3%)
	t(14;18)(q32;q21)	1/256 (0.4%)
	t(3;14)(p14.1;q32)	8/208 (4%)
Lung	t(11;18)(q21;q21)	22/62 (42%)
	t(1;14)(p11;q32)	5/62 (8%)
	t(14;18)(q32;q21)	4/62 (6%)
	t(3;14)(p14.1;q32)	0/18 (0%)
Ocular Adnexae	t(11;18)(q21;q21)	8/110 (7%)
	t(1;14)(p11;q32)	0/110 (0%)
	t(14;18)(q32;q21)	14/110 (13%)
	t(3;14)(p14.1;q32)	4/66 (6%)
Salivary gland	t(11;18)(q21;q21)	2/101 (2%)
	t(1;14)(p11;q32)	1/101 (1%)
	t(14;18)(q32;q21)	5/101 (5%)
	t(3;14)(p14.1;q32)	0/60 (0%)
Thyroid	t(11;18)(q21;q21)	1/18 (5.5%)
	t(1;14)(p11;q32)	0/18 (0%)
	t(14;18)(q32;q21)	0/18 (0%)
	t(3;14)(p14.1;q32)	3/13 (23%)
Skin	t(11;18)(q21;q21)	4/108 (4%)
	t(1;14)(p11;q32)	0/108 (0%)
	t(14;18)(q32;q21)	7/108 (6.5%)
	t(3;14)(p14.1;q32)	2/20 (10%)
Liver	t(11;18)(q21;q21)	0/10 (0%)
	t(1;14)(p11;q32)	0/10 (0%)
	t(14;18)(q32;q21)	5/10 (50%)
Intestine	t(11;18)(q21;q21)	3/20 (15%)
	t(1;14)(p11;q32)	2/20 (20%)
	t(14;18)(q32;q21)	0/16 (0%)
	t(3;14)(p14.1;q32)	0/10 (0%)

Frequency data derived from references [118, 124, 131, 132]

In the t(11;18), the apoptosis inhibitor gene *BIRC3* at 11q21 and *MALT1* at 18q21 cause a hybrid gene *BIRC3-MALT1* to form on the derivative chromosome 11. Occasional variant translocations involving 11, 18 and a third chromosome have been described, all resulting in the *BIRC3-MALT1* fusion [119]. MALT lymphomas are known to transform to DLBCL. DLBCL cases with the t(11;18) have only rarely been identified and are predominantly restricted to apparently de novo testicular and breast DLBCL cases [120, 121]. It appears that the t(11;18)-negative lymphomas develop secondary aberrations and are the only MALT lymphomas capable of transformation to DLBCL [122].

A second translocation involving the *MALT1* gene at 18q21 is the t(14;18)(q32;q21), which has an identical conventional cytogenetic appearance to the t(14;18) characteristically seen in follicular lymphoma (FL). The t(14;18) in MALT lymphomas juxtaposes *MALT1* at 18q21, rather than *BCL2*, to the promoter region of *IGH* gene on 14q32 resulting in deregulation of *MALT1* expression [117, 123]. Trisomy 3 and/or trisomy 18 have been observed in association with the t(14;18). Lymphomas with t(14;18) show strong cytoplasmic expression of both MALT1 and

BCL10 [124]. Unlike the indolent MALT lymphomas that are dependent on the continuous presence of *H. pylori*, MALT lymphomas with translocations targeting the *MALT1* gene can be found in cases without *H. pylori* and are resistant to *H. pylori* therapy.

Rare cases of t(14;18) involving the *BCL2* gene with *IGH* rather than *MALT1* have been described in MALT lymphomas. Although it has been suggested that these cases cluster in Hepatitis C-positive patients [125], a case of *IGH-BCL2*-positive MALT lymphoma in a Hepatitis C-negative patient who responded to *H. pylori* eradication therapy has been reported [126].

A less common translocation observed in MALT lymphomas is the t(1;14)(p22;q32) which transfers the *BCL10* gene to chromosome 14 where its expression is inappropriately stimulated by the neighbouring *IGH* enhancer. The upregulated *BCL10* gene product is truncated and loses its weak pro-apoptotic function but retains its ability to activate NFKB. Nuclear *BCL10* expression is also observed frequently in MALT lymphomas that do not exhibit the t(1;14) and has been also associated with the presence of the *BIRC3-MALT1* fusion protein [127]. Rare cases of t(1;2)(p22;p12) have also been reported juxtaposing *BCL10* adjacent to the immunoglobulin kappa (*IGK*) light chain gene [128]. A t(X;14)(p11.4;q32), placing *GRP34* under the transcriptional control of the *IGH* gene regulatory elements, has also been described in one case of parotid MALT lymphoma, two lung MALT lymphomas, one NMZL and one gastric DLBCL [129, 130].

Another translocation involving the *IGH* gene on chromosome 14, t(3;14)(p14.1;q32) has been described in MALT lymphomas, but is also reported in DLBCL and MALT lymphomas with a DLBCL component [131, 132]. The translocation involves the partner gene *FOXP1* on chromosome 3. Trisomy 3 has been observed in conjunction with the t(3;14) and three copies of the *FOXP1* gene identified in 17% MALT lymphomas and 12% MALT lymphomas with DLBCL. However, FOXP1 expression appears independent of the t(3;14) translocation or of copy number changes of *FOXP1*. The t(3;14) does not occur in association with any of the other three primary translocations characteristic of MALT lymphoma [131]. Other rare *IGH* translocations have been identified in single cases of MALT lymphoma, involving the partner genes *CNN3* (1p21.3), *TENM2* (5q34) and *KDM4C* (9p24.1) [133].

The translocations all appeared to occur mutually exclusively in a series of 252 primary MALT lymphomas, with the t(11;18), t(14;18), t(1;14) and trisomies of 3 and/or 18 seen in 13.5%, 10.8%, 1.6% and 42.1% of cases, respectively [118], and the t(11;18) and trisomies of 3 and/or 12 appear unlikely to occur together [134].

Using FISH, trisomies of 3, 12 and 18 were frequently observed in gastric, parotid and thyroid MALT lymphomas but not in most cases of primary breast MALT lymphomas [135]. Thymic MALT lymphomas appear to be most similar to parotid and thyroid tumours with trisomy 3 being the most frequent finding [136]. *MALT1* gene rearrangements have been considered rare in breast MALT lymphomas [135, 137] but were detected in 4/9 cases in one study [138]. Trisomies of 3 and 18 have also been observed in a high proportion of primary intestinal MALT lymphomas [139]. A recurrent deletion of 6q has been observed particularly in ocular adnexal marginal zone lymphomas. It involves a 2.9 Mb region at 6q23.2 to 6q24.1 and the target gene for the deletion is thought to be *TNFAIP3*, an inhibitor of NFKB signalling [140]. However, Kwee et al. detected loss of *TNFAIP3* at similar frequency across a variety of anatomical sites but found that gain of 6p was enriched in ocular adnexal disease and that 8q gain was more frequent in gastric MALT lymphomas [141].

Detection of the common translocations may be via conventional cytogenetics, FISH or RT-PCR. FISH has been applied to cytogenetic suspensions and also to paraffin-embedded tissue. Remstein et al. used two-colour FISH to identify the t(11;18) in nuclei isolated from paraffin-embedded tissue in MALT lymphomas in which the t(11;18) had been previously identified by RT-PCR [134]. FISH showed a fusion signal for the t(11;18) in 92% RT-PCR-positive cases. This study also confirmed that t(11;18) was rarely observed with trisomy 3 or 18.

Eradication of *H. pylori* infection with antibiotics induces complete remission in 70–80% MALT lymphomas but, for gastric MALT lymphomas, the t(11;18) appears to be a clonal marker for resistance to *H. pylori* eradication therapy and antigen independent growth. Liu et al. studied a series of cases with *H. pylori* gastritis, MALT lymphomas and mucosal DLBCL [142]. The *BIRC3-MALT1* fusion transcript was not detected in *H. pylori* gastritis and mucosal DLBCL but was found in 25/72 (35%) of MALT lymphomas at various sites. Its incidence was significantly higher in gastric cases that showed dissemination to lymph nodes or distal sites compared with those confined to the stomach.

Lui et al. extended their studies to 111 patients with *H. pylori*-positive gastric MALT lymphoma who were treated with antibiotics [143]. The t(11;18) was detected in 2/48 complete-regression cases, both of which relapsed subsequently without *H. pylori* reinfection. The translocation was found in 42/63 non-responsive cases, including 26/43 stage 1E. Its presence therefore appeared to be a strong indicator for non-response to antibiotics. Although there have been cases of t(11;18)-positive gastric MALT lymphoma that have achieved durable remissions with *H. pylori* eradication therapy alone [144], the t(11;18) has also been shown to be predictive of resistance to oral alkylating agents with less than 10% durable remission at long-term follow-up [145]. Addition of chlorambucil to rituximab improved response in t(11;18)-positive but not in t(11;18)-negative gastric MALT lymphoma in one prospective, non-randomised study [146].

BCL10 nuclear expression is observed in MALT lymphomas in the presence of the t(1;14) which results in upregulation of BCL10 but is also observed in lymphomas in the absence of translocations that directly target *BCL10*. Normal B-cells express BCL10 in the cytoplasm but MALT lymphoma cells carrying either t(1;14) or t(11;18) show nuclear expression. Such expression has been correlated with advanced disease [142] and resistance to *H. pylori* eradication therapy [147, 148].

Ferreira et al. studied nine MALT lymphomas by aCGH and demonstrated an altered genome in only 33% with no recurrent overlapping regions of imbalance identified [69]. Array CGH of 19 salivary gland MALT lymphomas identified recurrent gains of 1p32-1pter in 43%, 9q33-34 in 84%, 11q11-13 in 42%, chromosome 17 in 58% and 18q21-22 in 42%. Gains of 9q34, 11q13 and 18q21 were frequently concurrent [149, 150]. Deletion of 6q23.3 containing the NFKB inhibitor *TNFAIP3* was observed in MALT lymphomas of the ocular adnexa, salivary gland, thyroid and liver but not lung, stomach or skin. In ocular cases, *TNFAIP3* deletion was associated with a higher proportion of relapses and a shorter relapse-free survival [150].

Array CGH was also used to compare MALT lymphomas with and without the t(11;18). Chromosome gains and losses were considerably more frequent in t(11;18)-negative lymphomas with gains more frequent than losses; these included all or part of chromosomes 3, 12, 18 and 22 in 23%, 19%, 19% and 27%, respectively, and gain at 9q34, the site of the *TRAF2* and *CARD9* genes (interaction partners of BCL10 in NFKB activation) in 42% [151]. The simplicity of t(11;18) cases was confirmed by Braggio et al., with gains of three and eight and loss of 6q again occurring frequently in t(11;18)-negative cases [85]. In those cases without t(11;18), resistance to *H. pylori* therapy was marked by a greater number of genomic imbalances, particularly gain of 1p36.2, chromosome 3 and 18q and loss of 1p36.3 and 7q31-q33 [152]. Moreover, trisomy 3 cases were *H. pylori* negative, t(11;18) negative and resistant to eradication therapy [152]. In t(11;18)-negative gastro-intestinal MALT lymphomas, trisomy of 18q21, including *MALT1*, detected by FISH has been associated with an adverse outcome [153] and the presence of trisomy 18q21 has been strongly correlated with trisomy for 3q27/*BCL6* [154]. Gene expression analysis has revealed that MALT lymphomas harbouring either t(11;18), t(1;14) or t(14;18) show enhanced expression of NFKB target genes whilst translocation-negative cases show active inflammatory and immune responses [155].

Nodal Marginal Zone Lymphoma

Trisomy 3 is recognised as the commonest recurrent cytogenetic finding in nodal MZL. Other frequently observed abnormalities include trisomy 18 and structural abnormalities of chromosome 7 [156, 157]. A cytogenetic study of 103 MZL cases with an abnormal karyotype showed trisomy 3 or an extra copy of the long arm of chromosome 3 to be present in 38/103 (37%) of cases and as a sole abnormality in the stemline of 5/38 cases, but with clonal evolution evident in sidelines [157]. The 3q24 to 3qter segment comprised the most consistently over-represented region. Chromosome 7q deletions were the second most common abnormality, observed in 32/103 patients and in nine as a sole abnormality, occurring as either an interstitial deletion or an unbalanced translocation. The consistently deleted region was 7q33–7q35. Four patients had an unbalanced 3;7 translocation resulting in trisomy of 3q and a 7q deletion. Trisomy 18 or an extra copy of 18q was identified in 29/103 patients, six of whom showed trisomy of 18q as a result of an isochromosome of 18q. Deletion of 6q was seen in 20/103 patients, trisomy 12 in 15 patients and abnormalities of chromosome 8 leading to deletion of 8p were observed in 15 patients, three of whom had an isochromosome of 8q. Lymphoma associated translocations were observed in only 13% patients, including four with the typical mantle cell lymphoma t(11;14), four with t(3;14)(q27;q32) or variants, three with t(9;14)(p13;q32) and two with t(14;19)(q32;q13.1). Comparing their findings with karyotypes of patients with SLL/CLL, MCL and FL, the combination of +3 and del(7q), which was present in 10% MZL, was not observed in any of the other three diagnoses. However, as trisomies of 3, 12 and 18 and deletions of 6q are all recognised abnormalities in lymphoproliferative disorders, they cannot be regarded as specific for MZL. In microarray studies, recurrently gained regions identified in more than one study included 1q, 3q, 12q and 18q; the only recurrent region of loss was 1p [72, 85, 158].

Follicular Lymphoma

FL represent approximately 20–40% of non-Hodgkin's lymphomas. They are generally associated with an indolent clinical course and overall median survival of 8–10 years. The t(14;18)(q32;q21) translocation or its variants, t(2;18)(p12;q21) and t(18;22)(q21;q11.2), are observed in approximately 85% of FL. FL cells are localised to the germinal centre. The characteristic t(14;18)(q32;q21) juxtaposes the *IGH* gene at 14q32 to the *BCL2* gene on 18q21 (see Fig. 42.1). This juxtaposition results in overexpression of the BCL2 protein, which has anti-apoptotic properties. The BCL2 protein is not normally expressed in germinal centre cells.

The variant translocations, t(2;18)(p12;q21) and t(18;22)(q21;q11), involve the *IGK* or *IGL* genes, respectively, rather than *IGH*. There have also been complex translocations described involving a third chromosome breakpoint in addition to 14q32 and 18q21 [159]. The result of all of these rearrangements

appears to be the same, overexpression of BCL2. Despite the anti-apoptotic activity of BCL2, low-grade follicular lymphoma cells carrying the t(14;18) die quickly by apoptosis when cultured in vitro, making cytogenetic studies difficult.

The t(14;18) is observed in most grade 1 and grade 2 FL but in fewer grade 3A and a minority of grade 3B cases. The t(14;18) is also less frequently observed in FL arising in extranodal sites such as skin or testis. Guo et al. [160] identified 69% of FL as "typical" with low histological grade (1 and 2), co-expression of BCL2 and CD10 and containing the t(14;18). They considered this group to be a homogeneous disease entity but the rest to comprise a group of heterogeneous disorders. BCL2 expression may be demonstrated in some cases by immunohistochemistry in the absence of the t(14;18) and there is a case report of a FL with a t(2;18)(q11.2;q21) showing BCL2 overexpression as a result of juxtaposition to the *AFF3* gene at 2q11.2, a non-*IG* translocation [161]. A comparison of gene expression profiles between t(14;18)-positive and -negative FL showed germinal centre B-cell associated signatures in t(14;18)-positive cases whilst activated B-cell like, NFKB proliferation and bystander cell signatures were observed in the t(14;18)-negative cases. In 32% of t(14;18)-negative FL, there was weak or absent CD10 expression and most showed an increased Ki67 proliferation rate. Despite these distinct differences, no survival difference was observed between the two groups [162]. An aCGH study found trisomy 3, gain/amplification of 18q21-qter (including *BCL2*) and loss of 9p21 (*CDKN2A* locus) were significantly more frequent in t(14;18)-negative cases. Most of the t(14;18)-negative cases that showed BCL2 expression by immunohistochemistry exhibited gain/amplification of 18q21-qter and the majority were CD10 negative and MUM1 positive, suggesting that they were derived from late germinal centre B-cells [163].

Additional genetic aberrations are observed in more than 90% FL as, although the t(14;18) is considered the primary genetic event in FL, additional changes are required to produce the fully malignant phenotype. The most frequent secondary numerical aberrations include an extra X chromosome and trisomies of 7, 12 or 12q, 18 or a doubling of the der(18)t(14;18). Structural abnormalities frequently involve chromosomes 1, 6q and 10q22q24 [164–167]. There has been shown to be a correlation of del(1)(p36), del(6q), del(10q) and trisomy 7 with morphological progression but, beyond that, a consistent pattern has not been discerned. M-FISH analysis of a series of FL identified the commonly observed secondary abnormality add(1)(p36) to be an unbalanced 1;17 translocation in approximately one-third of cases [165].

Transformation to high-grade lymphoma occurs in 25–60% cases and is frequently accompanied by the further acquisition of secondary genetic changes. An average number of six chromosome abnormalities were reported in a FL karyotype in addition to the t(14;18) [164]; most of these changes were unbalanced, resulting in gain or loss of chromosomal material. The complexity of secondary abnormalities appears to correlate with grade; higher grade FL contain more abnormalities. A microsatellite study of 9p21 markers in 11 cases of FL that had progressed to DLBCL identified 9p deletions in 73% at transformation, suggesting that del(9p) might be an important secondary event in the histological progression of FL [168]. In another study of 210 patients with FL, 31% of whom transformed to higher grade lymphoma over a 10 year period, an additional X chromosome in the diagnostic karyotype of male patients was the only predictor of adverse outcome [169]. Recent studies have confirmed the importance of del(9)(p21) at transformation and identified other changes including amplification of 2p (including *BCL11A* and *REL*), gains of 6p and 17q21 and *MYC* translocations [170, 171].

Trisomy 7, deletion of 6q and an additional copy of the derivative 18, der(18)t(14;18), were identified as early additional genetic changes with each indicating the first step in different "pathways" of evolution. Deletion of 17p and trisomy 12 were significant negative predictors of overall survival in one large series [166] and del(6q), +5, +19 and +20 were associated with poorer overall survival and del(17p) with poorer event-free survival in another [167]. Deletion at 1p36 was identified in 27/29 t(14;18)-negative FLs and was correlated with predominantly diffuse morphology, often with low clinical stage but large localised inguinal tumours [172]. There appear to be two distinct clinical entities associated with 1p36 abnormalities: nodal-variant paediatric-type FL (PTFL) and t(14;18)-negative FL [173]. CN-LOH of 1p36 in association with mutations in the *TNFRSF14* gene has been reported in 40% cases of IRF4/MUM1-negative, nodal-variant PTFL. In contrast, deletions of 1p36 were observed in t(14;18)-negative FL cases but CN-LOH of 1p36 was rare (9%). PTFL could also be distinguished from t(14;18)-negative FL cases by the low genetic complexity and the relative rarity of mutations involving chromatic modifying genes in the former compared to the latter [173].

Using aCGH, 16 recurrent regional aberrations were identified that were independent predictors of overall survival in multivariate analysis on the following chromosomes:1p-, 1q+, 5p+, 6q-, 8q+, 17p- and 17q+. Two of these, deletions of 1p and 6q, were also shown to be predictors of transformation [174]. Schwaenen and colleagues reported that deletion of 6q was associated with shorter overall survival [175] and O'Shea et al. identified CN-LOH of 1p36 and 16p by SNP-A that predicted reduced survival and disease progression, respectively [176].

A subset of t(14;18)-negative FL contain a t(3;14)(q27;q32) translocation (see Fig. 42.1), resulting in overexpression of *BCL6* on 3q27. *BCL6* rearrangements (3q27) are less common in FL than in DLBCL and are detected in 9–14% of FL cases by conventional cytogenetics.

Paradoxically, the highest levels of *BCL6* expression are found in FL in cases that do not contain 3q27 rearrangements [177]. The t(14;18) is least commonly observed in pure FL 3B subtype, lymphomas composed almost exclusively of centroblasts. It is also rare in the distinct but related group of DLBCL with an associated FL 3B component (DLBCL/FL3B). Translocations involving BCL6 are reportedly rare in pure FL 3B but are relatively frequent in DLCBL/FL3B [178–180]. Analysis of *BCL6* aberrations by FISH in 100 t(14;18)-negative FLs showed that 77 contained a *BCL6* gene rearrangement or translocation and/or gain or amplification of the *BCL6* gene, whilst only 23 had no *BCL6* gene abnormalities. The cases with *BCL6* gene gain/amplification were more likely to show higher grade morphology, higher BCL2 and MUM1 expression and more likely to also show gain of 18q21 (*BCL2*) than other groups [181]. Jardin et al. studied 15 cases of FL with 3q27 translocations. Thirteen of the 15 had a t(3;14)(q27;q32), most were CD10 negative and BCL2 negative but there did not appear to be any significant differences in age, sex, performance status, bone marrow involvement or overall survival, when compared with FL with t(14;18) [177].

Balanced translocations, apart from the t(14;18) and t(3;14), are infrequent but usually represent lymphoma specific changes when present, such as the Burkitt t(8;14) translocation or its variants associated with high-grade transformation. At transformation, 8q24 (*MYC*) translocations are common [169]. Of interest is the observation that FL studied serially showed loss of some cytogenetic aberrations over time that had been present at diagnosis [182]. A small number of FL cases have been reported with a *MYC* translocation present at diagnosis in addition to the t(14;18); this finding may be associated with an aggressive clinical course [182]. However, Ladanyi et al. identified six cases with t(8;14) but no evidence of the t(14;18) in a series of 278 karyotypically abnormal FL. Sequencing showed that the breakpoints did not lie in the regions usually involved in the t(8;14) of Burkitt lymphoma. Moreover, the cases had an indolent course, suggesting that the t(8;14) in FL is not always the same translocation as that seen in high-grade lymphomas [183]. Other rare *IGH* translocations are the t(12;14)(p11.2;q32) placing the *SOX5* gene at 12p11.2 under the transcriptional control of the IGH enhancer [184]. Cases harbouring the cryptic t(6;14)(p25;q32) involving *IRF4*, which has a particular association with grade 3B FL and disease involving Waldeyer's ring, will meet criteria for the provisional entity Large B-cell Lymphoma with IRF4 Rearrangement in the 2016 revision of the WHO Classification [185–187].

It is not generally considered necessary to identify the t(14;18) to make a diagnosis of FL but it may be useful to confirm the diagnosis in small biopsies or with atypical morphology when other tests are inconclusive. Testing for t(14;18) can also be used to monitor therapy, detect recurrent disease and determine the effectiveness of bone marrow purging prior to autologous stem cell harvest. Conventional cytogenetic analysis can detect the t(14;18) but requires fresh tissue with viable dividing cells; in many centres, lymph node biopsies are not routinely submitted for karyotyping.

FISH can be applied to cytogenetic preparations and is also able to detect the t(14;18) in smears, cytospin preparations, touch imprints, frozen tissue and fixed paraffin-embedded tissue. It is best in the identification of the t(14;18) in diagnostic specimens and less effective in detecting residual disease. FISH has a higher sensitivity than PCR as FISH probes span almost all breakpoints whereas standard PCR primer sets cover only a limited number of breakpoint regions. However, PCR analysis is more effective for the detection of minimal residual disease [188].

Mantle Cell Lymphoma

Mantle cell lymphoma (MCL), an aggressive lymphoid tumour, is characterised by distinct clinical, morphological and genetic features. Whilst morphology and immunophenotyping have been widely used to define this entity, the most accurate method of diagnosis is via genetic methods.

The cytogenetic hallmark is the translocation t(11;14)(q13;q32) (see Fig. 42.1), which juxtaposes the cyclin D1 gene (*CCND1,* previously known as *BCL1* and *PRAD1*) with an enhancer sequence of the *IGH* gene at 14q32. Detection of the t(11;14) may be via conventional cytogenetics or FISH using a *CCND1/IGH* dual colour dual fusion translocation probe and FISH may be used on peripheral blood, bone marrow or lymph node samples (see Fig. 42.2). Successful FISH identification of the t(11;14) has also been reported on archived fine needle aspirate cytology slides [189] and paraffin sections [190]. The finding of the t(11;14) is of diagnostic rather than prognostic significance in mantle cell lymphoma. The translocation does not disrupt *CCND1* but results in overexpression and a quantitative increase in normal cyclin D1 protein. Whilst almost half of the 11q13 breakpoints of the t(11;14) in MCL cluster in an 8–10 kb major translocation cluster region, the other 11q13 breakpoints are scattered over more than 100 kb, making PCR-based approaches to identifying the translocation problematic. Comparative analyses of interphase FISH for detection of the t(11;14) with other methods such as conventional cytogenetics, PCR for amplification of the t(11;14) genomic breakpoint, competitive RT-PCR for detection of cyclin D1 transcript overexpression and immunohistochemistry for cyclin D1 protein detection identified FISH as by far the most sensitive method for detecting evidence of the t(11;14) [190–192].

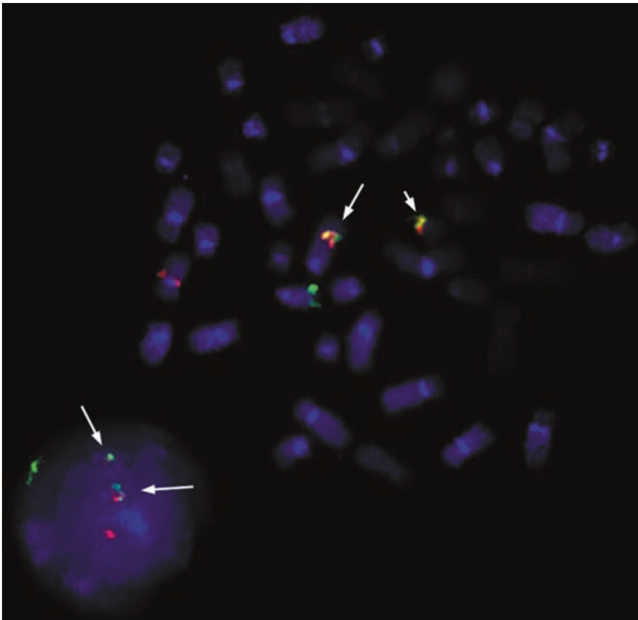

Fig. 42.2 Metaphase spread and interphase cell from a patient with mantle cell lymphoma showing *CCND1/IGH* fusion signals (*arrowed*). The two fusion signals shown on the metaphase spread are located on the der(11)t(11;14) (*short arrow*) and on the der(14)t(11;14) (*long arrow*). The SpectrumOrange™ signal (*CCND1*) is on the normal chromosome 11 and the SpectrumGreen™ signal (*IGH*) on the normal chromosome 14. The interphase cell shows the standard signal pattern of 2 fusions, 1 *red* and 1 *green* that denotes the presence of the balanced t(11;14)(q13;q32) (Probe: LSI *IGH/CCND1* dual colour dual fusion translocation probe, Vysis)

The most common entity from which MCL should be distinguished is CLL as they may have overlapping features, both being CD5-positive small B-cell neoplasms. Reports in the older literature of t(11;14) in CLL almost certainly referred to cases of MCL. A case of splenic lymphoma with histology and flow cytometry results that could not distinguish between splenic marginal zone lymphoma and a mantle cell lymphoma was confirmed as MCL with the demonstration of *CCND1/IGH* fusion signals [193]. Ho et al. identified 28 cases with typical flow MCL phenotype but FISH showed that 9/28 did not contain the t(11;14) and had cytogenetic abnormalities commonly found in CLL. No significant immunophenotypic or morphological differences between t(11;14)-positive and -negative cases could be discerned [194].

The t(11;14) is usually an obvious rearrangement on conventional cytogenetics, although complex translocations masking the t(11;14) have been described, requiring FISH with *IGH* and *CCND1* probes to identify the fusion signals when the t(11;14) in not visible in an abnormal clone. Despite the complex nature of these rearrangements, there are usually abnormalities involving the 11q13 and 14q32 breakpoints, providing a clue as to the underlying genetic rearrangement [195]. However, reports have illustrated the need for FISH despite the finding of an abnormal karyotype with no evidence of any apparent abnormalities of either chromosome 11 or 14. FISH has shown a *CCND1/IGH* fusion signal on a "normal" chromosome 14, apparently caused by an insertion of a sub-microscopic segment of 11q13 into 14q32 [196, 197]. The Spanish Cooperative Group for Hematological Cytogenetics identified 145 cases of MCL at diagnosis with an abnormal karyotype. All contained either a t(11;14), a variant *CCND1* translocation with a three-way translocation involving 11, 14 and a third partner chromosome, a variant translocation involving the *IGL* gene on chromosome 22 (t(11;22)), or a cryptic t(11;14). Nine patients showed the *CCND1/IGH* fusion by FISH only, despite exhibiting an abnormal karyotype [198]. A blastoid variant of MCL did not contain a t(11;14) but had a deletion of 11q and abnormalities of 13p and 21p. Additional M-FISH and locus specific FISH tests identified chromosome 11 and chromosome 14 sequences and *CCND1/IGH* fusion signals on both 13p and 21p [199]. An atypical t(11;14) was identified in 18/103 MCL cases and included patients with duplications of the *CCND1/IGH* fusion, three-way translocations and insertions, emphasising the importance of FISH to confirm unusual translocations [200].

As with most other translocations involving the immunoglobulin heavy chain locus, variant translocations involving one or other of the light chain genes have been reported. Wlodarska et al. reported three cases of the *IGK* variant, t(2;11)(p11;q13), with the 11q13 breakpoint mapped to the 3′ region of *CCND1*, in contrast to the 5′ breakpoint of the t(11;14) [201]. They further postulated that this variant may represent a more indolent form of MCL.

FISH, M-FISH, aCGH and SNP-A have identified extra abnormalities in 80–92% cases [192, 202, 203]. Additional abnormalities with recurrent breakpoints are listed in Table 42.2. There appear to be differences in the patterns of extra abnormalities between those cases shown to have primarily lymph node-based disease and those with peripheral blood disease, with the lymph node-based cases appearing more cytogenetically complex and more likely to show deletions and chromosome loss. Loss of 17p and gain of 3q have been associated with disease progression and to be independent poor prognosis indicators in multivariate analysis [195, 198, 204, 205]. Deletions of *CDKN2A* and *TP53* detected by multiplex ligation dependent probe amplification (MLPA) and PCR were independent predictors of shortened overall survival in the study from the European Mantle Cell Lymphoma Network [206]. The effect of co-existing *CDKN2A* and *TP53* deletions was additive; patients with deletions at both loci had a median overall survival of 1.8 years.

Blastoid and pleomorphic variants appear more likely to contain higher numbers of additional abnormalities, a

higher frequency of 1p and 17p deletions as well as 10p abnormalities, a higher proliferation index and a shorter survival [205].

The overall number of deletions has been shown to be a significant independent prognostic marker with three or more indicating poor clinical outcome [192]. Deletions of 11q23 and 6q21 have been associated with extranodal disease and deletions of 13q14 and 6q21 were independent predictors of poor outcome in multivariate analysis [207]. MCL studied using metaphase CGH has confirmed the common regions of gain and loss and found gain of Xq and loss of 17p to be associated with a significantly worse prognosis [208, 209]. Deletions of *TP53* have been demonstrated in a high proportion of MCL cases in leukaemic phase [210].

It has been suggested that the ability to identify the abnormal clone by conventional cytogenetics provides some prognostic information. Katzenberger et al. associated complex karyotypes with higher proliferation indices and an inferior prognosis. By conventional cytogenetics, MCL with more than two structural aberrations was characterised by a significantly worse outcome [192]. Complex karyotypes (three or more additional abnormalities) were an independent predictor of inferior survival in the study by Sarkozy et al. [211]. Cohen et al. reported that karyotypic complexity was associated with deletion of 17p. However, karyotypic complexity was not an independent adverse prognostic factor in this case series [212]. Woroniecka et al. correlated the presence of near-tetraploidy and two copies of the t(11;14) with the blastoid variant of MCL and a poor prognosis, the t(11;14) seen as a sole abnormality with an intermediate clinical outcome and a normal result by conventional cytogenetics with a better prognosis [213]. However, the number of cases in this study was small.

Over 80% of MCL cases show classical morphology with less than 15% blastoid or pleomorphic subtypes [192]. Most cases of blastoid MCL have a complex karyotype with three or more chromosomal abnormalities in addition to the t(11;14). Four blastoid MCL cases were characterised by extra *CCND1* copies identified by FISH [214]. Different patterns of additional abnormalities have been distinguished according to the morphological features of the blastoid mantle cells with abnormalities of 13, 18 and 8 commonly seen in "classic" blastoid MCL and abnormalities of 13, 17 and 3 most common in the "pleomorphic" blastoid MCLs. Tumours with prominent nucleoli in the malignant cells have commonly contained chromosome 17 abnormalities [215].

The association of the t(11;14) and one of the Burkitt translocations is a rare but reported observation. Hao et al. reported five cases of MCL with 8q24 abnormalities in addition to the t(11;14), three of which were shown by FISH to have a rearrangement of *MYC* and two an extra copy of *MYC* [216]. All had blastoid morphological features and 4/5 had leukaemic involvement. Vaishampayan et al. also described two cases of blastic transformation of MCL associated with a very short survival with t(8;14) in addition to t(11;14) in one and dup(8q) with an extra copy of *MYC* in the other [217]. Further cases of the association between blastoid MCL and a Burkitt translocation have been reported [218–220] and quantitative PCR showed *MYC* overexpression to be significantly associated with shorter survival in MCL [221]. Another two patients with blastoid variant of MCL and t(11;14) plus *MYC* rearrangements showed Burkitt-like morphology [222]. Thus, MYC overexpression appears to be implicated in blastic transformation of MCL.

A number of cyclin D1-negative MCL cases have been reported. Most of these have been identified as involving either the cyclin D2 locus (*CCND2*) at 12p13 or the cyclin

D3 locus (*CCND3*) at 6p21.2 [223–226]. Translocations involving *CCND2* predominate being observed in approximately 50% of cyclin D1-negative cases. *CCND2* rearrangements result in overexpression of cyclin D2 [227, 228] but immunostaining for cyclin D2 appears non-specific, as it has been observed in most B-cell lymphomas [229]. The t(6;14)(p21.1;q32.3) involving *CCND3* has been observed more often in other mature B-cell malignancies [230]. Despite gene expression analysis revealing upregulation of CCND2 and CCND3 mRNA in cyclin D1-negative cases and showing good correlation with protein expression, interphase FISH has identified translocations or amplification of *CCND2* or *CCND3* in some but not all cases [223, 227]. Of note was the incidence of CNS lymphoma in five of eight cases in one series of cyclin D1-negative MCL [224].

Diffuse Large B-Cell Lymphoma, NOS

Diffuse large B-cell lymphoma (DLBCL), not otherwise specified (NOS) are a group of B-cell neoplasms characterised by proliferation of large cells with a diffuse growth pattern. Estimated to make up approximately 40% of all cases of NHL, DLBCL is one of the commonest types of lymphoma. The WHO entity is defined by inclusion of large B-cell lymphomas that to not meet the criteria for categorisation as particular DLBCL subtypes or other discrete B-cell neoplasms and this makes for considerable clinicopathological heterogeneity within this disease grouping.

Conventional cytogenetics has a high success rate and abnormality rate in DLBCL. Karyotypes in DLBCL are usually complex; greater than 90% of cases have two or more abnormalities. In a study of 363 consecutive cases by Cigudosa et al. 72% of abnormal karyotypes were hyperdiploid, 19% were pseudodiploid and 9% were hypodiploid [231]. Both translocations and copy number changes are prevalent in DLBCL. M-FISH in 12 DLBCL cases showed five with structural abnormalities of chromosome 1, six with loss of 13q and structural abnormalities of chromosomes 7, 18, 6 and 3 in four, five, two and three cases, respectively [232].

The most common translocations in DLBCL involve the *IG* loci at 14q32 (*IGH*), 22q11.2 (*IGL*) and 2p11.2 (*IGK*). A 14q32 breakpoint has been observed in approximately 50% of cases analysed by conventional G-banding [231, 233]. Frequent non-random cytogenetic abnormalities are translocations involving *BCL6*, *BCL2* and *MYC*, which have reported in approximately 20–45%, 20–25% and 5–16% of cases, respectively [231, 233–237]. Less common translocations have also been reported, the *IMMP2L* gene at 7q31, *BCAS2* gene at 1p13 and the *NECTIN2* gene at 19q13 forming novel *IGH* translocations. A non-IG translocation between *MYC* and the tumour suppressor gene *SOCS1* has also been described [238]. FISH studies identified three cases of DLBCL with either a disruption of the *JAK2* gene at 9p24 caused by a t(8;9)(q13;p24) in one case or amplification of JAK2 with add(9)(p24) in two cases [239]. Non-random recurrent copy number changes identified by metaphase CGH include gain of Xq, 2p, 7q, 12p and 18q and loss of 6q and 17p [240]. Array CGH identified gain 1q, 2p, 3p, 3q, 6p, 7p, 7q, 9p, 12q and 18q and Loss 1p13.1-p36.33, 6q16-14, and 17p12-p13.2 [241].

Cell-of-origin (COO) gene expression profiling (GEP) subclassifies DLBCL into germinal centre B-cell type (GC), and activated B-cell type (ABC) or non-GC type [242, 243]. GC-type DLBCLs are thought to arise from germinal centre B-cells, whereas ABC type DLBCLs probably arise from post-germinal centre B-cells arrested during plasmacytic differentiation. Patients with GC-type DLBCL have significantly better responses to chemotherapy than patients with ABC type DLBCL lending weight to the idea that the two groups represent discrete biological entities [243]. However, thus far, translation of GEP COO findings to routine clinical practice has proved challenging. Immunohistochemistry to differentiate GBC and ABC types of DLBCL has shown variable correlation with, but does not precisely reproduce the segregation of patients using gene expression signatures [244]. However, it has become apparent that cytogenetic abnormalities in patients with DLBCL also tend to cluster according to the COO. Using a combination of array CGH and immunohistochemistry, Guo et al. showed differences in the genetic abnormalities in GCB and non-GCB subtypes of DLBCL in a series of 46 patients: GCB was more frequently associated with gain of 7q22.1 and loss of 16q, non-GCB was associated with gains at 11q24.3 and 3q13.2. Within the non-GCB group, those that showed BCL6 positivity by immunohistochemistry, had a higher frequency of gains of 14q23.1 and loss of 6q, whilst the BCL6-negative group were more likely to show gain of 1q, loss of 14q32.13 and a higher number of genomic imbalances overall [245].

The t(14;18)(q32;q21) results in deregulated expression of BCL2 due to juxtaposition of the *BCL2* gene to the immunoglobulin heavy chain enhancer. It is present in over 85% of cases of follicular lymphoma and is also observed in approximately 20% of DLBCL cases. Variant translocations involving *IGK* and *IGL* may also occur. DLBCL cases with *BCL2* translocations are associated with primary nodal disease and the GC type [243]. That is, most patients with a translocation involving *BCL2* are GC type but not all GC-type DLBCL have *BCL2* translocations. It has been proposed that DLBCL cases with a *BCL2* rearrangement may represent transformation of previously unrecognised follicular lymphoma. Frequent secondary abnormalities in t(14;18) karyotypes from DLBCL are trisomy 7 and trisomy 12 [246]. *BCL2* translocation was thought to be indicative of poor prognosis in DLBCL treated with CHOP chemotherapy alone by some

investigators [235, 247]. However with the advent of combination rituximab and multi-agent chemotherapy this no longer appears to be the case [248, 249]. Copy number changes also cluster according to COO. Using aCGH, Tagawa et al. found gain of 1q, 2p, 7q and 12q to be associated with GC-type DLBCL [250]. Gain or amplification of *REL* or 2p has been consistently observed by a number of investigators, [251–254] as has gain of 12q [241, 253–255]. In a comprehensive study combining oligonucleotide aCGH and gene expression profiling in DLBCL, Lenz et al. [254] demonstrated differential use of oncogenic pathways by the GC and ABC types. 12% of patients with GC type and no patients with ABC type DLBCL had amplification of the *MIR17HG* microRNA cluster on chromosome 13. Although this cluster had been linked to DLBCL by other investigators, the study by Lenz et al. was the first to show it was exclusively confined to the GC type. Other novel abnormalities associated with GC-type DLBCL were loss of *PTEN* on chromosome 10 (homozygous loss of *PTEN* was not identified in any ABC type tumours) and deletion of the *TP73* gene on chromosome 1p. Interestingly homozygous *PTEN* deletion was associated with the presence of the t(14;18). *IRF4* (6p25.3) translocations also appear to be a distinct subset of GC-type DLBCL [256] and will comprise the provisional entity LBCL with IRF4 rearrangement in the 2016 revision of the WHO [187].

Meanwhile, translocations involving *BCL6* have been linked to cases of extranodal lymphoma and the ABC (or non-GC) type DLBCL [242, 243]. The most common translocation involving *BCL6* at 3q27 is the t(3;14)(q27;q32) driving BCL6 expression as a result of juxtaposition of the gene to the *IGH* enhancer. Reciprocal translocations between *BCL6* and the light chain loci and other non-immunoglobulin gene partners have also been reported [257–259]. A novel t(3;10)(q27;q11.2) involving the *RASGEF1A* gene was recently reported [260]. In DLBCL cases where the t(3;14) is identified by conventional karyotyping recurrent secondary abnormalities are gain of chromosomes X, 11, 13, and deletion of 6q and 8p23 [246]. The impact of *BCL6* translocation on outcome in DLBCL is unclear. Most studies predate the rituximab era and variously report favourable [234, 261, 262], neutral [263], or adverse [235] prognostic significance. Since CHOP-R has replaced CHOP as first-line therapy for DLBCL it appears that *BCL6* rearrangement has lost any independent prognostic impact [249, 264].

Copy number changes associated with the ABC/non-GC COO by several investigators include trisomy 3/gain of 3q, gain/amplification of 18q, 19q and loss of 6q and 9p21 [243, 247, 250, 254, 255, 265, 266]. 18q amplification results in frequent overexpression of BCL2 mRNA and protein in the APC/non-GC type and was reported to be a poor-prognostic variable in some studies [240, 267] but not in others [241, 253, 254]. Another random, non-recurrent genetic abnormality in the ABC type is mutation of *CARD11* resulting in activation of NFKB signalling, and Lenz et al. reported that *CARD11* mutations and trisomy 3 tended to co-segregate in the small number of patients who had a *CARD11* mutation included in their data set [254]. In this study, ABC DLBCL patients with either trisomy 3, a 9p21 deletion (involving *CDKN2A* locus) or both had significantly worse outcomes than ABC type patients without these abnormalities. Other investigators have also reported patients with 9p21 deletion had adverse outcomes in the CHOP [250] and R-CHOP era [268].

MYC translocations are an important prognostic variable and tend to be more frequent in GC-type DLBCL. Whilst *MYC* translocations are characteristic of Burkitt lymphoma (BL) they are not unique to BL and can be observed in other B-cell lymphomas including CLL, DLBCL, mantle cell lymphoma, follicular lymphoma and plasmablastic lymphoma. They are also identified in high-grade B-cell lymphoma (HGBL) with *MYC* and *BCL2* and/or *BCL6* rearrangements and HGBL NOS, the two new provisional WHO entities having the most overlap with the superseded 2008 BCLU category [187].

The WHO classification restricts BL to tumours with a MYC translocation involving *IG* loci (*IGH* at 14q32, *IGK* at 2p11.2, or *IGL* at 22q11.2) in a simple karyotype. Simple karyotype is defined as no or only a few additional changes or less than six abnormalities detected by aCGH based on the seminal findings of Hummel et al. [269]. To date the guidelines have proved somewhat challenging to interpret in clinical practise as aCGH technology is yet to be widely taken up outside the research or clinical trial setting and the definition of “only a few” is somewhat imprecise. A 2010 study suggested that cytogenetically, distinguishing cases of BL from BCLU (mean additional abnormalities 1.7 and 3.3, respectively) is likely to be more difficult that distinguishing these two entities from DLBCL cases which displayed far more genetic complexity (mean additional abnormalities 21.7) [270]. From these studies it is clear that measures of karyotypic complexity play a role in the diagnostic decision-making algorithm and complement the information obtained from FISH testing in aggressive B-cell lymphomas. Thus an effort should be made to incorporate conventional metaphase karyotyping or molecular karyotyping by aCGH into the work up of lymphomas where there is a high pre-test probability of a *MYC* translocation.

A study measuring the frequency of *MYC*, *BCL6* and *BCL2* rearrangements in a large population of patients with de novo DLBCL using i-FISH found the incidence of MYC rearrangement was 14% [249]. *MYC* rearrangement was rarely present as the sole translocation (only 2% of cases); almost all tumours also had a co-existing 14;18 translocation, a *BCL6* rearrangement or both [249]. These so-called “double-hit” and “triple-hit” lymphomas will comprise the

HGBL with *MYC* and *BCL2* and/or *BCL6* rearrangement group in the 2016 WHO Classification. *MYC* rearrangement per se is associated with a poor prognosis in DLBCL in most published series [266, 271–274]. Double-hit and triple-hit lymphomas are also generally acknowledged to have a poor prognosis [269, 275]. Another large study, using i-FISH to identify *MYC* and *BCL2* gene abnormalities in 327 patients with DLBCL, showed that in addition to patients with double-hit having a poor prognosis, those with GC subtype and isolated *BCL2* rearrangements also had a significantly poorer outcome than those patients without *BCL2* rearrangements [276]. Double-hit DLBCLs are more likely to contain a *BCL2/IG* translocation together with a *MYC* translocation involving a non-*IG* partner gene. This is in contrast to BCLU, which usually present with immunoglobulin genes partnering both *MYC* and *BCL2* [277]. *BCL6/IGH* is much less common than *BCL2/IGH* as the second rearrangement and most of these cases have been found to be triple-hit lymphomas with involvement of *BCL2* as well as *BCL6* and *MYC* [278].

At this stage, it is unclear if the *MYC* translocation partner has prognostic significance. Johnson et al. found that patients with non-immunoglobulin partners (non-*IG-MYC*) tended to have a more favourable outlook than patients with *IG-MYC* translocations [279]. However, in the study by Barrans et al. involving patients treated with R-CHOP, any *MYC* rearrangement as a single parameter remained an independent indicator of poor prognosis [249]. Clipson et al. investigated the impact of *TP53* mutations in a series of 81 DLBCL with *MYC* translocations, and found that *TP53* mutation and *BCL2*, but not *BCL6* translocations had an adverse effect on outcome. In contrast, in those patients without a *MYC* translocation ($n = 153$), *TP53* mutation, *BCL2* and *BCL6* translocations had no effect on outcome [280].

In the study by Seegmiller et al. that excluded non-*IG-MYC* translocations only 1/4 “double hit” lymphomas was classified as a DLBCL; the other 3/4 were BCLU [270]. Despite the caveat that there is some inherent biological heterogeneity in the variably defined “double-hit” DLBCL group, on the whole it does appear that these patients are less likely to respond satisfactorily to R-CHOP regimens [249, 274, 279, 281].

A novel gene fusion between *TBL1XR1* (3q26) and *TP63* (3q28) was seen in 5% cases of DLBCL tested (6 of 115) and 1/81 follicular lymphoma—all DLBCL of the GCB subtype [282]. Also, translocations involving *FOXP1* at 3p13 have been reported in a variety of B-cell lymphomas including DLBCL. The most common is the t(3;14)(p13;q32) juxtaposing *FOXP1* with the *IGH* gene but translocations involving non-immunoglobulin genes have also been observed, generally disrupting the full-length FOXP1 transcript [283].

Gain or amplification of the 11q23-24 region has been described in DLBCL but not well characterised. 11q amplification in the DLBCL cell line KARPAS-422 showed peak amplification to include the region containing the *SIK2/SNF1LK2* gene. The *SIK2* gene was overexpressed in the cell line but overexpression was not detected in primary lymphoma samples [284]. Another study of the gain of 11q observed in DLBCL mapped increase in copy number to the 11q24.3 region in 23% of 166 cases analysed, an area containing the transcription factors *ETS1* and *FLI1*. Both of these genes showed significantly increased expression in the cases with copy number gain and cell line studies showed ETS1 and FLI1 cooperating in sustaining DLBCL proliferation and survival and regulating genes involved in germinal centre differentiation [285].

Chromosome abnormalities were identified in the bone marrow of 192/1585 patients who had had a staging bone marrow for DLBCL. Adverse outcome was associated with two or more cytogenetic abnormalities and specific abnormalities involving 19p13, 12q22-q24, 8q24 and 19q13 [286]. In another conventional cytogenetics study of 110 DLBCL patients with abnormal karyotypes only loss of 17p was associated with an inferior outcome. Loss of 17p was also associated with higher numbers of chromosome abnormalities [287]. High density SNP arrays were used to study 166 DLBCL samples; of the twenty recurrent genetic lesions identified that showed an impact on clinical course, loss of genetic material at 8p23.1 had the most statistically significant negative impact on outcome and was associated with additional aberrations—del(17p) and del(15q) [288]. Clonal heterogeneity, defined as the presence of several sub-clones with different genomic aberrations within a tumour, was identified using array CGH in 55/117 (47%) of DLBCL samples; the average number of copy number aberrations being 7.8 ± 4.3 in those cases without clonal heterogeneity and 12.7 ± 6.1 in those with clonal heterogeneity. Moreover, clonal heterogeneity was associated with gain of 19q13.12-0.43 and loss of 9p21.3 and 17p13.2-11.2. DLBCL with clonal heterogeneity was also shown to have a significantly poorer prognosis [289].

CD5-positive DLBCL has been associated with a poor outcome. Cytogenetic analysis revealed chromosome abnormalities in 10 of 12 cases studied with frequent breakpoints located at 1p13, 3q27, 6q13, 7q32, 14q32, 18q21 and 19q13 [290]. A novel translocation, t(14;16)(q32.33;q24.1) was also identified in a case of CD5+ de novo DLBCL involving the *IRF8* gene on chromosome 16 and *IGH* on chromosome 14 [291].

There appeared to be some differences in the cytogenetic abnormalities seen in germinal centre B-cell-like DLBCL in Asian vs. Caucasian patients with Asian patients showing greater frequencies of *BCL6* rearrangements and gains of 1q and 11q but with lower incidence of t(14;18) [292]. In 231 Chinese patients studied by conventional cytogenetics, FISH and immunohistochemistry, novel patterns of chromosome

abnormalities included gains of chromosomes 5, 13, 14q, 17, 19p, 20, 21p and Y, loss of chromosome 21 and recurrent translocations: t(7;15)(q22;q22), t(3;20)(p24;q13.1) and t(2;3)(q21;q25) [293].

T-Cell/Histiocyte Rich Large B-Cell Lymphoma

T-cell/histocyte rich large B-cell lymphoma (THRLBCL) is a morphological variant of DLBCL characterised by a small number of large CD20-positive B-cells surrounded by an abundant T-cell infiltrate and usually accompanying histiocytes. Morphologically these cases bear some resemblance to cases of nodular lymphocyte predominant Hodgkin lymphoma (NLPHL). Due to the relative paucity of neoplastic cells and contaminating stroma, successful identification of the malignant clone by conventional cytogenetics is problematic. Only two cases with abnormal karyotypes have been reported. Both karyotypes had a near-tetraploid modal number and were complex with numerical and structural abnormalities but no specific abnormality [294, 295]. *MYC*, *BCL2* or *BCL6* rearrangements were not detected. Interestingly, the case reported by De Laval et al. [295] had an isochromosome of 1q, a cytogenetic abnormality that is also frequently observed in NLPHL [296]. Franke et al. performed CGH on DOP-PCR amplified DNA isolated from microdissected CD20-positive cells taken from 17 THRLBCL tumours [297]. Copy number changes were present in all cases. The most frequent changes were gain of Xq, 4q, Xp, 18q21 and loss of 17p. On average THRBCL had less copy number changes than NLPHL cases (4.7 vs. 10.8). However, the authors had noted similar patterns of copy number change in NLPHL tumours previously [298] including gain of 4q that is an unusual finding in other types of lymphoma. Hartmann et al. also compared THRLBCL to NLPHL using array CGH: both lymphomas showed gains of 2p16.1 (involving the *REL* locus) and losses of 2p11.2 and 9p11.2 [299] leading to speculation that THRLBCL and NLPHL may share the same cell of origin.

Primary DLBCL of the CNS

Primary DLBCL of the CNS (CNS DLBCL) is an aggressive B-cell lymphoma restricted to the central nervous system. Investigation of CNS DLBCL by i-FISH has revealed that chromosomal translocations are common in this disorder. They frequently involve the immunoglobulin genes [300, 301]. In a FISH study by Montesinos-Rongen et al. rearrangements of *IGH*, *IGK* and *IGL* were present in 23%, 24% and 36% of cases, respectively [300]. *BCL6* translocations are also frequent, occurring in up to 47% of cases and do not necessarily involve immunoglobulin partners [300–302]. Non-immunoglobulin translocation partners for *BCL6* identified to date include *HIST1H4I*, *HSPCA* and *GAPDH* [302, 303]. The t(8;14), t(11;14) and t(14;18) have not been identified in CNS DLBCL [300] but *MYC* rearrangements by FISH were present in 3% of cases studied by Cady et al. [301]. Gain or amplification of 18q21 is frequent [300, 304]. In addition to 18q21 gain, Weber et al. also identified recurrent loss of 6q and gain of 12q, 22q by CGH [304].

In 2009 Schwindt et al. [305] analysed 19 tumours using a high density SNP-A. Regions of recurrent loss were identified at 3p14.2, 4q35.2, 6p21.32, 6q21, 8q12-12.2, 9p21.3, 10q23.2 and 12p13.2 and there were recurrent copy number gains of 18q21-23, 19q13.31 and 19q13.43 together with gain of the X chromosome and trisomy 12. There was also recurrent CN-LOH at 6p and 9p21.3. Deletion or CN-LOH involving 6p21.32, the site of the HLA Class II genes, was found in 73% of tumours and was the most frequent abnormality detected. Earlier work had also identified deletions at this site as common abnormalities in CNS DLBCL [306–309]. Another nineteen CNS DLBCL samples were subjected to a genome-wide analysis (array CGH and whole exome sequencing) and also showed the most common abnormalities to be deletion of 9p21.3 (*CDKN2A* and *CDKN2B*), deletion of 6p21 (*HLA*), loss of 6q21 (*PRDM1*), 6q23 (*TNFAIP3*) and 6q14.1 (*TMEM30A*). *BCL6* (3q27) and *FOXP1* (3p14) were involved in unbalanced translocations. Recurrent loss/deletion of the *TOX* (8q12) and *PRKCD* (3p21) genes was seen in CNS DLBCL cases but not in systemic DLBCL [289].

A functional consequence proposed to result from loss of HLA class II expression through homozygous deletion or CN-LOH is tumour escape from immune surveillance and absent HLA class II correlates with unfavourable clinical outcomes in some studies [310, 311]. Del(6)(q21), the next most frequent abnormality was present in 53% of cases and is common to DLBCL NOS and other B-cell lymphomas. These findings validate the work of other investigators who has previously reported recurrent loss of 6q, gain of 18q and copy number loss at 9p21.3 in CNS DLBCL using alternative molecular cytogenetic techniques [300, 301, 304, 309, 312, 313].

Gain of 18q21 results in additional copies of the *BCL2* and *MALT1* genes and both have been implicated in disease pathogenesis. However, more recent studies indicating that NFKB pathway activation is ubiquitous in this condition [314] suggest that perturbation of NFKB activity through *MALT1* amplification may be a critical oncogenic event in CNS DLBCL. Similarly, frequent deletion or silencing of *CDKN2A* at 9p21 indicates it is likely to be a critical tumour suppressor gene that must bypassed for CNS DLBCL lymphomagenesis [313, 315, 316].

In the study of 75 immunocompetent patients with CNS DLBCL by Cady et al. del(6q) was an independent predictor

of poor prognosis [301]. This finding was supported by McPhail et al. who used FISH applied to paraffin-embedded sections and identified 14/28 with del(6q) (5/14 homozygous deletions). The deleted group survived less than half the time of the no deletion group (median OS 221 days vs. 516 days) but due to small sample size significance was not achieved ($p = 0.054$) [317].

Loss of 6p22 and homozygous deletion of *CDKN2A* (9p21) in 29 newly diagnosed CNS DLBCL were associated with significantly shorter progression-free and overall survival [318] and in a series of 41 tumours examined by whole exome sequencing, focal deletion or somatic mutations in the *HLA* genes were associated with poor prognosis, and amplification of genes at 7q35 predicted for short progression-free survival [319].

Primary Cutaneous DLBCL, Leg Type

Primary cutaneous DLBCL, leg type (PC LBCL) is a large B-cell lymphoma of the skin often presenting on the leg in elderly women with frequent secondary dissemination. FISH studies in small numbers of patients have indicated that *IGH* translocations are common in this disorder (6/11 patients) [320]. *MYC* and *BCL6* rearrangements have been reported in 6/14 and 2/14 cases, respectively [321]. Copy number changes consistently identified by CGH include gain of 18q and loss of 6q [322].

Dijkman et al. compared 12 cases of PC LBCL to 19 cases of primary cutaneous follicle centre lymphoma (PCFCL) using BAC aCGH and noted distinct patterns of genetic imbalance in the two disorders. Other investigators also noted differences in copy number changes in PCFCL and PC LBCL by CGH [322] supporting their classification as discrete biological entities. In the study by Dijkman and colleagues [323] amplification of 18q was present in 67% of PC LBCL cases and involvement of the *BCL2* and *MALT1* genes was confirmed by i-FISH. Loss of 9p21.3 was identified in 41% of PC LBCL cases and was unique to the PC LBCL subset. Although the number of cases was small, detection of del(9)(p21) by BAC aCGH or *CDKN2A* gene silencing by DNA methylation were associated with poor-prognosis disease in this study. A follow-up study by Senff et al. [324] mapped 9p21 deletions by MLPA and measured *CDKN2A* methylation in a larger series of 64 cases and found deletion to be more common than methylation. Five-year disease specific survival was 43% for cases with a 9p21/*CDKN2A* abnormality as opposed to 70% for those without ($p = 0.06$).

FOXP1 protein is overexpressed in PC LBCL but FISH has not shown the presence of translocations involving the *FOXP1* gene at 3p13. Rather, it has shown low-level copy number gains (3 to 4 copies) of the *FOXP1* gene in 82% of 15 cases studied [325].

EBV-Positive DLBCL of the Elderly

An analysis of copy number alterations in 13 EBV-positive DLBCL identified relatively few genomic alterations compared to 23 EBV-negative DLBCL. The most common aberrations in the EBV+ cases were recurrent gains at 1q23.2-23.3, 1q32.1, 5p15.3, 8q22.3, 8q24.1-24.2 and 9p24.1, and losses at 6q27, 7q11.2 and 7q36.2-36.3. Chromosomal gain at 9p24.1 (*CD274*) was associated with poor overall survival [326]. A case report described the presence of a t(9;14)(p13;q32) in the lymphoma cells of an elderly patient with this disorder. FISH confirmed rearrangement of the *PAX5* gene at 9p13.2 [327].

Primary Mediastinal Large B-Cell Lymphoma

Primary mediastinal large B-cell lymphoma (PMBL) is a B-cell lymphoma presumed to be of thymic B-cell origin arising in the mediastinum without nodal or bone marrow involvement. Compared to DLBCL, it is more frequent in young women and has a more favourable prognosis. PMBL bears a strong resemblance to classical Hodgkin lymphoma (CHL) clinico-pathologically and so-called “grey-zone” lymphoma with features intermediate between the two conditions can pose a diagnostic dilemma.

The most common chromosome abnormalities seen in PMBL are amplifications of the short arm of chromosome 9 and translocations involving the *CIITA* gene on 16p13.13. Early cytogenetic studies identified gain of 9p, 12q and Xq as recurrent cytogenetic abnormalities in PMBL [328–330]. Bentz et al. investigated 43 cases by CGH and observed gains of 9q and Xq in 40% or more of instances [330]. Gain of Xq, 9p21 and 12q14 were confirmed in 87%, 75% and 35% or cases, respectively, using more sensitive i-FISH testing. For other types of B-cell lymphoma assayed by FISH the rate of 9p gain was very low (6/308 cases), identifying 9p gain as a distinctive feature of PMBL. Palanisamy et al. published the results of conventional karyotyping in 17 patients with PMBL. Clonal cytogenetic abnormalities were present in 11/17 (65%) cases. The karyotypes were hyperdiploid or near-tetraploid in the majority of cases with complex numerical and structural abnormalities and no specific aberration. A t(14;18)(q32;q21) was present in two cases and one case had a t(3;14)(q27;q32). Yamamoto et al. also described the presence of *IGH/BCL6* rearrangements located on the der(3)t(3;14) in a case of PMBL [331]. CGH results for 40 PMBL cases were also compared with 91 cases of DLBCL. Gain of 9, 19, X and loss of four were significantly more frequent in the PMBL cohort [332]. Bea et al. compared the chromosome CGH profiles of tumours that had been classified into the ABC and GC subtypes of DLBCL and PMBL by gene expression profiling and

confirmed 9p gain and 2p14-16 gain as distinctive findings in PMBL [255].

BAC aCGH studies in PMBL have been performed by Weesendorf et al. [333] and Kimm et al. [334]. Wessendorf et al. studied 37 cases and reported recurrent gain of 9p24 (68%), 2p15 (51%), 7q22 (32%), 9q34 (32%) and 12q (30%) [333]. Candidate oncogenes *REL* and *BCL11A* were included in a region of high-level amplification on 2p in this study; however the *REL* locus was not part of a larger minimal consensus region of 2p gain. Kimm et al. [334] performed BAC aCGH on samples from 20 patients with PMBL. Fifty-one regions of recurrent genomic imbalance were detected involving 1p, chromosome 2, chromosome 3, 4q, chromosome 5, 6q, 7p, chromosome 8, 9p, 11q, chromosome 12, 17p, chromosome 20, 21q and the X chromosome. Novel regions of gain were 2q13, 3q23, 3q26.1-q27.3, 5q33.3-q34, 7p12.3-p14.1 and 7p22.1-p22.3. Consistent with prior studies the *REL* locus was frequently gained or amplified and there were frequent gains on the X chromosome. *JAK2* copy number was increased in 62% of cases although the region of highest recurrence mapped to 9p13.1-p13.3 and excluded the *JAK2* locus. Recurrent regions of loss were 1p13.1-p13.2, 3p, 4q, 6q and 17p [334].

Weniger and colleagues [335] proceeded to investigate the consistently identified 2p14-p16 copy number gain in greater detail. A FISH probe hybridising to the *BCL11A* locus indicated gain or amplification in 75% or PMBL tumours tested and copy number gain correlated with transcript abundance. Meanwhile *REL* gain amplification was present by FISH in a similar proportion of cases and despite the fact that transcript levels were not consistently increased in cases with increased gene dosage, *REL* copy number increases were associated with nuclear accumulation of the REL protein [336].

In 2008 Lenz et al. [254] used combined oligonucleotide aCGH and gene expression profiling data to compare ABC and GC subtypes of DLBCL with PMBL. The authors identified 30 minimal common regions (MCRs) with subtype distinction. MCRs that occurred with the highest frequency in PMBL were del(6q), 9p amplification or gain, monosomy 10 and 20p gain or amplification. The best discriminator for PMBL was 9p amplification. It was observed in 45% of PMBL but only 11% and 7% of ABC and GCB DLBCL subtypes, respectively. Genes encoding *JAK2* and *PDCD1LG2 (PDL2)* were the most strongly upregulated in the 9p MCR [254, 337]. Meier et al. [338] reported 9p24 gain in 33% of PMBL cases studied by FISH in a tissue microarray study of lymphoma. Translocations involving the programmed death ligand genes *CD274* (*PDL1*) at 9p24.1 and *PDCD1LG2* (*PDL2*) at 9p24.2 are also recurrent in PMBL. Twa et al. used break-apart FISH probes to identify translocations involving these genes in 20% of 125 PMBCL cases with gene rearrangements correlating with elevated transcript levels [339].

Amplification of 9p is also common in classical Hodgkin lymphoma (CHL) and was investigated further using cell lines and primary tumours from patients with CHL and PMBL. Underscoring the importance of oncogenic JAK/STAT signalling in the pathogenesis of these two conditions is the finding that *SOCS1* loss of function mutations resulting in sustained phosphorylation of JAK2 and deregulated STAT activity are present in approximately 50% of PMBL and CHL tumours [340, 341]. With respect to *CD274/PDCD1LG2* amplification in PMBL Green et al. [342] showed *CD274* at 9p24.1 was amplified in 63% (26/41) cases of PMBL and that amplification correlated with transcript abundance. There was also overexpression of *CD274* in tumours from PMBL patients with 9p24.1 amplification using immunohistochemistry. In conclusion, taking into consideration the fact that PDL1 and PDL2 have been implicated in tumorigenesis through reduced immune surveillance, they are also attractive candidate oncogenes within the region of 9p characteristically amplified in the related disorders of PMBL and CHL.

ALK-Positive Large B-Cell Lymphoma

The ALK-positive large B-cell lymphomas represent a rare entity that frequently exhibits plasmablastic morphology. Translocations involving the *ALK* gene on 2p23 occur generally in T-cell or null cell phenotype lymphomas (see below). In 1997, Delsol et al. reported seven patients with large B-cell lymphoma that showed cytoplasmic ALK staining but no evidence of the t(2;5)(p23;q35) that is observed in the majority of ALK-positive T-cell or null cell anaplastic large cell lymphomas [343]. Western blotting of one case showed that the full-length ALK was expressed. Subsequent reports have identified a handful of cases of B-cell lymphomas carrying the t(2;5) and expressing the *NPM-ALK* fusion [344–346]. However, the majority of ALK-positive B-cell lymphomas in both adults and children contain a variant translocation, the t(2;17)(p23;q23), involving the *CLTC* gene at 17q23, which is associated with a distinctive fine granular cytoplasmic localisation of the ALK staining on immunohistochemistry [347–352].

Cryptic *ALK* rearrangements have also been observed, with insertions of *3'ALK* into the *NPM* locus creating a submicroscopic *NPM-ALK* fusion and insertion of *5'SEC31A*, a gene located at 4q21 that had not been previously reported in ALK fusions in lymphoma, upstream of the 3′ end of *ALK* [346]. There have since been two reports of a *SEC31A-ALK* fusion in LBCL—both also involving complex, cryptic rearrangements between 2p23 and 4q21 [353]. The *SEC31A-ALK* fusion was also associated with granular cytoplasmic ALK staining. Translocation partner genes with *ALK* at Xq21 and 12q24.1 have also been reported, both within a single lymphoma in an HIV-positive patient [354].

Burkitt Lymphoma

Burkitt lymphoma (BL) is an aggressive mature B-cell lymphoma of children and adults with a characteristic clinical presentation, morphology, and immunophenotype. Juxtaposition of *MYC* to an immunoglobulin enhancer (*IG-MYC* translocation) resulting in deregulated expression of the MYC proto-oncogene is the hallmark of this condition. In 85% of cases *IGH* at 14q32 is the partner gene, resulting in the reciprocal t(8;14)(q24;q32). In the remaining 15% of cases the translocation involves *IGK* at 2p11.2 or *IGL* at 22q11.2 resulting in the t(2;8)(p11.2;q24) or the t(8;22)(q24;q11.2) variant [355]. Although *MYC* translocations are strongly associated with BL they are not specific for this condition and are encountered in other aggressive B-cell lymphomas, albeit at lower frequency. The distinction is that in BL, there is strong evidence to support *IG-MYC* translocation as the primary or initiating event in lymphomagenesis, whereas in other B-cell disorders *MYC* rearrangement is more likely to occur during evolution of the neoplastic clone. Furthermore, *MYC* translocation is not absolutely required in BL because a small percentage of cases will meet stringent morphological and molecular criteria for BL in the absence of a demonstrable *MYC* translocation. In some cases this may be explained by methodological limitations. For example, screening for *MYC* rearrangement using a FISH break-apart probe may miss both unusual translocations where the breakpoint on 8q is a long way upstream or downstream of the *MYC* locus, and small insertion events. In other cases, evidence suggests that alternative genetic events, such as those leading to downregulation of MIR34B, can mimic the molecular and immunophenotypic consequences of *IG-MYC* translocation [356].

A gene expression profiling study by Dave et al. demonstrated that cases of BL with typical and atypical morphology were interchangeable at a molecular level. Higher expression of *MYC* target genes and germinal centre B-cell genes distinguished cases with a t(8;14) from other lymphomas and, together with reduced expression of genes in the NFKB pathway and MHC Class I genes, reliably distinguished BL from DLBCL with or without the t(8;14) [281]. A contemporaneous study by Hummel et al. [269] involved comprehensive characterisation of mature aggressive B-cell lymphomas using gene expression profiling, BAC/PAC aCGH and i-FISH for *MYC*, *BCL2* and *BCL6* translocations. Consistent with the findings of Dave et al. [281] there was also striking homogeneity of BL cases at a molecular level including cases with atypical morphology.

Using a set of 58 differentially expressed genes, Hummel et al. [269] proceeded to define a molecular gene signature of BL and used it to classify lymphomas into three groups: molecular BL (mBL), non-molecular BL (non-BL) and intermediate. On the basis of i-FISH and aCGH findings the same cohort were also assigned a molecular karyotype. “MYC-simple” was defined as the presence of a *MYC* rearrangement resulting in juxtaposition to an immunoglobulin enhancer, less than six copy number imbalances by aCGH (low genomic complexity score) and the absence of an *IGH-BCL2* fusion or a *BCL6* rearrangement. “MYC-complex” comprised either cases with a non-*IG-MYC* translocation, or an *IG-MYC* translocation together with a high genomic complexity score (six or more genomic imbalances), or a t(14;18) translocation or a *BCL6* rearrangement or any combination of the three. The “MYC-negative” group was all those remaining patients without evidence of a chromosomal rearrangement involving *MYC* at 8q24 by FISH. Eighty-eight percent of patients with mBL had an *IG-MYC* translocation and 91% had evidence of a *MYC* rearrangement, indicating that absence of a *MYC* translocation need not preclude the diagnosis of BL if the clinical presentation, morphology and immunophenotype are otherwise classical.

There was a strong correlation between the mBL gene expression signature and the “MYC-simple” karyotype. Those patients with an intermediate gene expression profile mostly had “MYC-complex” karyotypes, but occasional cases were “MYC-simple” or “MYC-negative.” The majority of cases with a non-mBL gene expression signature had “MYC-negative” karyotypes. Cases with “MYC-simple” karyotypes had significantly better outcomes than the combined “MYC-complex” and “MYC-negative group” (5-year OS 70% vs. 40%, $p = 0.005$). In contrast, in patients with an intermediate or non-mBL gene signature, the presence of a *MYC* rearrangement was associated with a poor prognosis [269].

In order to place the findings of Hummel et al. [269] in the context of conventional metaphase cytogenetic studies, Boerma et al. [355] systematically analysed cases listed in the Mitelman Database of Chromosome Aberrations in Cancer. They defined “true” BL using morphological criteria, presence of an *IG-MYC* translocation and absence of a *BCL2*, *BCL6* or *CCND1* translocation. Variant *IG-MYC* translocations were slightly more common in adults than children, and adults were more likely to have gain of 8q, but in many other respects the karyotypes were very similar, supporting the concept that BL constitutes the same biological entity occurs in children and adults. “True” BL was again characterised by low karyotypic complexity. In 40% of cases an *IG-MYC* translocation was the sole abnormality detected. Of the 205 paediatric cases studied, unbalanced chromosomal abnormalities were present in 60%: one imbalance was present in 33% of cases, two imbalances in 16% and more than two in the remainder. Seegmiller et al. [270] also studied the karyotypic complexity of 34 patients with *IG-MYC* translocations classified according to WHO 2008 criteria. The average number of cytogenetic imbalances was 1.7 in patients with BL, 3.3 in BCLU patients, 6.7 in patients

with plasmablastic lymphoma and 21.7 in DLBCL. Patients with a simple karyotype, defined as less than or equal to two additional cytogenetic abnormalities, had a significantly greater likelihood of having a BL diagnosis. Therefore the investigators proposed that a cytogenetic imbalance score, using a cut-off value of two may be a valuable discriminator between BL and BCLU cases.

Additional secondary abnormalities noted by Boerma et al. [355] in BL karyotypes were gain of 1q, predominantly as the result of a duplication event, trisomy 7 and trisomy 12; losses of 6q, 17p and 13q32-34 were less frequent. Gain of 1q was most often noted as a single additional cytogenetic abnormality but apart from this no clear patterns of secondary abnormality were identified. The pattern of secondary abnormalities in metaphase preparations is in keeping with patterns of genomic imbalance observed by CGH, aCGH and FISH techniques in BL [357]. Lundin et al. studied 20 cases of Burkitt lymphoma by SNP array and identified copy number aberrations in all but one case. Adults contained more abnormalities than children (median 3 vs. 1.5) and recurrent abnormalities included losses of 6q14.1-q22.33, 9p21.3, and 13q14.2-q14.3, gains of 1q23.3-q31.3, chromosome 7, 13q31.3, and CN-LOH for 6p12.2-pter, 9p23-pter, and 17p11.2-pter [358]. Another study compared the additional abnormalities seen in BL in children ($n = 13$) as compared to adults ($n = 11$) and showed that childhood BL was more likely to show 13q31.3q32.1 amplification, gain of 7q32q36 and CN-LOH of 5q23.3 whilst CN-LOH at 17p13 (site of *TP53* gene) and 18q21.3 was only detected in adult BLs [359]. Moreover, relapse or disease progression in 7 BL cases was associated with the acquisition of additional recurrent chromosome aberrations, mainly trisomy 21, gains of 1q and 7q, losses of 6q, 11q, 13q and 17p [360].

Gain of 1q, and 7q and loss of 13q have variously been reported to be associated with inferior outcomes by some investigators [361–363] but there is a dearth of large studies involving uniformly treated patients able to address this question. Nelson et al. [364] studied 90 patients in a multicentre Children's Cancer Group study to assess the prognostic importance of del(13q) and gain of chromosome 7 in BL in children. FISH testing using a MYC break-apart probe, a 13q probe and a chromosome 7 centromere probe were performed on paraffin-embedded tissue (see Fig. 42.3). *MYC* was rearranged in 93% of patients in keeping with results in the earlier study by Hummel et al. [269]. Del(13q) and trisomy 7 were identified in 42% and 10% of cases, respectively. Interestingly the frequency of 13q deletions in this study was far higher by FISH than by conventional cytogenetics suggesting the existence of additional sub-microscopic deletions or the presence of non-proliferating sub-clones not detected by examination of metaphase preparations. Although numbers were small, the presence or absence of a MYC translocation or an additional signal for the chromosome 7 centromere made no difference to outcome; however del(13q) detection by FISH was associated with significantly reduced 5-year overall survival [364]. In another study of 40 adolescents and adult BLs, treated with therapy that included Rituximab, losses of 11q, 13q, 15q or 17p were associated with poor response to treatment, shorter progression-free survival and shorter overall survival [365].

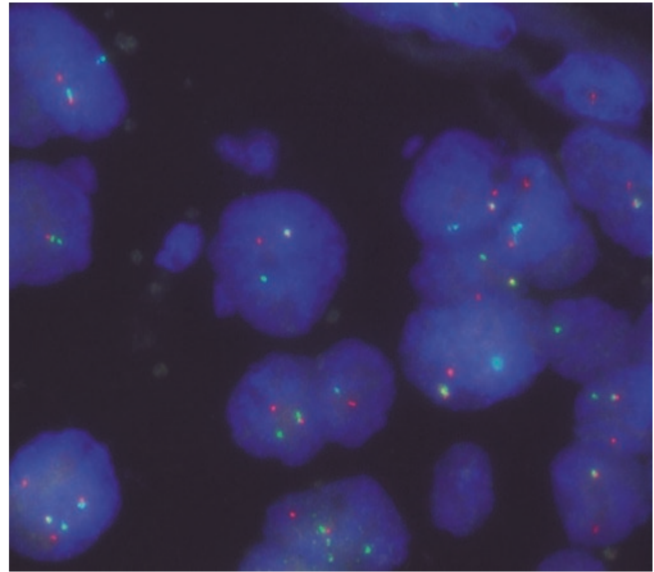

Fig. 42.3 Paraffin-embedded tissue section from the lymph node of a patient with Burkitt lymphoma. A *MYC* break-apart probe (LSI *MYC* dual colour break-apart rearrangement probe, Vysis) shows *MYC* signal rearrangements in most cells, indicating the presence of a translocation disrupting the *MYC* locus at 8q24. The fusion signal indicates an intact *MYC* locus and the red and green signals indicate the presence of a translocation splitting the SpectrumOrange™ labelled *5'MYC* and SpectrumGreen™ *3'MYC* signals apart. This result does not indicate the partner gene involved in the translocation with *MYC*

B-Cell Lymphoma, Unclassifiable, with Features Intermediate between DLBCL and Burkitt Lymphoma (BCLU)

B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and Burkitt lymphoma (BCLU) includes cases of high-grade B-cell lymphoma that do not meet the criteria for Burkitt lymphoma or DLBCL because of intermediate morphology, discordance between morphology and immunophenotype or for other clinical and biological reasons. Patients who meet the criteria for DLBCL who have a *MYC* translocation and patients who meet the criteria for Burkitt lymphoma in the absence of a *MYC* translocation are excluded from this category.

Between 35 and 50 percent of BCLU have a demonstrable *MYC* rearrangement but in contrast to Burkitt lymphoma (BL) many of these involve non-immunoglobulin translocation

partner genes or variant *IG-MYC* translocations involving *IGK* or *IGL* [269, 279]. It may be that in these cases the *MYC* translocation occurs as a secondary event at the time of disease progression, with an *IGH* translocation less likely due to a preceding primary translocation between *IGH* and another oncogene such as *BCL2* at the time of disease initiation [366, 367]. Seegmiller et al. [270] reported karyotypes from patients with BCLU had a mean complexity score of 3.3, whereas BL cases has a score of 1.6, suggesting a cut-off value of two as a useful discriminator in "grey-zone" cases with an *IG-MYC* translocation. Fifteen percent of all BCLU cases have a *BCL2* translocation, and BCLU is enriched for patients with so-called "double-hit" lymphomas (DHL) or "triple-hit" lymphomas, which harbour translocations involving *MYC* and *BCL2* and/or *BCL6* simultaneously [269, 270, 355, 368]. One recurrent translocation involving *BCL6* is the t(2;3)(q21;q27) [369] and two cases have been reported with complex karyotypes, a *BCL2* translocation and a *BCL6/MYC* translocation [370].

The incidence of DHL in a recent large study of 1260 cases of high-grade lymphoma was 4% [279]; approximately two-thirds fitted the criteria for BCLU and most of the remainder were DLBCL. In that subset of DHL cases harbouring an *IG-MYC* translocation rather than a non-*IG-MYC* translocation, studies have consistently found that "double-hit" patients were more likely to be older than patients with BL, have a variant *IG-MYC* translocation, and have greater genetic complexity [269, 270, 355, 368]. Additional non-random, recurrent additional abnormalities identified by conventional cytogenetics in DHL cases were trisomy 7, 8, 11, 12, 18, 20, an additional X chromosome and loss of 3q27-29, 6q, and 15q26 [355].

In the DHL cohort of BCLU and DLBCL cases studied by Johnson et al. the presence of a non-*IG-MYC* translocation was associated with a slightly more favourable outcome, although morphology and IPI remained more powerful predictors of outcome [279]. In other studies, unstratified DHLs whether classified as BCLU or DLBCL are reported to have a poor prognosis [367, 368, 371–373].

Apart from *MYC* and *BCL2* translocations in BCLU, Pienkowska-Gela et al. [374] described four cases with a dup(11)(q23q13) and no evidence of *MYC* translocation. These cases were finally diagnosed as BCLU. Salaverria et al. also identified 19 cases of high-grade B-cell lymphomas with 11q aberrations—interstitial gain of 11q23.2-q23.3 associated with loss of 11q24.1-qter—and showed this 11q abnormality to be frequently associated with morphologic and clinical features of BL despite the lack of a MYC translocation. High-level amplification was observed at 11q23.3, associated with overexpression of genes including *PAFAH1B2*, and deletion of the more terminal region of 11q included loss of the *ETS1* gene, which was also mutated in 4/16 cases tested [375]. Therefore, it appears that duplication of material on 11q represents a novel, recurrent, non-random abnormality in patients in this diagnostic category.

In order to address variable and inconsistent utilisation of the BCLU category, entities that previously fell into this category will be redistributed to the three new provisional entities in the 2016 revision of the WHO: Burkitt-like lymphoma with 11q aberration, high-grade B-cell lymphoma (HGBL) with *MYC* and *BCL2* and/or *BCL6* rearrangements and HGBL NOS [187].

B-Cell Lymphoma, Unclassifiable, with Features Intermediate between DLBCL and Classical Hodgkin Lymphoma

This entity is also known as grey zone lymphoma and appears to have genetic aberrations that are similar to primary mediastinal large B-cell lymphoma (see above). Eberle et al. analysed 27 cases and showed amplification at 2p16.1 (*REL*/*BCL11A* locus) in 33% and aberrations affecting the *JAK2/PDL2* locus at 9p24.1 in 55%. Rearrangement of the *CIITA* locus at 16p13.13 and gains of 8q24 (*MYC*) were observed each in 27% cases [376].

Mature T- and NK-Cell Neoplasms

T-Cell Prolymphocytic Leukaemia

T-cell prolymphocytic leukaemia (T-PLL) is a rare neoplastic disorder of post-thymic T-cells. Clinically the presentation is generally with circulating leukaemia and massive splenomegaly. Often the WCC is greater than 100×10^9/L, which means there is generally little difficulty in obtaining tumour enriched material from blood or bone marrow suitable to culture for karyotyping.

Cytogenetically, the disease is characterised by the inv(14)(q11.2q32) or the t(14;14)(q11.2;q32) which is present in approximately 80% of cases [239, 377–380]. These rearrangements place genes within the *TCL1A* locus under transcriptional control of the enhancer region of the T-cell receptor alpha delta (*TRA/TRD*) locus resulting in deregulated TCL1A expression. Where 14q32 rearrangements are absent, the t(X;14)(q28;q11.2), which translocates *MTCP1* (a *TCL1* homologue) to *TRA/TRD* with similar biological consequences, is usually present [377–379, 381]. Interestingly, patients with the inherited disorder ataxia telangectasia (AT) are predisposed to T-cell malignancy and the inv(14)/t(14;14) or the t(X;14) can be detected in small premalignant clones from these patients suggesting TCL1/MTCP1 deregulation is an early or initiating event during T-cell transformation but is insufficient for development of fully established malignancy [382]. In keeping with the concept that additional genetic

changes are probably required for neoplastic progression, sporadic T-PLL karyotypes are usually complex at diagnosis and typically share a distinctive pattern of secondary cytogenetic abnormalities including abnormalities of chromosomes 6, 8, 11, 12, 17 and 22 [377, 379, 380].

Changes in chromosome 8 are the most common secondary abnormalities and usually result in loss of material on 8p and trisomy for 8q, often as the result of formation of an isochromosome of 8q, an isodicentric chromosome 8p11, or a der(8)t(8;8)(p12;q11.2) [377, 378, 380, 383, 384]. Monosomy or deletion of 11q is the next most frequent abnormality and encompasses the *ATM* gene, which is generally considered the candidate tumour suppressor gene targeted by this deletion in T-PLL [379, 384, 385]. Unsurprisingly, given the association between T-PLL and AT, mutations in *ATM* are also frequent in sporadic cases, such that there is usually biallelic ATM loss of function in this condition even in those patients without 11q22-q23 deletion [385–388]. Deletion of 6q, 12p, monosomy 13/del(13q), monosomy 17/del(17p) and monosomy 22/del(22q) are also seen by conventional karyotyping and/or FISH studies at lower frequencies [377, 379, 389–394]. CGH analysis has identified additional gains on 5p, 6p, 14qter, 21 and 22q12-qter, additional losses on 7q, 9p, 11p, 16q, 17q, and enabled the CDR involved in the del(11q) to be mapped in finer detail [380, 393, 395]. 50K SNP-A analysis of five patients with inv(14)/t(14;14) T-PLL confirmed recurrent gains in 6p and 8q and losses in 6q, 8p and 11q. Furthermore, large novel recurrent areas of loss in 10p and 18p were identified and large regions of CN-LOH on 3q (that were overlapping in two patients), 6p, 9p, 11q and 13q were also reported [393].

JAK3 (19p13) mutations were observed in 11 of 32 patients (34%) with T-PLL; of interest was the finding of 19p13 rearrangements in another 4 of 21 patients lacking a JAK3 mutation [396]. Stengel et al. identified JAK3 mutations in 21% of 51 T-PLL cases; JAK3 mutations had a significant impact on overall survival [384].

T-Cell Large Granular Lymphocytic Leukaemia

This is a T-cell disorder with a distinct clinical presentation, cell morphology and commonly a CD3+ CD8+ CD57+ TCRαβ+ immunophenotype. T-cell receptor gene rearrangements studies are generally used to demonstrate clonality and in most patients the disease follows an indolent clinical course. A large Japanese case series reported normal karyotypes in 33/35 patients; one elderly male patient had a –Y clone and one patient had a structural abnormality of 14q [397]. Similarly Dhodapkar et al. reported a low rate of cytogenetic abnormalities in their series [398]. There are less than 30 published abnormal karyotypes from patients with this condition in the published literature and no consistent pattern of chromosomal derangement is apparent.

Reports are largely confined to conventional cytogenetic analysis. Most karyotypes have a near-diploid modal number and range in complexity from simple numerical aberrations and balanced reciprocal translocations to cases with multiple numerical and structural abnormalities [399, 400]. Man et al. have suggested that monosomy of chromosome 6 or del(6q) may be over-represented in this patient group [399] although deletion of 6q is not unique to this entity.

Chromosomal breakpoints involving the *TRG* and *TRA/TRD* loci at 7p14-p15 and 14q11.2, respectively, are described in patients with this disorder, including some cases of inv(14) or an X;14 translocation involving the *TRA/TRD* locus that are more commonly associated with a diagnosis of T-PLL [400]. Distinguished by a CD3+ CD8+ CD56+ CD57- immunophenotype, a poor prognosis variant of T-cell LGL with a tendency to behave more like aggressive NK cell leukaemia has also been proposed to exist by some investigators [401]. The presence of an isochromosome 7 has been reported in 3/13 cases of aggressive T-cell LGL described to date [401–405]. A case of T-LGLL, γδ variant, was studied by SNP analysis, which revealed CN-LOH at 17q, deletion of 3p21 plus trisomy 5 and monosomies of X and 21 [406].

Chronic Lymphoproliferative Disorder of NK Cells

Chronic lymphoproliferative disorder of NK cells (CLPD-NK) is an indolent disorder in which there is an expanded population of CD3- CD16+ NK cells for greater than 6 months in the absence of an identifiable cause. In retrospective case series of patients subsequently shown to have an indolent clinical course, a normal karyotype at diagnosis is usual [397, 407–409]. T-cell receptors are by definition in the germline configuration, meaning historically there has been a reliance on X-chromosome inactivation to demonstrate clonality in this disorder [408]. Although the presence of a cytogenetic abnormality does not automatically preclude a diagnosis of CLPD-NK, transformation to aggressive LGL leukaemia after 20 months was described in a patient with a mature NK cell lymphocytosis in whom a trisomy 8 clone was present at diagnosis. Evolution of his trisomy 8 clone was coincident with blastic transformation [410].

Aggressive NK Cell Leukaemia

This rare CD2+, surface CD3- (sCD3-), CD56+ NK cell neoplasm with cytoplasmic CD3ε expression is primarily

geographically restricted to Asia, Central and South America, strongly associated with EBV infection and usually involves the peripheral blood, bone marrow, liver and spleen. Although it has a distinct anatomical location and there are differences in patient demography, aggressive NK cell leukaemia (ANKL) appears to share some biological features with extranodal NK/T-cell lymphoma (ENKL). Hence, given their relative scarcity, patients with ENKTL and ANKL tend to be combined in case series where ANKL cases are usually in the minority. Biopsy material is frequently necrotic in this disorder rendering it unsuitable for cytogenetic assays. Furthermore, attempts to obtain abnormal metaphases from involved bone marrow are often thwarted by the low mitotic index of the malignant cells and cellular contamination by non-malignant cells [411] however results from aCGH studies suggest that genomic imbalances occur in the neoplastic cells in most cases.

No unique recurrent abnormalities have been reported in ANKL, although conventional and molecular cytogenetic studies in this disorder are limited. Abnormalities common to other NK cell neoplasms are also found in ANKL including del(6q), del(11q), del(13q), del(17p), trisomy 8, gain of the X chromosome, and isochromosomes of 1q, 6p, 7q and 17q, usually in karyotypes with a near-diploid modal number and three or more abnormalities [411–416]. Spectral karyotyping on a case of ANKL with a complex karyotype identified one translocation involving Xp21 and chromosome 15 together with a unbalanced t(1;8)(q10;p23), demonstrating translocation as a mechanism for gene deregulation in this condition. A translocation with an Xp21 and an 8p23 breakpoint, respectively, were also identified in an additional two cases of ENKL analysed suggesting they may be recurrent breakpoints in these related NK cell disorders [417].

Siu et al. [418] performed conventional cytogenetics and metaphase CGH on patients with ANKL and ENKL. The regions most commonly lost were 6q, 13q, 17p, 9p, 1p, 7p, 10p and 11q and the most frequent gains were observed at 1p, 6p, 11q, 12q, 17q, 19p, 20q and Xp. Del(17p), del(11q), and gain of Xp were more often observed in ANKL than ENKL. Del(6q), del(11q) and del(13q) have been considered the most frequent abnormalities in ANKL [415, 419]. However, a study of 22 Japanese patients confined purely to patients with ANKL failed to identify any instances of del(6q) suggesting that loco-regional differences in the frequency of cytogenetic abnormalities may also be at play [414]. More recently Nakashima et al. [420] performed aCGH on 10 ANKL and 17 ENKL samples. In this series, gain of 1q, together with loss of 7p and 17p were more likely to occur in the ANKL than in ENKL. Notably, loss of 6q and 13q was again infrequent in ANKL in this Japanese study.

Adult T-Cell Leukaemia/Lymphoma

Adult T-cell leukaemia/lymphoma (ATLL) is a T-cell neoplasm encountered in the human T-cell lymphotrophic virus type 1 (HTLV-1) endemic areas of Japan, the Caribbean and Central Africa. ATLL is divided into four clinico-pathological subtypes: acute, lymphomatous, chronic and smouldering. Since chronic infection with HTLV-1 is the causative or initiating event leading to an expanded population of terminally differentiated CD4+, CD25+, CCR4+, FOXP3+ regulatory T-cells, monoclonal integration of HTLV type 1 provirus into cellular DNA is the sine qua non of this disorder. Tumour clonality is readily demonstrable by other molecular means, and cytogenetic techniques are not considered necessary for optimal diagnosis and management of patients in routine clinical practice but may be incorporated into the design of clinical trials as investigational tools [421].

The long latency between HTLV-1 infection in childhood event and disease onset (classically at 50 years of age or older) suggests step-wise acquisition of additional genetic events is required for tumorigenesis. Accordingly, cytogenetic studies revealed karyotypes that were often complex with numerical and structural abnormalities. Frequent gain of chromosomes 3, 7, and 21 and loss of Y, 1p, 3q, 5q, 6q, 7p, 9q, 10p and 13q was seen by conventional karyotyping but no abnormality that was specific for ATLL [422–425]. Abnormality rates were high, with karyotypic abnormalities noted to be more frequent in aggressive than indolent disease [422]. In the study by Itoyama et al. [424] the presence of more than six unrelated abnormalities and abnormalities of 1p, 1q, 2q, 3q, 14q and 17q or loss of 2q, 9p, and 17q were associated with shorter overall survival. Abnormalities at 14q11.2 the site of the *TRA/TRD* locus are reported in approximately 10–15% of patients with ATLL [422, 424] and Haider et al. [426] demonstrated rearrangement of the *TRA/TRD* by FISH in one case of acute ATLL. A CGH study by Tsukasaki et al. [427] of 18 patients with indolent disease and 46 patients with aggressive disease found genomic imbalance was more likely in aggressive ATLL subtypes. Gains of 14q, 7q and 3p were common; regions of loss were less frequent than gains with the most commonly deleted regions being 6q and 13q; 14q and 7q gains were also reported in a smaller independent study by Ariyama et al. [428] involving ATLL cells lines and primary patient samples.

Oshiro et al. [429] compared BAC/PAC aCGH profiles from 17 cases of acute ATLL with 49 cases of lymphoma ATLL. A greater number of genomic imbalances were apparent in the lymphoma type. Recurrent regions of gain common to both types were 3p36, 3q25, 8q24, 9p24, 9q34 and 14q32. The most frequent regions of loss were common to both types were 2q37, 4q21, 6q14, 9p21, 17p13.1 and 19q13. Gain of chromosome 3 or 3p was more common in acute ATLL whereas gain of 7q and loss of 13q were observed

more frequently in lymphoma ATLL. Two-copy loss of 9p21 was frequent consistent with homozygous deletion of *CDKN2A* and *CDKN2B*, which has been associated disease progression from chronic to acute ATLL and with inferior clinical outcomes [430–432].

Deletions/mutations of the *TP53* locus at 17p13.1 have also been observed with disease progression and are estimated to occur in up to 40% of cases of aggressive (acute or lymphomatous) ATLL [423, 433–435]. A study by Tawara et al. [436] of patients with newly diagnosed ATLL found a p53 mutation rate of 17.9% with similar rates in patients with acute (18.6%) and chronic disease (15.4%) whereas *CDKN2A* mutation was over-represented in the acute disease subtype relative to the chronic variant (44.2% vs. 15.4%). Strikingly, *TP53* and *CDKN2A* mutations were mutually exclusive and patients lacking either mutation fared better in terms of overall survival. Furthermore, *TP53* and *CDNK2A* mutation retained their prognostic significance in multivariate analysis.

BCL11B is thought to play a crucial role in T-cell development and BCL11B overexpression has been reported in an acute case of ATLL [429]. Moreover, a t(2;14)(q34;q32) was found in another acute ATLL, forming a *BCL11B-IKZF2* fusion gene [437], and, in a cytogenetic study of 50 ATLL cases where 15% contained an abnormality of 14q32, a t(14;17)(q32;q22-23) was shown to also involve *BCL11B* [438].

Miyata et al. [439] performed BAC/PAC aCGH on DNA derived from skin lesions from patients with cutaneous disease. Gain of 1p, 7q, 18q and loss of 13q were recurrent findings (seen in greater than 20% of cases). Gain of 14q32, observed in 44% and 50% of acute and lymphoma subtypes of ATLL, respectively [429, 440], was only present in 14% of more indolent cutaneous cases. However the study was not geared to determine if 14q32 gain tracked with increased rates of disease progression to more aggressive ATLL. Gain of 1p and loss of 13q were independent predictors of poor prognosis [439].

Extranodal NK/T-Cell Lymphoma Nasal Type

The more common extranodal NK/T-cell lymphoma nasal type (ENK/TL-NT), a tumour involving the upper aerodigestive tract ("nasal" or NK/TL-N) or extranasal sites like skin, soft tissue, the gastro-intestinal tract and testis ("nasal type" or NK/TL-NT), shares many features with aggressive NK cell leukaemia (ANKL), including a strong association with EBV infection and geographical distribution through Asia, Mexico, Central and South America. A CD2+, sCD3-, cytoplasmic CD3ε, CD56+, cytotoxic granule NK cell phenotype not dissimilar to the immunophenotype of ANKL is the norm, but occasional cases have a cytotoxic T-cell phenotype and a monoclonal TCR gene rearrangement.

The inaccessible anatomical location of the tumours and frequent necrosis make it challenging to obtain appropriate tumour material for conventional cytogenetic studies in many cases. Nevertheless there is a high abnormality rate. Recurrent cytogenetic abnormalities observed by conventional karyotyping include del(6q), del(13)q, del(17p), gain of the X chromosome, trisomy 8, isochromosomes of 1q, 6p, 7q, and 17q and rearrangements involving Xp21, 8p23 and 11q23 [411] [412, 413, 417, 425, 441]. CGH studies by a Hong Kong-based group [418] of five cases of ENK/TL-NT revealed loss of X, 6q and 13q, and gain of 1p, 6p, 7q, 11q, 12q, 19, 20 and 22 in at least two cases. Using microsatellite markers in 15 patients the same group showed LOH of 6q, 13q, 17p and 11q in 81%, 67%, 31% and 29% of cases, respectively [419]. In 2001, Ko et al. [442] reported CGH studies in seven Korean patients with ENK/TL-NT and found gain of 2q, 13q, 10q, 21q, 3q, 5q and 17q to be most frequent; the regions most often lost were 1p, 17p, 12q and 13q. Notably only one patient in the Korean cohort [442] had deletion 6q, an extremely frequent finding in the Hong Kong study. Indeed, overall there was very little overlap between the CGH findings of Siu et al. [419] and Ko et al. [442]; however, it is unclear whether this discrepancy between the two studies reflects small sample size, methodological differences, differences in histopathological classification or geographical differences in disease biology.

IN 2005, Nakashima et al. [420] compared 10 cases of ANKL with 17 cases of ENK/TL-NT by aCGH. Gain of 2q, and loss of 6q16.1-q21, 11q22.3-q23.3, 5p14.1-14.3, 5q34-35.3, 1p36.23-p36.3, 2p16.1-16.3, 4q12 and 4q31.3-q32.1 were the strongest positive predictors for a diagnosis of ENK/TL-NT as opposed to a diagnosis of ANKL. Array CGH studies of seven patients with NK cell malignancy were reported by Iqbal et al. [443]. The pattern of genomic imbalances observed closely approximated the findings of Nakashima et al. [420] with some overlap with the data set of Siu et al. [419] including gain of 1q, 2q, 6p, 7q, 17q and 20q and loss of 6q, 11q, 13q, and 17p. Huang et al. [444] analysed nine cases of ENK/TL-NT by BAC aCGH. Recurrent areas of copy number gain were 1q21-q44, 4p16, 6p25-p11.1, 6q11.1-q14, 6q27, 7p11.2-q34, 7q11.2-q34, 7q35-q36, 8p23.3, 9q34, 10p15-p14, 11p15, 16p13.3, 17q12 and 22q11.21; recurrent areas of loss were 6q16-q25, 8p23-p22, 11q24-25 and 17p13.3. Interestingly, regional gain of 1q, del(6q) and del(17p) which were recurrent in this cohort were also found by Iqbal et al. [443]. Berti et al. [445] compared aCGH tumour profiles from three patients with primary cutaneous ENK/TL-NT to a skin tumour from one patient with disseminated ENK/TL-NT. Gain of 1q, 7q and deletion of 17p were seen in at least 2/3 patients with primary cutaneous disease and loss of 6q in one patient. The skin tumour from the patient with ENK/TL-NT also had gain of 7q along with loss of 9p and 12p that was not observed in

the primary cutaneous tumours. An array CGH study of 13 cases of ENK/TL-NT showed the most common abnormalities to be loss of 15q24 and 19q13.3 regions (both seen in 9/13, 69%). Moreover, loss of 8p11 was associated with a significantly shortened survival [446].

Enteropathy-Associated T-Cell Lymphoma

Enteropathy-associated T-cell lymphoma (EATL) is a highly aggressive primary T-cell neoplasm arising in the gastrointestinal tract. Monoclonal T-cell receptor gene rearrangements are present. Nonmonomorphic or type I EATL (known as enterophathy-associated TCL in the 2016 revision of the WHO [187]) is a disease of Western countries that has a strong association with coeliac disease. Tumour cells usually display surface expression of CD8 but not CD56 and have pleomorphic, anaplastic or immunoblastic morphology. In contrast EATL type II (recast as monomorphic epitheliotropic intestinal TCL (MEITL) in the 2016 revision of the WHO [187]) has a broader geographical distribution and an association with coeliac disease is not proven. Type II tumours have a monomorphic appearance and frequently co-express CD8 and CD56. Clonal cytogenetic abnormalities have been reported in only a small number of patients with EATL using conventional karyotyping without any consistent pattern of derangement being identified [447].

In 2002, Zettl et al. [448] analysed DNA from 38 formalin-fixed paraffin-embedded tumours or fresh-frozen tumours by CGH. Copy number aberrations were present in 87% of tumours studied. Strikingly gain of 9q was observed in 58% of cases, with particularly localised gain at 9q33-34 confirmed by FISH testing. Other frequently gained regions were 7q (24%), 5q (18%) and 1q (16%). 8p and 13q were deleted in 24% of cases, 9p in 18% and 16q in 8%. Clinical outcomes were worse in patients with tumours that carried more than three copy number aberrations. Interestingly, partial trisomy of 1q has been identified in a high proportion (6/7) patients with refractory coeliac sprue, a preneoplastic or precursor lesion to nonmonomorphic or type I EATL suggesting that deregulation of candidate genes on 1q is an early event in the transformation of intestinal T-cells [449]. FISH studies by Leich et al. [450] in 2007 identified gain of 7q in 14/51 EATLs tested. As this included ten cases that had been studied by CGH previously [448], the FISH patterns could be interpreted in conjunction with imbalances detected by CGH. In at least two cases, and up to six cases, the abnormalities detected were consistent with isochromosome formation as the mechanism for 7q gain in this disorder.

Deleeuw et al. [451] published the results of higher resolution aCGH studies on thirty samples in 2007, confirming and further refining the copy number imbalances detected by CGH. The 9q gain resolved into discrete regions of alteration at 9q31.3-q33.2, 9q33.2-q33.3 and 9q34.11-qter. There was copy number gain at 9q33.2-q33.3 in 67% of cases. The 5q gain was mapped to 5q34-35.2. The 1q gain was reconfigured to three regions: 1q23.1-23.3, 1q25.3-31.2 and 1q32.2-41. The most distal region on 1q was most frequently involved (47% of cases) and was highly amplified in one case. Gains on 7q were also found to be segmental and complex with gain of 7q33-34 being the most common. 36% of cases had loss of 8p22-23.2 making this the most frequently lost region. The 16q deletion was mapped to 16q12.1. The 9p copy number loss spanned 9p21.2-p21.3, a region that encompasses the *CDKN2A* and *CDKN2B* genes. The investigators noted that 9q gain and 16q loss were almost mutually exclusive and one or other abnormality was present in virtually all cases studies. Gain of the *MYC* oncogene at 8q24 was highly enriched for in samples from the monomorphic type II EATL patient cohort. Principal components analysis using all regions of alterations showed increased copy number at 8q24 and 1q gain were the major factors contributing to separation of nonmonomorphic/type I EATL from type II EATL. In summary, gain of 9q31 or deletion of 16q21 occur in greater than 80% of cases of both EATL (type I) and type II EATL and appear to be unifying or characteristic of the condition as a whole. Furthermore, gain of 1q32.2-q41 (73% vs. 20%) and 5q34-35.2 (80% vs. 20%) are strongly overrepresented in type I EATL compared to type II EATL whereas gain of *MYC* at 8q24 is less frequent in type I EATL than in type II EATL (27% vs. 73%). A recent study reported aCGH results for five Korean patients with type II EATL. Gains of 9q33-q34, 6p21.21 and 19q21 and loss of 3q26.31 were observed in at least two cases. In keeping with the findings of Deleeuw et al. the frequency of 9q gain was 80% and gain of 8q24 was seen in one patient [442].

Hepatosplenic T-Cell Lymphoma

Hepatosplenic T-cell lymphoma (HSTL) is a mature cytotoxic T-cell lymphoma involving the sinusoids of the spleen, liver and bone marrow that mainly affects young adults and children and can be seen in the setting of immunosuppression. Most tumours are derived from T-cells of the γδ lineage but rare cases that express TCR αβ heterodimers are also reported [452]. In cases where conventional cytogenetics has identified an abnormal clone, the modal number is most often in the near-diploid range and a mixture of abnormal and normal metaphases is usual. Isochromosome of 7q is the most common cytogenetic abnormality in HSTL [453–457]. Since a stemline with an isolated i(7q) is often encountered together with sidelines containing additional cytogenetic abnormalities, the i(7q) is thought to be the primary cytogenetic abnormality in this condition. More recently variants resulting in gain of 7q as a result of ring chromosome

formation have been reported [458–460]. It is unclear if loss of 7p material or gain of 7q material is of greater consequence in i(7q) formation in HSTL. However, rare cases that demonstrate gain of 7q without coincident 7p loss, or gain of additional copies of 7q with disease progression favour gain of genetic material on 7q as the event most likely to confer selective advantage on the neoplastic clone [458, 461, 462]. Ferreiro et al. used high resolution array CGH to study six cases of HSTL with i(7q) and three cases with r(7) and localised the common deleted region to 7p at 7p22.1p14.1 and the common gained region to 7q22.11q31.1 [463].

In most reported HSTL cases with i(7q) the karyotypes are relatively simple with no more than three abnormalities. Trisomy 8 is the most common secondary abnormality described, followed by loss of the Y chromosome [453–455, 458, 459]. Isochromosome of 7q is not specific for HSTL and has also been reported in other mature T-cell neoplasms, T-cell and B-cell acute lymphoblastic leukaemia, acute myeloid leukaemia, myelodysplastic syndromes and Wilm tumour. The difference is that in conditions other than HSTL the i(7q) is usually present in complex karyotypes, as a secondary abnormality or seen to arise during clonal evolution with disease progression. Thus, the combination of i(7q) with trisomy 8 in a relatively simple karyotype is most characteristic of HSTL.

However, HSTL cases without i(7q) also exist, including cases with increased complexity [464]. A case series investigating the frequency of TCR translocation events and isochromosome 7q formation in T-cell lymphomas did not identify any abnormalities in four cases of HSTL [441]; although at least three of these cases were confirmed to be of the αβ type in which i(7q) is infrequent [462]. An early study had suggested that i(7q) was an adverse prognostic factor in HSTL [465] but this was not borne out in retrospective analysis of a larger case series [464]. Yabe et al. identified trisomy 8 in 8 of 24 patients (33%) and showed that the trisomy 8 patients had a significantly shorter overall and event-free survival. However, these patients were not treated on a uniform protocol [457].

Mycosis Fungoides/Sézary Syndrome

Primary cutaneous T-cell lymphomas (CTCL) represent a group of malignancies of mature T-cells that manifest primarily in the skin. The most common CTCL is mycosis fungoides (MF) which presents with skin lesions containing clonal malignant T-cells but CTCL may also present in a leukemic form with skin involvement and lymphadenopathy, Sézary syndrome (SS). SS is an aggressive form of CTCL defined by the triad of erythroderma, generalised lymphadenopathy and the presence of neoplastic T-cells in skin, lymph node and peripheral blood. Approximately 10–20% MF transforms to a large T-cell lymphoma over time.

Conventional cytogenetic studies of CTCL have been hampered by the difficulty in producing good quality metaphase spreads from malignant cutaneous lymphocytes, which may be mixed with a large number of reactive lymphocytes. In consequence, low-grade CTCL have appeared more likely to have a normal karyotype. In contrast, high-grade CTCL have been reported to have deletions of 6q and 13q and trisomy of 7q; these abnormalities have been shown to involve deletion of 6q21, amplification of 7q21 and interstitial deletion of 13q14 [466].

A small study by Thangavelu et al. of 19 patients with SS / MF identified clonal abnormalities by conventional cytogenetics in 53% of cases [467]. The commonest abnormalities were deletions of 1p22-1p36, rearrangements involving chromosomes 10 and 17 and, in two cases, a der(8)t(8;17)(p11;q11) was seen. Regions of the genome encoding T-cell receptors were not involved in abnormalities.

Espinet et al. [468] studied another 21 patients with SS using both conventional cytogenetics and cross-species colour banding and found the most common structural abnormalities to involve 1q, 2q, 6q and 8q and the most common numerical abnormalities to be monosomies of 9 and 10 and trisomy 18 with monosomy 10 in 73% of abnormal cases. Multicolor FISH applied to 9 abnormal MF/SS karyotypes also showed abnormalities of 10q to be the most common, observed in 7/9 cases [469]. Recurrent breakpoints were: 1p32-36, 6q22-25, 17p11.2-13, 10q23-26 and 19p13.3 and one patient also showed the dicentric 8;17 translocation described previously in two patients with SS by Thangavelu et al. [467]. Loss of heterozygosity was examined at a number of loci in 19 MF patients and frequent LOH confirmed at 10q23 (*PTEN*) and 17p13 (*TP53*) [470].

Array data from a number of publications is summarised in Table 42.3. The most frequently reported copy number gains are of 17q and, in two series of SS cases, gain of 8q encompassing *MYC* was observed. The most frequent recurrent losses were of 10q and 17p.

Comparing aCGH studies of 22 patients with tumour-stage MF and 20 SS patients did not identify much overlap in the recurrent chromosome aneuploides seen in the two groups [471, 472]. Five SS patients and 2 MF patients were studied using a genomic microarray containing 57 oncogenes and showed oncogene copy number gains of *RAF1* (3p25), *CTSB* (8p22), *PAK1* (11q13) and *JUNB* (19p13) in 5/7 patients. A further 23 SS and 10 MF patients were subsequently studied by immunohistochemistry and showed expression of nuclear JUNB in 21/23 SS and 5/10 MF patients [473]. Salgado et al. studied 41 MF cases by aCGH and found that gain/amplification at 8q24 (*MYC*) and deletions of 9p21 (*CDKN2A/B*, *MTAP*) and 10q26-10qter (*MGMT*, *EBF3*) were significantly associated with shortened survival. They also made the observation that patients with

[b]MF-T: mycosis fungoides undergoing large cell transformation

genomically unstable tumours (those with >5 copy number changes) had significantly worse outcomes [474].

Deletions of 10q23.33-10q24.1 and 10q24.33-10q15.1 were confirmed in 43% MF/SS cases by microsatellite loss of heterozygosity studies [475] and duplication of 17q11.2-17q12 has been demonstrated by aCGH covering the region of the genome that contains the *ERBB2 (HER2)* and STAT family genes in both MF and SS, suggesting it may be a primary karyotypic event common to both disorders [476]. FISH for the *ERBB2 (HER2)* gene locus at 17q11.2-q12 has shown gain of copy number in 7/9 SS cases [477].

In 2005, Karenko et al. [478] reported clonal deletions or translocations affecting chromosome 12 with a breakpoint in 12q21 or 12q22 in 5/7 SS patients and a sixth patient with a clonal monosomy of chromosome 12. A reciprocal t(12;18)(q21;q21.2) in one patient was found to disrupt the *NAV3* gene. Locus specific FISH proceeded to show *NAV3* deletions in 50% early stage MF patients and 85% advanced MF or SS cases. However, subsequent FISH and microarray studies of advanced MF and SS patients failed to confirm the frequency of *NAV3* deletion or disruption [474, 479]. A 2011 FISH study in cutaneous T-cell lymphoma reported that translocations involving the T-cell receptor loci *TRA/TRD* (14q11.2), *TRB* (7q34) and *TRG* (7p14) were uncommon in these conditions. No *TCR* gene rearrangements were identified in the 13 SS and 6 MF cases tested [480].

Ungewickell et al. identified a group of SS cases with mutations or copy number gain of the *TNFRSF1B* at 1p36.22 resulting in activation of non-canonical NFKB signalling. *TNFRSF1B* alterations were enriched in SS cases compared to MF cases. Although they were associated with large cell transformation and reduced survival, they did not predict inferior outcomes in multivariate analysis [481]. Other recurrent abnormalities in this cohort were largely exclusive of *TNFRSF1B* alternations. They included deletions of the *NFKB2* and *TRAF3* genes (at 10q24 and 14q32, respectively) as well as *CTLA4-CD28* gene fusions and structural rearrangements involving the *CD274* (*PDL1*) at 9p24.1, the *TNFRSF10A* at 8p21 and the *TP63* gene at 3q28. Transient response to ipilimumab, an anti-CTLA4 antibody has been reported in a case of SS containing a *CTLA4-CD28* fusion [482]. *CTCLA4-CD28* fusions are also described in AITL and PTCL-NOS, whilst *TP63* rearrangements are also a feature of other lymphomas, including DLCBL, PTCL NOS and ALK-negative ALCL.

Peripheral T-Cell Lymphomas (Not Otherwise Specified) (PTCL NOS)

The genetics of PTCL NOS has not been extensively studied. A review of the cytogenetic findings of 58 cases showed the most frequent gain to be at 7q with minimum overlapping region at 7q22q31 (in 33% cases) and most frequent losses occurred at 6q22q24 and 10p13pter with each detected in 26% cases. Five cases had translocations involving band 14q11.2 at the region of the *TRA/TRD* genes and three contained rearrangements involving 11q23 [483].

A SNP array study of 47 cases identified recurrent gains of chromosome regions 1q32-43, 2p15-16, 7, 8q24, 11q14-25, 17q11-21 and 21q11-21 (in five or more cases each) and recurrent losses at 1p35-36, 5q33, 6p22, 6q16, 6q21-22, 8p21-23, 9p21, 10p11-12, 10q11-22, 10q25-26, 13q14, 15q24, 16q22, 16q24, 17p11, 17p13 and Xp22 (four or more cases each). Gain of the *REL* locus on 2p was detected by FISH in another 3/18 further cases studied and 5/27 PTCL NOS showed nuclear expression of REL by immunohistochemistry [484]. Another study using aCGH of 51 PTCL NOS identified DNA gains and losses in 29 cases (57%) with high copy number gain at 14q32.2 and homozygous loss at 9p21.3. Gains of 7p and 7q and loss of 9p21.3 showed a significant association with poor prognosis [440].

Zettl et al. used chromosome comparative genomic hybridisation to identify recurrent chromosomal losses at

13q21, 6q21, 9p21 to 9pter, 10q23-24, 12q21-q22 and 5q21 in 25% or more of PTCL NOS cases. Recurrent gains of chromosome 7q22-qter were observed in 31% cases with high-level amplification of 12p13 observed in three cases [485]. The cyclin dependent kinase 6 gene (*CDK6*) has been identified as a potential target for 7q22 amplification. Amplification of *CDK6* was demonstrated by interphase FISH on paraffin-embedded tissue sections in 5/23 (23%) PTCL NOS cases [486]. Yoshida et al. identified a minimal common deleted region in PTCL NOS at 6q24 containing just two genes: *STX11* and *UTRN* [487]. Expression of STX11 was reduced in PTCL cases and loss of function mutations were identified in one PTCL patient and T-cell lymphoma cell line. Interestingly, *STX11* deletion or mutation was associated with haemophagocytosis and germline mutations in *STX11* result in the autosomal recessive condition familial haemophagocytic lymphohistiocytosis type 4. Collectively, these studies suggest a role for *STX11* as a haploinsufficient tumour suppressor gene in PTCL NOS.

A SNP array study of 33 PTCL NOS and 40 angioimmunoblastic T-cell lymphomas (AITL) detected recurrent copy gain common to both conditions on chromosomes 8, 9 and 19 with common LOH detected on chromosome 2. Poor prognosis was linked to overexpression of *CARMA1* at 7p22 and of *MYCBP2* at 13q22, both being located within regions of frequent copy gain [488]. Truncated forms of *IKZF2* at a frequently deleted region at 2q34 were also identified.

Translocations involving *IRF4/DUSP22* locus on 6p25 have been observed in PTCL NOS cases. A study of 72 PTCL NOS cases revealed two with the t(6;14)(p25;q11.2) fusing *IRF4* and T-cell receptor alpha (*TRA*), both of which presented in the bone marrow and rapidly developed skin lesions, and also another case with a translocation involving *IRF4* but not *TRA* [489]. Occasional other cases of the t(6;14) have also been reported [490, 491].

The t(14;19)(q32;q13) has been observed in a variety of B-cell lymphomas; there have also been occasional reports of a t(14;19)(q11.2;q13) involving the *TRA/TRD* gene locus and resulting in nuclear BCL3 protein expression [450, 492]. Another three cases of t(14;19)(q11.2;q13) had the 19q13 breakpoint localised to within or downstream of the *PVRL2* gene; two of these cases showed high mRNA levels of both *BCL3* and *PVRL2* [493]. Shin et al. reported a Lennert's type (lymphoepitheloid) PTCL-NOS with a t(14;19)(q11.2;q13.3) involving *TRA/TRD* where the breakpoint on chromosome 19 was located distal to both genes, implicating a putative oncogene other than *BCL*3 or *PVRL2* [494]. Other cytogenetic abnormalities that are well-recognised in various subtypes of T-cell lymphomas such as translocations involving T-cell receptor genes and isochromosome of 7q are reportedly uncommon in PTCL NOS [441].

Angioimmunoblastic T-Cell Lymphoma

Angioimmunoblastic T-cell lymphoma (AITL) is a well-defined histopathological entity but there are few comprehensive studies of the genetics of this disorder. AITL cases express T-cell follicular helper (TFH) associated antigens such as CD274 (PDL1), CD10, BCL6, CXCL13, ICOS, SAP and CCR5. It has been recognised that two other peripheral T-cell cell lymphoma types, namely follicular T-cell lymphoma (FTCL) and nodal PTCL with TFH phenotype, also share a TFH phenotype and fall under the AITL listing in the 2016 revision of the WHO Classification [187]. There are two classes of gene mutations common to this group: firstly, mutations in epigenetic modifiers such as *TET2*, *IDH2* and *DNMT3A* that also have an association with myeloid malignancies, and secondly, mutations in the *RHOA* and *CD28* genes that are specific to T-cell disorders. There are also two recurrent chromosomal rearrangements which are associated with but not exclusive to lymphomas in this group: the t(5;9)(q33;q22) and a cryptic 2q33 rearrangement resulting in formation of a *CTLA4-CD28* gene fusion.

The t(5;9)(q33;q22) was identified in PTCL NOS and the breakpoints shown to involve the *ITK* and *SYK* genes on chromosomes 5 and 9, respectively. The translocation resulted in overexpression of the *SYK* gene under the control of the *ITK* promoter. The translocation was demonstrated in 5/30 (17%) PTCL cases, three of which were FTCL, but was not found in cases of AITL or anaplastic large cell lymphoma [495]. Overexpression of the *SYK* tyrosine kinase has been demonstrated by immunohistochemistry in 94% of 141 PTCL, in the absence of the t(5;9), whereas normal T-cells were negative [496]. Although there is at least one report of the t(5;9) occurring in a case of AITL [497], other studies confirmed association of the t(5;9) with FTCL [498] and the rarity of the t(5;9) in AITL [499].

CTLA4-CD28 fusions have been described in a variety of T-cell lymphomas including Sézary syndrome [481, 482]. Yoo et al. reported *CTLA4-CD28* fusions in 26/45 (58%) AITL, 9/39 (23%) PTCL-NOS and 9/31 (29%) extranodal NK/T-cell lymphomas [500]. However, frequent occurrence of the *CTLA4-CD28* fusion in these disorders has not been confirmed by other investigators [501].

Trisomy 3, trisomy 5 and an extra copy of X have been identified as recurrent abnormalities in most AITL cases [466] and trisomies of 3 and 5 were confirmed as typical abnormalities in another 20 AITL cases [502]. However, an aCGH study of 39 AITL cases revealed chromosomal imbalances in 72% with recurrent gains of 22q, 19 and 1p11-11q14, and recurrent losses of 13q and found +3 and +5 in only a small number of cases [503]. Interestingly, FISH studies have shown the trisomies to occur frequently in separate cells, suggesting the presence of multiple, possibly unrelated clones. Schlegelberger et al. [504] suggested that an addi-

tional X was associated with a shorter survival but trisomy 3 did not appear to impact on survival. FISH using break-apart probes for the *TRA/TRD* and *TRB* genes did not show any evidence of *TRA/TRD* or *TRB* translocation events in 24 cases studied [505]. Tissue microarray FISH identified 9p24 gains in 3/16 (19%) AITLs studied. Increased copy number correlated with increased proportions of tumour cells expressing phosphorylated JAK2 and phosphorylated STAT3 [338].

Anaplastic Large Cell Lymphoma (ALK Positive)

Anaplastic large cell lymphoma (ALCL) is a mature T-cell/null cell lymphoma, which may present with systemic or localised cutaneous growth. Systemic ALCL is characterised by deregulated expression of anaplastic lymphoma kinase (ALK) fusion proteins. Shortly after its initial morphological description, ALCL (ALK positive) was found to be characterised by a 2;5 translocation [506]. The t(2;5)(p23;q35) forms a fusion gene *NPM-ALK* on the derivative chromosome 5. *NPM* on 5q35 encodes an RNA-binding protein that shuttles ribosomal ribonucleoproteins between the nucleus and the cytoplasm. *ALK* on 2p23 encodes a receptor tyrosine kinase, a member of the insulin receptor subfamily of RTKs. The fusion gene formed by the t(2;5) causes the strong *NPM* promoter to drive transcription of the portion of *ALK* encoding its kinase domain, leading to its inappropriate expression in lymphoma cells. The resulting fusion protein can be identified within both the cytoplasmic and the nuclear/nucleolar compartments by immunostaining.

Ten to twenty per cent of *ALK*-positive lymphomas show *ALK* expression only in the cytoplasm. These cases usually represent *ALK* fusions with partners other than *NPM*. A number of variant translocations with cloned partner genes have now been described (see Table 42.4) and there are still further *ALK* rearrangements reported with the partner genes yet to be determined [506–514]. All of the *ALK* chromosomal aberrations lead to the expression and constitutive activation of ALK and the clinico-pathological features of cases with variant *ALK* fusions appear indistinguishable from *NPM-ALK*-positive cases.

Additional chromosomal abnormalities have been observed in most cases. Three paediatric cases of ALCL with t(2;5) showed complex aberrations ranging from 3 to 11 with both numerical and structural abnormalities [515]. Rare cases with a *MYC* translocation in addition to the t(2;5) have been described and appear to be associated with an aggressive clinical course [516, 517]. Array CGH was performed on biopsy material from 15 children with ALK-positive ALCL. Regions of genomic gain (range 1–38 per patient) were more common than regions of loss (range 0–3 per patient). The total number of aberrations ranged from 2 to 40. The highest number of gains was on chromosome 11 (in 93% patients) and imbalances were demonstrated at a number of regions on 11p and 11q. Gain of 7q36.3 was observed in 67%. Regions of loss were not associated with known tumour suppressor genes. A lower overall 3-year survival was associated with higher numbers of genomic imbalances, gains of the 11q12.2 region containing the *DDB1* gene and gains of 17q25.3 containing the *BIRC5* gene [518]. A study by Salaverria et al. of 43 ALK-positive and 31 ALK-negative ALCL using a combination of chromosome CGH, FISH and quantitative PCR identified chromosomal imbalances in 25/43 (58%) and 20/31 (65%), respectively. Both groups exhibited gain of chromosome 7 and loss of 13q but ALK-positive ALCL were more likely to show gains of 17p and 17q24-qter and losses of 4q13-21 and 11q14 [519]. No specific chromosomal aberrations were correlated with survival.

Table 42.4 Known *ALK* partner genes in ALCL

Fusion Gene	Chromosomal abnormality	Staining pattern of ALK protein	% of cases (%)
NPM-ALK	t(2;5)(p23;q35)	Nuclear and cytoplasmic	84
TPM3-ALK	t(1;2)(q25;p23)	Cytoplasmic	13
ATIC-ALK	inv(2)(p23q35)	Cytoplasmic	1
TPM4-ALK	t(2;19)(p23;p13.1)	Cytoplasmic	<1
TFG-ALK[a]	t(2;3)(p23;q21)	Cytoplasmic	<1
MSN-ALK	t(X;2)(q12;p23)	Membrane	<1
CLTC-ALK	t(2;17)(p23;q23)	Cytoplasmic (granular)	<1
MYH9-ALK	t(2;22)(p23;q11.2)	Cytoplasmic	<1
ALO17-ALK	t(2;17)(p23;q25)	Cytoplasmic	<1
TRAF1-ALK	t(2;9)(p23;q33)	Cytoplasmic	<1

Data derived from references [506–514]
[a]There are three different variants of this translocation: $TFG\text{-}ALK_s$ (short), $TFG\text{-}ALK_l$ (long) and $TFG\text{-}ALK_{xl}$ (extra long)

ALK-positive lymphomas may be identified by conventional cytogenetics, FISH, PCR and immunohistochemical staining using anti-ALK antibodies. FISH probes that span the *ALK* locus are available and identify *ALK* translocations in ALK-positive lymphomas irrespective of the translocation partners. FISH works reliably on both metaphase chromosomes and interphase cells.

Anaplastic Large Cell Lymphoma (ALK Negative)

In 2011, Feldman et al. used massively parallel sequencing techniques to identify a recurrent t(6;7)(p25.3;q32.3) translocation in ALK-negative ALCL associated with

downregulation of DUSP22 at 6p25.3 and upregulation of MIR29 at 7q32.3 [520]. King et al. reported that *DUSP22* rearranged cases of ALCL were characterised morphologically by a sheet-like growth pattern, doughnut cells and the absence of pleomorphic cells [521]. In 2012, Vasmatzis and colleagues described rearrangements in the *TP63* gene at 3q28 in 5.8% of PTCLs and 1% of DLBCL cases [522]. The most common abnormality was a paracentric inversion of chromosome, inv.(3)(q26q28), involving *TBL1XR1* gene at 3q26 and *TP63* at 3q28. The inversion generated a fusion protein with loss of the N-terminal transactivation domain of TP63 and a dominant-negative effect on other members of the TP53 family.

No gene rearrangements are specific to ALK-negative ALCL. However, larger screening studies using break-apart probes indicated that *DUSP22* and *TP63* gene rearrangements were present in approximately 30% and 8% cases, respectively. Parilla Casteller et al. showed that *DUSP22* rearranged cases had favourable clinical outcomes, equivalent to ALK-positive ALCL. The prognosis in *TP63* rearranged cases was poor, whilst cases lacking both a DUSP22 and a TP63 rearrangement had an intermediate prognosis [523].

In terms of copy number changes, the study by Salaverria et al. of 43 ALK-positive and 31 ALK-negative ALCL identified chromosomal imbalances in 20/31 (65%) ALK-negative ACLC [519]. Whilst both ALK-positive and ALK-negative groups exhibited gain of chromosome 7 and losses of 6q and 13q, gains of 1q and 6p21 were more frequent in ALK-negative ALCL. ALK-negative ALCL was also reported to contain trisomy 2 leading to an extra copy of the *ALK* gene but without showing any *ALK* gene rearrangements [524].

Hodgkin Lymphoma

The diagnosis of Hodgkin lymphoma (HL) is a histopathologic one and depends on demonstration of characteristic neoplastic Hodgkin Reed-Sternberg (HRS) cells or LP (lymphocyte predominant) cells in Classical Hodgkin lymphoma (CHL) and Nodular lymphocyte predominant Hodgkin lymphoma (NLPHL), respectively.

Study of HL using conventional cytogenetic techniques has been limited with less than 250 aberrant cases published to date, in part reflecting the challenges of standard techniques in this disease. Tumours often have a low mitotic index in vitro and as the neoplastic cells often make up only 0.1–10% of the tumour, large numbers of metaphases may have to be examined to overcome the problem of normal cell contamination. Furthermore optimal chromosome morphology is difficult to achieve and the extreme complexity of the abnormalities identified has precluded complete karyotyping in some instances. More recently application of molecular karyotyping to samples enriched for the neoplastic clone by way of FICTION (fluorescence-immunophenotyping and interphase cytogenetics as a tool for investigation of neoplasm), FACS, and laser microdissection with or without DNA amplification has provided important insights into the genetic changes driving these malignancies.

Classical Hodgkin Lymphoma

Classical Hodgkin lymphoma is defined by the presence of HRS and is subdivided histologically into nodular sclerosis, mixed cellularity, lymphocyte-rich and lymphocyte-depleted subtypes. To date no specific non-random, recurrent cytogenetic abnormality has been identified that correlates with any subtype, precluding a role for conventional karyotyping in disease sub classification. Conventional karyotyping generally has reported success rates of 57% [525] to 82% [526] and abnormality rates between 11% [527] and 59% [525]. In most published series abnormal karyotypes are complex with a modal number is in the triploid to tetraploid range and include both numerical and structural abnormalities. Gains of chromosomes 2, 5, 9, 11, and 12, losses of 10, 13, 16, 21 and Y and structural abnormalities involving 1p, 1q, 4q, 6q, and 7q are over-represented in most case series [525–532].

Development of the FICTION technique allowed FISH methods to be applied to non-dividing CD30+ cells within tumours [533] and analysis showed that these cells contained three or more copies of at least two of chromosomes 1, 8, 12 and 17 in most of the 30 cases studied, [533] suggesting that the CD30-positive cells harbour the near-triploid and tetraploid abnormalities observed in those cases where conventional cytogenetic studies have been successful. In 1999, Ohshima et al. [534] applied chromosome CGH to CD30+ flow sorted cells after DOP-PCR DNA amplification in nine cases of CHL and identified recurrent gain of 1p13, 12q24, and 7q35-36 and recurrent loss of 16p11-21. Joos et al. [535] performed chromosome CGH on microdissected CD30+ cells from 12 patients and found recurrent gain of 2p, 9p and 12q as well as amplification of 4p16, 4q23-24 and 9p23-24. The region of gain on 9p spanned the *JAK2* locus and *JAK2* amplification was confirmed in some tumours in this study by FISH [535]. Meier et al. reported 9p24 gain by FISH in 33% of CHL [338]. The importance of JAK-STAT signalling in CHL pathophysiology was confirmed by identification of *SOCS1* loss of function mutations resulting in deregulated STAT activity in Hodgkin lymphoma [341] after they were initially described in the related condition primary mediastinal B-cell lymphoma (PMBL) [340]. Subsequently, Green et al. [342] identified *CD274* (*PDL1*) and *PDCD1LG2* (*PDL2*) as key targets of 9p24 amplification in HRS cells

from nodular sclerosis CHL and in primary mediastinal B-cell lymphomas (PMBL) using combined aCGH data and gene expression profiling. *JAK2* was co-amplified and contributed to PD-1 ligand induction via a forward feedback loop. Since PDL1 and PDL2 are T-cell inhibitory ligands the authors proposed that deregulation may promote tumour immune escape in nodular sclerosis HD and PMBL [342]. Van Roosbroeck et al. screened 200 cases of CHL by interphase FISH for 9q24.1 aberrations and, as well as finding *CD274/PDCD1LG2* rearrangements in four (2%), also showed high-level amplification of 9p24.1 in 40 (25%) including four cases with selective *CD274/PDCD1LG2* amplification [536].

FICTION studies implicated *REL* as the candidate oncogene at 2p13 [537]. In 2001, Kupper et al. confirmed gain of the 12q14 locus, encompassing *MDM2* by interphase FISH on CD30+ cells [538]. The same group proceeded to analyse a larger cohort by CGH on HRS cells and showed gains of 2p15-p16 (the only region involved in more than 50% of cases) and 12q24 to be the most frequent recurrent gains followed by gain of 17p, 9p, 16p, 17q and 20q together with loss of 13q. The *REL* gene was included in the 2p15 amplicon and 2p gain was particularly enriched in the nodular sclerosis CHL subtype (88% of cases) [539]. The CGH findings of Joos et al. [535] were largely confirmed in a similar independent study which reported frequent gain of 17q, 2p, 12q, 17p, 22q, 9p, 14q, and 16p and loss of 13q, 6q, 11q and 4q using a comparable experimental approach [540]. Given the scarcity of HRS cells, rather than using FICTION, Salipante et al. isolated HRS cells by flow cytometric cell sorting before performing whole genome sequencing to detect genomic aberrations. Recurrent copy number aberrations involving *REL*, the PD-1 pathway and *TNFAIP3* were observed, and loss of the chromosome 1 region containing tumour suppressor *TNFRSF14* was observed in 8/19 (42%) cases [541].

A major limitation of CGH is the inability to detect balanced reciprocal translocations; however, their presence in CHL has been investigated using FISH-based translocations assays. Using a BCL3 FISH break-apart probe, the *BCL3* gene (also known as *RELB*) at 19q13.2 was shown to be either involved in translocations in CHL, including one t(14;19)(q32;q13.2), or to demonstrate gains greater than ploidy level in patients with CHL [542], in keeping with the *BCL3* rearrangements or copy number changes observed in CD30+ HL cell lines [492]. However *BCL3* rearrangements are also described in other lymphomas and are not specific to CHL. As 14q32 rearrangements had a reported frequency of 10–20% by conventional cytogenetics [526, 532, 543], a later study of 232 patients with CHL set out to determine the frequency of translocations involving the *IG* loci and to identify the translocation partners using FISH and FICTION techniques [544]. The investigators identified *IG* rearrangements in 20% of cases with involvement *IGH* being much more common than involvement of the kappa and lambda light chain loci. This result places translocations involving immunoglobulin loci amongst the three most frequent cytogenetic abnormalities in CHL, after 2p13-16 and 9p24 gain. Where translocation partners could be identified they included *BCL6*, *REL*, *BCL3* and *MYC*, demonstrating that *BCL6* translocations were not confined to or diagnostic for NLPHL HL. No translocations involving *CCND1*, *BCL2*, *MALT1* or *PAX5* were detected. In most cases, immunoglobulin translocation events appeared to be the result of erroneous class switch recombination events consistent with a germinal centre B-cells as the putative cell of origin in CHL in most cases. A t(4;9)(q21;p24) translocation has been observed in a small number of CHL cases, causing a *SEC31A-JAK2* fusion and making CHL cases with the translocation potentially amenable to JAK inhibitor therapy [545]. There have been rare cases of HL associated with follicular lymphoma. The t(14;18) is rarely seen in HL but Yoshida et al. demonstrated its presence via chromogenic in situ hybridisation and FISH in three cases of HL associated with FL [546].

HRS cells in CHL show constitutive activation of NFKB and genetic abnormalities of NFKB regulators have been identified: deletion of the *TRAF3* gene was seen using interphase FISH analysis in 3/20 primary CHL samples and gain of the key signalling component of the alternative NFKB pathway *MAP3K14* (17q21) was observed in 5/16 cases [547].

Hartmann et al. [548] studied CHL by aCGH. The authors took DNA extracted from pooled microdissected HRS cells from twelve highly unusual tumours comprised of over 70% HRS cells (in order to avoid introduction of biases inherent in DNA amplification) and hybridised them to 105K oligonucleotide arrays. They were able to obtain data of sufficient quality for subsequent analysis in ten cases. Copy number changes were extensive, gains were more frequent than losses, consistent with data from metaphase CGH studies, and many imbalances detected by CGH were confirmed. In addition novel regions of chromosomal imbalance were identified: 2p12-16, 5q15-223, 6p22, 8q13, 8q24, 9p21-24, 12q13-14, 17q12, 19p13, 19q13 and 20q11 were gained and Xp21, 6q23-24 and 13q22 were lost in at least 50% of cases, respectively. NFKB signalling is known to be constitutively active in CHL and, strikingly, again areas of gain and loss often involved NFKB family members including gain of *REL* at 2p, *BCL3* at 19q13, *RELA* at 11q23, *NFKB2* at 10q24, *CARD9* and *TRAF2* at 9q34, *JUNB* at 19p13 and deletion of *TRAFAIP3* at 6q23-24, all of which are predicted to perturb NFKB signalling. Intriguingly, lesions also involved noncoding microRNA loci but the functional significance of these changes for CHL biology remains to be determined.

Steidl et al. [549] performed aCGH analysis after whole genome amplification on microdissected HRS cells from 53

cases of CHL, including some patients who experienced primary treatment failure. The most frequent imbalances were gains of 2p15-16.1, 9p21.1, 9p24.1-24.3, 16p11.2-13.3, 17q21.21-32, 19q13.11-13.43 and 20q13.11-13.12 and losses of 6q23.2, 11q22.3 and 13q14.3-21.1 demonstrating considerable overlap with and validating the findings of Hartmann et al. [548]. Further novel findings from this study again centred on the NFKB signalling pathway. Gains on 20q involved the CD40 locus; canonical and non-canonical NFKB signalling are downstream of this TNF receptor family member that is frequently overexpressed in CHL. In addition there was an increase in *IKKB* copy number at 8p11.21, which may facilitate nuclear localisation of NFKB by targeting IKBA and IKBE for proteosomal degradation. This study refined the recurrent region of gain on 17q to a 3.9 MB region containing *MAP3K14*, a gene that encodes the NFKB inducing kinase (*NIK*) and plays a critical role in non-canonical NFKB signalling. Perhaps most notably, gain of 16p11.2-13.3 was associated with primary treatment failure in CHL in this relatively large cohort. One candidate gene mapping to this retained region is the multi-drug resistance gene *ABCC1*. It is possible ABCC1 does indeed mediate the inferior clinical outcomes seen in the cohort with 16p gain as the authors went on to demonstrate that knockdown of ABCC1 using siRNA particularly in CHL cell lines with 16p copy number gain restored anthracycline induced cytotoxicity in vitro [549].

Nodular Lymphocyte Predominant Hodgkin Lymphoma

NLPHL makes up just 5% of cases of HL, and as a consequence of its relative rarity has been much less extensively studied that CHL. Much as these tumours are set apart from CHL on the basis of their distinct clinico-pathological phenotype, it is also becoming apparent that these phenotypic differences are underpinned by discrete changes at the genetic level.

Conventional cytogenetic analysis in NLPHL has identified a clonal population in less than 25 cases, most of which were hyperdiploid with complex karyotypes [296, 525, 532, 550–553]. Franke et al. [298] performed metaphase CGH after DOP-PCR of DNA obtained from laser-microdissected CD20+ LP cells in 19 patients. The mean number of copy number changes was 10.8 reflecting at a molecular level the complexity observed in metaphase preparations. Chromosomal regions most frequently gained were 1p, 1q, 2q, 3p, 3q, 4q, 5q, 6p, 6q, 8q, 11q, 12q and X and the regions most frequently lost were 17 and 17q. This data set was not enriched for loci encoding genes involved in NFKB signalling in contrast to the pattern of recurrent chromosomal imbalances present in CHL. A 3q27 breakpoint was observed in two cases in this cohort where conventional cytogenetics was informative and FISH confirmed *BCL6* rearrangement. A follow-up study reported *BCL6* rearrangement in 11/23 (48%) NLPHL cases but in none of the 40 CHL patients tested [554]. Furthermore, interphase FISH/FICTION studies by an independent group to determine the frequency of immunoglobulin rearrangements in NLPHL identified aberrant signals in 5/24 tumours studies and all five cases were shown to have a reciprocal 3;14 translocation giving a frequency of 21% [555]. As *BCL6* rearrangement is common in DLBCL and less common but reported to occur CHL by other investigators [544], this abnormality is enriched in NLPHL patients but cannot be considered specific to this HL subtype. *BCL6* rearrangement in NLPHL has been shown to occur in CD20+ cells, to correlate with strong protein expression of BCL6, to involve both immunoglobulin and non-immunoglobulin translocation partners and can manifest as simple balanced reciprocal translocations or more complex rearrangements [554, 556]. Using FISH, Bakhirev et al. identified *BCL6* rearrangements in 5 of 11 (45%) cases of NLPHL but also saw *BCL6* gene amplification with large clusters of BCL6 signals without an increase in copies of chromosome 3 in 3 of 11 (27%) cases and extra copies of *BCL6* in the setting of multiple copies of chromosome 3 in 1 of 11 (9%) cases. Thus, *BCL6* aberrations were shown to be present in 9 of 11 (82%) cases [557].

In 2007, Stamatoullas et al. published the largest and most comprehensively karyotyped series of NLPHL patients [296]. This group was able to obtain analysable metaphases from all 13 patients with a confirmed diagnosis of NLPHL and identified clonal abnormalities in 12/13. All had complex karyotypes with complex defined as greater than three abnormalities and in most cases clonal abnormal metaphases were outnumbered by spreads with a normal karyotype. Striking, 11/12 patients had a model number in the near-diploid range with the exception being a patient with a tetraploid karyotype, suggesting near-triploidy is much more uncommon in this disorder than it is in CHL. Isochromosome of 1q ($n = 7$) or unbalanced translocation resulting in gain of 1q ($n = 3$) was the most common recurrent abnormality, followed by a high frequency of 3q27 and 14q32 breakpoints and frequent involvement of *BCL6* and *IGH* was confirmed by FISH, validating the findings of Wlodarska et al. [554] and Renne et al. [555]. However, this study failed to identify many of the copy number changes detected by CGH [298]. This study proposes near-diploid karyotypes, gain of 1q and *BCL6* translocations as some of the more distinctive cytogenetic features of NLPHL, although some of these findings are yet to be confirmed by other investigators and aCGH studies in particular are lacking.

Thus far, cytogenetic studies in HL have proved invaluable research tools for understanding tumour cell biology in CHL and NLPHL. Whilst showing some recent promise, the

abnormalities uncovered thus far lack specificity as biomarkers and have not demonstrated prognostic impact in independently validated studies. Therefore, to date cytogenetic studies have not been incorporated into routine clinical decision-making algorithms in these conditions.

Summary

Conventional cytogenetic analysis and FISH are now an integral part of the diagnosis of some but not all lymphoid malignancies. These tests are critical for the diagnosis of patients with mantle cell lymphoma and Burkitt lymphoma and for the identification of patients with high-grade B-cell lymphoma and "double-hit" or "triple-hit" *MYC*, *BCL2* and *BLC6* translocations. Both conventional cytogenetics and FISH panels are used to determine prognosis in chronic lymphocytic leukaemia and the finding of a t(11;18) in a MALT lymphoma predicts failure of *H. pylori* eradication therapy. However, for most lymphoma subtypes, although there are frequent cytogenetic abnormalities detected by a variety of methods, such testing does not materially add to the determination of diagnosis or outcome and so is not part of the routine testing algorithm for most lymphomas.

Acknowledgments This work was supported in part by a grant from the Victorian Cancer Agency. We would like to thank Bruce Mercer and Adrian Zordan for assistance with the preparation of figures.

Diagnosis and Treatment of Hodgkin Lymphoma

43

Peter H. Wiernik

Introduction

The successful treatment of Hodgkin lymphoma is one of the most impressive achievements of modern medicine. Today more than 90% of patients without fever, weight loss, or night sweats (B symptoms) are cured with optimal treatment, and 60–70% of those with B symptoms are cured as well. Fortunately, most patients do not have B symptoms at presentation. These cure rates have not been achieved without problems. Long-term complications of cure have interrupted the well-being of a sizeable fraction of survivors, and relapses—even late relapses—are still a problem. Current clinical research is focused on optimal noninvasive staging of disease, reducing the short- and long-term complications of treatment, and early diagnosis of serious long-term complications such as cardiac disease and second malignancies. New drugs with major activity against this lymphoma have recently been identified and their precise role in initial and late treatment is currently under investigation.

Etiology and Early Pathogenesis

Classical Hodgkin lymphoma is characterized by aberrant cytokine production which contributes to proliferation of Reed–Sternberg cells and to the maintenance of a favorable microenvironment for those cells. Especially important in this regard is overexpression of components of the TNF receptor family (CD30 and CD40) by Reed–Sternberg cells [1].

Evidence suggests that approximately 30–50% of patients with Hodgkin lymphoma, a B-cell neoplasm, harbor the Barr–Epstein virus (EBV) [2] and that the virus plays a pathogenetic role in those patients. The proportion of patients with EBV is higher in nonindustrialized countries [3] and in patients with advanced-stage disease [3]. In a Japanese study patients with CD20+ background cells in a lymph node biopsy were more likely to have EBV+ Reed–Sternberg cells than if background cells were CD20- [4]. Curiously, CD20+ background cells have a favorable effect on prognosis of patients with Hodgkin lymphoma, while EBV+ Reed–Sternberg cells have a negative effect in most studies [4, 5]. Furthermore, detection of EBV DNA in pretreatment whole blood [6] or plasma [7] is a significant negative prognostic factor. Infectious mononucleosis is a risk factor for EBV-related Hodgkin lymphoma in patients with HLA-A*01, but not in those with HLA-A*02 alleles [8]. Patients with HLA-A*01:01 or B*37:01 alleles are at increased risk for EBV+ classical Hodgkin lymphoma and those with DRB1*15:01 or DB1*01:01 are at decreased risk [9]. Patients with HLA allele E*01:01 may be protected to some degree from EBV infection as well [10]. The genetic variant, rs6457715, located at 6p21.3 near the HLA-DPB1 gene is present significantly more frequently in EBV+ Hodgkin's lymphoma than in EBV- cases, which suggests that this site may be a susceptibility locus for classical Hodgkin lymphoma [11]. HLA class I-restricted EBV-specific cytotoxic T-cell responses and other early events in the immune response to EBV infection in infectious mononucleosis play critical roles in the early pathogenesis of EBV-related Hodgkin's lymphoma. EBV-encoded small RNAs found in EBV-infected cells suppress p21cip1/waf1 transcription in Hodgkin cell lines KMH2 and L428 [3] and increase resistance to drugs known to cause apoptosis by elevating p21cip1/waf1 levels. In patients, EBV+ biopsies with suppressed p21cip1/waf1 levels were associated with an impaired disease-free survival compared with patients who were EBV-negative [12]. However, in contrast with other studies, Benharroch et al. [13] found that the presence of EBV latent membrane protein-1 in Reed–Sternberg cells did not correlate with inhibition of apoptosis in those cells. A recent authoritative review discusses the role of EBV in the pathogenesis of Hodgkin lymphoma in more detail [14].

The JC human polyomavirus (JCV) was detected in peripheral blood lymphocytes in 42 of 74 patients with Hodgkin lymphoma in one study [15]. In that study JCV positivity was associated with chromosomal instability and a poor prognosis. However, these findings have not been confirmed [16].

The malignant cell of Hodgkin lymphoma is the Reed–Sternberg binucleate cell [17]. Salipante et al. [18, 19] described a reciprocal translocation between chromosomes 2 and 3 which disrupts a novel gene at 3p21.31, resulting in its loss of expression. Loss of this gene expression leads to an increase of binucleate cells and may be responsible for the binucleate nature of the Reed–Sternberg cell.

Reed–Sternberg cells often express insulin-like growth factor-1 receptor (IGF-1R), and patients whose cells express IGF-1R have a better prognosis [20, 21]. Reed–Sternberg cells also often express matrix metalloproteinase-9 (MMP9), especially those positive for EBV. MMP9+ patients had impaired overall survival in one study [22] but not in another [23]. Both studies are from Brazil. Reed–Sternberg cells secrete lymphotoxin-α, which facilitates recruitment of T-cells into lymph nodes of patients with classical Hodgkin lymphoma [24].

The microenvironment surrounding Reed–Sternberg cells includes immune cells, fibroblasts, stromal cells, and endothelial cells, and this microenvironment is a functional component of the lymphoma. The specific characteristics of this microenvironment have important implications for pathogenesis and prognosis. There is cross talk between Reed–Sternberg cells and the microenvironment surrounding them [25] which inhibits cytotoxic effectiveness and induces immunosuppressive T lymphocytes, predominantly CD4+ T-helper cells [26] and monocytes [25]. Reed–Sternberg cells secrete numerous chemokines to control their microenvironment. Reed–Sternberg cells themselves occasionally express T-cell antigens. When this is the case, prognosis is impaired compared with patients whose Reed–Sternberg cells do not express T-cell antigens [27]. Certain environmental T-cells provide survival signals for Reed–Sternberg cells and others rescue Reed–Sternberg cells from NK cell attack [28]. On the other hand, Reed–Sternberg cells may induce differentiation of naïve T-cells toward T-reg cells and cytotoxic T-lymphocytes, and studies have shown that increased numbers of cytotoxic T-lymphocytes compared with T-reg lymphocytes is associated with a poor prognosis. Sirt1, secreted by most Reed–Sternberg cells may decrease T-reg function [29]. Indolamine 2,3-dioxygenase expressed by histiocytes, dendritic cells, and some endothelial cells in the microenvironment is an enzyme that suppresses T-cell immunity. It is most commonly detected in Hodgkin lymphoma patients with advanced stage of disease and high levels of expression are associated with a poor prognosis [30]. A proportion of tumor infiltrating macrophages >25% was found to confer an unfavorable prognosis on patients with stage I-II Hodgkin lymphoma [31]. Maturation and differentiation of macrophages is dependent upon CSF1R interactions with its ligands. This pathway is activated in classical Hodgkin lymphoma, although CSF1R+ tumor associated macrophages are uncommon in Hodgkin lymphoma [32]. IL13 production by Reed–Sternberg cells appears to facilitate fibrosis commonly seen in lymphoma tissue from patients with nodular sclerosis Hodgkin lymphoma [33]. PRMD1, a major regulator of plasma cell differentiation, levels are low in Hodgkin lymphoma tissue. FOXO, which is important in normal B-cell development, acts as a tumor suppressor in classical Hodgkin lymphoma and upregulates PRMD1, which also acts as a tumor suppressor [34].

Many genes that have been implicated in the pathogenesis of Hodgkin lymphoma include polymorphisms of toll-like receptor genes and certain haplotypes of the myeloid differentiation primary response protein 88 gene (MYD82) [35] which are found more frequently in tissue from Hodgkin lymphoma patients than normal controls. To date, more than 35 genes have been implicated in the development of Hodgkin lymphoma and testing for the expression of a dozen or so of them by RT-PCR on paraffin-embedded formalin-fixed biopsy tissue has allowed for the prediction of 5-year freedom from progression with some accuracy [36]. Clinical outcome in advanced classical Hodgkin lymphoma is associated with a specific miRNA signature (MIR21, MIR30D, and MIR92B) which is associated with pathogenesis and therapeutic resistance [37]. PRDX2, a tumor suppressor gene, is methylated and transcriptionally silenced in Reed–Sternberg cells as it is in the cells of several other hematologic malignancies [38]. TNFRSF14, another tumor suppressor gene, is downregulated in Reed–Sternberg cells of a large minority of Hodgkin lymphoma patients, which may contribute to the pathogenesis of the disease [39]. The detection of markers of cellular senescence such as p16 (INK4a) and p21 (CIP1/WAF1) in >30% of Reed–Sternberg cells appears to predict for improved event-free survival [40].

Genetic susceptibility for Hodgkin lymphoma has been associated with a number of loci, including 2p16, 5q31, 6p31, 8q24, 10p14, and, more recently, 19p13.3 [41]. In a study of 259 genes on formalin-fixed paraffin-embedded tissue, a 23 gene outcome predictor superior to the International Prognostic Index was identified that revealed patients at increased risk of death when treated with standard chemotherapy regimens [42]. Alterations of chromosome 9p24 in classical Hodgkin lymphoma activates the programmed death 1 (PD-1) ligand pathway. This activation correlates with increased numbers of CD68+ macrophages, increased PD-1 expression in the peritumor microenvironment, and decreased numbers of FoxP3+ T-cells, which leads to immune escape [43]. Progression-free survival was significantly shorter for patients with 9p24.1 amplification

and enhanced PD-1 expression, in patients with advanced disease and early-stage disease in recent studies [44, 45]. By mapping transcription factor motifs, high levels of interferon regulatory factor (IRF5) were identified in Hodgkin lymphoma cells and found to be crucial for their survival [46].

Paietta et al. described an ectosialyltransferase on the surface of cultured Hodgkin lymphoma cells that agglutinates lymphocytes and may serve as an immunomodulator contributing to the immunodeficiency associated with Hodgkin lymphoma [47–52]. The same cell line expresses both CSF-1 and cfms, which suggests that Hodgkin cells may be derived from the monocyte/macrophage lineage [53].

Recently it was demonstrated that hypoxia induces Reed–Sternberg cell characteristics in mature B-cells and it was proposed that hypoxic conditions in the germinal center may initiate differentiation of B-cells toward a Reed–Sternberg cell phenotype [54] and genome-wide association studies identified SNPs and HLA alleles common to Hodgkin lymphoma and multiple sclerosis, two diseases that share a number of epidemiological characteristics [55].

More detailed information on the etiology and pathogenesis of Hodgkin lymphoma is presented in other chapters in this section, and an excellent review of lymphomagenesis in Hodgkin lymphoma has recently appeared [56].

Patterns of Disease

Initial Presentation

Nearly all patients with Hodgkin lymphoma present with asymptomatic lymphadenopathy. The apparent onset of the disease occurs predominantly in the cervical–supraclavicular nodes (60–80%), and less commonly in axillary nodes or inguinal nodes (10–20%). In some cases the first manifestations of disease are cough or dyspnea related to mediastinal lymphadenopathy; in other cases they consist of systemic symptoms (fever, night sweats, or weight loss) with or without apparent superficial lymphadenopathy. Pruritus, which occurs only with nodular sclerosis histology, is a symptom with no prognostic significance. In rare cases a mediastinal mass is found by routine X-ray as the first evidence of lymphoma.

In most patients the pattern of lymph node spread is central (cervical, mediastinal, para-aortic). For reasons that are not yet clear, certain chains of lymph nodes (mesenteric, hepatic hilar, hypogastric, presacral, epitrochlear, popliteal) are seldom or rarely involved. Pulmonary hilar lymph nodes are clinically affected in about one-fifth of patients with mediastinal adenopathy, and they are more frequently involved when a large mediastinal mass is present. Bulky disease is defined as a neoplastic mediastinal mass > one-third the transverse diameter of the thorax at the level of T5 or T6 on a standing posteroanterior chest radiograph [57, 58], whereas in other sites it is defined as any mass with a diameter over 10 cm. Patients with bulky mediastinal involvement represent approximately 25% of all cases and may have extension of the tumor into lung, pericardium, or chest wall. Systemic symptoms are also often present. Rarely, extranodal Hodgkin lymphoma is primary in virtually any anatomic site, including lung, any part of the gastrointestinal system including liver, bone [59] and brain [60] which is more frequent in patients infected with HIV and may be more common in familial Hodgkin's lymphoma [61], and an occasional patient will present with backpain due to spinal compression from an epidural mass of lymphoma [62] or skin involvement [63] which can often be traced to regional lymphatic blockage from an enlarged lymph node and retrograde flow of tumor cells to the skin, and digital clubbing, which is occasionally associated with cavitating lung lesions of Hodgkin lymphoma [64–66].

Limbic encephalitis and cerebellar degeneration rarely complicate Hodgkin lymphoma but do not occur in non-Hodgkin lymphoma [67]. Rarely, patients present with or have a history of immune thrombocytopenic purpura or hemolytic anemia [68] and have a history of rheumatoid arthritis more frequently than expected [69]. In addition, patients with a history of certain chronic infections (sinusitis, tuberculosis, encephalitis, herpes zoster) may be at increased risk for Hodgkin lymphoma [70].

Vanishing bile duct syndrome is diagnosed rarely at presentation in Hodgkin lymphoma patients. Only about 25 cases have been recorded in the literature. It is characterized by cholestasis and progressive loss of interlobular bile ducts in more than 50% of portal tracts in patients who do not have infiltration of the liver with lymphoma. It may be caused by cytokine release from tumor cells or by an immunologic mechanism. Patients usually present with leukocytosis, transaminase and alkaline phosphatase elevations and direct hyperbilirubinemia, but the diagnosis must be made by liver biopsy. Many cases will resolve with full-dose chemotherapy for the lymphoma, but some cases have been fatal [71, 72].

Approximately 1 of every 200 patients with chronic lymphocytic leukemia will have a transformation to Hodgkin lymphoma within 10 years (Richter transformation) [73]. This transformation to Hodgkin lymphoma has a poorer prognosis for response to therapy and survival compared with de novo Hodgkin lymphoma [73–75].

The risk for developing Hodgkin lymphoma in HIV-infected individuals is 5–25 times greater than that of the general population [76] and may be increasing. With the advent of more effective HIV therapy, the risk of non-Hodgkin lymphoma has decreased and the risk of Hodgkin lymphoma has increased. One interpretation of this observation is that both lymphomas are etiologically related

but are expressed differently depending on the degree of host immunodeficiency. This suggestion is consistent with the observation of families with both lymphomas in the pedigree [77]. It seems clear from many studies [78–80] that HIV+ patients with classical Hodgkin lymphoma have the same outcome from proper treatment as do HIV- negative patients.

In the great majority of patients, the initial pattern of spread occurs predictably via lymphatic channels to contiguous lymph-node chains and other lymphatic structures. This observation has provided the basis for prophylactic irradiation of adjacent nodal chains in patients with apparently localized nodal disease eligible for treatment by radiotherapy alone [81, 82].

The pattern of disease presentation is related to the histopathologic subgroup. Most patients with lymphocyte predominant (LP) histopathology present initially with only peripheral sites involved (cervical, inguinal nodes) and are most often male patients with stage I disease. Nodular sclerosis (NS) patients usually present with supradiaphragmatic disease and mediastinal node involvement and are often females with stage II disease. In patients with one of these variants, limited extension of supradiaphragmatic disease and presence of systemic symptoms, or occult involvement elsewhere is extremely rare. Patients with mixed-cellularity (MC) histology usually present either with upper torso disease or with lymphoma on both sides of the diaphragm (stage III). Patients with lymphocyte-depleted (LD) histology are usually stage III or IV, elderly, or relapsed.

Vascular invasion, which is noted in about 20% of autopsy cases, appears most often in LD histology and in advanced phases of disease [83]. Most extranodal sites manifest a markedly greater degree of vascular invasion, which suggests that vascular invasion is a factor in extranodal spread and in lethal cases of Hodgkin's disease [83]. Spleen, liver, lung, and bone marrow are the most frequent extranodal sites involved. Bone marrow is only likely to be involved in advanced stages of disease with or without systemic symptoms. Liver invasion is always associated with spleen involvement. Often, extranodal sites are involved by direct extension from enlarged adjacent nodes, as is the case with lung, pleural, or pericardial involvement which almost always is due to contiguous spread from bulky mediastinal lymphadenopathy.

Unexplained histologic lesions such as non-caseating epithelioid granulomas in liver, spleen, and/or lymph nodes of patients with any stage of disease are frequently found [84]. These lesions do not impair prognosis if left untreated, and therefore are unlikely to represent early lymphoma. They may represent a host response to the lymphoma, but this is unproven.

Elevated hepatic enzyme levels, including alkaline phosphatase, do not always signal liver involvement with Hodgkin's lymphoma [85]. Hepatic enzyme levels tend to correlate directly with stage of lymphoma whether the liver is involved with lymphoma or not.

The pathologic findings at autopsy have changed with modern therapy, including a reduction in the extent of disease at the time of death [86]. On occasion, Hodgkin lymphoma is first diagnosed at autopsy, especially in elderly patients (14% of cases in one series) [87]. The cause of death in one large autopsy series was progressive disease in 37%, infection in 43%, and miscellaneous causes in 20% [88].

A unique form of Hodgkin's lymphoma designated nodular, lymphocyte predominant Hodgkin's lymphoma deserves special consideration. It is relatively uncommon and almost always presents as stage I or II. The median age of patients is approximately 40 years, most patients are male (except Black patients who are approximately 50% female [89]), and only about 6% have B symptoms [90]. Its histology is unique in that the Reed–Sternberg cells have multiple large vacuoles, giving them a "popcorn" appearance. Those cells express CD20 but lack expression of CD15 and CD30, which are expressed by Reed–Sternberg cells in classical Hodgkin's lymphoma [91, 92]. A minority of patients have a variant histology characterized by the presence of lymphoma cells outside the B-cell nodules and/or a B-cell depleted microenvironment [93]. Such patients have a poorer prognosis with standard therapy than those with typical histology [93]. A minority of patients approaching 17% will transform over a 30 year period to a diffuse large B-cell lymphoma [94, 95]. Risk factors for transformation include prior chemotherapy and splenic involvement [95]. If treated properly, transformation does not impair overall survival compared with patients who do not transform [95]. Mutated SGK1, DUSP2, and JUNB have recently been identified as novel key players in the pathogenesis of nodular lymphocyte predominant Hodgkin lymphoma [96]. Curiously, there is a high familial risk for nodular lymphocyte predominant Hodgkin lymphoma in first-degree relatives of patients, approximately threefold higher than for classical Hodgkin lymphoma, especially for female relatives of young patients [97]. Treatment recommendations for nodular lymphocyte predominant Hodgkin lymphoma have ranged from surgical excision alone, watch and wait, radiation alone, chemotherapy alone, combined-modality therapy, and rituximab with or without standard chemotherapy, depending on presentation [98]. In stage IA patients, all seem to result in similar excellent results in adults, except rituximab alone is associated with increased risk of relapse [99, 100]. In pediatric low-risk patients with early-stage disease, surgical excision alone may be all that is necessary for the majority of patients and less intensive chemotherapy without radiation therapy is recommended for the rest [101].

Staging Procedures and Prognostic Estimate

Staging Systems by Prognostic Factors

Criteria for staging of Hodgkin's lymphoma were defined at the Rye (1965), Ann Arbor, and Cotswolds (1970–1989) conferences [102, 103], and are still universally applied worldwide. The staging system takes into account the involvement of one or more nodal areas on the same (stage I–II) or both sides of the diaphragm (stage III), of extranodal sites contiguous (E suffix) or noncontiguous with nodal involvement (disseminated involvement), of extranodal organ or tissue (stage IV) involvement, and the absence or presence of systemic symptoms (fever and/or night sweats and/or unexplained loss of more than 10% of body weight within the preceding 6 months) to apply suffix A or B, respectively, to any disease stage.

The Cotswolds Committee stated a number of classification criteria based on recent better knowledge of the natural history and treatment of the disease due to the advent of modern imaging techniques. It was particularly recommended that (1) CT scanning (now, Pet-CT) be included as a technique for evaluating intrathoracic and infradiaphragmatic lymph nodes; (2) the criteria for clinical involvement of the spleen and liver be modified to include evidence of focal defects by two imaging techniques and that abnormalities of liver function be ignored; (3) the suffix X be introduced to designate bulky disease (no longer used); and (4) a new category of response to therapy be established termed unconfirmed/uncertain complete remission (CRu), to accommodate the difficulty of assessing persistent radiologic abnormalities of uncertain significance following primary therapy. Table 43.1 shows the Rye–Ann Arbor–Cotswolds staging system as currently applied.

In 1998 an International Prognostic Factor Project on advanced Hodgkin's disease was developed based on data from 1618 patients treated at 25 centers [104]. The prognostic score was defined as the number of adverse prognostic factors at diagnosis (Table 43.2).

Certain blood tests and biopsy examinations have been more recently described as indicators of prognosis and not evaluated in the international prognostic score. Serum ferritin levels correlate with stage of disease [106] and prognosis [107, 108]. In a recent study, serum ferritin levels >350 μg/L were associated with a lower complete remission rate, progression-free survival and overall survival than observed in patients with lower ferritin levels [107]. CD34+ peripheral blood cells in a concentration >0.0045 × 10^9/L predicted a reduced progression-free survival in a study of 60 newly diagnosed patients [109]. The CD68+ count in biopsy specimens inversely correlated with progression-free survival [110]. Detection of circulating cell-free DNA with genomic imbalances such as gain of chromosomes 2p and 9p has been proposed as a biomarker of Hodgkin lymphoma that may be useful in prognostication [111]. Two studies have shown that a low absolute lymphocyte count to absolute monocyte count ratio in peripheral blood has prognostic significance in Hodgkin lymphoma [112, 113]. A low ratio predicts for poor event-free and overall survival. High concentrations of myeloid-derived suppressor cells (CD66b + CD33dim HLA-DR) correlate with unfavorable international prognostic index scores and a shorter progression-free survival [114].

Table 43.1 The Rye–Ann Arbor–Cotswolds staging

Classification
Stage I
Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer's ring) or involvement of a single extralymphatic site (IE)
Stage II
Involvement of two or more lymph node regions on the same side of the diaphragm (hilar nodes, when involved on both sides, constitute stage II disease): localized contiguous involvement of only one extranodal organ or site and lymph node region(s) on the same side of the diaphragm (IIE): the number of anatomic regions involved should be indicated by a subscript (e.g., II_3)
Stage III
Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by involvement of the spleen (III_s) or by localized contiguous involvement of only one extranodal organ site (IIIE) or both (III_s E) III1: with or without involvement of splenic, hilar, celiac, or portal nodes
III2: with involvement of para-aortic, iliac, or mesenteric nodes
Stage IV
Diffuse or disseminated involvement of one or more extranodal organs or tissues, with or without associated lymph node involvement

Designations applicable to any disease stage:
A: No symptoms
B: Fever (temperature above 38 °C), drenching night sweats, unexplained loss of more than 10% of body weight within the preceding 6 months
E: Involvement of a single extranodal site that is contiguous or proximal to the known nodal site

Recommended Pretreatment Evaluation

Table 43.3 outlines the procedures deemed necessary for correct staging of Hodgkin lymphoma [115]. An adequate surgical biopsy, possibly of more than one intact lymph node, should be undertaken for pathological examination. Inguinal nodes should not be biopsied if other equally suspicious peripheral nodes are present. When the diagnosis of Hodgkin lymphoma is made from biopsy of an extranodal site, a concomitant nodal biopsy for confirmation of diagnosis is desirable.

A detailed history must be obtained with information about the presence or absence of unexplained fever and its duration,

Table 43.2 The International prognostic score for advanced stages (IPS-7)

Independent variable with negative prognostic significance			
Variable	Value		
Albumin	<4 g/dL		
Hemoglobin	<10.5 g/dL		
Sex	Male		
Age	≥45 years		
Stage	IV		
Leukocytosis	White blood cells >15,000/mm^3		
Lymphocytopenia	Absolute lymphocyte count <600/mm^3 or <8% total white blood count		
Rates of freedom from progression and overall survival at 5 years according to individual and grouped prognostic scores			
Prognostic score	*N* patients (%)	Rate of FFP (%)	Rate of OS (%)
Single negative factors			
0	115 (7)	84 ± 4	89 ± 2
1	360 (22)	77 ± 3	90 ± 2
2	464 (29)	67 ± 2	81 ± 2
3	378 (23)	60 ± 3	78 ± 3
4	190 (12)	51 ± 4	61 ± 4
5–7	111 (7)	42 ± 5	56 ± 5
Grouped negative factors			
0 or 1	475 (29)	79 ± 2	90 ± 2
2 or more	1143 (71)	60 ± 2	74 ± 2
0 to 2	939 (58)	74 ± 2	86 ± 2
3 or more	679 (42)	55 ± 2	70 ± 2
0 to 3	1317 (81)	70 ± 2	83 ± 1
4 or more	301 (19)	47 ± 2	59 ± 2

FFP freedom from progression, *OS* overall survival.
Data from Hasenclever D, Diehl V. A prognostic score for advanced Hodgkin's disease. N Engl J Med. 1998;339:1506. Recent data suggest that consideration of age, stage and hemoglobin level may provide a simpler and more accurate prognosis [105]

Table 43.3 Recommended procedures for proper staging

Recommended procedures
Adequate surgical biopsy reviewed by an experienced hemopathologist: in primary extranodal lymphomas, biopsy should also include a palpable lymph node when palpable
Detailed history with special attention to the presence or absence of systemic symptoms
Careful physical examination, emphasizing node chains, size of liver and spleen, Waldeyer's ring inspection, and bony tenderness
Routine laboratory tests: complete blood count, erythrocyte sedimentation rate, liver function tests, serum uric acid, serum lactate dehydrogenase
Whole-body PET-CT scan
Unilateral bone marrow biopsy in stages III–IV and any stage with B symptoms
Cytologic examination of any effusion
Any further study suggested by clinical symptoms or signs

unexplained sweating (especially at night) and its severity, unexplained weight loss as a percentage of usual body weight and rapidity of loss, and pruritus with its extent and severity. The presence of alcohol-induced pain, peculiar to Hodgkin lymphoma patients, a family history of Hodgkin lymphoma [116] or other hematologic malignancy [77, 117], any history of immunosuppressive illness, such as infection with human immunodeficiency virus (HIV), or EBV infection, such as mononucleosis or a previous history of neoplasm together with any previous chemotherapy or radiation therapy should also be documented. A careful and complete physical examination must be performed with special attention to the number of enlarged lymph nodes and their dimensions, presence or absence of enlarged liver or spleen involvement, and Waldeyer's ring involvement. A complete laboratory workup is required. A whole body PET-CT scan prior to any therapy should be performed [118]. Radiolabeled fluorodeoxyglucose positron emission tomography (^{18}FDG-PET) has emerged as a very useful tool in evaluating the presence of active neoplastic tissue in residual masses after therapy, especially in the infradiaphragmatic areas. By utilizing the ^{18}FDG metabolism of neoplastic cells, ^{18}FDG-PET scanning seems to be able to recognize small lesions (less than 1 cm in diameter), with a high sensitivity approaching 100% despite a low specificity (slightly superior to 70%). PET scanning may reveal involved areas undetectable with other imaging techniques [119]. It should be noted, however, false-positive PET scans are not uncommon [120]. This is particularly true for bone marrow, where a positive PET scan may be due to red marrow hyperplasia due to anemia in patients with advanced lymphoma [121]. Furthermore, in some studies interim PET scans have not been predictive of outcome [122] and inter-reader reliability has been poor in others [123]. Nevertheless, PET-CT is currently the standard radiographic method for staging Hodgkin lymphoma [118, 124].

Evaluation of Response and Follow-Up Studies

After completion of planned therapy, response should be documented on the basis of clinical findings, and the results of a PET-CT scan supplemented by tissue biopsies if necessary. A number of patients have residual abnormalities after therapy, typically mediastinal widening. It is well known that residual non-PET avid masses, especially in the mediastinum do not necessarily represent residual disease but rather may indicate necrosis or fibrosis, and abnormal radiographic findings may persist for months to several years in such patients who are otherwise without evidence of disease [125]. Within the bounds of acceptable morbidity, pathologic

examination such as mediastinoscopy may be appropriate, although the difficulties of sampling artifacts should be kept in mind.

It is becoming commonplace to obtain a second PET-CT scan after two or three cycles of therapy to assess treatment progress if it cannot be fully assessed by physical examination alone. In this scenario, treatment may be reduced in intensity, i.e., omit radiation therapy after chemotherapy for early-stage patients if the repeat scan is negative [126], or it may be intensified if resolution of disease is slow or not apparent, by intensifying chemotherapy or adding radiation therapy. This approach at present seems valid for early-stage patients (some authorities disagree), but most studies of advanced-stage patients do not have long enough follow-up data to fully evaluate the results [127–134].

After completion of therapy, it is recommended that patients be seen at 3 month intervals during the first and second posttreatment years, at 4–6 month intervals from the 3rd to 5th year, and annually thereafter. The frequency and type of follow-up studies depend on and should focus on the initial sites of disease, as well as the detection of medium and long-term sequelae of treatment. Appropriate workup should be initiated when symptoms or signs of possible recurrent disease are noted. Because of the relatively high incidence of second neoplasms, investigations useful for the early detection of new malignancies, particularly breast and lung cancer should be part of the follow-up studies for patients in remission [135, 136]. Screening mammography or breast ultrasound, even in young women treated by mantle-field irradiation, is an example of this policy [136] and one should be mindful of the relatively high risk of cardiac complications of treatment. However, routine PET/CT or CT imaging for patients in complete remission is not recommended because yields are extremely low [137–139].

Treatment

Evolution of the Treatment Strategy

Treatment of Hodgkin's lymphoma has continuously improved since the 1960s and 1970s, and today 90% or more of all patients can be cured by first- or second-line therapeutic strategies [140]. Hodgkin lymphoma represents a remarkable example of how progress in clinical research can, occasionally, outpace progress in basic research (Table 43.4).

Radiation therapy progressively developed following the work of Gilbert (1939) and Peters (1950) and became a

Table 43.4 Chronologic flow of major concepts and events influencing treatment evolution of Hodgkin lymphoma

Investigator(s) (years)	Major concepts and events
Gilbert (1925–1939)	Concept of destruction of all lesions with the first course of radiation therapy: segmental irradiation to encompass suspected microscopic disease
Peters (1950–1958)	Improved 5- and 10-year survival by prophylactic irradiation of adjacent lymphoid areas: first three-stage clinical classification
Kinmoth (1952)	Lower extremity lymphangiography
Easson and Russel (1963)	Concept of cure by radiation therapy
Lukes (1963–1964)	Relationship of histologic features to clinical stages and prognosis
Kaplan (1962–1965)	Development of wide-field technique with radiation in continuity with multiple-node chains (mantle, inverted Y, and total lymphoid radiation therapy): identification of tumoricidal dose levels
Rosenberg and Kaplan (1965)	Evidence for an orderly progression in the spread of Hodgkin's disease
Lacher and Durant (1965)	Increased complete remission rate with vinblastine plus chlorambucil compared with single agents
Frei (1966)	Efficacy of a cyclic four-drug combination (MOPP)
Kaplan and Glatstein (1969)	Staging laparotomy and further studies on the pattern of anatomic distribution
DeVita (1970–1980)	Concept of high cure rate in advanced disease with MOPP
DeVita, Young (1971–1973)	No advantage of maintenance chemotherapy in complete responders
Rosenberg (1968–1981)	Trials with combined radiation therapy and chemotherapy, especially MOPP
Wiernik (1968–1985)	Trials of combined-modality therapy with MOPP and radiation therapy
Bonadonna and Santoro (1973–1987)	Development of non-cross-resistant chemotherapy (ABVD)
Wiernik (1976)	Randomized trials of MOPP versus combined-modality therapy for early-stage disease
Longo et al., Cimino et al. (1982–1990)	Randomized trials of MOPP versus radiation therapy alone for early-stage Hodgkin's disease
Canellos, Connors, Viviani et al. (1980–1998)	Randomized trials comparing MOPP, ABVD, and hybrid or alternating MOPP/ABVD in advanced stage
Santoro et al., Horning et al. (1990–1997)	Low-toxic brief chemotherapy (ABVD, VBM) and involved-field radiotherapy for early-stage Hodgkin's disease

(continued)

Table 43.4 (continued)

Investigator(s) (years)	Major concepts and events
Horning, Chopra, Sweetenham Josting et al. (1990–2000)	Studies with high-dose chemotherapy and bone marrow transplantation for salvage therapy
Diehl, Horning, Wiernik (1987, 1995, 2006)	New-generation intensive regimens (BEACOPP, Stanford V, MVC) for advanced stages and salvage therapy
Younes (2010)	Brentuximab vedotin major activity in advanced disease
Ansell (2015)	Nivolumab major activity in advanced disease

major treatment for Hodgkin lymphoma with the beginning of the megavoltage era. Studies by Kaplan and the Stanford group [81] led to the development and refinement of many concepts and techniques that constitute modern radiation therapy for lymphomas and particularly for Hodgkin lymphoma [141–144]. Until the end of the 1960s, radiation therapy was the only successful therapeutic tool that, under appropriate circumstances, was able to achieve cure in a sizeable fraction of patients with Hodgkin lymphoma. Chemotherapy was developed after the end of World War II, and lymphomas and leukemias were among the first neoplasms shown to respond to drug treatment. Although the great majority of available cytotoxic agents can produce objective responses in Hodgkin lymphoma, it was only in 1970 with the four-drug regimen known as MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) that DeVita and Carbone documented that chemotherapy could induce durable complete remissions and cure with high frequency in advanced Hodgkin lymphoma [145].

In the late 1970s and 1980s, radiation therapy and chemotherapy were sequentially combined for the treatment of early as well as advanced stages to maximize relapse-free survival (RFS), and to improve the cure rate. In an attempt to eradicate both MOPP-sensitive and MOPP-resistant neoplastic cells, Bonadonna et al. designed the ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, dacarbazine) regimen and mounted a number of prospective trials that proved its effectiveness as a non-cross-resistant regimen to MOPP [146–151]. Further attempts to improve the cure rate took into consideration the Goldie–Coldmann hypothesis [152] by testing the effect of early introduction of as many effective drugs as possible in treatment strategies. Trials from the Milan, Vancouver, and other groups compared alternating MOPP/ABVD with the so-called hybrid regimen which alternates half MOPP and half ABVD [153–155]. The hybrid regimen or MOPP alternating with ABVD has not demonstrated any real advantage over ABVD alone [156].

In 1992 Canellos and colleagues from the Cancer and Leukemia Group B (CALGB) confirmed in a large randomized study that ABVD alone was superior to MOPP. Since then, ABVD chemotherapy has become the gold standard against which all newer regimens should be tested [157].

In the 1990s, further efforts to improve the outcome of patients with Hodgkin lymphoma have consisted of the intensification of primary chemotherapy with hematopoietic colony-stimulating factor (CSF) support, with the aim both to increase complete remission rate and to minimize late toxic effects. A major example is the BEACOPP regimen (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone) [157, 158], designed by Diehl and coworkers from the German Hodgkin's Study Group, as well as of the Stanford V regimen of Horning et al. (weekly alternation of doxorubicin, vinblastine, mecloretamine, vincristine, bleomycin, etoposide, plus prednisone) [159, 160]. Recently, it was demonstrated that the Stanford V regimen is not superior to ABVD in any outcome measure [161], nor is BEACOPP.

The question of whether a clinical dose–response effect can be exploited with the use of high-dose chemotherapy with autologous [162–167] and allogeneic [168–170] stem cell rescue has been tested worldwide as salvage therapy for relapsed or refractory patients. Since initial attempts in the early 1980s, numerous investigators used high-dose chemotherapy with autologous bone marrow transplantation (ABMT) or peripheral blood stem cell transplantation (PBSCT) for salvage treatment of patients with relapsed Hodgkin's disease. An early publication of a randomized comparison between high-dose and standard-dose chemotherapy [167], demonstrated that a proportion of patients could be cured after relapse with this high-dose strategy. Thus, the trend toward a better outcome for patients treated by high-dose chemotherapy for relapse, along with the low morbidity rate, now reported as <1–4% for autologous and 10–20% for allogeneic transplants confirms the validity of these approaches.

Improvement in treatment results has been achieved in all stages of the disease. Today, no stage is beyond cure when treated appropriately at the time of diagnosis or when treated for recurrence. New agents such as brentuzumab vedotin and nivolumab seem destined to increase the number of disease-free long-term survivors of Hodgkin lymphoma even further. This represents a dramatic improvement in the overall prognosis of a disease that 40 years ago was considered to be almost universally fatal.

General Treatment Strategy

Careful patient selection remains important to identify those who will benefit from each treatment strategy, especially concerning the multimodality approach, such as the following:

1. In early stages (I, IIA), the multidisciplinary approach is now considered standard, but is seriously challenged by data on chemotherapy alone [171–179]. As the vast majority of these patients (approximately 90%) can be cured, the choice of treatment is presently aimed at reducing both acute and late toxicities by introducing less toxic drugs and reducing the dose and extension of radiation fields, or eliminating radiation therapy altogether, especially in children.
2. In patients presenting with massive mediastinal involvement, the role of combined-modality therapy is well established in all stages of disease [177].
3. In patients with more advanced stages of disease (IIA$_2$, IIB, III–IV A and B), the percentage of nodal relapses is about 20% even after effective chemotherapy [180–183].

The usefulness of consolidation radiotherapy to all sites of disease has long been a matter of debate. Some groups prefer to irradiate all nodal sites of disease at diagnosis even if the advantage of this approach is not fully demonstrated [179]. It is likely that irradiating all nodal areas in a patient with extensive stage IV disease will not enhance the probability of cure, whereas radiotherapy may be advantageous in those patients with advanced, exclusively nodal disease, but not more effective than continuing chemotherapy.

Although improved in the last 25 years, salvage treatment is curative only in about one-half of relapsed patients, except under the most favorable circumstances, such as limited-stage relapse beyond the 12th month of initial complete remission [182, 183]. As pointed out by Rosenberg [184] new salvage therapies should not be evaluated hastily since curability and comparisons of toxicities require 5–10 years of careful evaluation.

Nearly one-third of patients with Hodgkin's lymphoma die without evidence of lymphoma at autopsy, and in a significant number of patients, death is attributable to complications of therapy [184].

Therefore, treatment programs should be designed not only to improve therapeutic results but prevent or reduce iatrogenic complications such as cardiac and neoplastic as well. Long-term complications of treatment are discussed next.

Treatment of Early Stages (IA–B, IIA)

The vast majority of patients with early-stage Hodgkin's disease (IA–IIA) can be cured by currently available therapeutic options. Thus, a major aim of treatment is to limit medium- and long-term toxic effects rather than to further increase the cure rate. However, it should be noted that there is no complete agreement on the definition of early stages, as some authors include cases with bulky disease or B symptoms, whereas others do not (Table 43.5). As a consequence, it is somewhat difficult to draw precise conclusions from published series concerning the same treatment modalities but with different patient selection criteria.

However, it seems clear that radiation therapy alone or chemotherapy alone can cure over 90% of patients with Stage IA or IIA without bulky mediastinal disease, and that patients with bulky mediastinal disease require combined-modality therapy for optimal results.

Table 43.5 Prognostic subgroups in stage I–II

EORTC	
Very favorable	CS IA, female sex, age < 40, and LP histology, or NS histology and nonbulky mediastinum
Favorable	Cases classifiable neither as very favorable nor as unfavorable
Unfavorable	One of the following factors: bulky mediastinum, stage A with ESR >50, B with ESR >30, age > 50, more than four sites involved
GHSG	
Unfavorable	Bulky mediastinum or elevated ESR, or
	• Three involved sites, or
	• Disseminated extranodal or splenic involvement
Favorable	All others
Stanford	
Very favorable[a]	CS I and female sex, or
	CS I mediastinum, or
	CS I and male sex with LP histology, or
	CS II, female sex, age < 27, and <three involved sites
Harvard	
Very favorable	CS IA and female sex, or
	CS IA and male sex with LP histology, or
	CS IA and male sex with peripheral cervical site

[a]Treated with mantle-field irradiation alone, non-laparotomy staged

Radiotherapy

Up to the 1980s, the standard approach to stage IA–IIA Hodgkin's disease included staging laparotomy and splenectomy and, if these procedures are negative, mantle-field irradiation at therapeutic doses (36–44 Gy), followed by irradiation of para-aortic nodes and the splenic pedicle (subtotal nodal irradiation, STNI) at lower doses (30–36 Gy). With this approach, up to 90% of patients were alive at 10 years with a freedom from progression of 70–80% in one study [185]. Relapsing patients could, in fact, obtain second durable remissions by salvage chemotherapy. This approach has been reconsidered by a number of research groups. First, many radiation therapists documented a relapse rate in stage

IIA that was at least double that initially reported, and in stage IIB patients a failure rate of about 50% was observed with radiation alone [171, 186, 187]. However, it should be pointed out that selection criteria often included the so-called unfavorable early stages as outlined by the European Organization for Research and Treatment of Cancer (EORTC): MC and LD histologies, male sex, age older than 40 years, erythrocyte sedimentation rate more than 70, and mediastinal mass. In the presence of one or more unfavorable features, patients treated with extensive radiation therapy alone had a 6-year RFS of 53% versus nearly 100% when treated with combined-modality therapy [187]. Furthermore, the Stanford group tested subtotal nodal irradiation versus involved-field irradiation plus six cycles of MOP(P) in pathological stages IA–IIA, and concluded that adjuvant chemotherapy could replace radiation of occult disease [187]. The results of a number of major trials comparing radiotherapy, chemotherapy, and combined-modality therapy are shown in Table 43.6.

Over the last decade, indications for radiotherapy in early-stage Hodgkin's disease have been progressively revised. At present, only a limited-stage IA presentation with no adverse factors is considered to be appropriately treated with mantle-field or subtotal nodal irradiation alone. For all others, combined-modality treatment or chemotherapy alone is recommended [192–195]. Radiation therapy for Hodgkin lymphoma is discussed extensively in Chap. 46.

Chemotherapy

In the second half of the 1980s chemotherapy was introduced in the management of early-stage Hodgkin's lymphoma. Some groups have tested the efficacy of chemotherapy alone in this setting in order to eliminate late effects related to combined-modality therapy. Two groups published randomized comparisons between MOPP chemotherapy and radiotherapy, reaching opposite conclusions. The Italian group [196] found that radiation therapy was ineffective as salvage treatment after MOPP failure; thus in their opinion, radiation therapy remains the treatment of choice. The National Cancer Institute (NCI) group observed a superiority of MOPP chemotherapy over radiation therapy and concluded that MOPP was at least as effective as radiation therapy [172].

The National Cancer Institute of Canada and ECOG compared two courses of ABVD (doxorubicin, bleomycin, vinblastine and dacarbazine) followed by radiotherapy with four to six courses of ABVD alone. After a median of 4.2 years PFS was better for patients who received radiation therapy. Progression after ABVD alone was more frequent in sites that would have been irradiated in the other arm of the study, but there was no difference between the arms with respect to freedom from second progression or death rate [197]. Therefore, patients who progressed after initial treatment with ABVD alone could be successfully treated with salvage radiation therapy if required. BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) was developed as a chemotherapy regimen initially thought to be superior to ABVD. However, in several recent long-term follow-up studies ABVD and BEACOPP appear to yield equivalent results in terms of response rate, progression-free and overall survival. In fact in some but not all studies [198] overall survival is actually impaired by BEACOPP compared with ABVD due to an increased frequency of late developing second malignancies [199]. In summary, the longer the follow-up of comparative studies, the less difference in outcome between these two regimens is observed.

Studies have been conducted in an effort to determine whether both major drug regimens for Hodgkin lymphoma

Table 43.7 Common combination chemotherapy regimens for treatment of Hodgkin lymphoma

ABVD: All drugs administered IV on days 1 and 15 of a 28 day cycle at a dose of:	
Doxorubicin	25 mg/m^2
Bleomycin	10 units/m^2
Vinblastine	6 mg/m^2
Dacarbazine	375 mg/m^2
Maximum eight cycles total, including two cycles after complete remission.	
BEACOPP: All drugs administered on a 21 day cycle	
Bleomycin	10 units/m^2 IV day 8
Etoposide	100 mg/m^2 IV days 1–3
Doxorubicin	25 mg/m^2 IV day 1
Cyclophosphamide	650 mg/m^2 IV day 1
Vincristine	1.4 mg/m^2 day 8 (maximum dose, 2 mg)
Procarbazine	100 mg/m^2 PO days 1–7
Prednisone	40 mg/m^2 PO days 1–14
Maximum of eight cycles total, including two cycles after complete remission	

can be made less toxic in the short- and long-term while retaining efficacy. One such study determined that bleomycin and dacarbazine cannot be omitted from the ABVD in advanced-stage patients without significantly reducing its efficacy [200] while another study demonstrated that discontinuing bleomycin and/or vincristine because of drug-specific adverse events during treatment did not impair progression-free or overall survival in advanced-stage patients after BEACOPP treatment [201]. This information can probably be considered valid for early-stage patients as well (Table 43.7).

Most trials of the last 25 years have focused on the role of a combined chemotherapy–radiotherapy strategy in early-stage Hodgkin's disease. The debate arises from the evidence that salvage chemotherapy in patients relapsing after radiotherapy alone offers cure rates as high as initial combined-modality therapy. On the other hand, delivering chemotherapy after extensive radiotherapy results in a higher risk of second malignancies. At the Milan Cancer Institute, 116 patients with pathologically staged favorable presentation who were treated with extended-field radiotherapy were non-randomly compared with 85 patients with unfavorable presentations who were treated with MOPP (nitrogen mustard, vincristine, procarbazine, and prednisone) and radiotherapy. At 10 years, the freedom from progression was significantly different between stages I and II in the favorable group (85% vs. 59%), respectively, whereas stage lost its prognostic significance in the unfavorable group treated with combined-modality therapy [202]. Furthermore, in the favorable group a higher incidence of acute leukemia as a consequence of salvage chemotherapy was observed.

At Stanford, 67 patients with favorable pathological stages I and II (A and B), or IIIA were randomized between subtotal or total nodal irradiation alone or involved-field irradiation plus six cycles of the VBM regimen (vinblastine, bleomycin, methotrexate). At 5 years, freedom from progression was 70% after radiation alone and 95% after combined-modality treatment ($p < 0.0001$) [189]. In a subsequent trial, the authors focused on favorable clinical stages I and II: 78 patients were randomized to receive either extended-field irradiation (subtotal nodal) or involved-field irradiation after VBM. With a median follow-up of 4 years, 92% of the extended-field group and 87% of the combined-modality group were free of progression. Despite the fact that comparable results between the two groups would support the use of combined-modality therapy in all patients, the authors did not recommend its routine use outside of a clinical trial [190].

The Milan group compared two different radiotherapy strategies following primary chemotherapy by randomizing 103 patients to receive STNI or involved-field radiotherapy after four courses of ABVD. In a preliminary report, with a median follow-up period of 38 months, the response rate was 100%, freedom from progression was 95%, and survival was 100% without any difference between the two groups [191].

In a meta-analysis, the role of adjuvant chemotherapy was assessed in 13 randomized trials involving 3888 early-stage patients. The addition of chemotherapy to radiotherapy halved the 10-year risk of failure (16% vs. 33%), with a small statistically insignificant improvement in survival (79% vs. 76%). A reduction of Hodgkin's disease deaths of borderline significance (12.3% vs. 15.4%) was partly counterbalanced by an insignificant increase in deaths from other causes (12% vs. 10%) [144]. However, it could be argued that this meta-analysis refers to studies begun in the 1970s or early 1980s, when MOPP was the most frequently used combination. Thus, it is possible that less toxic regimens such as ABVD will reduce mortality from causes other than Hodgkin lymphoma and establish the combined-modality advantage. In another meta-analysis, Loeffler et al. [203] concluded that combined-modality therapy for advanced-stage disease resulted in inferior survival outcome compared with chemotherapy alone. In summary, at present the optimal initial treatment for early-stage Hodgkin's lymphoma is not known. Radiation alone, chemotherapy alone, or combined-modality therapy all have their advocates [204–206]. A reasonable approach is as follows: Stage IA: radiation therapy alone; Stage IIA or B with a large mediastinal mass: combined-modality therapy; All others: chemotherapy alone. Clearly, in young patients radiation therapy can be omitted if a PET/CT scan is negative for residual disease after two cycles of induction chemotherapy [207].

Nodular lymphocyte predominant Hodgkin's lymphoma patients need to be considered differently with respect to

treatment from classical Hodgkin's lymphoma patients. Limited-field radiotherapy is considered standard for early-stage disease (>90% of patients), since it has been shown to be as effective in all outcome measures as combined-modality therapy and more effective than chemotherapy alone [91, 208]. However, recent studies have demonstrated efficacy for rituximab in this Hodgkin's variant whose Reed–Sternberg cells are CD20+ [92]. New regimens that include rituximab are currently in clinical trial for this entity. However, as discussed above, surgical excision of stage I disease alone is frequently curative in this lymphoma, especially for pediatric patients.

Treatment of Advanced Stages

Stage IIB, III_2, and IV patients according to the Ann Arbor staging system are considered to be advanced. There is no consensus in the literature concerning stage III_1A, which is considered early stage by some investigators and advanced stage by others.

Conventional Approach

Primary chemotherapy is the standard approach for advanced stages. Up to the 1990s, the gold standard was the MOPP regimen [209], which induced complete remission in approximately 80% of patients. Of those, approximately 30% relapsed within 5–10 years.

MOPP is inferior to ABVD in the treatment of Hodgkin lymphoma. The first trial demonstrating the superiority of an ABVD-based regimen over MOPP was conducted at the Milan Cancer Institute in patients with stage IV disease. The alternating MOPP–ABVD regimen demonstrated a 15–20% advantage over MOPP [148]. Subsequently, the same group [150] demonstrated a significant advantage in terms of complete remission rate, freedom from progression, and RFS favoring ABVD (three courses followed by extended-field radiotherapy and three more courses) as compared with MOPP (same schedule) in 232 pathologically staged IIB and III patients. The comparable overall survival in the two groups was probably related to the fact that salvage ABVD was given to MOPP-resistant patients. The long-term results of this trial confirmed the efficacy of a combined-modality approach. As far as delayed toxicity is concerned, no signs of myocardial damage were seen in either arm. However, other studies with longer follow-up have reported a 10-year incidence of 5.5% cardiac disease-related hospitalizations after ABVD alone and 9.2% after ABVD plus mediastinal irradiation, compared with a 2.2% rate expected in the general population [210]. The ABVD group showed more pulmonary radiation fibrosis than the MOPP group, in particular after the last three cycles of bleomycin-containing chemotherapy. Permanent testicular failure occurred only after MOPP. Although MOPP was definitively more leukemogenic than ABVD, the frequency of solid tumors was about the same with the two combinations [211]. Clearly, the incorporation of alkylating agents (mechlorethamine and procarbazine) in the MOPP regimen is responsible for the increased incidence of sterility and leukemogenesis observed with that treatment.

In the CALGB study comparing MOPP, ABVD, and MOPP alternating with ABVD in 362 patients with advanced-stage disease ($IIIA_2$, IIIB, IV), 8-year freedom from progression was 37% for MOPP, 52% for ABVD, and 50% for alternating MOPP and ABVD. A similar difference in overall survival did not emerge. A 3% incidence of fatal febrile neutropenia in the MOPP group was counterbalanced by a similar incidence of fatal pulmonary toxicity with ABVD, and 1% of each after MOPP–ABVD [212].

Some groups have tested the alternating MOPP/ABVD with the so-called hybrid MOPP/ABVD, which consists of alternating half courses of MOPP with half courses of ABVD, with the aim of more rapid delivery of all active drugs in concert with the Goldie–Coldman hypothesis. In the Vancouver trial, alternating MOPP and ABVD was compared with hybrid MOPP–ABV, with ABV given on day 8 of each 28-day course. Both regimens produced excellent results, but the hybrid regimen was associated with a higher incidence of life-threatening febrile neutropenia and stomatitis, leading to a lowering of the upper age limit from 65 to 55 years in mid-study [153]. In 415 patients treated at the Milan Cancer Institute, alternating and hybrid programs (half MOPP and half ABVD every 14 days of each 28-day cycle) produced comparable results [154] in terms of both survival and acute toxicity.

The North American Intergroup [155], compared sequential MOPP followed by ABVD with hybrid MOPP/ABV in 737 patients with advanced-stage (III_2A, IIIB, IV) Hodgkin's disease with the aim of testing the Goldie–Coldman hypothesis by introducing doxorubicin late (sequential) or early (hybrid) in the therapeutic program. Patients assigned to the sequential schedule received six MOPP courses followed, if complete response was attained, by three ABVD courses. Patients in the hybrid group received MOPP–ABV as designed by Connors et al. [153]. Complete remission was achieved in 83% of cases on the hybrid and 75% in the sequential group ($p = 0.02$). After a median follow-up period of 7.3 years, the 8-year FFP was 64% for MOPP/ABV and 54% for MOPP → ABVD ($p = 0.01$). The 8-year OS rate was significantly better for MOPP/ABV as compared with MOPP → ABVD (79% vs. 71%, $p = 0.02$). Acute life-threatening (grade 4) or fatal (grade 5) toxicity was more frequent in the hybrid regimen. However, seven cases of acute myeloid leukemia and two of myelodysplasia were

diagnosed in patients receiving MOPP → ABVD as compared with one case of acute myeloid leukemia in the hybrid regimen ($p = 0.01$). Overall (Table 43.8), six to eight courses of ABVD alone has emerged as the gold standard in advanced-stage Hodgkin's disease, with which new-generation regimens should now be compared.

Newer Intensive Combinations

Optimization of dose intensity, inclusion of new active drugs, and the appropriate use of hematopoietic growth factors have been studied as methods by which the cure rate might be enhanced in patients with advanced Hodgkin's disease.

There has been much enthusiasm until recently for the BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) and escalated BEACOPP regimens developed by the German group. In an early report [157], moderate dose escalation over the standard BEACOPP regimen was performed with granulocyte colony-stimulating factor (G-CSF) support, and maximal doses of three component drugs (doxorubicin, etoposide, cyclophosphamide) were given with acceptable hematological toxicity. The intended doses of doxorubicin, etoposide, and cyclophosphamide were substantially escalated from 25 to 35, from 650 to 1200, and from 100 to 200 mg/m^2, respectively. Of 60 patients enrolled, 56 (93%) achieved complete remission, with an overall survival and freedom from progression at 32 months of 91% and 90%, respectively. Another report gave the results of a randomized comparison of standard BEACOPP with escalated BEACOPP and COPP–ABVD, involving 505 evaluable patients with advanced-stage (IIB, IIIA with risk factors, IIIB, and IV) disease. Four courses of COPP–ABVD were compared with eight courses of baseline BEACOPP without G-CSF and with eight courses of escalated BEACOPP with G-CSF, all followed by radiotherapy to bulky sites (30 Gy) and to areas of residual disease (40 Gy) [157]. The interim analysis at 23 months showed a significant inferiority of the COPP-ABVD regimen in terms of progression rate and freedom from progression compared with the pooled results of both BEACOPP schemes. The 24-month freedom from progression rate was 75% for COPP/ABVD and 84% for BEACOPP pooled ($p = 0.034$). There were insufficient data to compare the two BEACOPP variants. The acute toxicity of COPP/ABVD and baseline BEACOPP was similar, whereas escalated BEACOPP showed increased but manageable hematological toxicity. Therefore, recruitment in the COPP/ABVD arm was discontinued. In a further interim analysis of 689 patients (COPP/ABVD 235 patients, baseline BEACOPP 241, escalated BEACOPP 213), escalated BEACOPP showed better freedom from progression at 2 years than baseline BEACOPP (89% vs. 81%). As yet, no significant differences in survival have emerged, however. Of concern is the higher number of secondary acute leukemias observed with escalated BEACOPP (4 vs. 1) whereas secondary non-Hodgkin's lymphomas (three cases) occurred only in the baseline BEACOPP group. Nevertheless, the authors concluded that results with escalated BEACOPP in advanced-stage Hodgkin's lymphoma challenged ABVD as the standard of care for this population [213]. The same study group tested BEACOPP without etoposide (BACOPP) in elderly patients (age 60–75 years) with early-stage disease with unfavorable characteristics, or advanced-stage. The regimen was effective in this population but there was an unacceptably high toxic death rate of 11% [214]. In an important presentation, Gianni et al. [215] demonstrated comparable 3-year overall survival with ABVD or BEACOPP first-line therapy for advanced-stage patients plus autologous transplant as salvage for relapse. Freedom from progression rate at 3 years was 16% higher in the BEACOPP group, but the freedom from second progression rates were similar, as were overall survival rates. The authors concluded that 71% of the ABVD-treated patients were cured by initial therapy and would have been overtreated if they had received

BEACOPP instead. BEACOPP was associated with a fourfold higher toxic death rate compared with ABVD.

In the HD12 trial, the German Hodgkin's Study Group attempted to determine whether eight cycles of escalated BEACOPP followed by irradiation might represent overtreatment. Advanced-stage Hodgkin's lymphoma patients were randomized to receive four or eight cycles of escalated BEACOPP followed by four cycles of baseline BEACOPP. A second randomization assigned patients to receive radiotherapy as described in the previous trial or no radiotherapy. The study demonstrates that substantial reduction in irradiation dose after BEACOPP chemotherapy is warranted [216].

Among numerous newer multidrug regimens in which etoposide was substituted for vincristine and epidoxorubicin for doxorubicin, it is worth mentioning VEBEP (etoposide, epidoxorubicin, bleomycin, cyclophosphamide, and prednisone). The Milan group reported their results with this regimen given every 21 days without growth factor support and followed by radiation therapy (30–36 Gy) to pretreatment-involved nodal sites. In 73 patients with stages IIB or III–IV or relapsing after radiotherapy, complete remission was achieved in 94% of cases with freedom from progression and overall survival at 6 years of 78% and 82%, respectively. Hematological toxicity was acceptable, with 86% grade IV neutropenia, which resolved in the majority of cases by the next treatment cycle. The majority of male patients developed gonadal damage, reversible in half of them. No secondary leukemia or myelodysplasia had been detected at the time of publication [217]. Overall (Table 43.9), these regimens as well as others induce complete remission in up to 99% of cases with freedom from progression at 5 years of about 80%. None of these regimens are clearly superior to ABVD.

It has been demonstrated that bleomycin and vincristine doses can be reduced or omitted from the BEACOPP regimen without appreciable loss of efficacy, which raises the question how important these agents are in the treatment of Hodgkin lymphoma [218]. On the other hand, it has been demonstrated that dacarbazine cannot be omitted from the ABVD regimen without loss of significant activity [200].

Table 43.9 Five-year results of chemotherapeutic regimens in advanced Hodgkin's disease

Regimen (ref)	CR (%)	OS (%)	FFP (%)
BEACOPP intensified [213]	95	NR	84
MVC [219] (88% of patients had B symptoms)	90	NR	79
VEBEP [217]	94	82	78

CR complete remission, *OS* overall survival, *FFP* freedom from progression
Whatever treatment is to initiated for a given patient, it is important to begin treatment as soon after diagnosis as possible [SSSS] because delay may lead to inferior results

A simple regimen of mitoxantrone, 8 mg/m^2 given I.V. daily on days 1–3 plus vinblastine, 8 mg/m^2 I.V. on days 1 and 22, and lomustine orally 100 mg/m^2 on day 1 (MVC) has yielded results similar to more complicated regimens [219] and deserves further study.

Newer drugs in development such as brentuximab vedotin are under investigation in combination with other agents for the treatment of newly diagnosed patients with advanced disease [220]. Such combinations may ultimately render present-day regimens obsolete. New agents in development are discussed below [221].

High-Dose Consolidation with Stem Cell Support

A number of nonrandomized trials have tested high-dose consolidation after achievement of complete remission with standard regimens in patients with particularly adverse prognostic presentations. Up to now there has been no evidence for the usefulness of such an approach in any subset of patients. As a matter of fact, up to 40% of relapsed patients are cured with high-dose chemotherapy as salvage treatment (see discussion that follows). Thus, giving high-dose consolidation therapy may be overtreatment.

Carella et al. studied one course of CBV (cyclophosphamide, BCNU, etoposide) or BEAM (BCNU, etoposide, cytarabine, melphalan) followed by peripheral stem cell reinfusion in 22 patients with advanced-stage disease in first remission after MOPP-ABVD. Selection criteria consisted of bulky disease, age over 40 years, high serum lactate dehydrogenase (LDH) level, and anemia at onset. After a median follow-up time of 83 months, overall and RFS were 80% and 77%, respectively [222].

Delain et al. [223] treated 26 high-risk patients with an estimated probability of cure less than 40% (stage IV and at least two of the following factors: B symptoms, bulky mediastinal disease, two or more extranodal sites, bone marrow involvement, inguinal node involvement, high LDH serum level, or low hematocrit) with high-dose chemotherapy and peripheral blood stem cell support (PBSCT) as consolidation of first-line chemotherapy. At the time of transplantation, 19 patients were in complete remission and seven in good partial remission after MOPP-ABVD or similar regimens. Actuarial 5-year overall survival, freedom from progression, and event-free survival were 69%, 79%, and 58%, respectively. Only normal serum LDH level was found statistically significant as a prognostic indicator in univariate analysis. Of note, procedure-related mortality in the first 90 days after engraftment was 7%. Better results were obtained by Nademanee in 20 high-risk patients according to the same criteria, who were given high-dose therapy and total-body irradiation after complete remission induction. All patients were alive and disease-free at

43 months [224]. Zinzani et al. [131] utilized autologous stem cell transplantation after high-dose chemotherapy in advanced-stage patients who were PET scan-positive after two cycles of ABVD and compared results with patients who were PET scan-negative after two cycles of ABVD. The 2-year progression-free survival was 76% for the patients who were PET+ during ABVD treatment and 81% for those who were PET-negative. The authors concluded that the intense chemotherapy with transplantation allowed the poor responders to ABVD to have a similar outcome as the ABVD complete responders. Again, it must be stressed that all these results come from small nonrandomized heterogeneous series and must be evaluated with caution.

Role of Consolidation Radiotherapy in Advanced Stage

Soon after MOPP was introduced, it became clear that the majority of chemotherapy relapses occurred at sites of initial disease, particularly nodal sites and sites of bulky tumor, and that addition of radiotherapy markedly reduced the frequency of these recurrences, thus increasing the rates of both complete remission and disease-free survival [225, 226]. Because of these observations, adjuvant irradiation was widely adopted. However, with growing awareness of the second tumor risk associated with irradiation, both radiotherapists and chemotherapists have reservations about this approach [227, 228].

There is general agreement on the need for combined-modality treatment in patients with mediastinal bulky disease [227–229]. Disease-free survival of 80–90% is observed after combined-modality treatment, which is nearly twice that reported after MOPP or radiation alone. Some partial remissions obtained with chemotherapy can be converted to complete remissions with radiotherapy, but such patients do not show an increased cure rate according to randomized trials [229, 230]. So-called risk-adapted therapy which consists of intensifying chemotherapy or adding radiotherapy to standard chemotherapy if a PET scan obtained after two courses of the latter shows residual disease is under investigation in a number of studies but, to date, results are controversial [231, 232].

The issue of whether irradiation has a role as consolidation therapy after complete remission is achieved is still a matter of debate. Groups at Yale, Duke, and Memorial Sloan-Kettering strongly support low-dose adjuvant irradiation (18–30 Gy) to previously involved sites for patients in remission after chemotherapy. In a cohort of 184 Yale patients with either newly diagnosed stage IIIB or IV disease or recurrent disease after irradiation alone, overall survival was 54% at 15 years [233]. However, an unacceptable incidence of second neoplasms was observed in those treated with combined-modality therapy for disease recurrence after radiation alone (41% at 20 years vs. 12% in the newly diagnosed patients) [181]. In a similar analysis at Memorial Sloan-Kettering, the actuarial 10-year overall survival and progression-free survival were 74% and 70%, respectively [234]. Second-malignancy incidence was only 4%, but the median duration of observation was too short to properly address that issue. A German investigation showed that while 20 Gy is sufficient to control initial sites of nonbulky disease or uninvolved sites following two double cycles of COPP/ABVD relapse patterns indicate that patients destined to relapse need more systemic rather than local therapy [235]. In a SWOG study, 278 patients in complete remission following a MOPP–ABVD-derived regimen were randomized to receive low-dose irradiation (10–20 Gy) to previously involved sites or no further treatment. The 5-year remission duration estimated at 79% for patients who received radiation therapy was not significantly different from the 68% observed in those who did not. Although low-dose irradiation improved the 5-year remission duration in the subgroups with nodular sclerosis (82% vs. 60%, $p = 0.002$) or bulky disease (75% vs. 57%, $p = 0.05$), overall 5-year survival was not improved in any subgroup [236]. The GELA group [237] published the results of a randomized comparison between two cycles of chemotherapy and nodal radiotherapy consolidation for patients with stage IIIB-IV Hodgkin's disease in complete remission or good partial remission after six cycles of MOPP-ABV hybrid or ABVPP (doxorubicin, bleomycin, vinblastine, procarbazine, prednisone). After induction therapy, 418 patients were evaluable for consolidation treatment comparisons. After a median follow-up period of 48 months, the 5-year freedom from progression did not differ between chemotherapy (79%), and combined modality (74%). After MOPP-ABV, 5-year overall survival was similar for chemotherapy (85%) and combined modality (88%); after ABVPP the 5-year survival was 94% for chemotherapy and 78% for combined-modality therapy. In conclusion, these results do not support the use of consolidation with radiotherapy instead of two further courses of chemotherapy after doxorubicin-induced complete remission for patients with advanced Hodgkin's disease.

In 1998 [203], the International Database on Hodgkin's Disease Overview Study Group published a meta-analysis of 1740 patients from 14 controlled adjuvant irradiation clinical trials. In studies comparing the addition of radiation to chemotherapy versus the same chemotherapy alone, tumor control at 10 years was significantly improved by 11%, but overall survival was similar. Trials in which the addition of radiation to chemotherapy was compared with the addition of further chemotherapy showed that there was no difference in tumor control in the two groups if an appropriate number of drug cycles were administered. However, overall survival was 8% better in the chemotherapy alone group because of fewer late treatment-related deaths. Adjuvant radiotherapy was thus recommended only for a few specific indications

such as bulky mediastinal disease. Thus, according to "evidence-based-medicine" criteria, there is no clear indication for consolidation therapy after complete remission in advanced stages of Hodgkin's disease.

Salvage Therapy

The vast majority of relapsing patients will require some form of systemic therapy. The issues involved in salvage treatment of Hodgkin's disease revolve around such concepts as non-cross-resistant chemotherapy, multidrug resistance, and response to escalated doses of chemotherapeutic agents [238, 239].

Prognostic Factors and Choice of Treatment

Salvage treatment for Hodgkin's lymphoma is required for essentially four subsets of patients with different prognostic implications (1) patients relapsing after radiotherapy alone; (2) patients relapsing after more or (3) less than 12 months from the achievement of complete remission with first-line chemotherapy; and (4) chemoresistant induction failure patients. At present, the widespread use of high-dose chemotherapy with stem cell support in virtually all patients relapsing after chemotherapy has eliminated the distinction between categories (2) and (3) (see discussion that follows). As a matter of fact, the number of cases in the first group is progressively decreasing, as only a few patients are now given front-line radiotherapy alone (see earlier text).

In the past, duration of first complete remission has been considered the main prognostic factor predicting second chance of cure. In fact, a number of trials demonstrated prolonged disease-free survival by retreatment with the same regimen that resulted in a prolonged initial complete response. Of 32 patients relapsing after primary chemotherapy at the NCI, 59% achieved a second complete remission when retreated with MOPP [240]. However, only 29% of patients whose initial remission was less than 1 year achieved a second complete remission, compared with 93% of patients whose initial complete remission was >1 year. The duration of second remission was also longer in patients whose initial complete remission exceeded 1 year than in those whose initial remission was less than 12 months. Similar results were also reported by the Milan group [241, 242], as well as by other investigators.

Today, the duration of first complete remission represents only one of the prognostic variables considered when second-line treatment is planned. A number of other factors, such as extension of disease at relapse, presence or absence of B symptoms, performance status, and response rate to induction therapy preceding high-dose consolidation, have demonstrated their prognostic significance in this setting [243].

Patients over the age of 60 are at increased risk for lung toxicity of bleomycin. Several recent studies have suggested that, while ABVD is currently preferred over other regimens for treatment of elderly patients, no more than two courses should be given with or without radiation therapy [244–247]. In the future ABVD may be replaced by brentuximab vedotin alone [248] or in combination with dacarbazine [249] or other agents for the initial treatment of elderly patients.

Relapse

Initial relapses of Hodgkin lymphoma tend to occur predominantly in the first 2–4 years after completion of treatment. Late relapses (beyond 5 years) are uncommon and account for 5–15% of patients in reported series [240, 250–252]. Relapses decades after initial diagnosis have occasionally been reported [253, 254].

In patients treated with inadequate radiation therapy, new manifestations of lymphoma are usually observed in the adjacent lymph node chain(s). In these cases, new disease manifestations in noncontiguous untreated areas are relatively rare. True recurrence (relapse within an irradiated field) is rare. Marginal recurrence, relapse at or immediately adjacent to the margins of a previous radiation field, is more frequent and may occur in 15–25% of cases treated with radiotherapy alone [252]. A trend toward recurrence in nodal areas and particularly in initial and contiguous sites can also be seen after complete remission in Hodgkin lymphoma treated with chemotherapy. In fact, relapses in previously involved sites occur in about 70% of relapsed cases after chemotherapy alone and are directly related to the volume of tumor mass prior to therapy.

Relapse after Radiation Therapy

As previously noted, 20–40% of patients with stages I and II Hodgkin lymphoma who are treated with primary radiation therapy will eventually relapse within 3 years. In a few instances, radiation therapy alone has been successfully used to salvage patients when the relapse occurred in a single lymph node chain more than 5 years after completion of the initial radiotherapy. In all other cases, the survival of patients treated with chemotherapy after radiation relapse is at least equal to that of advanced-stage patients initially treated with the same chemotherapy combination. Indeed, an apparent survival advantage of patients with radiation relapses over the primary treatment group has been attributed to a more favorable patient mix, with generally more limited extension of disease. Overall and disease-free survival range from 60% to 80% [250, 255].

Even in this case, stage at relapse is an important prognostic variable. At Stanford the 10-year relapse-free survival was 88%, 58%, and 34%, respectively, for those in stage IA, in stage IIA or IIIA, and in stage IV or with B symptoms at the time of relapse. As far as the choice of chemotherapy regimen is concerned, the same considerations outlined for first-line chemotherapy are of value. From the available evidence, ABVD exhibits the same superiority over other regimens for post-radiation recurrence that it does in initial treatment of advanced disease [149, 151].

Relapse After Chemotherapy

The treatment of choice for patients relapsing after chemotherapy has been historically represented by non-cross-resistant regimens at conventional doses. In the past, relapses after MOPP could be safely treated with ABVD with a second chance of cure as high as 40% [241]. However, the vast majority of patients now receive front-line treatment with ABVD or some variant of it. Thus, a number of new regimens have been devised that induce complete remission in no more than 50% of all patients, with 50–70% of the responders eventually relapsing again. Such patients have a probability of survival at 5 years after relapse of only 15–30% [256–258].

Somewhat better results come from regimens containing intermediate- or high-dose ifosfamide combined with etoposide or new active drugs such as vinorelbine [259–261]. In small series, up to 70% of patients are disease-free after 2 years [259], and of note, there is no difference in outcome between relapsed and primary refractory cases. MVC mitoxantrone 8 mg/m^2 on days 1–3, vinblastine 8 mg/m^2 days 1 and 22, and lomustine 100 mg/m^2 day1 is a new regimen given every 6–8 weeks for four cycles. A 91% CR rate with a median duration of response of 11 months and a median overall survival rate of 34% was reported in 45 relapsed patients most of whom received ABVD as initial treatment [219].

Several new drugs in early clinical development have shown substantial clinical activity against Hodgkin lymphoma and may ultimately revolutionize its treatment. Brentuximab vedotin is an anti-CD30 monoclonal antibody coupled to a tubulin inhibitor, monomethyl auristatin. The antibody binds to CD30 on Reed–Sternberg cells. The entire compound is then internalized, the linker is cleaved and monomethyl auristatin is released in the cytoplasm and causes apoptosis [262]. The first phase I study in patients with relapsed or refractory CD30+ lymphoma (Hodgkin lymphoma and anaplastic large cell lymphoma) tumor regression was observed in 86% of evaluable patients [263]. In a subsequent phase II trial of 102 relapsed or refractory Hodgkin lymphoma patients who failed an autologous stem cell transplant and then received brentuximab vedotin, 34 patients achieved a complete remission and 16 of those remained progression-free after a median follow-up of >53 months [264]. In another phase II study in relapsed or refractory patients who had received and failed salvage therapy but had not had a stem cell transplant, 9 of 30 patients had a complete response by PET scan after brentuximab vedotin alone [265]. A meta-analysis was performed on 903 Hodgkin lymphoma patients reported in the literature up to July 1, 2015, who received multiple treatments for relapsed or refractory lymphoma (including 529 patients who had received high-dose chemotherapy and an autologous stem cell transplant) and were subsequently treated with brentuximab vedotin [266]. The overall response rate was 63% and the complete response rate was 32%. Other recent studies [267–270] have given equally impressive results. The toxicity of brentuximab vedotin in these studies has been primarily grade 1–2 hematologic, fatigue, nausea and peripheral sensory neuropathy, which resolves completely or partially after discontinuation of treatment. In general, the drug has been well tolerated although approximately one-third of patients had treatment delayed due to toxicity at some point. Rarely severe dermatologic reactions, acute pancreatitis, or progressive multifocal leukoencephalopathy may occur. The usual dose and schedule is 1.6–1.8 mg/kg intravenously every 3 weeks for eight to ten cycles. This agent will almost certainly be studied in combination with other agents for newly diagnosed and refractory or relapsed patients in the near future.

Nivolumab, a PD-1 blocking antibody was recently reported to have major activity in relapsed or refractory Hodgkin lymphoma [271]. Most of the patients in this small phase II study had failed an autologous stem cell transplant and/or brentuximab vedotin. Yet 17% had a complete response and 70% had a partial response to nivolumab, 3 mg/kg I.V every 2 weeks on an open ended schedule. Toxicity of any grade occurred in 78% and grade 3 toxicities were observed in 22% of patients. These impressive results will insure that this agent will be fully evaluated as a treatment for Hodgkin lymphoma. Pembrolizumab [272], a humanized monoclonal anti-PD-1 blocker is also under investigation in relapsed and refractory Hodgkin lymphoma.

Bendamustine [273, 274] has also shown significant activity in previously heavily treated relapsed or refractory patients with Hodgkin lymphoma, even after failure of brentuximab vedotin [275].

90Y–daclizumab, a radiolabeled anti-CD25 monoclonal antibody given I.V. produced 14 complete responses in 46 evaluable relapsed patients with Hodgkin lymphoma in a recent phase II study. Unfortunately, six patients developed a myelodysplastic syndrome after treatment [276]. Whether this was due to previous treatments or the antibody is not clear. Further studies are necessary. Other new agents in early preclinical or clinical development that show activity against Hodgkin lymphoma include auranofin [277], AFM13 [278] and ixazomib [279].

For the first time in decades we have new agents with substantial activity against Hodgkin lymphoma. Clinical investigators throughout the world will be occupied for years to come determining the best ways to capitalize on this embarrassment of riches.

Stem Cell Transplantation

High-dose therapy with autologous stem cell rescue (Tables 43.10 and 43.11) is applicable to a large proportion of patients with relapsed or refractory Hodgkin lymphoma. On examining the literature (Table 43.10), a 5-year freedom from progression of approximately 40–50% emerges despite the heterogeneity of case series in terms of the number of patients treated, induction and conditioning regimens, and eligibility criteria [167, 280–286].

Recent trials (Tables 43.10 and 43.11) suggest the possibility of cure by high-dose therapy even in patients with primary refractory disease, defined as those never achieving complete remission with first-line chemotherapy. Lazarus et al. [289] reported on 122 chemotherapy-resistant patients who obtained a complete response rate of 50% with high-dose therapy and a 38% 3-year overall survival. Similar data

were provided by a German group [291], which reported a 5-year overall survival of 19% among 67 patients with primary refractory disease. Of note, overall survival was 53% for the 25 patients who actually could receive high-dose consolidation. This somewhat lower probability of cure as compared with the International Transplant Registry data is considered to result from different data methodology in a single center than that employed for the multicenter database. The GELA/SFGM group studied an especially unfavorable group of patients with relapsed or refractory Hodgkin's disease and demonstrated the feasibility of tandem administration of high-dose chemotherapy [287]. Of 43 patients, 32 (74%) completed the treatment. Platelet recovery after the second transplant (TBI or busulfan-containing preparative regimen) was delayed. There were two veno-occlusive disease episodes, one fatal, and one case of hemorrhagic cystitis, but no grade IV toxicity with a reduced dose of busulfan. The 2-year survival for patients receiving the two procedures was 74%, and that for the whole series was 65%.

The mini-BEAM regimen is certainly efficacious, but stem cell collection is impaired after its use [288, 292]. Stem cell collection may be improved by plerixafor [293]. The Cologne group demonstrated the feasibility of giving three or four courses of dexaBEAM prior to high-dose BEAM with adequate stem cell collection, which suggests the need to achieve as maximal a response as possible with conventional induction therapy prior to high-dose therapy [291]. Other regimens containing etoposide, platinum compounds, cytarabine, ifosfamide, or vinorelbine are also frequently used and combine antilymphoma activity with stem cell-mobilizing potential [294].

Further improvement of outcome for patients with relapsed Hodgkin lymphoma should focus first of all on increasing the complete remission rate with induction therapy, which may be achieved by increasing the dose intensity of effective regimens, or by including new active drugs, such as gemcitabine, vinorelbine [295], or mitoxantrone [219] in induction regimens. Second, the concomitant use of immunologically targeted strategies such as immunotoxins or monoclonal antibodies should be explored in this setting with the aim of reducing minimal residual disease [296, 297].

Some have advocated tandem autologous stem cell transplantation for very poor-risk patients [298] but this approach may not be necessary in light of new antilymphoma agents now available.

The question that still is not answered is whether or not autologous stem cell transplantation after high-dose chemotherapy ± irradiation is superior to other treatments for relapsed or refractory Hodgkin lymphoma patients. A review of 154 patients transplanted at Stanford from 1988 to 2002 and survived ≥2 years revealed 54 deaths after a median follow-up of approximately 10 years (34 from Hodgkin lymphoma, 13 from second malignancies and seven from other causes). The number of deaths from Hodgkin lymphoma is not less than one would expect from relapsed or refractory Hodgkin lymphoma patients treated otherwise [299], and one would expect the number of deaths from second malignancies to increase as follow-up continues.

There are three trials in the literature in which relapsed or refractory Hodgkin lymphoma patients were randomized to receive an autologous stem cell transplant-based treatment or a non-transplant treatment. Two meta-analyses (by the same authors) of these trials showed no overall significant survival benefit for transplanted patients [300, 301].

Allogeneic stem cell transplantation has been studied in relapsed and refractory Hodgkin lymphoma, including with reduced intensity conditioning [302] and with umbilical cord stem cells [303, 304]. At least one meta-analysis found no apparent survival plateau in these studies [305]. Furthermore, there is a high incidence of post-transplant lymphoproliferative disease in some of these studies [304], which impairs survival [306]. Currently, less than half of patients with relapsed or refractory Hodgkin lymphoma are cured with standard salvage chemoradiotherapy followed by high-dose therapy and autologous stem cell transplantation [307]. It is likely that stem cell transplantation for Hodgkin lymphoma will suffer the same fate it did as treatment for chronic myeloid leukemia as new agents for the lymphoma currently under study are perfected.

Treatment Sequelae

Unfortunately, recent improvement in the cure rate of Hodgkin's disease patients has been partially offset by treatment-related mortality and morbidity. In the Stanford experience [308], 15 years after diagnosis the mortality rate from causes other than Hodgkin's disease is greater than that from Hodgkin's disease itself (Table 43.12). Because the median age of patients 15 years after treatment was only 44 years, mortality from causes other than Hodgkin's disease is a serious problem. Few additional disease-related deaths occur beyond 15 years, although late treatment-related deaths continue to occur. Quality of life in some long-term survivors may be significantly impaired, according to a "fatigue score" [309].

Cardiac Complications

Cardiovascular complications of mantle irradiation and anthracycline chemotherapy are the second most frequent cause of treatment-related mortality in Hodgkin's lymphoma patients. Valvular heart disease incidence is directly related to mediastinal radiation dose, and with modern techniques that employ 30Gy or less the 30-year risk is increased by only about 1.4% [310].

Table 43.12 Causes of death among 2498 patients treated at Stanford University [308]

Cause of death	*N*	Percent
Hodgkin's disease	333	44
Second neoplasms	160	21

Unknown	22	3

In a Dutch study of 2524 survivors of Hodgkin lymphoma [311] 1713 cardiovascular events were identified in 797 patients. After 35 years or more patients had a four- to six-fold increased incidence of coronary artery disease or congestive heart failure compared with the general population. The highest relative risks were observed in patients treated before the age of 25 years, and half of patients with cardiovascular disease developed multiple events. Mediastinal radiation increased the risk for coronary artery disease and anthracyclines increased the risk for valvular disease. In another large retrospective study of 1919 patients diagnosed at a median age of 30 years, [312]1238 cardiac events were recorded in 703 patients after a median follow-up of 9 years: 19% were ischemic heart disease, 12% were congestive failure, 16% were arrhythmias and 11% were valvular disease. Older patients, Black patients, and men, especially those who presented with advanced-stage lymphoma appear to be at highest risk of cardiovascular death after treatment for Hodgkin lymphoma [313, 314]. Recent evidence suggests that vigorous exercise after lymphoma treatment may favorably modify the incidence of treatment-related cardiovascular events [315–318]. Coronary computed tomography angiography has been recommended as a follow-up procedure especially for patients treated with combined-modality therapy at a young age [319].

Radiation-related pericarditis occurs in 25–30% of patients treated with radiation therapy. It is usually transient and self-limiting, but constrictive pericarditis requiring surgery with or without tamponade may occur [197] as late as 10 years after mediastinal irradiation [320]. The early postoperative outcome of cardiac surgery for radiation-related cardiac damage is generally like that of the population as a whole [321].

Pulmonary Complications

Pulmonary morbidity and mortality are related both to mantle field irradiation and to bleomycin [322]. Major risk factors include age over 40 years [323] cumulative dose of bleomycin as high as 300–400 U/m^2, concomitant mediastinal irradiation, and oxygen therapy [325]. In addition, the administration of both bleomycin and gemcitabine together leads to a substantial increase in pulmonary toxicity above that expected with bleomycin alone [324].

Bleomycin-induced mortality after ABVD occurs in approximately 4% of patients [325]. The primary lung lesion is macrophage-rich fibrosis. Careful monitoring of respiratory function during treatment may be helpful in decreasing such a risk in that bleomycin can be discontinued if impaired pulmonary function is detected early [325] and doing so has no effect on complete remission rate, PFS or overall survival [326]. This observation raises the question whether bleomycin adds any therapeutic activity to the ABVD regimen at all (discussed above). Early radiation pneumonitis and to some extent bleomycin pneumonitis may respond to corticosteroid administration, but late radiation pulmonary fibrosis is untreatable [323]. PET scanning may be more helpful than CT scanning in following the evolution of bleomycin pulmonary toxicity after treatment [322]. Patients with radiation or bleomycin lung toxicity usually have impaired exercise tolerance, especially if decreased DLCO and decreased total lung capacity are demonstrated [327]. A number of agents have been shown in rodents to prevent or lessen bleomycin pulmonary activity [328–330] but none have entered clinical trial yet.

Second Neoplasms

The mechanisms involved in the development of second malignancies in Hodgkin lymphoma are likely based on the damage and repair at a gene level caused by treatment. Alterations in cell cycle, repair, detoxification, and stress response pathways are likely involved [331]. Interestingly, Hodgkin's lymphoma patients with a family history of cancer are more likely to develop a second malignancy after treatment and the risk increases directly with the number of first-degree relatives with cancer [332].

When MOPP was the standard chemotherapy regimen, acute myeloid leukemia and myelodysplasia were the first second malignancies to be observed. They occurred primarily from months to several years after completion of chemotherapy, primarily due to nitrogen mustard and procarbazine. The occurrence of acute leukemia after ABVD or Stanford V treatment is extremely rare [333, 334]. Radiation therapy does not seem to play a role in acute leukemia etiology [333]. The overall incidence of acute myeloid leukemia and myelodysplasia within 10 years from initial treatment for Hodgkin lymphoma ranges in most series from 1% to 4% or less. The highest incidence of this complication occurs in patients treated with extensive radiation therapy plus MOPP or MOPP-like chemotherapy, in patients older than 40 years at the start of chemotherapy, and in those subjected to staging

laparotomy with splenectomy. Furthermore, it seems that patients who initially undergo radiation therapy and subsequently receive salvage chemotherapy represent the subgroup at highest risk for developing leukemia or myelodysplasia. This is a refractory hematologic neoplasm and virtually no patients survive this complication [335–337]. The excess risk for AML is highest in patients diagnosed with Hodgkin's lymphoma at age 35 years or older, and has declined after 1984, when MOPP began to be phased out [338]. In summary, the incidence of AML and myelodysplasia in patients treated for Hodgkin lymphoma is directly related to the cumulative dose of alkylating agents [339] or BCNU [340] received.

Typically, treatment-related leukemia is characterized by a latency period of months to 5 years or more, a preceding myelodysplastic phase, trilineage bone marrow dysplasia, and abnormalities of chromosome 5 and/or 7 [337]. Topoisomerase II inhibitors, primarily epipodophyllotoxins but also anthracyclines when given in combination with alkylating agents, have also been implicated in the development of a clinically and cytogenetically distinct form of secondary acute myeloid leukemia in both adult and pediatric patients. In contrast to alkylating agent-related leukemia, this form of therapy-related leukemia lacks a preceding myelodysplastic phase and is characterized by a shorter latency period, myelomonocytic or monocytic morphology, and balanced chromosome translocations involving bands 11q23 or 21q22. The cumulative dose of epipodophyllotoxins as well as dose-dense administration are implicated in the induction of this type of secondary leukemia [341].

Hematological malignancies have been studied also in survivors after high-dose therapy with stem cell support [342, 343]. It must be emphasized that acute myeloid leukemia and myelodysplasia often result from chemotherapy and/or radiation therapy given for the primary malignancy prior to transplantation rather than from high-dose chemotherapy administered as a transplant preparative regimen. As a matter of fact, the latency period from first-line therapy and development of leukemia is 4–6 years, whereas it is substantially less from the high-dose chemotherapy–PBSCT time (median 2.7 years) [342, 343]. In a report from the University of Chicago Medical Center concerning 641 patients, of whom seven (1.1%) developed therapy-related acute leukemia [341]. The disease-specific incidence of therapy-related leukemia was 6.3% of patients treated for Hodgkin lymphoma. The median latency periods from the time of initial treatment and from that of high-dose therapy were 5.5 and 1.5 years, respectively [342, 343]. Thus, it is more likely that the development of secondary leukemia resulted from pretransplant chemotherapy, which implies that early detection of therapy-related cytogenetic abnormalities may be useful to exclude patients from high-dose chemotherapy–PBSCT programs [344].

A small number of patients treated with intensive combined-modality therapy have developed aggressive non-Hodgkin's lymphoma shortly after completing treatment. This transformation is especially common in patients with nodular lymphocyte-predominant Hodgkin lymphoma for whom a >10% conversion to diffuse large B-cell lymphoma has been reported [345]. In a series of 1391 Hodgkin's disease patients treated with various approaches from 1972 to 1996, the possible role of splenectomy in the development of non-Hodgkin's lymphoma was investigated. After a median follow-up period of 84 months, a total of 20 cases of non-Hodgkin's lymphoma were observed, with a cumulative risk of 0.8% at 5 years and 3.5% at 20 years. Splenectomy or splenic irradiation and age over 40 years were associated with relative risks of 5.69% and 3.05% respectively, for unknown reasons.

The major second malignancy problem in Hodgkin lymphoma patients is the development of solid tumors most often within irradiation fields years to decades after completion of treatment. That risk continues into the fourth decade and probably beyond [346]. These tumors are mostly due to radiation therapy, but some data suggest that MOPP chemotherapy may lead to an elevated risk of lung cancer in patients with Hodgkin's lymphoma [347]. The risk is no greater after conventional therapy followed by autologous stem cell transplantation than after conventional therapy alone.

The literature has focused mainly on secondary acute myeloid leukemia, myelodysplasia, and breast cancer as important second neoplasms after treatment for Hodgkin lymphoma. However, lung cancer [348–351], sarcomas [351], head and neck cancer (especially salivary gland tumors) [352, 353], and gastric cancer [354] occur with increased frequency as well. The median latency period is relatively short for acute myeloid leukemia and myelodysplasia, but it may be as long as 18 years or more for lung cancer [351], which is primarily adenocarcinoma. High doses of mediastinal irradiation and smoking increase the risk of lung cancer after lymphoma treatment. Lower doses of radiation may [355] or may not [356] reduce the risk of second solid tumors.

The excess risk of breast carcinoma is almost completely restricted to women who received radiation therapy before the age of 30 [136]. Those treated in the second decade and the first half of the third decade of life are subject to the maximum cumulative risk [358], with shoulders of the risk peak extending into the second half of both the first and third decades. The risk curve is consistent with the current understanding of breast carcinogenesis. In fact, the first breast carcinomas appear at the end of the first decade after irradiation [358] and continue to appear in women observed for the longest period (three decades). In one series, actuarial calculation observed an overall 19% incidence of breast cancer 30 years after irradiation and 26% for those treated before age 21 [358]. A recent large population-based study puts the

incidence at 6.5% [357]. That study found a decline in the use of radiation therapy for the treatment of Hodgkin lymphoma from 1973–2011 and a consequent fall in the incidence of secondary breast cancer during that period. These second tumors appear within or at the edge of irradiation fields [359], and shorter duration of intact ovarian function after irradiation was associated with a significant reduction in breast cancer risk [358]. Systematic follow-up of women who received radiation treatment for Hodgkin's lymphoma leads to earlier detection of breast cancer and presumably saves lives [360–362]. Zeng et al. [363] studied the impact of prior chest radiation therapy on breast tissue background parenchymal enhancement on screening MRI and found that enhancement was significantly higher in irradiated patients compared with age matched unirradiated controls. Breast density was not different between the 2 groups, however. The clinical significance of these findings, if any, is not clear at present. Specifically, it is not known whether women with enhancement of background parenchyma on MRI are more likely to develop secondary breast cancer.

Sarcomas, breast and thyroid carcinomas occurred with similar frequency and latency in pediatric Hodgkin lymphoma patients treated with high-dose or reduced-dose radiation therapy [355]. Melanoma and non-melanoma skin cancers have also been reported in patients treated for Hodgkin lymphoma, especially as children.

Hodgkin lymphoma patients who develop a second neoplasm are at risk for additional neoplasms [364]. Armstrong et al. studied 1382 survivors of childhood Hodgkin lymphoma who developed a second neoplasm and found that 28% developed another cancer and of those, 40% developed still another cancer or cancers [365]. The incidence of multiple new cancers was 41% in patients with one new cancer who had been irradiated for Hodgkin lymphoma compared with 26% in those who were not irradiated after 15 years of observation post Hodgkin lymphoma treatment. There may be a genetic basis for the development of a second malignancy after treatment for Hodgkin lymphoma. Best et al. [366] found two variants at chromosome 6q21 associated with second malignancies in patients who received radiation therapy as children for Hodgkin lymphoma. This finding needs further exploration especially in children who ultimately develop multiple posttreatment malignancies. Second malignancies are a significant cause of morbidity and mortality of patients treated for Hodgkin lymphoma as teenagers or young adults [367] and adults [368].

Pregnancy and Infertility

Pregnancy during remission from Hodgkin lymphoma does not increase the risk of relapse [369]. As many as 3% of all patients with Hodgkin lymphoma are pregnant at the time of diagnosis [370]. During the first trimester it is best to defer lymphoma treatment if at all possible. If not, consider single agent vinblastine therapy until the second or third trimester [370]. Combination chemotherapy is safe during the latter two trimesters. Radiation therapy should be avoided during the entire pregnancy unless absolutely necessary [370, 371].

Cancer testis antigen CT45 is expressed by Reed–Sternberg cells in 50–60% of Hodgkin lymphoma patients, which is the highest rate of all malignancies [372]. It is not known whether or not this finding has anything to do with the oligospermia found in 10–25% of patients before treatment [373, 374]. Cryopreservation of semen is routinely performed by many centers before treatment of young male patients. In one study it doubled the likelihood of posttreatment fatherhood [375]. However, this is not always feasible because many males with Hodgkin lymphoma have oligospermia or other sperm abnormalities such as DNA damage [376] at the time of diagnosis, and their sperm samples often do not meet the criteria of most reputable sperm banks [377]. Oligospermia or azoospermia prior to treatment is more common in patients with B symptoms [378].

In general, infertility is more common in male patients owing to the higher sensitivity of their reproductive organs to chemotherapy-related damage, especially that induced by alkylating agents and procarbazine. The MOPP and BEACOPP regimens [379] have induced infertility in up to 70% of male patients, whereas ABVD and other nonalkylating agent-based regimens less frequently induce infertility, which is usually irreversible for years [380]. Furthermore, gonadal damage is related to patient age at the time of treatment. In a large recent study 45% of females treated with ABVD, 35% of females treated with BEACOPP, 53% of males treated with ABVD and 33% of males treated with BEACOPP attempting conception after lymphoma treatment had children [381]. BEACOPP is significantly more toxic to ovarian function than ABVD, but in women treated with GnRH analogs during combination chemotherapy, 91% had normal ovarian function 2 years post chemotherapy [382], and women treated with BEAM and stem cell transplantation before age 40 years are significantly more likely to undergo early menopause compared with those treated with ABVD [383, 384]. Prepubertal patients carry a lower risk of infertility after treatment for Hodgkin's lymphoma [385, 386].

Sterility problems appear to be less common in adult women than in men, probably because the germ cells of the ovary with their low proliferative rate are less sensitive to drugs than are those of the testicle. Of women treated with regimens containing procarbazine or alkylating agents, most become amenorrheic [150], for years, especially those with advanced-stage disease or age over 30 years [387]. Those who use oral contraceptives may have a return of menses sooner than those who do not [387]. Infertility decreases in frequency from 1 to 10 years after chemotherapy. Reestablishment of menses and the possibility of

pregnancy in a treated woman are also correlated with age and the cumulative dose of drug exposure. However, amenorrhea is no guarantee of infertility, and patients should be made aware of that fact. Most data indicate that the risk of spontaneous abortion or fetal abnormalities in patients previously treated with combination chemotherapy is not increased compared with the risk to the general population, but there are presently no data on the risk to subsequent generations, if any. Despite the potential infertility associated with Hodgkin's disease and its treatment, it may be relatively short term in many patients. Pregnancy occurs in patients treated for Hodgkin's disease and spouses of treated male patients with surprising frequency [388]. Gonadotropin-releasing factor (triptorelin) administered monthly during chemotherapy may prevent or reduce the gonadotoxicity of chemotherapy in women receiving initial but not salvage therapy [388]. Ovarian cryopreservation may be a useful method of preserving fertility in young women prior to therapy. In a study of 24 patients, all ovarian specimens obtained were free of evidence of Hodgkin's lymphoma, even in patients with subdiaphragmatic disease [389].

Finally, some women treated with chest irradiation may not be successful at breastfeeding [390].

Thyroid Complications

Thyroid dysfunction is related to neck irradiation, and chemotherapy seems to play no role in its incidence or severity [391]. Of 1787 patients treated at Stanford, 50% exhibited thyroid damage within 20 years [392].

The median latency period from therapy for thyroid dysfunction was 4.6 years, and the most frequent dysfunction was hypothyroidism (47%), usually subclinical, followed by Graves disease (3.1%), benign alterations (3.3%), and autoimmune thyroiditis (1.3%). Others have reported similar data [393]. Furthermore, an increased incidence of thyroid cancer is reported, especially in pediatric patients [355, 394]. The risk of developing thyroid dysfunction persists for up to 25 years after treatment. For unknown reasons, white pediatric patients are 2.5 times more likely to develop hypothyroidism after irradiation for Hodgkin lymphoma than are black children [395]. Clinical examination and laboratory tests are recommended at 6 month intervals during the first 5 years and annually thereafter. Patients found to have an elevated level of thyroid-stimulating hormone following neck irradiation should be treated with thyroid hormone for the rest of their lives [396].

Renal Disease

Idiopathic minimal change nephrotic syndrome (MCNS) is an uncommon immune-mediated glomerular entity occasionally occurring in patients with classical Hodgkin lymphoma. Audard et al. [397] found that c-mip was selectively expressed in Reed–Sternberg cells of patients with Hodgkin lymphoma and MCNS but not in Hodgkin lymphoma patients without MCNS. Upregulation of c-mip may be a useful marker for MCNS.

Familial Hodgkin Lymphoma

In our databank of over 750 pedigrees of families with multiple hematologic malignancies there are 61 families with multiple cases of Hodgkin lymphoma, 69 families with both Hodgkin lymphoma and non-Hodgkin's lymphoma, 19 families with Hodgkin lymphoma and myeloma and/or Waldenström's macroglobulinemia, and 35 families with Hodgkin lymphoma and various leukemias. We recently reported on 26 families with both myeloma and Hodgkin lymphoma in their pedigrees [117] and there are several patients reported in the literature that have both B-cell neoplasms. In 90% of these pedigrees anticipation is present, which suggests a genetic rather than an environmental basis for the observation [22]. The data suggest that familial Hodgkin lymphoma may be more common than previously recognized, and that a basic commonality among most B-cell hematologic malignancies exits that is not generally appreciated. The fact that Hodgkin lymphoma in sibs more often than not occurs in sibs of the same sex led us to postulate the existence of a Hodgkin lymphoma gene at the short arm telomeres of the sex chromosomes near the SHOX locus [398]. Familial Hodgkin lymphoma is more fully discussed in Chap. 41.

Other Complications and Associations

De Bruin et al. [399] studied 2201 5-year survivors of Hodgkin lymphoma treated before the age of 51 years to determine if they had an increased risk for stroke and transient ischemic attacks. After a median follow-up of 17.5 years, 55 patients had a stroke, 31 had transient ischemic attacks and ten had both at a median age of 52 years. The standardized incidence ratio for stroke and transient ischemic attack was 2.2 and 3.1, respectively. Mediastinal and neck irradiation were independent risk factors for both and chemotherapy was not associated with an increased risk for either. Most ischemic events were caused by large artery atherosclerosis or cardioembolism. These heretofore unrecognized complications of radiation therapy need to be taken into account when deciding on therapy.

Hydrocele may develop in patients who have undergone staging laparotomy (now obsolete) or para-aortic nodal irradiation presumably due to disruption of para-aortic and/or pelvic lymphatics [400]. Small bowel obstruction may also uncommonly occur after laparotomy or abdominal irradiation [401].

Radiation to the para-aortic lymph nodes, especially if the tail of the pancreas is included in the field, increases the risk for diabetes mellitus in survivors of Hodgkin lymphoma. The incidence of diabetes is directly related to the radiation dose [402].

Chronic fatigue among survivors of Hodgkin lymphoma is significantly more common than in the general population [403, 404]. Clinical depression is strongly associated with high levels of fatigue [403], which may lead to work loss [404, 405]. Patients treated for advanced stages of Hodgkin lymphoma have poorer sexual quality of life long-term than others [406].

Adolescent and young adult Hodgkin lymphoma survivors have fewer infections during childhood than do controls. They also appear to have a deficit of rare gut microbes It is not known whether this decreased microbial diversity is due to the lymphoma, its treatment or other factors [407].

Future Considerations

New risk scores based on molecular characteristics of Hodgkin's lymphoma as well as histologic and immunologic characteristics [408] may ultimately replace those currently in use, which are based primarily on clinical characteristics. Such new methods of predicting risk may lead to more precise individualized therapy.

New data suggest there may be a role for rituximab in classical Hodgkin's lymphoma [409, 410]. Rituximab plus ABVD improved event-free survival by an average of 17% compared with ABVD alone across all prognostic groups [409]. New trials studying the efficacy of rituximab in classical Hodgkin's lymphoma are ongoing and may yield important results.

A variety of new agents not discussed above, such as lenalidomide [411], everolimus [412], and panobinostat [413] have shown clinical activity in this lymphoma that deserves further study. ABT-737, a new small molecule that inhibits the Bcl-2 family of apoptosis regulators, is active against cell lines derived from patients with Hodgkin's lymphoma [414] and will be evaluated in clinical studies. Brentuximab vedotin, as discussed above, will play a major role in the future treatment of Hodgkin lymphoma.

Finally, Blacks and Hispanics have an increased risk of death from Hodgkin's lymphoma compared with whites, at least in California. The cause is most likely poorer access to health care and/or presentation at advanced stages compared with Whites [415]. That is unacceptable in modern times.

44 Radiotherapeutic Management of Lymphomas

John P. Plastaras and Eli Glatstein

Staging

Effective management of lymphomas first requires an understanding of the extent of the disease. This guides not only choice of therapies, but also helps define the goals of therapy. Cure of lymphoma requires elimination of all clinically evident disease, as well as regional and systemic subclinical disease. Ideally, we stage patients with cancer in general to allow for meaningful comparisons of results among countries, institutions, eras, and treatments. The staging system for lymphomas is unusual in that it favors the techniques of the radiation oncologist, rather than the surgeon, which is true for most neoplasms. The difference between Stage II and III is often a difference in what can be easily encompassed within radiation fields. Peters noted improved survival in patients treated with radiation to both involved and non-clinically involved sites [1]. Today radiotherapy can be delivered to a wide range of volumes with a range of doses, allowing for tremendous flexibility. The choices made by the radiation oncologist depend on both the probability of subclinical involvement and probability of disease control. This requires careful assessment of clinical factors, disease extent, and knowledge of the patterns of relapse.

The staging of lymphomas has evolved over time, most notably by advances in imaging. At the time of the development of curative regimens for lymphomas, lymphangiography and plain radiography had been an important complement to the physical exam. The advent of staging laparotomy with splenectomy for HL was for a time an important method to detect subdiaphragmatic disease [2]. Body computed tomography (CT) scanning had been a standard for some time for staging [3]. Although Gallium-67 scanning enjoyed some popularity for a time, especially as a predictor of response, it has been replaced by ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography (PET). FDG-PET, first used for lymphoma in 1987, is not only sensitive in lymphoma, but also is prognostic [4–6]. In lymphoma, FDG-PET upstaging and downstaging changes management (18% in early-stage HL), and has an estimated sensitivity of 90% and specificity of 91% [7, 8]. It has become a standard staging study for HL and aggressive NHL, and in fact, the standard definitions of response, including complete response (CR) is now described in terms of PET uptake [9]. The five-point Deauville scale is now being used for both interim and final treatment response assessment [10]. Due to the evolving practices of staging, historical eras need to be considered.

Dose–Response

Increasing doses of either radiation or chemotherapy result in increasing tumor cell kill and normal tissue toxicity. Kaplan demonstrated that for HL, there is a clear dose response with radiation alone. Doses as low as 10–20 Gy can control about 50% of involved sites, but to achieve >98% local control, 44 Gy was needed regardless of size [11]. The Kaplan data included all sizes and all patient as there was no curative chemotherapy at the time (Fig. 44.1) More modern series with modern radiotherapy techniques suggests that somewhat lower doses can achieve similar results, but larger masses require higher doses [12, 13]. The newer data which support lower doses include many patient who received multiagent chemotherapy as well. NHL, which generally have more malignant cells per volume of tumor than HL, generally require higher doses [14]. It is intuitive that a greater number of tumor cells requires higher dose, therefore it is important to think logarithmically if the goal is to reduce the number of malignant cells to statistically less than 1.

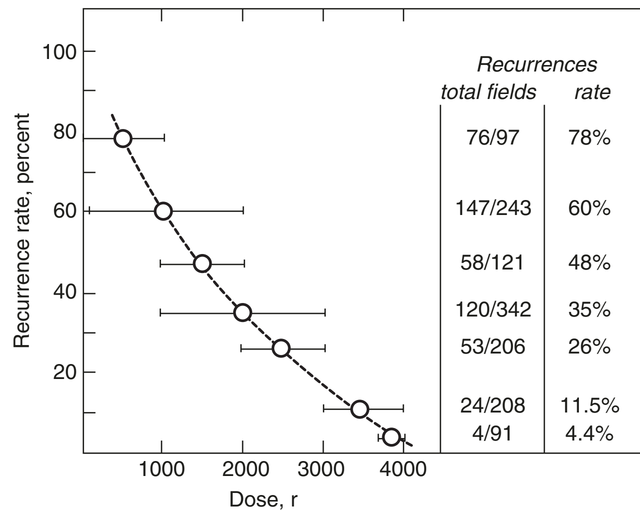

Fig. 44.1 Composite data on recurrence rate as a function of dose, with recurrence rates plotted to the midpoint of dose ranges indicated by the horizontal bars and brackets (reproduced with permission from the American Association for Cancer Research. From Kaplan HS. Evidence for a tumoricidal dose level in the radiotherapy of Hodgkin's disease. Cancer Res 1966;26(6):1221–4)

Unfortunately, normal tissues are also sensitive to dose, which establishes the principle of establishing a therapeutic index. Both acute and especially late effects need to be considered. Hematologic toxicity is the predominant factor that limits not only the maximum tolerated single chemotherapy cycle dose, but also the number of cycles that can be given. Cumulative chemotherapy doses can increase the risk of late side effects, but it is more challenging to adjust the doses during treatment. For example, increasing doses of doxorubicin correlate with depressed left ventricular function, even when the cumulative doses were below the accepted "threshold" level [15, 16]. There is an association between the risk of leukemia and cumulative chemotherapy dose following treatment for HL, especially for alkylating agents [17]. With radiation, the dose–response for late toxicity is complicated by the fact that dose per fraction increases late complications in addition to the total dose. Furthermore, because radiation effects on normal tissues only occur within the treated fields, knowledge of what organs were treated is also important. Dose-related toxicities with radiation include thyroid dysfunction, pneumonitis, pulmonary fibrosis, xerostomia, soft tissue hypoplasia in children, and valvular and coronary artery disease [18–25]. The dose that is ultimately given is defined by the minimum dose required to control all tumor sites with the fewest and least severe side effects. The doses required will vary with the age of the patient, the tumor volume, the amount of chemotherapy in the regimen, and comorbid conditions.

Combined-Modality Therapy

Tailoring of Local–Regional Therapy

A major premise in lymphoma management is that the amount of treatment should be adjusted to the risk of treatment failure because of concern about acute and late toxicity. Chemotherapy may be tailored by adjusting the number of agents, duration or number of cycles of chemotherapy, total dose of individual drugs, and the frequency and time interval over which agents are given. What cannot be accomplished with chemotherapy is anatomically distinct dose variation according to tumor burden. With radiation therapy, fields can be selected that treat only volumes that are at risk to be involved by lymphoma. Within a treatment field, critical normal tissues can be partially or totally excluded from radiation exposure. A modest dose reduction of only 10% has major implications in terms of minimizing morbidities. Differential doses can be delivered to differently targeted tumor volumes through customized blocking, selection of radiation energy, manipulation of the direction of entry of the radiation beam, and field size reductions during the course of therapy. Advances in imaging have allowed improved radiation treatment planning. CT-based radiation treatment planning allows for cross-sectional confirmation that target nodal sites are adequately covered by radiation fields [26–28]. CT planning decreases the risk of inadvertently shielding target volumes compared to plain film planning, which may have resulted in "marginal misses" in the past [29]. Advances in the physics of radiotherapy have allowed the treatment of irregular target volumes to high doses while sparing nearby critical structures. Intensity modulated radiotherapy (IMRT) uses computer-based algorithms and automated control of adjustable "multileaf collimator" blocking to sculpt radiation doses around structures like the parotid gland, heart, or lungs. IMRT may be appropriate for certain patients with mediastinal malignancies, but the concern of spreading low dose to large volumes may be of concern when considering the possibility of second malignancies [30, 31]. Proton radiotherapy, which has no exit dose, may also be a useful technique for minimizing late toxicities in lymphoma patients, especially young women with mediastinal involvement [32].

Operator Dependence

It is not disputed that the skill and experience of a surgeon and their team can dramatically impact outcomes, especially if the procedure is complicated. A similar phenomenon is observed with radiotherapy in lymphoma where outcomes vary with experience, skill, era, and equipment [33, 34]. The

prediction of the extent and location of volumes at risk, design of radiation treatment plans, and the actual delivery of the intended dose varies with the subspecialty expertise of the physicians, medical physicists, dosimetrists, and radiotherapy technicians. Quality assurance in radiotherapy has received considerable attention, although many of the same issues are relevant in the optimal delivery of chemotherapy.

Patterns of Failure

After chemotherapy alone, the majority of treatment failures occur in sites of initial involvement, especially large volume disease [35–37]. After radiotherapy alone, the great majority of treatment failures occur outside of the radiation fields [38]. Complementary patterns of failure establish the rationale of improved efficacy with CMT, as well as the decrease in morbidity resulting from truncating both chemotherapy and radiation therapy.

Potential Advantages of Combined-Modality Therapy

If the only goal of CMT were improved efficacy, one would simply add radiotherapy on top of a full course of chemotherapy. This would result in all of the side effects of both treatments, with the added possibility of supra-additive toxicity with a marginal additional benefit. A basic principle of cancer treatment is to use the least amount of therapy to achieve efficacy. With the complementary efficacy based on patterns of failure and complementary non-overlapping toxicities, less intense chemotherapy and less intense radiotherapy may be combined to maximize efficacy while minimizing toxicity. The challenge has been to determine how much radiation can substitute for how much chemotherapy and in what settings. The optimal combination of the elements in CMT will likely vary depending on the stage, likely extent of subclinical disease, bulk, patient-related factors, and response assessment.

Risk- and Response-Adapted Therapy

Fortunately, because our treatments are effective for many NHL and the majority of HL patients, late treatment effects must be considered while maintaining high cure rates [39]. There are many permutations of how chemotherapy and radiation are blended, including the number of drugs, number of cycles, radiation volumes, and doses. We know that we overtreat many patients, but in general, we don't really know which ones. Risk-adapted therapy attempts to predict how much and what kind of therapy each patient needs at the outset. Response-adapted therapy uses information obtained after some therapy has been given to tailor therapy. Historically, risk-adapted therapy has relied on basic predictive clinical and laboratory factors. For example, in most cooperative group trials, patients with HL are grouped into at least three, sometimes four, risk groups based on stage, number of involved sites, bulky disease, age, B symptoms, and/or ESR: unfavorable, intermediate, favorable, and, sometimes, very favorable [40–42]. There is less clarity about the groupings in NHL, but these have focused on stage, bulk, and the varying forms of the International Prognostic Index (IPI). Within these risk categories, decisions about radiation take into account the volume of clinically evident disease and the probability of subclinical disease. Historically, the types of radiation fields varied from total nodal (mantle and "inverted Y" fields), subtotal nodal, extended field, and involved-field radiation. Today "involved node" and "involved site" radiation therapy are currently used, which incorporate pre-chemotherapy imaging, response assessment, and 3D volume-based radiation planning (see below). The use of radiation may be used only in certain scenarios, such as with bulky disease or a limited number of involved nodal sites. For HL, the results of clinical studies support an algorithm to tailor the number of cycles of chemotherapy and the volume of radiation based on risk grouping and site/size of involvement [38]. Response-adapted therapy has gained increasing acceptance, especially in HL. Conceptually, an early test of responsiveness to treatments is likely to be a strong predictor of long-term outcome that will trump other prognostic risk factors. The challenge has been to identify the appropriate early test. Shrinkage of masses on CT scanning has been unsatisfactory, resulting in terms like "Complete Response, Unconfirmed." This is due to the fact that a lymphoma mass is not entirely composed of malignant cells, and even if the mass is sterilized, some enlargement may remain on cross-sectional imaging. Functional imaging with nuclear isotopes may overcome this issue. Although early work with gallium scanning was used to predict results after chemotherapy, FDG-PET is now the standard for response-adapted therapy. The definition of a complete response by the Lymphoma Working Group now includes complete resolution of metabolic uptake by FDG-PET. This definition is justified by convincing data that disappearance of FDG uptake after chemotherapy predicts long-term outcomes [43–45]. In HL, PET response after 2 cycles of ABVD overshadows other prognostic factors [46]. Although FDG-PET is a powerful imaging biomarker in HL, omission of RT in early responders has been shown to be nonequivalent to CMT in two separate large trials. The UK RAPID trial randomized non-bulky HL patients after ABVD × 3 with Deauville 1 and 2 (less than mediastinal blood pool) responses to no further

treatment or IFRT [6]. Designed as a non-inferiority study, omission of RT was "not non-inferior" by both intention to treat and per protocol analyses. Similarly, the EORTC/LYSA H10 trial had to close the non-radiation containing arms in both favorable and unfavorable arms that used a response-adapted design after ABVD × 2 [47]. Ongoing trials are still exploring how best to use this powerful imaging biomarker, despite its inability to predict which patients can avoid consolidative RT in limited-stage HL.

Hodgkin Lymphoma

Today, much is understood about the role of radiotherapy as monotherapy for HL. With the success of treatment of HL in the 1960s and 1970s with radiotherapy alone, long-term follow-up has taught us many lessons about late radiation effects. Over time, multi-agent chemotherapy has become the backbone to cure classic HL. Today, only limited-stage nodular lymphocyte-predominant (non-classic) HL is commonly treated with radiotherapy alone. For classic HL, current research attempts to define the optimal use of radiotherapy in the context of CMT.

Evolution of Field Design and Involved Site Radiotherapy

The International Lymphoma Radiation Oncology Group (ILROG) has recommended that "modern" radiotherapy for lymphoma, termed "involved site radiotherapy" (ISRT), use small volumes without elective nodal radiation with image-based treatment planning customized to each patient's unique anatomy [26–28]. The EORTC/GELA have adapted a stricter protocol-based version of limited volume radiation termed "involved node radiotherapy" (INRT) [48]. This requires that patients have their initial PET/CT scans in the radiotherapy treatment position and that intravenous contrast be used in radiation treatment planning CT scans [49]. The adoption of ISRT and INRT into routine practice did not happen until around 2013 when it was recommended by the NCCN and the ILROG's first guideline to ISRT was available. However, to understand the history of lymphoma treatment and the majority of the published literature, an appreciation for historically used radiation fields is critical. Previously, standardized fields incorporated groups of nodal and extranodal lymphoid areas in modular units largely based on bony landmarks. These standard modules included the Waldeyer ring, neck, axillary, mediastinal, spleen, para-aortic, inguinal-femoral, and pelvic areas. Involved-field radiotherapy (IFRT) used standard field borders to electively treat limited nodal groups surrounding regions of disease [50]. For example, a standard neck field would have been used for a single midjugular node, a single supraclavicular node, or a chain of nodes extending from the base of the skull to the clavicle. Combinations of involvement were covered in specialized fields such as the mantle (neck, axillae, hilae, and mediastinum) or the inverted Y (femoral, inguinal, pelvic, and para-aortic areas). Treatment of additional uninvolved nodal groups contiguous to IFRT borders was called extended-field radiotherapy (EFRT). Subtotal nodal irradiation (STNI) included the mantle, para-aortic, and spleen fields and had been considered standard extended-field therapy for stages I and II supradiaphragmatic HL. Total nodal irradiation also included pelvic irradiation. The majority of these fields were treated with simple field arrangements, namely anterior-posterior/posterior-anterior fields.

With the advent of CT imaging and three-dimensional treatment planning systems, at risk volumes could be better defined and targeted with more complex beam arrangements. It is clear that many treatment failures in the past were related to inadvertent shielding of gross tumor [29, 52]. In radiotherapy for other malignancies, image-based treatment planning customized to each patient's unique anatomy have replaced standardized fields. In HL however, recently published cooperative groups studies still employed standardized IFRT, including the German Hodgkin Study Group (GHSG) HD10, HD11, and HD13 studies. Although the GHSG is testing involved-field (which includes elective nodal RT) versus involved nodal radiation in the HD17 trial, volume-based planning has replaced the use of bony landmarks alone for radiotherapy planning [53]. As mentioned above, the ILROG has already endorsed omission of elective nodal irradiation in the case of chemosensitive disease [26–28]. The combination of targeting much smaller target volumes with highly conformal techniques (IMRT, proton therapy) should lead to dramatically lower radiation-related toxicity in the modern era as demonstrated in Fig. 44.2.

Early-Stage Disease

Prior to the era of multiagent chemotherapy, it was discovered that radiotherapy alone with extensive fields (STNI or total nodal irradiation) could cure early-stage HL in adults 75–80% of the time. However, cure rates could be improved by adding multiagent chemotherapy, such as doxorubicin–bleomycin–vinblastine–dacarbazine (ABVD), to large-field radiation [38, 54]. The evolution of clinical trials for HL demonstrated that CMT with smaller fields was superior to large-field radiation alone, which then lead to the question of whether radiotherapy could be omitted altogether [55]. An NCI Canada/ECOG study stratified 399 patients into favorable or unfavorable groups and randomized them to either ABVD alone (4–6 cycles depending on response) or a regimen containing radiation (favorable group received STNI

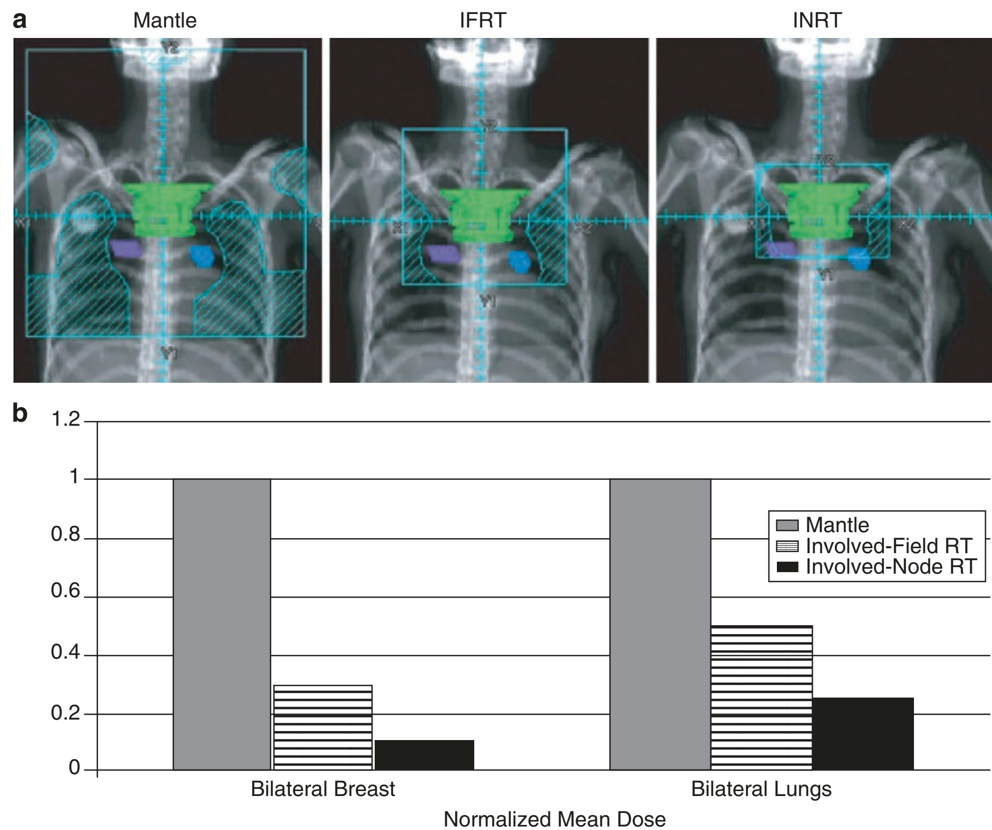

Fig. 44.2 (**a**) Representations of fields for a historic mantle field, IFRT, and INRT (similar to ISRT). Postchemotherapy target volume is shown in *green*, hila are shown in *blue* and *violet*. (**b**) Proportional reduction in breast and lung dose using the three techniques. Reproduced with permission from Hodgson et al. [51]

alone; unfavorable group received two cycles ABVD then STNI) [56]. Freedom-from-disease progression at 12 years was superior in those patients receiving radiation (92% vs. 87%, $p = 0.05$). However, overall survival was worse among those receiving STNI (87% vs. 94% $p = 0.04$), with excess deaths coming from second cancers and other causes in the STNI group. Although the radiotherapy used in this study was well outdated by the time the long-term results were published in 2012, the favorable outcomes in the ABVD only arm have been used as an argument against the need for CMT. The EORTC/GELA H9F trial used a reduced intensity chemotherapy regimen (EBVP × 6 cycles) with no radiation, 20 Gy, or 36 Gy involved-field radiation. The chemotherapy only arm had to be stopped due to excessive relapses [57].

In favorable risk HL patients, fewer cycles of chemotherapy and lower doses of radiation may still achieve disease control. The GHSG HD10 study compared 2 vs. 4 cycles of ABVD and 20 Gy vs. 30 Gy IFRT [58]. There was no significant difference between 4 × ABVD and 2 × ABVD in terms of overall survival at 5 years (97.1%; vs. 96.6%) or freedom from treatment failure (93.0% vs. 91.1%). In terms of radiation dose, there were no significant differences between 30Gy and 20Gy IFRT in terms of overall survival (97.6% vs. 97.5%) or freedom from treatment failure (93.4% vs. 92.9%), which has led to the adoption of ABVD × 2 and 20 Gy as an acceptable option for very favorable patients. Unfortunately, omission of dacarbazine or bleomycin from ABVD × 2 is not equivalent to the full four-drug regimen as shown in the HD13 [59].

In unfavorable risk early-stage patients, the GHSG HD11 study compared 4 cycles of ABVD with 4 cycles of BEACOPP (standard) as well as 20 Gy vs. 30 Gy IFRT [60]. Disease control was equivalent with ABVD with less toxicity and 30 Gy was superior to 20 Gy in the context of ABVD, so ABVD × 4 with 30 Gy became the standard for unfavorable risk early-stage patients.

The Stanford V chemotherapy regimen uses seven drugs (doxorubicin, bleomycin, nitrogen mustard, vinblastine, vincristine, etoposide, and prednisone) given in a dose-dense and intense fashion over a short period of time, supplemented with involved-field radiation therapy to all sites with bulky involvement (tumors at least 5 cm in transverse dimension, macroscopic lesions in the spleen, or massive mediastinal disease) [61]. This regimen uses lower doses of each agent to maximize efficacy with less toxicity. Long-term results in early-stage patients with bulky disease as well as advanced disease are excellent, adding this regimen as alternative to ABVD [62].

In growing children, the doses of radiation traditionally used in HL (30–40 Gy) may result in significant musculoskeletal hypoplasia, therefore, efforts to limit radiotherapy have been intense among the pediatric group. The Pediatric

Oncology Group (POG) compared 6 months of MOPP–ABVD chemotherapy with 4 months of the same chemotherapy and low-dose (25.5 Gy) IFRT therapy in children with stage I-IIIA HL, showing that radiotherapy could substitute for 2 months of chemotherapy [63]. The AHOD0031 study assigned treatment groups based on early response assessment following two cycles of doxorubicin, bleomycin, vincristine, etoposide, cyclophosphamide, and prednisone (ABVE-PC) [64]. "Rapid early responders" who achieved complete response were randomized to 21 Gy of IFRT. Event-free survival at 4 years was not significantly better with IFRT compared to no RT (87.9% vs. 84.3%, $p = 0.11$). In that trial, all "slow early responders" were given 21 Gy IFRT, but they found that those who were PET-positive at response assessment benefited from intensified chemotherapy.

Although rare, nodular lymphocyte-predominant HL should be considered differently from classic HL. It usually presents as limited stage, and in these very favorable patients the risk of extensive subclinical disease may be judged so minimal that treatment aimed at only the clinically evident disease may be warranted [39, 65]. Pediatric patients with IA lymphocyte-predominant HL located in a peripheral site such as the upper neck, axilla, or femoral nodes have frequently been treated with only involved-field radiotherapy [66]. Even very low dose radiation (4 Gy) can even result in durable responses in some patients with nodular lymphocyte-predominant HL, although higher doses (30–36 Gy) are more standard [67]. When using radiation alone, "involved site" radiotherapy for nodular lymphocyte-predominant HL does involve electively treating adjacent lymph node groups (ILROG HL ref).

Stage IIB Bulky and Advanced-Stage Disease

Patients with stage IIB bulky disease have been included with other Stage III/IV patient in clinical trials; however, CMT in IIB bulky HL results in very good outcomes in the modern era [68]. In both Stage IIB bulky and III/IV HL, chemotherapy is the primary effective treatment, but radiotherapy can be more easily incorporated in Stage IIB bulky patient. The role of radiation therapy in patients with Stage III/IV disease is less clear, but may be of use in select patients, namely those with a partial response (PR) after chemotherapy.

The EORTC employed response-adapted scheme patients where stage III/IV patients were treated with MOPP-ABV for 6–8 cycles depending on the response after 4 cycles. If patients had a CR after 4 or 6 cycles, they were randomized to either IFRT to 24 Gy or observation. If they only had a PR after 6 cycles, no further chemotherapy was given and instead IFRT was given in a non-randomized fashion [69]. For the randomized patients with CRs, there was no difference in 5-year event-free or overall survival rates. The non-randomized PR patients who all received IFRT had event-free and overall survival rates similar to the CR randomized arms [70]. Thus, the role of radiation in advanced-stage patients has been primarily limited to those who do not achieve a CR.

Alternate chemotherapy regimens for advanced-stage disease have been studied. For high risk patients with advanced disease, dose escalated BEACOPP appears to have better results as reported in the GHSG HD9 trial, which has led to this being the reference therapy on the subsequent GHSG trials [71]. The HD15 study only used radiation in advanced-stage patients with FDG-avid residual masses >2.5 following BEACOPP [72]. The use of the Stanford V regimen in advanced-stage disease employs radiation to sites of initially bulky disease to 36 Gy [62]. Omission of radiation when using Stanford V results in poorer outcomes, emphasizing the important role of radiation in this abbreviated chemotherapy regimen [73]. In our opinion if the chemotherapy regimen has be altered, resulting in deviation from recommended agents, doses, as schedule, radiation therapy should be considered as additional adjuvant.

Surveillance for Late Effects

It is clear that survivors of HL are at increased risk for cardiovascular disease and second malignancy. The risk of cardiovascular disease appears to be at least partially related to radiation dose, specifically related to the mean heart dose [19, 20, 22, 74]. The rate of second solid malignancies in the HL survivors increases with the interval after irradiation, with the highest risk when treatment occurs at an early age [75]. Breast cancer seems to be most significantly increased in women who received radiation during their early teenage years to higher doses [76]. The use of smaller radiation volumes has resulted in lower risk of second malignancies, however it appears that the increased risk of second cancers is intrinsic to the diagnosis of HL, regardless of the era of diagnosis [77, 78]. More conformal techniques, such as proton therapy for female patients with mediastinal disease, may lower the risk of second cancers [79]. Breast cancer screening with mammography alone may not be sufficient to detect breast cancer in female HL survivors, and breast MRI will likely play an important role in close surveillance [80]. Lung cancer is also a common problem in HL survivors who are smokers; it is rare in nonsmokers, therefore smoking cessation counseling is crucial [81]. The coordination of surveillance for cardiac disease, second malignancies, and endocrine abnormalities requires ongoing follow-up in HL survivors who may benefit from comprehensive survivorship care plans [82].

Non-Hodgkin's Lymphoma

The natural history of NHL has been more difficult to understand than that of HL, making various therapeutic approaches hard to evaluate. Part of the difficulty has been to categorize the spectrum of diseases falling under the rubric of NHL. It is useful for clinical purposes to consider the management of the NHLs in three categories: the low-grade, the intermediate-grade, and the high-grade lymphomas. Because the large majority of NHLs are B-cell lymphomas carrying the CD20 marker, the advent of rituximab has probably been the single most important advance in treating all stages of disease [83]. Radioactive isotopes bound to anti-CD20 monoclonal antibodies have produced excellent tumor responses [84].

Low-Grade Lymphomas

Stages I and II

In the advanced-stage low-grade lymphomas, there has been no convincing evidence of cure with multiagent chemotherapy [85, 86]. Radiation therapy, however, in early-stage low-grade lymphomas has resulted in approximately 50% freedom from relapse and survival rates at 10 years in clinically staged patients [87]. Although this cure rate is probably even better with modern staging, only a minority of patients stage I, low-grade lymphoma are initially treated with radiotherapy [88, 89]. Contrary to National Comprehensive Cancer Network treatment guidelines, patients are often only observed or given rituximab [88]. Relatively modest doses (24 Gy) are considered optimal for limited-stage low-grade lymphomas based on randomized data, so toxicity is low, even when sensitive regions need treatment, like the abdomen/pelvis [90]. The majority of relapses after regional radiation are out of the radiation field, usually in other nodal or lymphoid sites, depending on histologic subtype [91]. The addition of chemotherapy (and in particular immunochemotherapy) to radiotherapy has a DFS benefit but no overall survival benefit [92].

Advanced Stage

In stage III low-grade lymphomas with limited involvement, 40–50% of patients appear to be free from disease at 10 years after comprehensive lymphatic irradiation [93–95]. Concerns for long-term toxicity, however, has resulted in the use of systemic chemotherapy in this group of patients instead, in particular single agent rituximab as first line therapy. A promising but rarely used initial treatment of advanced stage of follicular lymphoma is radioimmunotherapy [96]. Unlike other treatments for advanced-stage low-grade lymphoma, radioimmunotherapy may have a tail on the survival curve [97]. In addition to producing long-term disease-free intervals in patients with stage I, II, or "early" stage III disease, radiation therapy also has value as a palliative agent. Very low dose radiation (4 Gy) provides frequent and sometimes durable palliation with minimal toxicity [98, 99].

Intermediate-Grade Lymphoma

The role of radiation in intermediate-grade NHL in adults has been studied by several prospective randomized trials. The Eastern Cooperative Oncology Group (ECOG) randomized patients who had a complete response after eight cycles of cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) chemotherapy to no further therapy or involved-field radiation to 30 Gy [100]. Patients with a PR received involved-field radiotherapy to 40 Gy. There was a significant improvement in rates of both disease-free survival and local control with the addition of radiation therapy in the complete responders, but no survival difference. Patients who received irradiation after PRs had disease-free and overall survival rates similar to those of the complete responders who did not receive irradiation. During the same time interval SWOG compared three cycles of CHOP chemotherapy and involved-field radiotherapy with eight cycles of CHOP chemotherapy [16]. At the initial report, progression-free survival rates were similar for the two treatment arms, but the survival rate was better in the radiation therapy arm because of excess cardiac mortality attributed to the additional cycles of chemotherapy [101]. When updated, the 7-year failure-free survival curves and the 9-year overall survival curves overlapped. Excess late relapses and deaths in CHOP × 3-RT arm appeared to have negated the initial benefit, but this occurred more frequently in patients with adverse risk factors. In favorable risk patients, CHOP × 3 + RT remains a standard treatment for Stage I and non-bulky Stage II. In the GELA LNH93–1 trial, patients <61 years with localized Stage I or II aggressive lymphoma with no age-adjusted IPI adverse features were randomized to: (1) CHOP × 3 + involved-field RT to 39.6 Gy or (2) chemotherapy alone with dose-intensified doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone (ACVBP) plus sequential chemotherapy consolidation (MTX, leucovorin, etoposide, ifosfamide, Ara-C) [102]. At 5-years the ACVBP arm had improved event-free survival (82% vs. 74%) and overall survival (90% vs. 81%). This study demonstrated that very intensive chemotherapy may improve outcomes in younger patients, although that particular regimen is rarely used. The RICOVER-60 trial has shown in a non-randomized but prospective trial that the use of consolidative radiotherapy in

patients with initially bulky disease (≥7.5 cm) is associated with improved survival [103]. The currently unpublished UNFOLDER trial enrolled bulky patients with the same size criteria, but had to prematurely halt non-radiation containing arms due to excessive events, hinting at the importance of radiotherapy in DLBCL patients with bulky disease. Other indications for consolidative radiation after full-course chemotherapy include partial responders and those with skeletal involvement [104].

Amplification of c-MYC along with either BCL-2 or BCL-6, so-called double hit DLBCL have a much worse prognosis, but it is unclear if the resistance to R-CHOP chemotherapy also extends to radio-resistance. This is an emerging area of interest, but we have leaned towards using higher radiotherapy doses in these patients when safe.

High-Grade Lymphoma

Presently, there are no convincing survival data that CMT is beneficial in Burkitt or lymphoblastic NHL, despite frequently (but often transient) responses. If radiotherapy is to be used for these uncommon lymphomas, it is probably best to use twice daily radiation since the cells have an especially high growth fraction and a very short cell cycle. This will allow exploitation between fractions notably of repopulation but also cell redistribution with the cell cycle.

Summary

Radiation is an effective tool in both HL and NHL. In HL, its optimal role may be in CMT regimens except at the most favorable end of the prognostic spectrum, where it may be used as monotherapy. Problems with quality assurance in the past have confounded our understanding of optimal radiation doses and treatment volumes as well as the potential value of radiation either as monotherapy or as an integral part of CMT regimens. Developments in imaging and treatment planning with the advent of involved node and involved site radiotherapy should decrease the toxicity of radiation therapy in the future. The role of radiation therapy in CMT regimens for early-stage intermediate-grade lymphomas is well established, but questions remain regarding optimal dose and treatment volume and the potential value of radiation therapy in more advanced disease. In low-grade lymphoma, radiation therapy currently appears to hold the greatest promise for durable, perhaps permanent, disease control, with appropriate radiation treatment volumes. Imaging biomarkers, namely FDG-PET/CT has dramatically impacted the use of radiotherapy for lymphomas, allowing for smaller more targeted fields as well as informing who will most benefit from localized treatment.

45 Diagnosis and Treatment of Non-Hodgkin's Lymphoma of Adults

David G. Crockett, James O. Armitage, and Julie M. Vose

Introduction

The non-Hodgkin's lymphomas (NHL) represent a diverse group of neoplasms with many different clinical presentations, associated laboratory abnormalities, responsiveness to treatment, and clinical outcome. The cell of origin and stage of maturation arrest prior to uncontrolled proliferation are important to the understanding of this diversity (Table 45.1). In the USA, the incidence of NHL steadily increases from childhood through age 80 years; unlike Hodgkin's disease, no peak incidence exists for young adults. NHL is the seventh most common malignancy in men and women, respectively, and is among the most rapidly increasing malignancies [1]. They represent the seventh most common cause of death from cancer in the USA, with the age-adjusted incidence being about three times that of Hodgkin's disease [1]. The incidence of non-Hodgkin's lymphoma is twice as frequent among whites as blacks, and there is an almost 50% increase in presentation in males compared with females. The reason for this gender and race predominance is unknown; however, it may reflect a different pattern of occupational exposure or a difference in the immune status of males compared with females. Links among agricultural work (organochlorine-based pesticides), wood products, and organic solvents have been established [2].

According to Surveillance Epidemiology and End Results (SEER) data, the incidence rose approximately 3–4% per year in the 1970s and 1980s and has stabilized at 1–2% per year growth with the greatest rise observed for diffuse large B-cell lymphoma (DLBCL) in the elderly [3]. The exact reasons for these increases are currently unclear; however, there are accepted associations. Immune suppression and stimulation are important cofactors for the development of NHL [4–6], and these may be in the form of inflammatory, infectious, or neoplastic etiologies. Immunodeficiency predisposes to the increased incidence of Epstein–Barr virus (EBV)-associated NHL. Equally important is the potential role of chronic immune stimulation in autoimmune diseases such as rheumatoid arthritis or Sjögren's syndrome [7, 8]. Secondary immune suppression associated with treatment of autoimmune diseases may also contribute to pathogenesis of NHL; however, this is difficult to separate from the immune stimulation from the underlying autoimmune disease.

Other relationships exist for *H. pylori* and mucosa-associated lymphoid tissue (MALT) lymphoma, hepatitis C and splenic lymphoma, or Borrelia infection and cutaneous MALT lymphoma [9, 10]. Viruses integrate into the genome to alter gene expression or proliferation and may function as cofactors in the development of NHL. EBV has a direct role in immunocompromised patients due to HIV, posttransplant lymphoproliferative disease, and Burkitt's lymphoma (BL) [11, 12]. Human T-cell leukemia/lymphoma virus-1 (HTLV-1) has a direct causative role in adult T-cell leukemia/lymphoma, with a 5% lifetime risk in carriers. Human herpes virus 8 (HHV-8) has been associated with primary effusion lymphoma [13].

More than three decades of discoveries in the areas of immunology, histochemistry, and molecular biology have advanced our understanding of these complex diseases. NHL is characterized by a monoclonal expansion of lymphoid cells, excluding the primitive precursors that yield acute lymphoblastic leukemia and plasma cells that yield multiple myeloma. The malignant cell for most lymphomas can be traced to a specific stage in lymphoid maturation; NHL most commonly derives from mature B cells of germinal center origin, but may also include T cells or NK cells. With the advent of modern therapy based on these new data, patients with non-Hodgkin's lymphoma can now frequently be treated successfully to alter the natural history of the disease. This chapter outlines the clinical presentations,

Table 45.1 Non-Hodgkin lymphoma histologic types

Lymphoma type	Relative incidence	Histopathology	Cell markers
Precursor T-cell leukemia/ lymphoma	40% of lymphomas in childhood	Lymphoblasts with irregular nuclear contours, condensed chromatin, small nucleoli, and scent cytoplasm without granules	TdT, CD2, CD7
Follicular lymphoma	40% of lymphomas in adults	Small "cleaved" cells (centrocytes) mixed with large activated cells (centroblasts). Usually nodular ("follicular") growth pattern	CD10, surface Ig
Diffuse large B-cell lymphoma	40–50% of lymphomas in adults	Variable. Most resemble B cells of large germinal centers. Diffuse growth pattern	CD10 and surface Ig
Mantle cell lymphoma	3–4% of lymphomas in adults	Lymphocytes of small to intermediate size growing in diffuse pattern	CD6
B-cell chronic lymphocytic leukemia/lymphoma	3–4% of lymphomas in adults	Small resting lymphocytes mixed with variable number of large activated cells. Lymph nodes are diffusely effaced	CD6, surface immunoglobulin
MALT lymphoma	~5% of lymphomas in adults	Variable cell size and differentiation. 40% show plasma cell differentiation. Homing of B cells to epithelium creates lymphoepithelial lesions	CD5, CD10, surface Ig
Burkitt's lymphoma	<1% of lymphomas in the USA	Round lymphoid cells of intermediate size with several nucleoli. Starry-sky appearance by diffuse spread with interspersed apoptosis	CD10, surface Ig
Mycosis fungoides	Most common cutaneous lymphoid malignancy	Usually small lymphoid cells with convoluted nuclei that often infiltrate the epidermis, creating Pautrier micro-abscesses	CD4
Peripheral T-cell lymphoma not-otherwise-specified	Most common T-cell lymphoma	Variable. Usually a mix of small to large lymphoid cells with irregular nuclear contours	CD3
Nodular sclerosis form of Hodgkin's lymphoma	Most common type of Hodgkin's lymphoma	Reed–Sternberg cell variants and inflammation. Usually broad sclerotic bands that consist of collagen	CD15, CD30
Mixed-cellularity subtype of Hodgkin lymphoma	Second most common form of Hodgkin's lymphoma	Many classic Reed–Sternberg cells and inflammation	CD15, CD30

diagnostic and staging evaluations, prognostic factors, and therapeutic considerations for the various types of non-Hodgkin's lymphomas.

Clinical Presentation

The clinical presentation of NHL is tremendously variable and may masquerade as any known signs or symptoms. Most patients with NHL come to medical attention because of adenopathy or constitutional symptoms; however, other problems such as abdominal fullness caused by splenomegaly, pain in involved sites of disease, anemia, infection, skin manifestations, neurologic symptoms, or systemic symptoms such as fever, night sweats, or weight loss can occasionally be the first signs of disease. These constitutional manifestations are usually the result of cytokines and chemokines that are produced by the lymphoma cells as well as the host microenvironment. The childhood NHL often differ in presentation from their adult counterparts. Childhood lymphomas have a propensity for early widespread dissemination with more frequent central nervous system (CNS) and peripheral blood dissemination. Follicular lymphomas are very rare in children, and while most childhood lymphomas are B cell in origin, there are an increased number of T-cell cases compared with adults.

The clinical features of untreated patients are often typical for the individual histologic subtype of NHL. For example, patients with follicular lymphomas most often present with painless adenopathy in the cervical, axillary, or inguinal regions. In some patients, large retroperitoneal or mesenteric lymph nodes result in symptoms that bring the patient to a physician. Even though the patient may appreciate only one or a few enlarged lymph nodes, examination and evaluation often reveal widespread lymphadenopathy. The nodes may have been present for years with either fluctuation in size or gradual enlargement. Patients with follicular lymphomas often have splenomegaly, which is especially prevalent in the later stages of the disease. Bone marrow involvement is present more frequently in nodular lymphomas than in diffuse non-Hodgkin's lymphomas. For example, one study showed a 24% incidence of bone marrow involvement with follicular lymphomas compared with a 14% involvement with diffuse lymphomas [14]. Other studies have shown up to a 50% incidence of bone marrow involvement in follicular lymphomas [15]. Occasionally patients with bone marrow involvement will also present with peripheral blood involvement; however, this more frequently occurs with progressive or relapsed disease [16].

Diffuse non-Hodgkin's lymphomas are extremely variable and no single clinical description can adequately describe them. Small lymphocytic non-Hodgkin's lymphoma

is characterized by either focal or generalized lymphadenopathy and often splenomegaly. The disease is the tissue manifestation of the same monoclonal proliferation of the B lymphocyte that is associated with chronic lymphocytic leukemia (CLL). This disease, like CLL, most often occurs after the fifth decade and tends to be slowly progressive. The bone marrow is usually involved with this type of lymphoma, with occasional occurrences of a monoclonal gammopathy or hypogammaglobulinemia.

The most common diffuse lymphoma subtype, diffuse large B-cell lymphoma (DLBCL), often occurs as a relatively localized but rapidly progressive disease. Patients with DLBCL often present with disease in the lymph nodes; however, this subtype can occur in non-lymphatic tissues. For example, occurrences in the gastrointestinal tract, testes, thyroid, skin, breast, CNS, or bone are more frequently seen in diffuse histologies than in nodular non-Hodgkin's lymphoma [17–21]. Occurrence of non-Hodgkin's lymphoma in Waldeyer's ring is associated with an approximate 20% risk of simultaneous or subsequent involvement of the gastrointestinal tract in other sites [22].

Because of this association, when patients present with involvement in Waldeyer's ring, a complete evaluation of the small and large bowel should be included in their initial evaluation. Bone marrow involvement with DLBCL at presentation is unusual, with only 10% of the cases being positive. Diffuse infiltration of visceral organs by the aggressive diffuse lymphomas is very rare at presentation; however, relapsed or progressive lymphoma can cause these manifestations. Invasiveness of the aggressive diffuse lymphomas can result in peripheral nerve compression, spinal cord compression, great vessel or airway compression, or painful osseous lesions.

Lymphoblastic lymphoma is histologically and cytologically similar to acute lymphocytic leukemia and is most commonly seen in older children and young adults. Approximately 50% of patients present with mediastinal lymphadenopathy, and a higher percentage are males. Although the disease may appear to be localized at the time of diagnosis, there is usually rapid dissemination to the bone marrow, peripheral blood, and meninges [23]. Burkitt's non-Hodgkin's lymphoma, originally described in endemic Africa, usually presents with large extranodal tumors involving the bones of the jaw and abdominal tumors [24]. In contrast, sporadic cases in the USA most often present with abdominal tumors, with subsequent bone marrow and CNS involvement as the disease progresses [25].

Diagnosis

Because every enlarged lymph node does not necessarily represent NHL, histologic diagnosis is the most important first step toward initiating proper care of the patient. Palpable lymphadenopathy can be found in normal patients; however, the size is normally less than 1 cm. Lymphadenopathy could be associated with several benign conditions such as infectious mononucleosis, syphilis, cytomegalovirus, autoimmune disorders, granulomatous diseases, or drug hypersensitivities such as that seen with phenytoin. Since many patients with NHL are in the younger age range, infectious mononucleosis should be considered before a lymph node biopsy. A lymph node biopsy specimen from this condition is sometimes difficult to distinguish from NHL [26]. Patients with lymphomatoid granulomatosis have a 12% incidence of developing overt lymphoma [27]. Many other malignant conditions such as metastatic carcinomas, germ cell neoplasms, or melanomas can also present with lymphadenopathy. Young male patients with malignant axillary lymph node enlargement are most likely to have a lymphoma or a malignant melanoma. In women, the same two tumors as well as breast carcinoma would be the most likely diagnosis.

An adequate biopsy is essential for diagnosis, and an excisional biopsy should be performed. The largest or most rapidly enlarging node may be chosen because it may reveal the most aggressive histology and provide the most tissue. Fine-needle aspiration is usually not adequate for initial diagnosis but may be used to confirm relapse. Every patient with NHL does not always present with peripheral lymphadenopathy that is easily biopsied, and other procedures may be required for diagnosis, but must be approached with caution. Other sites of presentation that may require biopsy for diagnosis include skin, gastrointestinal tract, breast, or testes. Visceral presentation such as hepatic, splenic, or pulmonary involvement may occasionally require an open biopsy for diagnosis. Also, retroperitoneal, mesenteric, or pelvic disease may require a diagnostic laparotomy for diagnosis confirmation. Unexplained neutropenia, anemia, a leukoerythroblastic picture, or thrombocytopenia necessitates a bone marrow biopsy that usually diagnoses marrow involvement with NHL. Patients at risk of CNS involvement should undergo lumbar puncture with evaluation of cerebrospinal fluid by cytology and flow cytometry [28]. Burkitt's lymphoma and extranodal DLBCL are associated with increased risk of CNS disease and should also undergo lumbar puncture during initial diagnostic testing [29]. Furthermore, many treatment regimens contain chemotherapy CNS prophylaxis for these high-grade lymphomas with increased risk of CNS disease. The storage of fresh-frozen or paraffin embedded tissue is highly encouraged for future diagnostic tests based on molecular profiling.

When a lymphoma is suspected clinically, the pathologist should be notified so that special processing procedures can be used if they are available, including cytogenetics, surface markers, immunohistochemistry stains, and molecular biologic studies, in addition to routine histology. These

additional studies can add valuable information to the cases that are difficult to identify on routine testing and provide insight into the aggressiveness of the subtype. Patients with an undifferentiated neoplasm by routine histology can have a NHL in a small percentage of cases. Because this is one of the more treatable causes of what appears to be an undifferentiated neoplasm, special stains should be an important part of the evaluation of a specimen with this initial diagnosis. The accuracy and reproducibility of pathologists in the diagnosis of NHL are essential for the care and treatment of patients. Even the expert pathologists who developed the Working Formulation were able to reproduce their initial diagnosis on re-reviewing a slide only 53–93% of the time [30].

Evaluation and Staging Procedures

A thorough history and a physical examination are important for optimal management. Patients should be questioned about systemic symptoms, and performance status should be assessed. Further questions should be directed to potential causative factors, such as prior malignancy, chemotherapy, or radiation treatment, autoimmune or immunodeficiency diseases. This includes a detailed history for exposure to HIV, hepatitis C, and HTLV-1. No NHL patients should be managed without a comprehensive physical examination, with detailed attention to lymph nodes, liver, and spleen (Table 45.2).

Once a histologic diagnosis of NHL has been confirmed by biopsy, various staging procedures must be done to direct the therapy as well as to provide for prognostic information for the patient. The histologic subtype and the condition of the patient direct the type and speed of staging procedures. For example, a patient with an aggressive NHL that is rapidly progressive requires prompt staging procedures that are the minimum required before the initiation of therapy. On the other hand, indolent non-Hodgkin's lymphoma can be staged at the convenience of the patient and physician. Treatment decisions can then be made with all the knowledge from the staging procedures available for discussion.

Baseline studies that should be obtained in most patients include complete history and physical examination; blood testing including complete blood count, platelet count, liver chemistries, lactate dehydrogenase (LDH), calcium, and renal function studies; computed tomography (CT) of the chest, abdomen, pelvis; PET scan; and bone marrow biopsy. Additional studies that may be appropriate in certain circumstances include cytologic examination of any effusion present (i.e., pleural or pericardial effusions or ascitic fluid) and viral serologies for hepatitis C, HIV, or HTLV-1. EBV viral loads can be useful in nasal NK/T-cell lymphomas or post-transplant lymphoproliferative disorders (PTLD) [31, 32]. A thorough evaluation of the gastrointestinal tract should be pursued if any symptoms are present or if the primary presentation of lymphoma was in Waldeyer's ring.

The clinical presentation and sites of disease usually dictate the need for further diagnostic testing. CT or magnetic resonance imaging (MRI) of the brain or spinal cord should be performed if any signs or symptoms of CNS lymphoma or high-grade lymphomas such as Burkitt's lymphoma or extranodal DLBCL are present. 18-Fluoro-2-deoxyglucose (FDG)-positron emission tomography (PET) provides sensitive functional imaging for lymphomas for initial assessment and end of treatment response. For example, 98–100% of follicular, mantle cell, and DLBCL NHL are detectable by

Table 45.2 Staging evaluation of lymphomas

Evaluation	Mandatory	As indicated
Confirm diagnosis	Adequate biopsy reviewed by experienced hematopathologists	Immunophenotyping
		Cytogenesis
		Molecular studies
General overview	Careful history and physical examination	Blood coagulation studies
	Complete blood count (including platelet count)	Serum and viral protein studies
	Chemistry screen (including liver and renal function studies)	Serum electrolytes, uric acid, Hepatitis B testing
Prognostic categorization	Serum LDH	Erythrocyte sedimentation rate
	Serum albumin	Serum β_2-microglobulin
		Tumor growth fraction
		Microarray analysis
Anatomic disease	Whole-body CT scans	Ultrasonography
		Magnetic resonance imaging
		FDG-PET scans
		Upper/lower GI scope
Occult sites of involvement	Bone marrow biopsy	Lumbar puncture with flow cytometry
		Biopsy of suspicious sites
		Blood flow cytometry
		Blood and bone marrow PCR

FDG-PET [33]. Although a few studies has shown the prognostic value of FDG-PET to predict early relapse, there does not appear to be convincing literature to support the use of surveillance imaging, including FDG-PET, CT, or MRI [34]. After therapy has been initiated, and at appropriate intervals, previously positive tests should be repeated for evaluation of the effectiveness of the therapy.

The results of these tests are utilized for designation of the proper staging classification for the patient. Patients are classified according to the Ann Arbor staging system, which was originally developed for Hodgkin's lymphoma [35]. The histologic subtype, presence or absence of B symptoms, and the classical Ann Arbor stage are important for initial evaluation and stratification of the patient for appropriate treatment. However, the heterogeneity and hematogenous pattern of dissemination in NHL causes the staging system to have more limited value when compared to the contiguous lymphoma node spread with Hodgkin's lymphoma. Consequently, important modifications to the Ann Arbor staging system were made at the Cotswold Conference, thereby making it more applicable to NHL [36]. The Cotswold modification includes a framework to measure the number of anatomic sites, the "bulk" of the disease, and the type or number of extranodal sites (Table 45.3).

Table 45.3 Cotswold staging of lymphomas

Stage	Features
I	Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, and Waldeyer's ring)
II	Involvement of two or more lymph node regions on the same side of the diaphragm
III	Involvement of lymph regions or structures on both sides of the diaphragm
IV	Involvement of extranodal site(s) beyond that designated E
For all stages	
A	No symptoms
B	Fever (>38 °C), drenching sweats, and weight loss (10% body weight over 6 months)
For stages I–III	
E	Involvement of a single extranodal site contiguous or proximal to known nodal site
Cotswold modifications	
(i)	Suffix to designate bulky disease as more than one-third widening of the mediastinum or >10 cm maximum dimension of nodal mass
(ii)	The number of anatomic regions involved should be indicated by a subscript (e.g., II3)
(iii)	Stage III may be subdivided into:
	III1, with or without splenic, hilar, celiac, or portal nodes
	III2, with para-aortic, iliac, or mesenteric nodes
(iv)	Staging should be identified as clinical stage or pathologic stage
(v)	A new category of response to therapy, unconfirmed/uncertain complete remission should be introduced because of the persistent radiologic abnormalities of uncertain significance

Prognostic Factors

Histopathology

Many histologic classifications have been formulated, in an attempt to classify the NHL into prognostic categories [37–40]. Histologic classification schemes have been developed to organize lymphomas into groups with shared pathogenesis and clinical behavior with an aim to guide treatment. The Kiel classification (accepted in Europe) incorporated information of the cell of origin, while the Working Formulation (accepted in North America) provided clinical grouping and pathologic divisions that were largely based on cell size (small vs. large), cell shape (round vs. not round), and growth pattern (follicular vs. diffuse) [38, 39]. The Working Formulation was a further attempt to create an easily applied classification that would help to improve the prognostic significance of the histologic diagnosis, which included low-, intermediate-, and high-grade categories [39]. Over the years, these classifications have evolved from exclusively morphologic classifications to those that incorporate immunophenotype and molecular genetic information. The Revised European-American Classification of Lymphoid Neoplasms (REAL) offered a histopathologic classification containing some entities felt to represent specific clinical-pathologic cases that may behave in a specific clinical manner [40]. The evolution of the various classification systems is the result of how the molecular genetic information has been applied to understand the molecular pathogenesis of lymphoma, by way of the identification of hallmark genetic abnormalities. This has ultimately culminated in the World Health Organization Classification of Neoplastic Diseases of Hematopoietic and Lymphoid Tissues [40], which is now the most widely accepted classification system (Table 45.4). A revised 4th edition without any new definite entities was released in 2016. This update attempts to incorporate new diagnostic, prognostic, and therapeutic implications of research over the 8-year gap since the last WHO classification was released [41].

Histologic transformation from a low-grade to a high-grade NHL is associated with more aggressive behavior of the lymphoma and a poor prognosis. Histologic transformation occurs in approximately 5–40% of follicular or small lymphocytic lymphomas, usually many years after the original diagnosis [42, 43]. The transformation of small lymphocytic lymphoma to DLBCL was originally described many years ago and given the name Richter's syndrome [44]. This transformation occurs in approximately 30% of these patients; however, a larger proportion of patients undergo a gradual acceleration in the clinical course of their disease over time. In general, DLBCL comprises multiple disease entities as suggested by its variable clinical presentation, natural history, morphologic variants, and molecular

Table 45.4 WHO classification of lymphomas

Mature B-cell neoplasms
• Chronic lymphocytic leukemia/small lymphocytic lymphoma
• B-cell prolymphocytic leukemia
• Lymphoplasmacytic lymphoma (such as Waldenström's macroglobulinemia)
• Splenic marginal zone lymphoma
• Hairy cell leukemia
• Plasma cell neoplasms
– Plasma cell myeloma
– Plasmacytoma
– Monoclonal immunoglobulin deposition diseases
– Heavy chain diseases
• Extranodal marginal zone B-cell lymphoma, also called MALT lymphoma
• Nodal marginal zone B-cell lymphoma (NMZL)
• Follicular lymphoma
• Primary cutaneous follicle center lymphoma
• Mantle cell lymphoma
• Diffuse large B-cell lymphoma, NOS
– Germinal center B-cell type
– Activated B-cell type
• Primary mediastinal (thymic) large B-cell lymphoma
• Primary DLBCL of the central nervous system
• Intravascular large B-cell lymphoma
• Primary cutaneous DLBCL, leg type
• ALK+ large B-cell lymphoma
• Plasmablastic lymphoma
• Intravascular large B-cell lymphoma
• Primary effusion lymphoma
• Burkitt's lymphoma
• B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical Hodgkin lymphoma
• Posttransplant lymphoproliferative disorders (PTLD)
Mature T-cell and natural killer (NK) cell neoplasms
• T-cell prolymphocytic leukemia
• T-cell large granular lymphocytic leukemia
• Aggressive NK cell leukemia
• Adult T-cell leukemia/lymphoma
• Extranodal NK/T-cell lymphoma, nasal type
• Enteropathy-type T-cell lymphoma
• Hepatosplenic T-cell lymphoma
• Subcutaneous panniculitis-like T-cell lymphoma
• Blastic NK cell lymphoma
• Mycosis fungoides/Sezary syndrome
• Primary cutaneous CD30-positive T-cell lymphoproliferative disorders
– Primary cutaneous anaplastic large cell lymphoma
– Lymphomatoid papulosis
– Primary cutaneous gamma-delta T-cell lymphoma
– Primary cutaneous CD8+ aggressive epidermotropic cytotoxic T-cell lymphoma
• Angioimmunoblastic T-cell lymphoma
• Follicular T-cell lymphoma
• Peripheral T-cell lymphoma, NOS
• Anaplastic large cell lymphoma (ALK+, ALK-)

characteristics [45]. The diverse morphologic variants include germinal center B-cell type, activated B-cell type, and EBV+ DLBCL, NOS have some known molecular correlates and are beginning to be recognized as distinct diseases. Other DLBCL subtypes such as primary mediastinal B-cell lymphoma (PMBL), primary cutaneous leg-type, T-cell/histiocyte-rich, primary DLBCL of the central nervous system, and intravascular large B-cell lymphoma have been identified as distinct subtypes of DLBCL for longer based on a combination of clinical, histologic, and molecular findings [40]. It is also important to recognize that large cell "transformation" of an indolent B-cell lymphoma/leukemia, a relatively common occurrence, involves pathways of lymphomagenesis that are distinct from those of de novo DLBCL, but share similar histologic, immunophenotypic, and oncogenetic characteristics [45].

Sites of Disease

Most NHL occur within lymph nodes; however, several extranodal presentations are seen with some frequency. Primary CNS lymphomas were previously rarely reported. However, with the acquired immunodeficiency syndrome (AIDS) epidemic, many more primary CNS lymphomas have been noted [46]. Most non-AIDS-associated primary CNS lymphomas are small non-cleaved lymphoblastic, and DLBCL lymphomas. Many of the series in the literature are older and involve the delivery of less than optimal therapy. However, with newer techniques, approximately one-fourth of the patients have prolonged disease-free survival [47, 48]. Patients with the AIDS-associated primary CNS NHL have had a much poorer median survival of 3 months [49]. Another extranodal area that may be involved with NHL is the testes. The histology is most frequently DLBCL and most patients are elderly. In most previous series, patients treated with orchiectomy alone relapsed with disseminated disease in a few months [50]. More recent series have improved results utilizing combined modality of chemotherapy including intrathecal prophylaxis and contralateral testes radiation [51]. Considering the gastrointestinal tract as a whole, primary lymphoma of the gastrointestinal tract is the most common extranodal site. As noted previously, involvement of Waldeyer's ring correlates with an increased risk of gastrointestinal lymphoma up to a 20% incidence. The most frequent gastrointestinal location for lymphoma is gastric, followed by small intestine, ileocecal area, and large intestine [52]. NHL of the gastrointestinal tract has been associated with nontropical sprue [53] and systemic sclerosis [54]. Because of their location, some gastrointestinal lymphomas must be treated with local surgical excision before initiation of chemotherapy or radiation therapy, especially extensive small or large intestine lesions. Gastric lymphomas can occasionally be treated with chemotherapy without the necessity of prior gastrectomy.

Age

Age has been found to be a prognostic factor in several studies [55]; however, several other studies have not confirmed this fact. When age groups have been stratified for causes of death other than lymphoma, one study found no difference in the adjusted survival of older patients [56]. However, older patients often have more difficulty with chemotherapy side effects and may have increased morbidity due to drug-related toxicity [57]. Several studies report a diminished complete response rate in the elderly patients; however, it is not clear whether this is due to lower drug doses administered or other factors [58]. In most large unselected series, the median age of the patients is usually in the early to mid-sixties. However, patients in many chemotherapeutic trials have a median age of 45–55 years. With this age difference in clinical trials, comparisons are difficult between the various aggressive regimens. Further evaluation of these regimens in unselected patient populations may lead to different results in older patient populations.

Tumor Bulk

Several studies have now identified larger tumor bulk as an adverse prognostic factor [59]. Tumor bulk is defined in different studies from 5 to 10 cm. The complete remission rate and the relapse rate have been found to be inferior in patients with large tumor bulk. In patients with stage I and II disease who were treated with radiation therapy only, one study found that those with a tumor size less than 3 cm in diameter had a 5% local recurrence rate compared with an 18% local recurrence rate with tumors 3 cm or more in diameter [60].

Laboratory Analysis

Elevated serum LDH has also been associated with a poor prognosis in a number of analyses [61]. A number of analyses performed on the lymphoma tissue itself have recently been shown to be helpful in predicting outcome with therapy. The immunophenotype is now fundamental for the accurate classification of lymphoma, with most of B-cell origin. Immunophenotyping studies have shown in a number of studies that a T-cell immunophenotype is an adverse prognostic factor [62, 63], although a few other studies have not confirmed this fact [64].

Indicators of rapid proliferation such as Ki-67 and DNA proliferative index have also been analyzed for their relationship to prognosis. Investigators at Arizona evaluated 105 patients with DLBCL utilizing the anti-Ki-67 monoclonal antibody. In their analysis, 19 patients with Ki-67 levels higher than 60% had a median survival of 8 months compared with a median survival of 39 months for the 86 patients with Ki-67 levels of 60% or less [65]. Proliferative activity and DNA aneuploidy as identified by flow cytometry have also been evaluated for use as predictive indicators of prognosis in patients with DLBCL. One study of 50 newly diagnosed patients found that high proliferative activity was the single most important pretreatment adverse prognostic factor in these patients. In that study, DNA aneuploidy was detected in 62% of cases; however, it did not seem to have any prognostic significance.

Molecular genetics have advanced the understanding of lymphomagenesis by the identification of relevant genes that are important in proliferation, differentiation, and death. The application of this technology has further provided vital insights into the unique molecular signatures of distinct types of B-cell malignancies, thereby relating lymphomas to normal stages in B-cell development and physiology [66, 67]. The molecular consequences include oncogene activation or loss of tumor suppressor genes caused by a variety of chromosomal lesions, including translocation, deletion, or mutation. Most of these genetic lesions are currently associative, since the downstream effect of these abnormalities is not well understood. Regardless, this molecular understanding has provided new ways to classify and predict clinical outcome, which is certainly the pathway to targeted and individualized therapy for NHL.

The identification of nonrandom chromosomal abnormalities in patients with NHL has been described in multiple studies [68–71]. Certain chromosomal abnormalities can be associated with specific histologic subtypes of lymphoma such as t(14;18)(q32;q21) in follicular lymphomas [70], t(11;14)(q13;q32) in mantle cell lymphoma (MCL) [71], and t(8;14)(q24;q32) in Burkitt's lymphoma [69]; structural abnormalities such as the deletion of 6q can be associated with NHL as well [72]. Other chromosomal changes are outlined in Table 45.5. The genetic hallmark of follicular lymphoma, t(14;18)(q32;q21), leads to the rearrangement and overexpression of the bcl-2 gene and is present in up to 90% of cases. Inhibition of apoptosis by bcl-2 plays an important role in lymphomagenesis [72]. Interestingly, bcl-2 overexpression is turned off in follicular lymphoma cells that have undergone aggressive transformation.

The common molecular abnormality of DLBCL involves deregulation of bcl-6, with 35% of cases illustrating an abnormality in the 3q27 region [73]. Bcl-6 is a transcription factor that is important in the normal functioning of the germinal center B cells as well as the germinal center cell formation during antigen presentation [74]. Therefore, DLBCL with high expression of bcl-6 are usually of germinal center B-cell origin, which distinguishes them from other DLBCL

Table 45.5 Molecular abnormalities in lymphomas

NHL histologic type	Translocation	Proto-oncogene involved	Proto-oncogene function
Lymphoplasmacytic lymphoma	t(9 114)(p13;q32)	*pax-5*	Transcription factor regulating B-cell proliferation and differentiation
Follicular lymphoma	t(14;18)(q32;q21)	*bcl-2*	Negative regulator of apoptosis
	t(2;18)(p11;q21)		
	t(18;22)(q21;q11)		
Mantle cell lymphoma	t(11;14)(13;q32)	*bcl-1/cyclin D1*	Cell cycle regulator
MALT lymphoma	t(11;18)(q21;q21)	*api_2/mlt*	*api_2* has anti-apoptotic activity
	t(1;14)(p22;q32)	*bcl-10*	Anti-apoptosis
Diffuse large B-cell lymphoma	del(3)(q27)	*bcl-6*	Transcriptional repressor required for GC formation
Burkitt's lymphoma	t(8;14)(q24;q32)	*c-myc*	Transcription factor regulating cell proliferation and growth
	t(2;8)(p11;q24)		
	t(8;22)(q24;q11)		
Anaplastic large T-cell lymphoma	t(2;5)(p23;q35)	*npm/alk*	*alk* is a tyrosine kinase

subtypes [75]. The exact functional significance is largely unknown, although some studies have found an improved survival in these patients [76].

Burkitt's lymphoma is characterized by a translocation between *c*-myc on chromosome 8 and one of the three immunoglobulin chain loci, occurring with a respective frequency of 80%, 15%, and 5% on chromosomes 14, 22, and 2, respectively, which encode in turn for the IGH and lambda and kappa light chains [40]. t(8:22) is usually found in lambda-expressing cells, whereas the t(8:2) is found in kappa-expressing cells. The quantitative overexpression of c-myc has been shown to result in deregulation of cellular growth and is capable of blocking phenotypic maturation. Therefore, c-myc overexpression appears to be central to the pathogenesis of BL, and it is thought that the translocation occurs in pre-B-cell development during the normal rearrangement of the immunoglobulin loci. MCL cases almost always contain the t(11;14)(q13;q32) translocation between the IGH and the cyclin D1 (PRAD1, bcl-1) genes [77]. Deregulation of bcl-1 leads to overexpression of its gene product cyclin-D1, which promotes progression from G1 to S of the cell cycle [78].

International Prognostic Indices

Clinical stage is a powerful and independent predictor of prognosis. The largest evaluation of prognostic factors for aggressive lymphoma was made in 2031 patients and published as the International Prognostic Index [79]. In the multivariate analysis, age (less than 60 years vs. 60 years or older), tumor stage (I–II vs. III–IV), serum lactate dehydrogenase (normal vs. higher than normal), performance status (ECOG 0–1 vs. 2 or higher), and number of extranodal sites of disease (0 or 1 vs. 2 or more) were identified as being highly predictive of outcome. These risk factors were put together into an analysis so that the number of factors was highly predictive of outcome. Patients with 0 or 1 risk factor had a complete remission (CR) rate of 87% and a 5-year survival rate of 73%; those with two risk factors had a CR rate of 67% and a 5-year survival rate of 51%; with three risk factors, the rate was 55% and the 5-year survival rate was 43%; with four or five risk factors, the CR rate was 44% and the 5-year survival rate was 26%. This prognostic index should be evaluated in all new patients with aggressive lymphoma to plan their clinical courses, since it is the standard for assessing clinical prognosis and treatment stratification. Although it has yet to be fully revalidated in the rituximab era, a revised prognostic model for R-CHOP (Revised-IPI) is available from retrospective analysis [80]. Other prognostic indices have evolved for other subtypes of lymphoma. The Follicular Lymphoma International Prognostic Index (FLIPI) has been validated, as age, stage, LDH, hemoglobin level, and number of nodal areas reliably predict survival [81]. Finally, a validated prognostic index for MCL (MIPI) has been published and also widely accepted [82, 83] (Table 45.6).

Gene expression profiling has emerged as an important prognostic tool. On the basis of gene signatures, DLBCL can be divided into at least three different subtypes: germinal center B-cell-like (GCB), activated B-cell-like (ABC), and primary mediastinal B-cell lymphoma (PMBC). The term non-GCB is reserved for classification based on immunohistochemistry protein expression rather than gene expression. These categories possess a different overall survival and superiority in patients with the germinal center type versus the activated type [68]. Using these gene expressions profiled, a molecular prognostic model of survival has been developed for CHOP-treated DLBCL and is independent of IPI. However, like many new facets of NHL treatment, this molecular prognostic model has yet to be validated in the rituximab era. Gene expression

Table 45.6 Prognostic classification systems for lymphomas

International Prognostic Index for aggressive lymphomas			
Risk group	IPI score[a]	CR rate (%)	5-Year OS rate (%)
Low	0, 1	87	73
Low intermediate	2	67	51
High intermediate	3	55	43
High	4, 5	44	26
Revised International Prognostic Index (R-IPI)			
Risk group	IPI score[a]	4-Year OS rate (%)	
Very good	0	94	
Good	1–2	79	
Poor	3–5	55	
Follicular International Prognostic Index (FLIPI)			
Risk group	IPI score[a]	Distribution (%)	10-Year survival rate (%)
Low	0–1	36	71
Intermediate	2	37	51
Poor	≥3	27	36
Mantle Cell International Prognostic Index (MIPI)			
Risk group	MIPI score = [0.03535 × age (years)] + 0.6978 (if ECOG > 1) + [1.367 × log10 (LDH/ULN)] + [0.9393 × log10 (WBCs per 10^{-6} L)]	Distribution (%)	5-Year survival rate (%)
Low		80	82
Intermediate		41	75
High		37	35

CR complete response, *ECOG* Eastern Cooperative Oncology Group, *IPI* International Prognostic Index, *LDH* lactate dehydrogenase, *OS* overall survival

[a]One point is given for the presence of each of the following characteristics: age > 60 years, elevated serum LDH level, ECOG performance status ≥2, Ann Arbor stage III or IV, and more than two extranodal sites

profiling for other types of lymphoma have also found subsets with different prognostic outcomes. For example, in follicular lymphoma, two subsets were found based on the immune effector cells in the microenvironment of the involved lymph nodes and in an 81 gene expression panel [84, 85].

Treatment

Background

Optimized care requires an understanding of a comprehensive approach to all medical facets of each patient, and most importantly, the correct histologic diagnosis. The treatment strategy for NHL varies based on several factors including histologic subtype, stage, age, performance status, and other prognostic factors, as discussed under patient staging and evaluation. However, it is important to be mindful that the WHO classification is not organized with treatment in mind. Management of acute problems such as spinal cord compression, superior vena cava syndrome, hypercalcemia, and obstruction may specifically direct initial therapy. Adequate treatment is often multidisciplinary, involving surgical oncologists, medical oncologists, and radiation oncologists. The initial goal of therapy is generally the attainment of a complete remission defined as the documented disappearance of disease from previously involved sites. In general, treatment response should be documented by physical findings, and all abnormal tests should be repeated. The guidelines outlined by a workshop of the National Cancer Institute in 1998 and more recently in 2007 and 2013 should be used to follow response, as this workshop standardized and refined initial evaluation and response criteria [86–88]. Final treatment assessment is usually performed 4–6 weeks after completion of therapy unless progression occurs earlier. The frequency and extent of investigations during follow-up depend on the risk of recurrence. Although a common practice, routine surveillance radiographic analysis has not proven to be predictive of outcomes in studies. Further discussion of treatment has been organized based on shared biologic and clinical features.

The fundamental genetic changes that lead to lymphoma involve deregulation of cellular proliferation and death, events that are controlled by cell cycle checkpoints and by the induction or suppression of apoptosis. Abnormalities in these pathways might determine the sensitivity of tumor cells to the cytotoxic effects of irradiation and chemotherapy [89, 90]. Clinical strategies which take advantage of these abnormalities in the regulation of the cell cycle and

apoptosis have an increasingly important role in the design of novel therapeutic approaches. The classic principles of chemotherapy, including pharmacology, drug resistance, and tumor cell kinetics, continue to form the foundation of treatment strategies. Understanding these principles provides the basis for good treatment decisions. Dose intensity has long been considered important in the treatment of NHL; however, the heterogeneous nature of NHL and the addition of rituximab to most treatment schema have diminished differences in response to more toxic chemotherapy regimens.

Indolent Histologic Subtypes

Follicular Lymphoma

The so-called favorable indolent histologic subtypes of cutaneous T-cell lymphoma (CTCL), and the small lymphocytic (SL), follicular small cleaved (FSC), and follicular non-Hodgkin's lymphoma are not as common as the aggressive NHL's. The indolent histologies compose 20–45% of the lymphomas in most series. While follicular NHL can occur in younger patients, CTCL and SL lymphoma most often occur in patients over 60 years of age. When careful staging procedures as outlined previously are followed, over 90% of the patients have advanced stage disease at diagnosis.

Patients with these indolent histologic subtypes have a prolonged natural history with a median survival in most series of 10–15 years or more [91, 92]. Also, except in a few cases of truly localized disease, these indolent histologic subtypes of NHL cannot be cured. The therapy offered to the patient must take this incurability into account. Patients with few serious signs or symptoms of their disease can be placed into the "watch and wait" category until they show signs or symptoms of their disease, making treatment essential [93, 94].

Treatment of these NHL is generally initiated for constitutional symptoms, organ compromise, and/or evidence of rapid tumor proliferation. Most patients under these circumstances have bulky disease, diffuse bone marrow infiltration, and threatened organ function. When the disease does advance so that treatment is necessary, localized radiation therapy can be used for symptomatic adenopathy; also, single or combination chemotherapeutic agents can be used for more extensive disease. Multiple chemotherapeutic agents have been found to be effective in this clinical situation [95–98], including purine analogs, alkylators, anthracyclines, and rituximab. In addition, targeted agents, radioimmunotherapy, and allogeneic stem cell transplantation are now in current treatment paradigms. With most of these modalities, a complete or partial response can be achieved at least initially. However, a relapse rate of 10–15% per year occurs, with only a small percentage of patients remaining in remission after 10 years of follow-up.

Table 45.7 lists common chemotherapy regimens for indolent NHL [99–104].

Follicular lymphomas are classified into three grades based on the number of centroblasts per high-power field; grades 1 and 2 are indolent, whereas grade 3 is more aggressive. Grade 3 disease is biologically diverse and includes both grade 3a follicular lymphoma and grade 3b large B-cell lymphoma, which has a follicular growth pattern but clinically resembles DLBCL [105]. A number of clinical features are associated with outcome of follicular lymphoma (FL). In a study of 4000 patients with FL, age greater than 60 years, Ann Arbor stage III or IV, hemoglobin level less than 12 g/dL, abnormal serum LDH level, and involvement of five or more lymph node areas were adverse prognostic features, which are the criteria that make the FLIPI more discriminating than the IPI.

Most follicular lymphomas present at advanced stage, but approximately 15–30% are stage I or II. Based on retrospective studies, radiotherapy alone has been the standard of care, with median survival approaching 15 years and up to one-third of patients being progression free. It is difficult to determine if these results reflect the benefit of radiotherapy or the indolent nature of early stage disease. A retrospective

Table 45.7 Common chemotherapy regimens for indolent NHL

Clinical group	Treatment	Complete response (%)	Overall response (%)	Median PFS range
Untreated	CVP ± R	10–40	60–80	3–5 Years
Symptomatic	CHOP ± R	40–80	90–100	5–7 Years
	FND ± R	70–90	90–100	5–7 Years
	R ± Maintenance R	15–40	60–75	2–3 Years
	Bendamustine +R	30–40	90–100	5–6 Years
Relapsed	Rituximab	10–20	40–60	8–24 Months

	Idelalisib	6	57	11 Months

CHOP cyclophosphamide, adriamycin, vincristine, and prednisone, *CVP* cyclophosphamide, vincristine, and prednisone, *FND* fludarabine, mitoxantrone, and dexamethasone, *OS* overall survival, *PFS* progression-free survival, *R* rituximab

analysis of 43 patients with untreated stage I or II FL found that 63% did not require therapy over the median follow-up of 86 months and only four patients showed histologic transformation, with a survival rate of 85% [106]. Combination chemotherapy followed by involved-field radiation therapy for early stage disease yielded a similar 10-year survival rate of 82% [107]; however, the benefit of treatment was further negated by two cases of myelodysplasia and 12 secondary malignancies. Although it can cause long-term toxicities, radiotherapy still remains a popular treatment of choice [108]. Quite simply, these data illustrate that no clear perfect treatment exists, other than a treatment strategy that is individualized for each patient.

Several randomized trials have compared observation with single-agent or combination chemotherapy in patients with asymptomatic advanced stage lymphoma. Aggressive treatment with ProMace-MOPP was compared with observation, but this study did not prove that early treatment was beneficial [93]. Another randomized study compared observation to chlorambucil, and also demonstrated a similar OS at a follow-up of 16 years [109]. Although these two randomized trials support observation, they were performed before the use of rituximab, which has been shown to prolong survival in symptomatic patients [110]. For asymptomatic patients, single agent rituximab induction and 2 year maintenance was compared with a watch and wait approach and showed 86% versus 46% of patients did not need new treatment at 3 years. Giving only 1 month of rituximab weekly was no worse than 2 years in terms of needing new treatment at 3 years. There was no improvement in quality of life with therapy although illness coping and mental adjustment to cancer scores were better in the treatment groups [111].

Initial chemotherapy for patients with symptomatic disease should be tailored based on the nature and pathobiology of the disease; for example, high tumor burden usually requires combination regimens, while slower progressive disease may require a single agent regimen. Table 45.7 contains a representation of the common regimens employed.

Perhaps the most important advance in therapy for indolent lymphomas has been the use of rituximab (chimeric anti-CD20). In the original trials, rituximab was administered weekly for 4 weeks to patients with multiple relapsed indolent NHL. They found a CR rate of 6% and an overall response rate of 50% in the trial [101]. It has also been used in combination with CHOP in patients with indolent NHL and found to have a 97% response rate [100]. This antibody has evolved into the standard therapy for many patients with indolent NHL.

Other trials have shown statistically significant response rates, progression-free survival (PFS), and molecular remissions [103, 112]. Rituximab was also tested as a first-line treatment, followed by maintenance therapy every 6 months in patients without progression [113]. The advantage was clearly demonstrated by a response rate of 47% following induction, with an increase to 73% during maintenance, including a 37% CR rate, and a median PFS was 34 months. The role of a 4-week induction course followed by maintenance at 3, 5, 7, and 9 months was tested in untreated or relapsed/refractory FL. The overall response rate was 67% and 46% in untreated and relapsed/refractory patients, respectively, and the median EFS was 12 and 23 months for the observation and maintenance groups, respectively [105]. Untreated patients benefited most from maintenance, with an EFS increasing from 19 to 36 months. Additionally, the large multinational PRIMA trial gave half of the subjects maintenance rituximab every 8 weeks for 2 years after rituximab plus chemotherapy. This resulted in a 75% PFS versus 58% in the no maintenance group, although overall survival did not differ [114].

Without question, rituximab has improved response and survival when added to standard conventional chemotherapy regimens. R-CHOP is clearly superior to CHOP on the basis of overall response rates, median PFS, and a slight survival advantage [115]. When CVP was compared with and without rituximab, the addition of rituximab also significantly improved response, progression, and survival [102]. Other combinations where rituximab has been used include F-RCM and R-FND regimens, as well as after FM and CHOP in patients who did not achieve a molecular remission [103]. These trials clearly indicate that rituximab significantly improves the efficacy of chemotherapy and OS.

Other promising new combinations with rituximab include bendamustine (BR) and lenalidomide (R^2). The BR regimen showed impressive PFS in the first line when compared directed to R-CHOP in a German study of indolent lymphomas. With a median follow-up of 45 months, median PFS was not reached versus 40.9 months with a hazard ratio of 0.61 for BR [98]. These data were supported by the BRIGHT study which showed BR approached non-inferiority to R-CHOP for a complete response (CR-rate ratio 1.27 p = 0.0569) with a trade-off of more nausea and drug-hypersensitivity reactions [116]. Data for PFS and OS were not yet mature. The use of lenalidomide with rituximab has shown in a small phase II trial to give an 87% complete response and an additional 11% partial response [117]. In the second line, overall response rate was 76% with a median time to progression of 2 years [118]. An international phase 3 study with R^2 is currently in progress.

Patients who show benefit from an initial treatment can be retreated in a relapsed setting with the same agents, although alternative combinations may be selected. Idelalisib is a first in its class oral inhibitor of the delta isoform of the phosphatidylinositol 3-kinase located in the lipid bilayer of B cells. In a phase 2 study of heavily pretreated patients with indolent lymphomas, response rates were 57% with a median duration of response of 12.5 months [104].

Anti-CD20 antibody therapy has been combined with radioactive isotopes. There were two drugs commercially available in the form of iodine-131 tositumomab (Bexxar) and yttrium-90 ibritumomab tiuxetan (Zevalin); however, Bexxar was discontinued in the US in February 2014. There was a lack of comparative single agent studies and restrictions of administration led to a low usage rate and ultimate discontinuation of an effective drug from the market. Ibritumomab tiuxetan showed a response rate of 74% in rituximab refractory patients with follicular lymphoma with time to progression of 6.8 months [119]. In the relapsed or refractory setting, Ibritumomab tiuxetan out-performed rituximab with an overall response rate of 80% versus 56% with double complete response rates but no difference in time to progression [120]. Thus the role of radioimmunotherapy is currently limited to relapsed patients with limited bone marrow involvement with adequate normal marrow elements and no evidence of MDS markers by FISH.

High-dose therapy with autologous hematopoietic stem cell support for indolent lymphoma has been tested as consolidation in first response, relapse, and transformation [121, 122]. For patients with relapsed FL, autologous hematopoietic cell transplant (Au-HCT) does appear to produce long-term disease-free survival in selected patients. The patients who appear to benefit the most are those who are transplanted after receiving <3 prior chemotherapy regimens and have a lower FLIPI at the time of relapse. For multiply relapsed FL patients, Au-HCT does not produce a favorable risk-benefit ratio [123]. However, for FL patients in first remission, the incidence of secondary malignancies, especially MDS and AML, complicates Au-HCT and must be taken into consideration for those patients with long expected lifespans. Despite recent advances in novel B-cell inhibitors, if clinical trials are not available, most centers utilize Au-HCT for selected first or second relapsed FL patients who have a shortened disease-free interval or other indications of a poor outcome with standard therapy.

Allogeneic transplantation (Al-HCT) can be performed after either conventional myeloablative or reduced-intensity conditioning [124]. The latter approach is an encouraging development since it has substantially reduced treatment-related morbidity and mortality, consisting mainly of acute and chronic GVHD and infectious complications, without a major increase in relapse risk [125]. Although relapse and progression occur less often after myeloablative allogeneic HCT, this modality should be used cautiously because of its prohibitive non-relapse mortality. Most currently published trials were initiated in the pre-rituximab era. As such, the role of Au-HCT and Al-HCT need to be re-evaluated in the setting of initial therapy with rituximab-containing regimens and prospective studies are urgently needed to validate these strategies. Individual patient evaluation and treatment planning should be considered.

Small Lymphocytic Lymphoma (SLL/CLL)

Small lymphocytic lymphoma is clinically similar to CLL. Since the typical patient population is generally older and the disease can often be indolent and asymptomatic for many years, conservative therapy is usually favored. Historically, purine analogs, such as fludarabine, cladribine, and pentostatin, alone or in combination have been employed with the best success [126]. The efficacy of fludarabine or cladribine alone has been consistently demonstrated to show response rates between 30 and 50% [127]. Fludarabine and cyclophosphamide or fludarabine and mitoxantrone have shown promise, but with substantial toxicity [128]. As in CLL, the combination of fludarabine and cyclophosphamide and rituximab (FCR) has yielded complete remissions. The role of high-dose therapy followed by hematopoietic stem cell transplantation is limited given the older patient population. However, younger patients can be treated with allogeneic transplantation with low-dose conditioning, especially when the patient has a HLA identical matched sibling [129].

A steady stream of new monoclonal antibodies or oral B-cell inhibitors have become available for treatment in the first line or relapsed setting which has shifted the treatment away from purine analog based regimens such as FCR. These new therapies will be discussed in detail in a separate chapter.

Three other indolent, low-grade NHL deserve further mention. Extranodal marginal zone lymphoma is another subtype of indolent, low-grade NHL. Localized gastric MALT lymphoma is unique because of its association with *H. pylori* and resolves with appropriate antibiotic treatment [130]. The presence of t(11;18) in the tumor cells predicts a poor response to antibiotic therapy [131]. Patients with localized disease and persistent lymphoma despite antibiotics can be effectively treated with rituximab [132]. Durable complete remissions are typical with radiotherapy. Nodal marginal zone lymphoma is a rare disease, mainly of older women. Most patients present with lymphadenopathy, often in the neck [133]. There is little consensus about treatment and the site that is involved and the age of the patient dictate management. The principles of therapy that were described for follicular lymphomas are usually the best treatment approach(es). Splenic lymphoma with villous lymphocytes represents another special lymphoma that presents with splenomegaly and B cells with villous projections in the blood. Treatment of hepatitis C with interferon-α alone or in combination with the antiviral agent ribavirin is associated with regression of splenic lymphoma [134]. Splenectomy was once used for diagnosis and treatment, but rituximab is highly effective and should be considered before splenectomy.

Aggressive Non-Hodgkin's Lymphoma

DLBCL is the most common, aggressive NHL and usually presents in the sixth or seventh decade, but also affects individuals of all ages. The presentation is quite variable, ranging from localized to disseminated disease, with or without nodal involvement. Primary mediastinal B-cell lymphoma (PMBL) represents a clinicopathologic variant of DLBCL, usually presented in young females as a mediastinal mass. DLBCL often frequently arises as a transformation from indolent NHL.

Unlike indolent NHL, radiation treatment alone is associated with high recurrence rates, thereby necessitating systemic chemotherapy. Early stage disease (I/II) has been subjected to clinical trials with or without radiation therapy. Initially, combined therapy became the standard based on an early trial showing an OS advantage for limited course CHOP plus involved-field radiation over CHOP [135]. Long-term follow-up unfortunately showed late systemic relapses in the combined-modality arm [136]. The improved outcomes with R-CHOP are now limiting the necessity of radiotherapy in early stage DLBCL. Advancements in PMBL treatment have also been shown to obviate the need for radiation in most patients with a disease that was once thought to require radiation. A dose-adjusted regimen of doxorubicin, vincristine, and etoposide infused over 96 h with bolus intravenous cyclophosphamide, rituximab, and oral prednisone (DA-EPOCH-R) has been showing promise [137]. For example, if the initial disease was less than 10 cm and post treatment PET scan is negative, radiation therapy can be omitted. In a more recent prospective trial with DA-EPOCH-R, in which 65% of patients had disease greater than 10 cm, there was an overall survival rate of 97% without radiation [138]. This was confirmed in much longer follow-up of a retrospective cohort. Omitting radiation may be important to eliminate the long-term toxicities, especially in younger patients.

As most patients with DLBCL present with later stage disease, systemic chemotherapy is the mainstay of treatment. The CHOP regimen is one of the oldest regimens in cancer therapy and was developed in the mid-1970s when anthracycline doxorubicin was added to the cyclophosphamide, vincristine, prednisone backbone [139]. Since the response rate was only 44%, many anticipated improvements were added to the CHOP platform in an attempt to improve response rates. Ultimately, these many attempts at modifying the regimen proved unfruitful as proven by a four-arm study evaluating 899 patients randomized to receive CHOP, m-BACOD, ProMACE-CytaBOM, or MACOP-B demonstrated that the 3-year estimates of time to treatment failure for these arms were 41, 46, 46, and 41%, respectively [140]. There were no risk groups according to the International Prognostic Index, as developed by Shipp et al. [79] that benefited from one of the four arms of the treatment trial compared with other arms.

As in the indolent NHL, rituximab has made the greatest impact on the treatment of DLBCL. Table 45.8 illustrates supporting trials. A study by GELA which showed CR rates (76% vs. 63%) and EFS rates (47% vs. 29%) favoring R-CHOP over CHOP [141, 142]. A U.S. intergroup and European MInT group study confirmed these findings in a similar patient population and R-CHOP became the standard of care in DLBCL [143, 144]. Since the establishment of rituximab's benefit in DLBCL, researchers have moved to test the effect of rituximab in dose-dense CHOP. The RECOVER-60 trials compared CHOP-14 with and without rituximab, randomized between six and eight cycles. No significant difference in outcomes was noted [145]. Although an excellent 3-year EFS rate of 66% was noted, it is difficult to extrapolate these results to the rituximab era. A definitive trial comparing R-CHOP 14 to R-CHOP 21 was completed showing no molecular or clinical subgroup benefited from the dose dense regimen [146]. R-CHOP remains the standard of care for the vast majority of DLBCL.

Table 45.8 Clinical trials for diffuse large B-cell lymphoma

Study	Therapy	Patient group	Event-free survival	Overall survival
Phase III	R-CHOP	Age ≥ 60 years	47% at 5 years	58% at 5 years
R-CHOP versus CHOP	GELA	All IPI		
Phase III	R-CHOP	Age ≥ 60 years	53% at 3 years	44% at 10 years
R-CHOP versus CHOP	U.S. Intergroup	All IPI		
Phase III	R-CHOP-like [*] MlnT	Age ≤ 60 years	79% at 3 years	93% at 3 years
Phase III	R-CHOP-14 (X6)	Age ≥ 60 years	66% at 3 years	78% at 3 years
R-CHOP-like versus CHOP		Low IPI		
Phase III	ACVBP	Age ≥ 60 years	39% at 5 years	46% at 5 years
Phase II, NCI	DA-EPOCH-R	All age ≥ stage2	79% at 5 years	80% at 5 years
Phase II, CALGB	DA-EPOCH-R	All age ≥ stage2	81% at 5 years	84% at 5 years
Phase II, Spain PETHEMA	DA-EPOCH-R	All age	48% at 10 years	64% at 10 years

While it is clear that rituximab has significantly improved the overall outcome of DLBCL, several studies suggest that its benefit is limited by tumor pathobiology [147, 148]. Rituximab's benefit was primarily in bcl-2-positive DLBCL, while another study showed that benefit was limited to bcl-6-negative DLBCL. These biomarkers likely relate to the new molecular taxonomy of DLBCL defined by gene profiling and suggest that rituximab might primarily benefit tumors that are derived from a postgerminal center B cell [149], and patients with both the germinal center B and activated B genetic subtypes benefit from rituximab [150].

There have been three phase II studies to report favorable outcomes using DA-EPOCH-R for DLBCL in general suggesting that tumor cell of origin (GCB or ABC) respond equally well. About 40% of patients in the two U.S. studies had IPI 3 or higher [151–153]. There have been no phase III studies with head-to-head comparison to R-CHOP and the exact subset of patients that benefit the most has yet to be determined.

The role of high-dose chemotherapy and Au-HCT in the initial treatment of DLBCL remains controversial [154, 155], since the studies that have suggested a benefit were performed in the pre-rituximab era [156]. In the most recent study with two-thirds of the patients receiving R-CHOP instead of CHOP, there was no survival benefit demonstrated [155]. However, it is widely accepted that Au-HCT is useful in second or third relapse, in the setting of chemosensitivity to additional salvage chemotherapy. Nevertheless, Au-HCT is also associated with late toxicities, including leukemia and secondary myelodysplasia, which must be considered in the risk benefit of treatment [157]. The role of Al-HCT is often limited, given the older age group of DLBCL, but has been employed with only modest success in younger patients due to high treatment-related mortality.

Burkitt's lymphoma (BL) occurs in the first two decades of life, is highly aggressive, and is derived from a germinal center B cell. The high apoptotic rate accounts for its "starry sky" appearance. Immunophenotypically it is CD20 positive, CD10 positive, and TdT negative [158]. Three clinical variants are recognized: endemic BL, which is found primarily in equatorial Africa; sporadic BL, which presents worldwide but is the most common type in Western countries; and immunodeficiency-associated BL, which is associated with HIV infection. There are important clinical differences in these variants. Endemic BL typically presents with jaw and facial bone disease and is virtually always associated with EBV. Sporadic BL usually presents with ileocecal disease and is associated with EBV in 30–50% of cases. Immunodeficiency-associated BL usually occurs in HIV-positive populations and is associated with nodal disease and is variably associated with EBV. BL may be associated with CNS involvement, particularly when there is bulky or disseminated disease.

BL requires emergent chemotherapy for all disease stages. The high tumor proliferation rate led to the use of dose-intense regimens with a short cycle time to theoretically minimize tumor regrowth between cycles [159]. Multiple drugs, administered in alternating combinations, are employed, and the high rate of spread to the CNS has led to the standard use of CNS prophylaxis [160, 161]. Though most BLs occur in children, Magrath and colleagues demonstrated that adults and children have a similar disease outcome when treated with the same regimen [162]. Toxicity is an important clinical limitation of these regimens in adults, particularly in older patients, in whom severe morbidity and even mortality occur. However, no significant modifications of the previous mentioned regimens have made significant improvements. Relapsed BL is extremely chemoresistant and is always uniformly fatal. Table 45.9 lists several treatment regimens for Burkitt's lymphoma [163–167] (Table 45.9).

MCL is a rare B-cell lymphoma and has a median age of 60 years and male predominance [40]. Its pathobiology is due to dysregulation of the cell cycle, with almost all cases showing the t(11;14) translocation and overexpression of cyclin D1 (bcl-1). Cyclin D1, CD20, and CD5 are virtually diagnostic of MCL. The aggressiveness of this disease can be anywhere from an indolent course to an aggressive and treatment refractory course. Using prognostic tools such as the MIPI and noting the proliferative index as measured by the ki-67 stain may help to tailor the most appropriate approach. One study showed a clinically meaningful ki-67 cutoff of 30% [168].

Table 45.9 Chemotherapy regimens for Burkitt's lymphoma

Therapy	Histology (number)	EFS rate	OS rate
LMB 89	Burkitt's and L3 ALL (420)	92% at 5 years	92% at 5 years
BFM 90	Burkitt's and L3 ALL (322)	89% at 6 years	14 deaths
CODOX-M/IVAC	Burkitt's	85% (children) and 100% (adults) at 2 years	2 deaths
CODOX-M/IVAC	Burkitt's (52)	65% at 2 years	73% at 2 years
CODOX-M/IVAC	Burkitt's (25)	84% at 2 years	89% at 2 years
Liposomal O			
Hyper-CVAD	L3 ALL	61% at 3 years for disease-free survival	49% at 3 years
R-Hyper-CVAD	Burkitt's and L3 ALL (28)	88% at 3 years	89% at 3 years
DA-EPOCH-R	Burkitt's (19 DA-EPOCH-R, 11 SC-EPOCH-RR)	95–100% at 6 years	90–100% at 6 years
Short course EPOCH-double dose R			
CALGB 10002	Burkitt's (105)	74% at 4 years	78% at 4 years

For patients presenting with advanced stage disease and median survival can range from 3–5 years. While OS is improving with the development of more effective therapies involving Au-HCT, cure remains elusive for most patients [83]. Treatment approaches are limited by the older median age of patients with MCL, but more aggressive regimens are used in younger patients. Fractionated cyclophosphamide administered with doxorubicin, vincristine, and dexamethasone (hyper-CVAD) alternating with high-dose methotrexate and cytarabine has shown great promise over traditional CHOP-based regimens [162, 169]. This effect was further consolidated with Au-HCT. As with other NHL, the CD20-positive nature of MCL made the addition of rituximab attractive. Hyper-CVAD with rituximab alternating with high-dose methotrexate and cytarabine was reported in untreated MCL [170]. Though the regimen was effective, the unacceptable toxicity in older patients led the authors to recommend it only in patients under 66 years of age. As such a modified dosing schedule for older patients is often employed, but has not been validated in a controlled clinical trial.

Several phase II studies support the role of consolidation with Au-HCT in first-line MCL patients after induction therapy [171, 172]. Incorporating Rituximab into the induction chemotherapy followed by autologous transplant for patients up to 69 years of age resulted in 64% 5 year overall survival [173]. Allogeneic stem cell transplantation with reduced-intensity conditioning has shown to be feasible in MCL [174].

For indolent forms of mantle cell lymphoma, several clinical trials have assessed the efficacy and safety of bendamustine and rituximab (BR) in patients with relapsed MCL [175]. Rummel and colleagues showed an RR of 90% and a 38% CR, PFS was 24 months. As previously discussed, the phase 3 study comparing BR to R-CHOP for first-line treatment of indolent mantle cell showed a ORR were similar (93.8% vs. 93.5%), but patients treated with BR had a significantly longer median PFS. Additionally, the BRIGHT study's mantle cell subgroup showed superiority in response rates with BR compared to R-CHOP [116].

The proteasome inhibitor bortezomib has shown promising activity in patients with relapsed or refractory MCL. After demonstrating activity in two small phase II studies, a large multicenter study reported a response rate of 33% with 8% CR in relapsed or refractory MCL [176, 177]. Combinations of bortezomib or rituximab and chemotherapy have been investigated in MCL. Another option in relapsed MCL patients is rituximab plus bortezomib. Preliminary results from a Phase II Study of VELCADE (bortezomib) in Combination With Bendamustine and Rituximab in Subject With Relapsed or Refractory Follicular Lymphoma (VERTICAL) showed excellent response rates with acceptable toxicities [178]. A phase III study of 487 patients with newly diagnosed mantel cell lymphoma not eligible for stem-cell transplant were given either R-CHOP or bortezomib substituted for vincristine (VR-CAP). At 40 months of follow-up there was a PFS advantage of 14 versus 25 months and a 4 year overall survival of 54 versus 64% [179]. Currently bortezomib is FDA approved for use in MCL.

Conventional Salvage Therapy

Once a patient has relapsed after initial chemotherapy for NHL, the ability to induce a remission with subsequent salvage therapy is reduced and the ability to cure the patient with conventional chemotherapy is less than 5% in most series. The salvage treatment should be approached in an individual manner. Although most relapsed aggressive lymphomas require combination chemotherapy, it is important to note that patients with local disease can be salvaged with radiation therapy. Initial historical regimens included IMVP-16 and MIME [180, 181]. These regimens have since evolved into MINE, ESHAP, and MINE-ESHAP [182]. Now there are a variety of active chemotherapy regimens for relapsed or refractory NHL [182–186] (Table 45.10).

Platinum-containing regimens, such as ESHAP and ICE, are currently among the most widely used types of salvage treatment. Salvage treatment should include different agents from past treatment to avoid drug resistance. The addition of rituximab appears to enhance the activity of salvage regimens as demonstrated by results with R-ICE and ICE, which showed a CR rate of 53% and 27%, respectively.

Patients with chemotherapy-sensitive disease have the best outcome with Au-HCT, and it is recommended at initial relapse; it has yielded OS and EFS rates in the range of 40–50% and 30–40%, respectively [185, 187]. Au-HCT rarely achieves cure in BL and lymphoblastic lymphoma, but is often successful in ALK-positive anaplastic large cell lymphoma (ALCL). NHL that are rarely cured with initial treatment, such as PTCL, are less likely to benefit from ASCT. It is important

Table 45.10 Salvage chemotherapy regimens

Therapy	Patient group	CR rate (%)	OR rate (%)	OS rate
DHAP	Relapsed or refractory lymphoma	31	58	25% at 2 years
ESHAP	Relapsed or refractory lymphoma	37	70	31% at 3 years
EPOCH	Relapsed or refractory DLBCL	36	70	30% at 6 years
R-ICE	Relapsed or refractory DLBCL	53	88	–
RGemOX	Relapsed or refractory DLBCL	34	43	41% at 1 year

CR complete response, *DHAP* dexamethasone, cytarabine, and cisplatin, *ESHAP* etoposide, methyl-prednisone, cytarabine, and cisplatin, *EPOCH* etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin, *OR* overall response, *OS* overall survival, *R-ICE* rituximab, ifosfamide, carboplatin, and etoposide

to consider that the incorporation in up-front therapy with rituximab has biased the relapsed population toward greater resistance. The incorporation of rituximab or radioimmunoconjugate into conditioning regimens can also enhance the benefit of ASCT, thus pointing out the importance of controlled ASCT trials in the post-rituximab era [188]. Of course, patients with chemotherapy-resistant disease do poorly with Au-HCT and should be considered for experimental treatments such as Al-HCT or clinical trials with novel agents or novel combinations. Agents such as lenalidomide have shown some promise in relapsed and refractory subtypes of NHL such as DLBCL and MCL [189, 190].

Uncommon NHL Classifications

Primary central nervous system lymphoma (PCNSL) is a rare and highly aggressive lymphoma that is confined to the CNS and is usually of diffuse large B-cell histology. Challenges in evaluation have been addressed in a report of an international workshop to standardize the criteria for baseline evaluation and response [191]. The incidence of PCNSL is particularly high in the setting of HIV infection, and is virtually always associated with EBV. In HIV, PCNSL is usually multifocal, while in HIV-negative patients it often presents as a solitary intracranial mass and is rarely associated with EBV. Treatment of PCNSL differs from that of systemic DLBCL because many chemotherapy agents do not adequately penetrate the blood–brain barrier. Combined modality with high-dose methotrexate and radiotherapy has been a mainstay of treatment because of better responses to either single modality [192, 193]. Unfortunately, such combined-modality treatment is associated with severe long-term neurotoxicity and there has been much interest in developing regimens that obviate or defer the need for radiation until relapse. The Bonn group and others have adopted such an approach and have reported promising results with chemotherapy and deferred radiation in younger patients [194, 195]. Studies are also addressing the role of immunochemotherapy with rituximab and other novel agents that promise to further improve the outcome of PCNSL [196]. Rituximab is of special interest, since it has been shown to cross the blood–brain barrier, especially with higher doses.

PTLD encompass a broad spectrum of diseases that occur in the setting of allogeneic hematologic and solid organ transplantation and show considerable heterogeneity [197]. It is approached by withdrawal of immunosuppression and administration of rituximab. Chemotherapy may be required if a clone develops which is immune independent [198]. Other similar clinical syndromes include methotrexate-associated lymphoproliferative disease (LPD) and EBV-associated LPD. Both of these entities are treated by withdrawal of the offending agent, if necessary, chemotherapy [199].

In the setting of HIV infection, many subtypes of NHL develop. Classifiably the incidence of PCNSL is increased 3600-fold and of BL is 1000-fold [200]. These can be AIDS-defining illnesses; however, a few other lymphomas can develop. These include Hodgkin's lymphoma, extranodal marginal zone lymphoma, and certain T-cell lymphomas [201, 202]. The introduction of HAART has had a dramatic and positive impact on the outcome of HIV-related lymphomas. Traditionally, treatment was less intensive in order to avoid further immunosuppression. Also HAART therapy was held to further reduce potential interactions and side effects. Through studies by the AIDS Malignancy Consortium and private investigators, it has been clearly shown that HAART therapy is quite beneficial during induction therapy for HIV-related lymphomas [203]. With better supportive care, treatment regimens have intensified to include R-CHOP without interruption of HAART therapy, with an appreciable improvement in RR. Currently, the same criteria for considering Au-SCT in patients with non-HIV lymphoma should be used as there is no difference in survival or non-relapse mortality [204].

There are a variety of T-cell or combined T-cell/NK cell disorders, approximately 14 subtypes, but are not well studied. They are relatively uncommon and account for approximately 15% of all NHL [205]. Generally, T-cell/NK cell lymphomas are clinically aggressive and incurable, with the exception of ALCL and early stage T/NK cell, nasal-type lymphoma [206]. ALCL is a CD30-positive T-cell lymphoma with an excellent prognosis and is highly curative, usually associated with the t(2;5)(p23;q35) translocation. This results in expression of the nucleophosmin anaplastic lymphoma kinase (ALK). ALK-positive ALCL tends to have a significantly better prognosis than do ALK-negative cases. In adults, CHOP-based therapy considered the standard of care, and all patients should be approached with curative intent. As with any T-cell lymphoma expressing CD30+, the drug antibody conjugate brentuximab vedotin can be used with success in the relapsed setting, potentially a 57% complete response in relapsed ALCL [207].

Extranodal T/NK cell nasal-type lymphoma is prevalent in Asia and the Central/South Americas. Universally, it is associated with EBV and has a predilection for the nasal cavity, nasopharynx, palate, skin, GI tract, and testis. Optimal chemotherapy is not well defined, but when localized, radiation therapy is quite effective [208].

Peripheral T-cell lymphoma is usually associated with a poor outcome. CHOP potentially with etoposide (CHOEP) is associated with good responses [209], but these are usually transient with almost universal relapse. Enrollment on clinical trials is highly encouraged as there are only a few moderately effective salvage agents each with around a 25–35% response rate such as alemtuzumab, bendamustine, romidepsin, belinostat, and pralatrexate [210–214]. Au-HCT after

induction with CHOP has shown good event-free survival, but is not curative. However, a graft-versus-lymphoma effect has been described and suggests a curative potential with Al-HCT.

Angioimmunoblastic T-cell lymphoma (AITL) is characterized by skin rash, organomegaly, hemolytic anemia, and systemic constitutional symptoms. Patients usually exhibit immunodeficiency in the form of dysfunctional polyclonal hypogammaglobulinemia. These features usually distinguish it from peripheral T-cell lymphoma. Optimal therapy has not been defined for AITL, but anthracycline-based regimens or cyclosporine has shown efficacy [215, 216]. Most patients succumb from progressive disease or infection.

Hepatosplenic T-cell lymphoma is another rare T-cell NHL which usually presents with marked hepatosplenomegaly and bone marrow involvement. Outcome is extremely poor and characterized by rapid progression and death. However, Al-HCT has been associated with prolonged remission and potential cure [217].

Conclusion

The last several decades have ushered an explosion of information which has directly translated into targeting care not only to individualized patients, but also to individualized subtypes of NHL. Just as rituximab marked a major therapeutic advance when added to CHOP chemotherapy, we are likely to see the impact of new B-cell targeted therapy. Unfortunately, T-cell NHL remains a challenging group of diseases with much room for improvement. With advances in treatment resulting in more long-term remissions, it is important to remember late complications such as anthracycline-related cardiotoxicity and secondary malignancies. The future of NHL treatment will involve better characterization to facilitate more targeted therapy.

Non-Hodgkin Lymphoma of Childhood

46

Tony H. Truong, Sarah Alexander, and Sheila Weitzman

Introduction

Childhood non-Hodgkin lymphoma (NHL) is a diverse group of tumors derived from cells of lymphoid lineage. They occur as clonal proliferations at various stages of lymphocyte development. In contrast to adult NHL, childhood NHL is typically high grade although intermediate-grade (primary mediastinal B-cell lymphoma (PMBCL) and low-grade lymphoma can be seen. Current international cooperative group trials have resulted in cure of over 80% of children with NHL. Active research by these collaborative groups has advanced the understanding of the molecular mechanisms underlying the various diseases and has allowed for the addition of targeted therapies which are improving outcomes. Ongoing research into prognostic factors and further understanding of these molecular pathways will allow further improvement in survival and minimize the late effects in survivors of childhood NHL.

Epidemiology

Among childhood cancers, pediatric lymphomas account for 15% of cases and as a group are the third most common malignancy in children [1]. Approximately 50% of pediatric lymphomas are non-Hodgkin lymphoma, with the remainder being Hodgkin lymphoma [2]. Differences in incidence vary according to gender and race with NHL being commoner in males than females and approximately twice as common in whites than blacks among those less than 10 years of age [2]. The striking male to female preponderance (2.7:1) decreases with advancing age and varies among subtypes of NHL with incidence being approximately equal among male and female patients with primary mediastinal B-cell lymphoma [3, 4]. Worldwide, there is geographic variation in incidence with a strikingly high incidence in Cuba and Morocco (15 per million) compared to an incidence of 5 per million children in North America [5]. Endemic Burkitt lymphoma (BL) in central Africa accounts for almost half of all pediatric cancer in that region and the incidence reaches 50 per million children [5].

Etiology

Multiple genetic mutations within a single cell are required for malignant transformation. Like most neoplasms, lymphomas arise because of the inappropriate expression or loss of function of genes that regulate cell proliferation, differentiation, and programmed cell death (apoptosis). The malignant clone may result from increased proliferation of cells due to inappropriate expression of an oncogene such as *c-myc*, believed to be an important mechanism in high-grade pediatric lymphomas, or to alteration in genes, such as *bcl-2*, controlling apoptosis leading to decreased cell death, resulting in a more indolent clinical course, as is seen in adult low-grade lymphomas. The loss of a tumor suppressor gene expression and/or function, a mechanism common in many solid tumors, may also be seen in some patients with T-cell leukemia or lymphoma.

Viral infections may induce genetic changes and play a critical role in the pathogenesis of NHL. Examples of this include the role of EBV in the development of the endemic (African) Burkitt lymphoma (BL) and that of human T-cell leukemia/lymphoma virus (HTLV) I and II in the development of adult T-cell lymphoma or leukemia. The oncogenic potential of EBV and HTLV is increased by infection early in childhood. The EBV genome is found in the DNA of tumor cells in 95% of cases in endemic BL but in only 15% of sporadic cases [7, 8].

The distribution of endemic BL coincides with the geographical malaria belt in Africa. Malaria stimulates B-cell proliferation and T-cell suppression, and the interaction of this chronic effect with EBV is believed to be a key factor in causing the translocation of the c-myc oncogene next to one of the immunoglobulin genes and thus in the pathogenesis of endemic BL [9]. The variation in incidence within this region, combined with case clusters and shifting foci of endemic BL, suggests the presence of additional cofactors such as concurrent infection with mosquito borne arboviruses and tumor promoters from local plant extracts [10].

The role of radiation in the development of lymphomas is not clear. Although there is an increased risk of NHL in patients treated with combined radiation and chemotherapy, there was no correlation of lymphoma incidence with increased radiation dose in atomic bomb survivors [11]. A possible association of pesticide exposure and NHL remains unproven. A French study of household exposure to pesticides suggested that insecticide use during pregnancy and paternal household use of pesticide were associated with an increased risk of childhood acute leukemia and NHL [12].

Abnormalities of the immune system, especially in T-cell-mediated immunity, pose an increased risk for the development of lymphoma. As many as 10% of children with congenital or acquired immunodeficiency develop NHL (Table 46.1), the highest incidence being in patients with ataxia-telangiectasia and Wiskott–Aldrich syndrome. In general, these patients tend to develop large-cell or Burkitt-type NHL, but not lymphoblastic lymphoma [13]. NHL is the commonest malignancy associated with the acquired immune deficiency syndrome (AIDS) and often occurs before the age of 4 years in those who are infected from a human immunodeficiency virus (HIV)-positive mother [14]. In AIDS patients, primary central nervous system (CNS) lymphoma is invariably associated with EBV [15]. Iatrogenic immunosuppression of patients undergoing allogeneic hematopoietic stem cell or solid-organ transplantation has resulted in a significant incidence of Epstein–Barr virus (EBV)-related and to a lesser extent of non-EBV-related posttransplant lymphoproliferative disease (PTLD). Uncontrolled EBV-induced B-cell proliferation secondary to T-cell dysfunction produces a spectrum of disease from polyclonal hyperplasia to true monoclonal malignant lymphomas.

Classification

Over the last 50 years, lymphoma classifications have evolved from being solely morphology-based to incorporation of molecular abnormalities inherent to such entities. The Revised European–American Lymphoma (REAL) [16] and recently updated World Health Organization (WHO) classifications [17] define the subtypes of lymphoma by a combination of morphology, immunophenotype, cytogenetic abnormalities, and clinical presentation. The histologic spectrum of pediatric NHL is considerably narrower than that of adult NHL, with the majority of childhood NHL being limited to four major categories (Table 46.2). By the WHO classification system, 40–45% of children with NHL have Burkitt lymphomas, 25% have T- or B-cell lymphoblastic lymphoma with T lineage predominating, 10% have anaplastic large-cell lymphoma (ALCL), and 10% diffuse large B-cell lymphoma (DLBCL), while the remainder are rare and unclassified subtypes [13]. Lymphoblastic lymphoma is morphologically and immunophenotypically indistinguishable from acute lymphoblastic leukemia (ALL) as reflected in the designation of T- or B-lymphoblastic leukemia/lymphoma in the WHO classification. An arbitrary cutoff of 25% marrow involvement distinguishes stage IV NHL from ALL, a distinction of questionable biologic significance. Nonetheless, this differentiation

Table 46.1 Incidence of malignancy in congenital immunodeficiency [6]

Syndrome	Tumor	Risk (%)	Percent of malignancies that are NHL
Ataxia-telangiectasia	NHL Leukemia, HL, adenocarcinoma	>12	41–66
Common variable ID	NHL, HL, leukemia, gastric carcinoma	8–10	45–62
Severe combined ID	NHL, HL, leukemia, occupational adenocarcinoma	5	31–76
X-linked agammaglobulinemia	Leukemia, NHL, HL, adenocarcinoma	6	33
Wiskott–Aldrich Syndrome	NHL, leukemia, HL	>10	59–75
Bloom syndrome	Leukemia, NHL, HL, adenocarcinoma	25	
X-linked lymphoproliferative disease (after EBV infection)	NHL, HLH, EBV and non-EBV-related LPD	24–35

remains important for the accurate comparison of the results of therapeutic trials. All other types of lymphoma, such as the many subtypes of non-anaplastic peripheral T-cell lymphomas, comprise only 1–2% of pediatric NHL [18] but form the majority of the less common T-cell subtype of PTLD. Primary mediastinal B-cell lymphoma which, like the adult counterpart, is of intermediate grade, comprises under 3% of pediatric NHL [4].

Pathology

The majority of pediatric NHL are diffuse, aggressive, high-grade lymphomas, which tend to arise in extranodal lymphoid tissue such as thymus or Peyer's patches. The aggressive nature of most pediatric NHL is thought to reflect the growth rate of the counterpart normal lymphocyte precursor [18]. The stages of lymphocyte differentiation at which childhood lymphoma and leukemia are thought to arise [19, 20] are shown in Figs. 46.1 and 46.2.

This rapid growth rate is reflected by the presence of numerous mitotic figures. Macrophages surrounded by a clear area, giving a starry sky appearance, may be seen in all four types of childhood lymphoma, although it is most commonly associated with BL. DLBCLs contain large nuclei compared to their surrounding histiocytes. PMBCL is characterized by large lymphoid cells with abundant cytoplasm usually in the presence of sclerosis indicated by thick bands of collagen fibers. The morphology of LBL is indistinguishable from that of ALL, a homogenous proliferation of medium-sized cells with high nuclear/cytoplasmic ratio. Finally, a diffuse proliferation of large cells with abundant, faintly basophilic cytoplasm and pleomorphic, often reniform

nuclei characterize ALCL. In addition to the four major types of NHL, children may present with a number of lymphoproliferative disorders, generally in the setting of congenital or acquired immunodeficiency.

Molecular Biology

The most common molecular alterations in NHL are rearrangements in immunoglobulin (Ig) and T-cell receptor (TCR) genes. Normally, rearrangement of Ig heavy and light chains and all four chains of the TCR occurs at precise times during differentiation. In B cells, heavy chain rearrangement occurs before light chain and κ light chain before λ. In T cells, γ- and δ-chain genes rearrange before α and β. DNA polymerase chain reaction (PCR) methods are used to identify these Ig and TCR gene rearrangements and thereby establish clonality.

Rearrangements of these receptor genes are not always lineage-specific. Ig gene rearrangements may be seen in T-cell disease, and TCR rearrangements in B-cell disease. Rearrangements involving light chain receptor genes tend to be more specific for B-lineage disease than heavy chain gene rearrangements, which may also be observed in other lineages [22]. PCR measurement of specific Ig rearrangements is being utilized to detect minimal residual disease (MRD) after induction chemotherapy in B-NHL [23], while PCR measurement of the protein product of the t(2;5) translocation in blood and bone marrow is being evaluated as a measure of minimal disseminated disease (MDD) at diagnosis and MRD after initiation of therapy in patients with ALCL [24]. In T-cell lymphoblastic lymphoma (T-LL), MDD and MRD can be evaluated by PCR amplification of genetic abnormalities and clonal TCR rearrangements or by flow cytometric methods [25] and these appear to be of prognostic significance [26].

Clinical Presentation

Pediatric NHL usually arises in lymphoid tissue, grows rapidly, and tends to spread, so that the majority of children present with locally advanced or metastatic disease. Only 10–15% of childhood NHL present with primary peripheral nodal disease and a minority present with involvement of extralymphatic tissue such as bone, skin, lung, and gonad. Involvement of the CNS presents as leptomeningeal (headache, neck stiffness, back pain) or cranial nerve palsies. Paraplegia due to spinal cord compression also occurs. There is a clear link between the different subtypes of NHL and their clinical presentation, described later in this chapter.

Diagnosis

The aggressive nature of most pediatric NHL stresses the urgency to obtain a diagnosis and begin therapy as soon as possible. Correct diagnosis requires morphology, cytochemistry, immunophenotyping, cytogenetics, and molecular genetics. Whenever possible, diagnostic tissue should be obtained from the most accessible site and large samples are generally preferred. On occasion, when the clinical situation limits the ability to obtain tissue under a general anesthetic, as in the case of a mediastinal mass, alternative tissue specimens may yield enough material for diagnosis and for limited additional studies such as cytogenetics or molecular genetics. This may include aspiration of pleural or pericardial fluid, bone marrow aspirate and biopsy, tissue biopsy

under local anesthetic and as a last resort fine-needle aspiration (FNA) of the tumor. In view of new biology-based approaches to therapy, however, fresh-frozen tissue is becoming increasingly important and excisional biopsies are often required to obtain adequate samples.

Before the patient is sent for biopsy, investigations to assess the extent of disease and of tumor-induced complications need to be made in a timely fashion. In particular, patients with large abdominal tumors need to be evaluated for gastrointestinal obstruction or perforation, as well as for renal impairment due to kidney infiltration, obstruction, or hyperuricemia. Patients with an anterior mediastinal mass need urgent evaluation for airway or superior vena cava (SVC) compression, right ventricular outflow compression, pleural effusion, and cardiac tamponade. It is important that these patients not be put under general anesthesia or into a supine position for the investigations, but instead procedures should be done with patients prone or lying on their side, and no patient with airway obstruction should be sedated for a procedure without consultation with an experienced anesthesiologist.

When anesthesia is considered to be too hazardous and diagnosis cannot be obtained from a peripheral node, pleural/pericardial fluid, or bone marrow, the mediastinal mass may be reduced in size by administration of corticosteroid therapy until a biopsy can safely be performed. An open biopsy must be performed as soon as possible, generally no longer than 24–36 hours after starting steroids, so that sufficient viable tissue is available for pathologic diagnosis and for important biology studies. A single-institutional review of 23 children with mediastinal lymphoma who received pre-biopsy steroids showed that 5 of 23 (22%) had a delay in diagnosis, failure in definitive diagnosis, or inaccurate staging as a result [27]. Appropriate prophylactic measures, such as the use of hydration and agents directed at reducing the risk of urate crystal formation, should be started early since steroid therapy may result in tumor lysis syndrome (TLS).

Staging and Risk Stratification

A comprehensive assessment includes complete blood cell count and differential, blood chemistry for renal and liver function studies, uric acid, potassium, phosphate, and calcium (tumor lysis syndrome) and lactate dehydrogenase (LDH) as a measure of tumor burden. Studies of the primary tumor include chest X-ray, computed tomography (CT) of neck, chest, abdomen, and pelvis (and occasionally head), ultrasound, and echocardiogram. Magnetic resonance imaging (MRI) scans are done for CNS and paraspinal disease, although limitations exist especially within the pediatric population. Extension of disease is determined by CSF examination and bilateral bone marrow aspirate and biopsy. Tests for CMV, VZV, hepatitis viruses, and EBV are recommended prior to therapy. HIV status should be assessed if clinically indicated.

The most widely used staging system for pediatric NHL is the St. Jude's system (Table 46.3), which is applicable to all major subtypes and separates patients with localized disease (stages I and II) from those with advanced disease (stage III and IV) [28]. Recently, a new Revised International Pediatric NHL Staging System (IPNHLSS) and Response Criteria was developed to address limitations of the former staging system, by incorporating new histiologic subtypes, giving recognition to sites of extranodal involvement, and improved diagnostic and imaging methods [29, 30].

Patients with stage IV NHL have bone marrow involvement with less than 25% blasts and/or have CNS disease; more than 25% tumor cells in the bone marrow is, by the WHO classification scheme, called leukemia. CNS disease is defined as blasts in cerebrospinal fluid, leptomeningeal infiltration, isolated cranial nerve palsy, or intracranial tumor masses. Isolated extradural disease which does not confer the same prognosis should be defined as stage III lymphoma, as should multifocal bone disease. The role of

Table 46.3 International pediatric non-Hodgkin lymphoma staging system

Stage	Description
Stage I	Single tumor with exclusion of mediastinum and abdomen (N; EN; B or S: EN-B, EN-S)
Stage II	Single EN tumor with regional node involvement
	≥Two N areas on same side of diaphragm
	Primary GI tract tumor (usually in ileocecal area), involvement of associated mesenteric nodes, that is completely resectable (if malignant ascites or extension of tumor to adjacent organs, it should be regarded as stage III)
Stage III	≥Two EN tumors (including EN-B or EN-S) above and/or below diaphragm
	≥Two N areas above and below diaphragm
	Any intrathoracic tumor (mediastinal, hilar, pulmonary, pleural, or thymic)
	Intra-abdominal and retroperitoneal disease, including liver, spleen, kidney, and/or ovary localizations, regardless of degree of resection (except primary GI tract tumor [usually in ileocecal region] involvement of associated mesenteric nodes that is completely resectable)
	Any paraspinal or epidural tumor, regardless of whether other sites are involved
	Single B lesion with concomitant involvement of EN and/or nonregional N sites
Stage IV	Any of the above findings with initial involvement of CNS (stage IV CNS), BM (stage IV BM), or both (stage IV combined) based on conventional methods

B bone, *BM* bone marrow, *EN* extranodal, *N* nodal, *S* skin

Data from Rosolen A, Perkins SL, Pinkerton CR, Guillerman RP, Sandlund JT, Patte C, et al. Revised International Pediatric Non-Hodgkin Lymphoma Staging System. J Clin Oncol 2015 Jun 20;33(18):2112–2118 [29]

fluorodeoxyglucose (FDG) positron emission tomography (FDG-PET) in staging and response evaluation is emerging as a powerful tool with increased sensitivity compared to CT, but its use for therapeutic stratification and modification is still being investigated [30, 32]. Significant differences in intensity and length of therapy as well as in prognosis for patients with localized and advanced-stage NHL emphasize the importance of accurate disease staging.

For risk stratification of mature B-NHL, a more useful clinically based grouping system was developed by the Lymphome Malins de Burkitt (LMB) group [33]. Group A (low-risk) defined as resected stage I and abdominal primary tumor completely resected stage II; Group C (high-risk) defined as bone marrow disease (≥25% L3 blasts) and/or CNS disease; Group B (intermediate-risk) comprises all others. In addition, an elevated LDH level at diagnosis that is above twice the upper limit of normal [33] or ≥500 U/L [34] continues to have negative prognostic significance among intermediate-risk patients and is currently used to stratify LMB Group B patients into high- and low-risk strata in an ongoing international B-NHL clinical trial. A similar "grouping" system is utilized by the Berlin-Frankfurt Muenster (BFM) study group which incorporates LDH levels within the R1-R4 grading system [35]. International Response Criteria have recently been developed to improve the assessment of treatment response based on contemporary imaging, flow cytometric and molecular techniques [30].

Treatment Approaches and Prognosis

Surgery is occasionally needed to deal with acute complications such as intussusception, bleeding, or bowel perforation but most importantly to obtain adequate tissue for diagnosis. Localized abdominal tumors seen at the time of laparotomy are often easily resected, and the prognosis is generally excellent. Surgery should not be performed for the purpose of resection or for debulking large tumors; in addition, surgical interventions that delay the onset of chemotherapy should be avoided. The place of surgery in the assessment of residual tumors postchemotherapy is controversial. The French Society for Pediatric Oncology (SFOP) demonstrated that 75% of residual abdominal masses were necrotic [33] and suggested that second-look surgery was necessary to define remission status. The success of intensification of therapy in patients with viable disease found by biopsy suggests that an accurate assessment of residual tumor may be useful and prognostic.

Radiation therapy (RT) has been relegated to a secondary role in the treatment of NHL. In patients treated with adequate chemotherapy, RT has been shown to increase both short-term and long-term morbidity without providing therapeutic advantage. RT is therefore omitted in most modern protocols except for patients with CNS disease. Even for patients presenting with a paraspinal mass and paraplegia, no advantage of addition of RT has been demonstrated, and RT should be limited to patients who fail to respond rapidly to chemotherapy [13]. Possibly because of rapid cell cycling, radiation given in single daily fractions is relatively ineffective in Burkitt lymphoma [36], although a later study suggests that hyperfractionation with at least three fractions per day may have some benefit [37]. This should be taken into account when total body irradiation (TBI) is considered for relapsed BL in the setting of hematopoietic stem cell transplantation.

Combination chemotherapy is the primary treatment modality for childhood NHL. The use of multiagent, intensive chemotherapy regimens, based on alkylators, anthracyclines, and high-dose methotrexate, has markedly improved survival for children with NHL. The treatment protocol should be based on the subtype and extent of disease. Supportive care measures to reduce the risk of TLS should be considered and instituted early at presentation [38].

Burkitt Lymphomas

Pathology

Burkitt lymphoma (BL) represents the neoplastic transformation of a relatively mature B-cell precursor that expresses surface immunoglobulin [39]. BL exhibits a diffuse monomorphic proliferation of cells with a high nuclear/cytoplasmic ratio and deeply basophilic cytoplasm containing lipid vacuoles. Single-cell necrosis with ingestion of debris by macrophages, leading to the starry sky pattern, is frequently present. The nuclei are similar to or slightly smaller than histiocyte nuclei, and the lymphoma cells have been categorized as small noncleaved lymphocytes. The cells in BL are fairly monomorphic in size and shape, with clumped or irregularly distributed nuclear chromatin and two to five nucleoli. Previously a category of disease named Burkitt-like lymphoma was utilized. In the Burkitt-like subtype, there is more heterogeneity in cell size, and nucleoli tend to be fewer and more prominent. There has been much controversy concerning the significance of Burkitt vs. Burkitt-like histology. Recent work from the BFM group, using gene expression analysis, is beginning to shed light on this distinction affirming that the majority of Burkitt-like lymphomas are molecularly identical to BL and can be treated with the same regimen. Flow cytometry and immunohistochemistry demonstrate B-cell markers CD19 and CD20 and IgM class surface immunoglobulin with light chain κ or λ restriction. CD10 (common ALL antigen) is usually present in BL. Terminal deoxynucleotidyl transferase (TdT) is negative in Burkitt lymphoma cells, reflecting their mature phenotype.

Molecular Biology

BLs have characteristic cytogenetic changes, which in 80% of cases involve translocation of the *C-MYC* proto-oncogene on chromosome 8 (involved in cell proliferation and differentiation) to the Ig heavy chain gene locus on chromosome 14 (t[8;14] [q24;q32]). In the remaining 20% of cases, *C-MYC* is translocated to the κ light chain gene locus on chromosome 2 (t[2:8] [p11;q24]) or to the λ light chain locus on chromosome 22 (t[8;22] [q24;q11]). Although the t(8;14)(q24;q32) is common to both sporadic and endemic BL, the breakpoints within the two genes are different. Both chromosomal translocations result in juxtaposition of *C-MYC* next to the highly active *Ig* gene, leading to deregulation and uncontrolled expression of the C-MYC protein [39]. Gene expression profiling can be used to classify mature B-NHL into BL and DLBCL with increased precision. With this technology, Burkitt-like lymphoma was found to group with histologically classical BL based on similar gene expression signatures and together comprising 63% of pediatric B-NHL [40]. There remains debate on whether *C-MYC*-negative cases can be considered as true BL. A recently identified subgroup of lymphomas that resemble BL morphologically but lack *C-MYC* rearrangement and known to have 11q alteration is considered a new entity in the revised WHO classification [17, 41]. Cytogenetic abnormalities have not been used for risk stratification, but data suggest that rearranged *MYC* (8q24), del(13q), +7q, del(17p), and abnormalities in 13q and 22q are independent predictors of poor prognosis among B-NHL [42–45].

Clinical Presentation

Despite a similar histologic appearance, the sporadic and endemic BL differ in their clinical presentation. The peak age for presentation is 11 years in the sporadic type (North American and European) and 7 years in the endemic (African) type with a male predominance of 2–3:1 in both [46].

In the sporadic type, 60–90% of BL present with abdominal disease, while the remainder arise from B lymphocytes in the Waldeyer ring lymph nodes (tonsils, adenoids), peripheral nodes, or the mediastinum [33, 47, 48]. BL arises most commonly from relatively mature B cells in Peyer's patches within the gastrointestinal (GI) tract, most commonly at the ileocecal junction. Gonadal and kidney involvement is common. Bowel obstruction is a common presenting symptom. Eighty percent of patients present with an abdominal mass or with abdominal pain, abdominal distension, nausea, and vomiting. A localized BL may act as the lead point for an intussusception, and the tumor is not infrequently diagnosed during surgery for acute appendicitis. Involvement of tonsil or adenoid may lead to airway obstruction, commonly associated with nontender cervical adenopathy.

Jaw involvement occurs in only 15% of patients with sporadic BL and then usually as part of multiple bone metastases, whereas endemic (African) BL commonly presents with jaw tumors (70%) as well as involvement of the GI tract and kidneys. Peripheral lymph node involvement is unusual in patients with the endemic form of the disease. Bone marrow and CNS involvement may be seen with BL. Endemic BL patients more commonly present with CNS disease (leptomeningeal, cranial nerve palsies, and paraplegia), whereas bone marrow disease occurs more frequently in patients with sporadic BL.

BL is an extremely fast growing malignancy with a cell cycle doubling time of 2–3 days and a high spontaneous rate of apoptosis [46]. Patients with these tumors have the highest risk of any malignancy of developing TLS before or after the start of therapy. The survival of patients with BL was very poor until chemotherapy protocols were designed to take advantage of the very rapid cell cycling.

Treatment

Treatment of Localized Burkitt Lymphoma

Survival of patients with localized BL and B-large-cell lymphomas exceeds 95% at 5 years of follow-up, permitting investigators to focus on reducing treatment-related morbidity [13, 49].

In the Pediatric Oncology Group (POG) 9219 trial, patients with stage I and II nonlymphoblastic disease treated with 9 weeks of cyclophosphamide–doxorubicin-vincristine–prednisone (CHOP)-based chemotherapy achieved an event-free survival (EFS) close to 90% and demonstrated that radiation therapy can be safely omitted even for bone disease [49]. A similarly excellent outcome was achieved by the international FAB/LMB 96 study with a 4-year EFS of 98% and overall survival (OS) of 99%, after two courses of COPAD chemotherapy, a regimen that does not include intrathecal therapy [50]. It is difficult to compare efficacy of the two protocols as the POG trial enrolled patients with stage I and II resected and unresected disease, whereas the FAB/LMB96 study enrolled only patients with resected disease (stage I or stage II); unresected disease was assigned to Group B. It appears that either strategy is acceptable for localized B-NHL. Regardless of the exact therapy, the patients who relapsed did so within a year from diagnosis.

Treatment of Advanced (Stage III and IV) Burkitt Lymphoma

During the last few decades major improvements have been seen in the cure rate of BL and mature B-ALL, from less than 30% in the early 1980s to close to 90% currently. Starting

with the St. Jude Total B therapy [28], chemotherapy protocols have been developed based on the very rapid growth rate of these tumors; these include short-duration, dose-intensified, rapidly cycling courses involving high-dose S-phase drugs that cross the blood–brain barrier. Most successful protocols combine high doses of cyclophosphamide given in divided doses over a period of 3–5 days in combination with high-dose methotrexate (MTX) as well as high-dose cytosine arabinoside (Ara-C), together with vincristine and with or without anthracycline. All protocols include a corticosteroid in the form of prednisone or dexamethasone.

Reports of the best outcomes include those of the Société Française d'Odontologie Pédiatrique (SFOP) LMB 89 protocol (Table 46.4). A total of 561 patients were allocated to three risk groups (A, B, and C) and therapy was adapted to each risk group. This protocol resulted in an OS of 91% at 5 years, 87% for stage IV, 88% for B-ALL, and an improvement in DFS for CNS-positive patients to 79% from 19% in the earlier LMB 81 study [33]. The 5-year DFS was 95% for patients with a low LDH compared to 87% for those whose LDH was increased twofold or more ($p < 0.001$), except in Group C patients in whom neither LDH nor bone marrow involvement was predictive of outcome. To build upon these excellent results, the SFOP, the Children's Cancer Group (CCG), and the United Kingdom Children's Cancer Study Group (UKCCSG) combined to conduct the French–American–British FAB/LMB 96 trial, which aimed at reducing therapy and minimizing toxicity while maintaining efficacy of LMB89. Among children with intermediate-risk B-cell NHL (Group B), a reduction to half-dose cyclophosphamide (1.5 g/m^2) in Induction Block 2 (COPADM1) and the omission of Maintenance Block M1 yielded a 4-year EFS of 91%, no different from the full dose arm [48]. Delay in therapy of >21 days between courses 1 and 2, however, significantly adversely impacted survival, stressing the importance of treatment intensity [51].

For Group C patients, the probability of 4-year EFS and OS was 79% and 82%, respectively. FAB/LMB96 randomized patients who responded following COPADM2 to either a standard arm or a reduced intensity arm, leading to a 4-year EFS of 90% vs. 80%, respectively, and early closure of the reduced intensity arm [31]. This dimimution in efficacy was noted in both CNS-negative (94% vs. 86%) and CNS-positive (84% vs. 72%) patients. Importantly, CNS-positive patients showed similar outcomes to LMB89 (EFS 79%) after high-dose methotrexate (8 g/m^2) and additional intrathecal chemotherapy while omitting cranial irradiation [31]. An important finding of this study was the delineation of groups with poorer outcomes who require intensification or alternative therapy in future protocols, such as those who responded poorly to the COP prephase (incomplete responders 78% vs. nonresponders 30% 4-year EFS), patients with combined bone marrow and CNS disease (61% 4-year EFS), and those with primary mediastinal diffuse large B-cell lymphoma (72% 4-year EFS) [48].

Other groups have produced similar results. In the BFM-NHL 86/90 and 95 studies, the BFM confirmed the safe omission of cranial radiation even for CNS-positive disease and the importance of high-dose methotrexate and high-dose Ara-C in advanced disease. They also confirmed that toxicity could be reduced and efficacy maintained by shortening intravenous methotrexate to 4 h vs. 24 h in those with limited stage B-NHL (Groups R1 and R2: stage I, II, and III with LDH < 500 U/L—failure-free survival (FFS) 95%) but not in patients with advanced disease (Table 46.5) [35].

Both the BFM and LMB groups showed that patients with residual disease following three courses of chemotherapy could be successfully treated with high-dose chemotherapy (HDCT) and autologous bone marrow transplant (ABMT). In BFM-90, only 1 of 6 patients suffered from disease progression and in LMB-89, 9 patients out of 12 achieved a CR

IV indicates intravenously, *h* hour; *IT* intrathecally

Reproduced with permission from Woessmann W, Seidemann K, Mann G, et al. The impact of the methotrexate administration schedule and dose in the treatment of children and adolescents with B-cell neoplasms: a report of the BFM Group Study NHL-BFM95. Blood 2005; 105:948–58

[a]Doses were adjusted for children younger than 3 years. In courses A, B, AA, and BB, intrathecal therapy was administered 24 h after beginning of MTX intravenous infusion

[b]Doses are 12 h apart

[c]Patients were randomized to receive MTX as continuous intravenous infusion either over 24 h or over 4 h. In the 24-h arm, 10% of the MTX dose was given within 0.5 h, 90% of dose intravenously over 23.5 h. Racemic folinic acid (leucovorin) intravenously 15 mg/m^2 at hours 42, 48, and 54 after beginning of MTX. In courses AA and BB, the dose of leucovorin at hour 42 was 30 mg/m^2 intravenously. Adjustment of leucovorin dose in case of impaired MTX excretion as previously described [4]

[d]For CNS-positive patients, chemotherapy was applied intraventricularly as described in "Chemotherapy"

[e]Courses AA and BB are the same as A and B, respectively, with the exception listed

[f]Subdivided into three doses

[g]Maximum dose was 2 mg; vincristine was not given in patients of branch R1

[h]Maximum dose was 5 mg

after HDCT and ABMT [33, 34]. By comparison, four of five partial responders in BFM-86 treated with chemotherapy alone died. These results suggest that surgery to confirm residual tumor is necessary, as high-dose therapy may be successful for tumors that respond slowly but remain chemotherapy-sensitive. The role of PET-scans to allow avoidance of second look surgery has not yet been established.

Although it is generally accepted that cranial radiation does not improve results, the outcome for CNS-positive patients remains inferior at 82% compared to 88% 4-year EFS for bone marrow-positive/CNS-negative patients, and ≥90% 4-year EFS for the BM-positive/CNS-negative patients randomized to standard treatment (Table 46.4) [31]. Further intensification of methotrexate is currently being tested for this subgroup.

The addition of the anti-CD20 monoclonal antibody rituximab to chemotherapy is standard for all adult B-NHL but its value in pediatric CD20-positive NHL had not been definitively tested until recently. The COG study ANHL01P1 was a non-randomized pilot study designed to evaluate the safety of rituximab when added to Group B and Group C LMB-type therapy (Table 46.4) [53]. Results show that rituximab was well tolerated on the LMB backbone and though not designed to test efficacy, the best outcomes within Group B and C therapy were achieved with 3 year EFS of 95% and 90%, respectively [52, 53]. Even Group C patients with BM and CNS involvement, the worse prognostic group, showed remarkable improvement in 3 year EFS of 93%, in this pilot study.

The first interim analysis of the ongoing randomized Intergroup trial Inter-B-NHL Ritux 2010, evaluating the efficacy of rituximab in addition to standard LMB chemotherapy for patients with higher risk disease (group B/high LDH and group C) confirmed improvement in the rituximab arm,

resulting in an early 1-year EFS of 94% vs. 82%, mandating the early cessation of randomization in the study [54]. The addition of anti-CD20 antibody to chemotherapy is, therefore, now being considered standard of therapy for mature B-NHL in those countries where it is available.

Summary of the Findings of the Cooperative Group Trials

1. Advanced-stage Burkitt and B-cell ALL can successfully be treated with a short duration (3–6 months) of very intensive, multiagent alkylator-based chemotherapy.
2. Successive cycles of chemotherapy need to be given with minimal delay to prevent progression of these rapidly growing tumors.
3. Improvement in cure rate in advanced-stage disease occurred with increasing intensity of chemotherapy, particularly higher doses of methotrexate.
4. The addition of high-dose antimetabolite therapy, such as high-dose MTX and high-dose Ara-C, and intrathecal therapy is successful in prophylaxis and treatment of CNS disease, although CNS-positive patients have an inferior prognosis compared to CNS-negative patients. Intensification of methotrexate dose intensity through prolongation of the duration of high-dose MTX infusion is being tested by the LMB group.
5. Involvement of the bone marrow alone at diagnosis is no longer indicative of a poor prognosis. However, involvement of both CNS and bone marrow still carries an inferior prognosis.
6. A high LDH level at diagnosis remains an adverse prognostic factor in patients on intermediate risk therapy but not in the most intensively treated patients.
7. Most patients with BL who relapse will do so within the first 8 months after diagnosis. Patients with BL who survive disease-free for 10 months are likely to be cured.
8. Patients with residual, histologically proven disease after three therapy courses have an increased risk of disease recurrence, which is not reduced by local surgery or radiation, but may be improved by intensification of therapy.
9. Anti-CD20 monoclonal antibody therapy is emerging as an effective agent that can be added to traditional chemotherapy without significant additional toxicities and with improvement in EFS.

Lymphoblastic Lymphoma

Pathology

Unlike ALL, the majority of childhood lymphoblastic lymphomas (LBL) are of T-cell origin (85–90%) rather than B-precursor (10–15%) [55]. T-LBL and B-LBL appear histologically similar, but T-cell LBL most commonly presents with advanced-stage disease, whereas precursor B-cell LBL more often presents with localized disease and may present at unusual sites such as skin or bone or with disease below the diaphragm [56, 57].

LBL consists of cells that are morphologically indistinguishable from ALL. There is diffuse proliferation of medium-sized cells with a high nuclear/cytoplasmic ratio and scant amounts of basophilic cytoplasm (usually less basophilic than Burkitt lymphoma cells). The nuclear chromatin is finely stippled with indistinct nucleoli, and some degree of nuclear convolution may be seen in up to 50% of cases [58]. Mitotic activity is prominent and the starry sky histological pattern is commonly seen. The cells stain strongly for acid phosphatase; TdT is usually positive. By convention, LBL that involves more than 25% lymphoblasts in the bone marrow is called lymphoblastic leukemia and is indistinguishable from T or B-lineage ALL (B-ALL/T-ALL).

T-cell LBL is derived from thymic T cells most of which express the pan-T antigen CD7 as well as CD3. Other antigens that may be expressed depending on the stage of differentiation are CD1a, CD2, CD4, CD5 and CD8, and CD45RO, as well as other markers of immature T cells such as CD4 and CD8 double positivity or double negativity. CD10 (CALLA) is positive in about 50% of T-LBL cases [58].

Despite the morphologic similarity between LBL and ALL, subtle differences in the immunophenotype suggest that T-cell ALL may be derived from early to intermediate thymocytes, whereas T-LBL is more frequently derived from cells in the intermediate to late thymocyte stage [59]. Recent techniques using gene expression profiling have further enhanced the ability to distinguish between these two entities (see next section in this chapter).

Precursor B-cell LBL expresses the phenotype of common childhood precursor B-cell ALL (CD10, CD19, CD22, HLA-DR, TdT).

Diagnosis of T-LBL may be made on cytological and immunologic evaluation of pleural and/or pericardial effusions; however, care must be taken in the interpretation. Any large anterior mediastinal mass may, as a consequence of compression, result in the presence of thoracic duct lymphocytes, which morphologically resemble T lymphoblasts within pleural and pericardial fluid. The presence of TdT within the cells may be necessary for confirmation of the diagnosis. The combination of flow cytometric analysis and cell block immunohistochemistry on samples obtained by FNA, pleural or pericardial aspiration may obviate the need for biopsy in patients at high anesthetic risk [60]. Flow cytometry on CSF samples has been shown to improve detection of occult leptomeningeal disease in ALL and LBL. Adult patients who were CSF cytology negative but

FCM positive and who received standard CNS prophylaxis had a higher CNS relapse rate and lower 2-year OS, suggesting that these patients require more intensive CNS-directed therapy [61].

Molecular Biology

The study of chromosomal abnormalities in T-LBL has lagged behind that of T-ALL due to lack of adequate biopsy samples, nonetheless, chromosomal aberrations reported in T-ALL have been shown to be found in a proportion of T-LBL cases. Clonal TCR- rearrangements are present in most T-LBL and a proportion will demonstrate specific translocations of additional loci [25]. Many different translocations may be seen in T- LBL, usually involving translocation of a proto-oncogene to one of the TCR genes, α/δ, on chromosome 14 or less commonly, β, on chromosome 7, resulting in aberrant expression of the oncogene. The commonest translocations are t(11;14)(p13;q11) in 7%, t(10;14)(q24;q11) in 5%, and t(1;14)(p32–p34;q11) in 3% of cases [62, 63]. All the translocations found in LBL were previously reported in T-ALL except for t(9;17) which to date has only been found in T-LBL [21]. Studies utilizing genomic and gene expression analysis have shown both similarities and differences between T-LBL and T-ALL. In a recent study, activating NOTCH-1 mutations, found in more than 50% of cases of T-ALL, were found in 60% of T-LBL, suggesting a common pathogenetic mechanism for the two diseases. The study also found differences in expression of genes involved in chemotaxis and angiogenesis and the authors concluded that unique molecular characteristics drive the malignant T-cell precursors to colonize predominantly bone marrow or nodes [64]. Similarly, activating NOTCH 1 mutations were found in 60% of T-LBL patients in a BFM study and as previously reported by others was associated with a favorable prognosis while loss of heterozygosity (LOH) on chromosome 6q14–q24, found to be present in 25 pf 217 patients (12%), was associated with an unfavorable prognosis (EFS 27% vs. 86%) [65]. By contrast, mutations in the tumor suppressor gene FBXW7, responsible for degradation of the active protein intracellular NOTCH1 (ICN1) and found in 10–30% of T-ALL and T-LBL did not affect the 5 year pEFS in multivariate analysis [21]. LOH6q status will be used to identify very-high-risk T-LBL patients in future BFM trials [66]. Strategies that target NOTCH1 upregulation as well as mTOR pathways are currently being investigated in T-ALL and T-LBL [67].

In B-LBL, clonal rearrangements of the IgH gene are usually present and recurrent translocations more commonly seen in precursor B-ALL such as t(9;22)(q34; q11.2), t(12;21)(p13;q22), t(5;14)(q31;q32), and t(1;19)(q23; p13.3) may be found [68].

Clinical Presentation

T-LBL affects males more than females (2.5:1), with a peak age in the early second decade. Fifty percent of patients present with a mediastinal mass, often with pleural and/or pericardial effusions, right ventricular outflow obstruction, and/or a SVC syndrome. Associated symptoms include dyspnea, dysphagia, chest pain, and swelling of the face, neck, and arms. LBL are high-grade lymphomas and TLS may occur, especially if kidney infiltration is present. Urgent diagnosis and therapy are absolutely mandatory. Lymphadenopathy is present in 50–80% of patients and is usually supradiaphragmatic (cervical, supraclavicular, and axillary). Isolated or prominent abdominal disease is rare, although liver, spleen, kidneys, and abdominal lymph nodes may be involved. Bone marrow involvement is found in around 20% of cases, CNS involvement in around 5% and gonadal involvement may also occur [21].

B-LBL tends to present with localized disease and most frequently involves lymph nodes, skin, subcutaneous tissue, and bone, but may occasionally present with intra-abdominal disease. Bone marrow infiltration was found in 30% of patients with B-LBL in the BFM trials and CNS involvement in 5% [21]. B-LBL may occur as isolated skin disease often affecting the craniofacial area. Isolated skin B-LBL shares similar pathologic features to skin B-LBL that is associated with systemic disease and clinical staging is required for differentiation. By contrast, cutaneous T-LBL is usually associated with disseminated disease [69].

Treatment

Treatment of Localized Lymphoblastic Lymphoma

Around 15% of T-LBL presents with stage I or II disease. Early attempts to treat this subgroup with the short duration chemotherapy which was successful in localized mature B-NHL failed with a pEFS of 63% at 5 years in the POG 9219 trial, despite 6 months of continuation therapy with 6-mercaptopurine and low-dose methotrexate. However, an overall survival (OS) of more than 90% at 5 years was achieved by successful treatment for relapsed disease [49]. By contrast, the BFM group used more intensive therapy up-front and achieved an EFS of 92% in localized LBL, using the standard arm of the BFM T-cell ALL protocol [70, 71]. This protocol included standard BFM induction and a consolidation phase (protocol M) consisting of four doses of high-dose (5 g/m^2) methotrexate followed by maintenance therapy for 2 years. No reinduction therapy or local or cranial radiation was given for stage I and II patients.

Similarly, the COG A5971 study treated 60 patients with localized LBL, 75% of whom had B-LBL, with 24 months therapy based on CCG ALL-type therapy without cranial irradiation, and achieved a 5 year EFS and OS of 90% and 96%, respectively. No significant difference was found by stage (I vs. II), immunophenotype (T vs. B), elevated LDH, primary site or age. Unlike the POG 9219 study, patients who relapsed after this intensity of chemotherapy had a very poor salvage rate with four of five relapsed patients dying of disease. No CNS relapses occurred but patients with localized LBL continue to require CNS prophylaxis in the form of intrathecal chemotherapy.

The role of high-dose methotrexate (HDMTX) in localized LBL, utilized in the BFM and French LMT studies, but not in the equally successful EORTC studies, remains uncertain [72]. Based on the results of the COG A5971 randomized study (see discussion in next section), HDMTX is likely not needed in localized LBL.

Table 46.6 Outcome for patients with lymphoblastic lymphoma

Protocol	Number	Stage or risk group	Outcome (%)	References
Localized disease				
BFM-90/95	44	I/II	92% 5-year EFS	Reiter et al., Burkhardt et al. [56, 70, 71]
POG 9219	46	I/II	63% 5-year EFS	Link et al. [49]

Advanced disease				
BFM-90	101	III/IV	90% 5-year EFS	Reiter et al. [70]
BFM-95	169	III/IV, CNS-	82% 5-year EFS	Burkhardt et al. [56]
COG A5971	254	III/IV	80–84% 5-year EFS (all arms)	Termuhlen et al. [77]
AIEOP LNH-97	114	III/IV	74% 7-year EFS	Pillon et al. [75]
SFOP LMT96	79	III/IV	85% 5-year EFS	Bergeron et al. [76]

Treatment of Advanced Lymphoblastic Lymphoma

Lymphoblastic lymphoma has been shown to respond optimally to protocols designed for T-ALL. Local radiation therapy, although effective, results in significant late risks, particularly when applied to the mediastinum, and is unnecessary if adequate chemotherapy is given [11]. All the current cooperative clinical trial group protocols have resulted in an EFS between 75% and 90% [73–77]. The results are summarized in Table 46.6.

Early studies demonstrated the importance of methotrexate intensification [73], and of the addition of l-asparaginase [74]. In 2000, the BFM group published the results of the BFM-90 protocol for patients with advanced-stage (III and IV) T-LBL using 24 months of therapy including a 6-week reintensification block. They achieved a 90% EFS at 5 years for 101 patients with T-cell LBL treated on this protocol without local radiotherapy [70]. Therapy was assigned based on stage, but patients who failed to respond adequately to induction therapy by day 33 as defined by less than 70% reduction in mass, more than 5% blasts in the BM, and/or persistent blasts in the CSF were reassigned to a high-risk ALL protocol (eight patients). The follow-up BFM-95 study showed that omission of prophylactic cranial radiotherapy for patients with CNS-negative stage III or IV T-LBL did not result in increased CNS relapses when four courses of high-dose methotrexate (5 g/m^2) were administered [56]. A contemporaneous COG study (A5971) evaluated CNS prophylaxis and early intensification of therapy with cyclophosphamide and anthracycline in patients with CNS-negative stage III or IV T-LBL on BFM-90-like chemotherapy; 254 patients were randomized to either four doses of 5 g/m^2 MTX with no IT-MTX in maintenance or intensified intrathecal methotrexate. The 5-year EFS for the four arms was 80%, 81%, 80%, and 84%. Age less than 10 years and radiologic response at 2 weeks was associated with improved EFS and OS [77].

Patients with CNS disease at diagnosis had 5-year EFS of 63% despite 4 doses of high-dose MTX and cranial irradiation, with the failures being due to relapse and not toxicity, however, as with earlier trials the small number of patients with LBL with CNS disease at diagnosis do not allow for further conclusions [77].

The cooperative group studies also showed that most of the relapses occur early and the optimal duration of therapy for advanced-stage LBL remains between 18 months (SFOP stages I-III) and 24 months (BFM, COG, AIEOP, SFOP). The EURO-LB 02 trial showed no difference in EFS for 119 patients randomized to 18 vs. 24 months [21]. The same study as well as the randomized EORTC CLG study demonstrated that attempts to improve relapse-free survival by replacing prednisone with dexamethasone in induction failed due to excessive treatment-related mortality in the dexamethasone arms [21, 78].

The role of high-dose MTX in advanced-stage CNS-negative LBL remains controversial. The COG A5971 randomized study showed no survival advantage to high-dose MTX as compared to intensified IT MTX but the latter patients received 11 doses of IT MTX during maintenance, compared to no IT therapy in maintenance for the high-dose MTX group [77]. A comparison of the short- and long-term toxicities of the two therapies would be of great interest but that data is not available.

The use of specific anti-T-cell therapy is currently under investigation. A recently closed COG phase III study tested the addition of nelarabine, a prodrug of Ara-G shown to be toxic to T lymphoblasts through the accumulation of Ara-G nucleotides, to a BFM backbone in high-risk patients with T-ALL but the results are not yet published. The current phase III COG study is evaluating the addition of bortezomib, a selective proteasome inhibitor, to an augmented BFM backbone for patients with T-ALL and T-LBL. If successful, these or similar anti-T-cell specific drugs may be added to the therapy of T-LBL.

Prognostic Factors in T-LBL

The poor salvage rate of patients with advanced-stage T-LBL has resulted in attempts to define subgroups of patients who may require intensified therapy.

Of the clinical parameters only age at diagnosis was found to be prognostic with patients less than 10 years of age having a superior outcome in the BFM, COG A5971 and St Jude Children's Research Hospital (SJCRH) trials. In the SJCRH study this difference was less apparent in the most recent era, suggesting that the more intensive therapy in the current protocols may eliminate the prognostic significance of age [79]. In the COG A5971 trial CNS disease at diagnosis resulted in a significantly poorer outcome but the numbers were too small for firm recommendation [77]. Patients with CNS disease continue to receive more intensive therapy with the addition of high-dose MTX, extra intrathecal therapy and cranial irradiation.

There are currently no reliable clinical prognostic factors for patients with advanced LBL. However, some promising biologic parameters which may be helpful in the future. The ability to evaluate minimal disseminated disease (MDD) by flow cytometry in T-LBL is emerging as a useful prognostic tool [25]. If these results are confirmed in further studies, MDD testing could identify a high-risk subgroup of patients for therapy intensification.

The BFM group have reported that loss of heterozygosity at chromosome 6q14-q24 is significantly associated with an unfavorable prognosis (EFS 27% vs. 86%, $P < 0.0001$) while NOTCH1 mutations were associated with a favorable prognosis (EFS, 84% vs. 66%; $P = 0.021$) [65]. Both prognostic markers will be used as stratification criteria in future BFM trials for lymphoblastic lymphoma.

Finally, early response to therapy is emerging as a prognostic factor.

The EORTC showed that clinical and radiological response to the 7 day prednisone prephase was significantly prognostic, but this needs to be confirmed by other study groups. The COG A5971 study showed that the radiologic response at 2 weeks significantly correlated with EFS and OS. The presence of a residual mediastinal mass at day 33 or at the end of induction was not found to be associated with a decreased survival in the BFM90–95 studies, however, all patients with <70% reduction at end induction had had therapy intensified [18]. It is as yet unclear whether a positive PET-FDG scan in a residual mass at end induction will improve the prognostic value of this finding by helping to differentiate active from necrotic tumor.

Early results suggest that minimal residual disease (MRD) testing by flow cytometry for aberrant immunophenotype and real-time quantitative PCR (RQ-PCR) for clonal TCR-gene rearrangements may be useful in response assessment [80]. To date, however, the place of MDD and MRD assessment in risk stratification remains investigational.

The presence of MDD at diagnosis of T-LBL, that is the detection by flow cytometry of lymphoblasts circulating in peripheral blood despite morphologically negative bone marrow has been shown by the COG and the Italian AIEOP group, to be significantly prognostic of relapse. Recent COG studies have incorporated MDD at diagnosis into risk stratification with the high risk group (>1% $CD3^+$, TDT^+ Cells in peripheral blood at diagnosis) being randomly allocated to the addition of nelarabine and now bortezomib to a standard ALL–type chemotherapy backbone.

B-Lymphoblastic Lymphoma

Because of small patient numbers, the correct treatment for B-lineage LBL (B-LBL) has not been defined in pediatrics. Patients with B-LBL treated with BFM-95 ALL-type therapy achieved a 5-year EFS of 92% [56]. Similar results were reported in the LMT and EORTC trials [81]. Patients with B-lineage LBL should be included on T-cell LBL or ALL-directed regimens and treated for 18–24 months.

Summary of the Findings of the Cooperative Group Trials

The findings of the Cooperative Group protocols may be summarized as follows:

1. Intensive ALL-type therapy results in an EFS of 90% in localized T and B-LBL.
2. Current intensive protocols have improved EFS to 80–85% for advanced-stage T LBL.
3. High-dose MTX (5 g/m^2 per dose) for at least four doses or intensified intrathecal therapy appears to be equally efficacious in advanced-stage T-LBL.
4. L-Asparaginase therapy was shown to be important in POG studies.
5. Local radiation therapy is not indicated if adequate chemotherapy is given.
6. Prophylactic cranial irradiation may be omitted in CNS-negative patients whose therapy includes steroids, intensified intrathecal chemotherapy, and/or high-dose MTX.

7. The SFOP and BFM studies suggest that even in patients with testicular disease at diagnosis, testicular radiation is only indicated for residual disease after high-dose MTX.
8. The length of the maintenance therapy as well as the optimal maintenance drugs remains unclear, but most current protocols utilize ALL-like therapy for a total duration of 18–24 months.
9. There are no clinical parameters including age, gender, site of disease, or LDH which are useful for risk stratification in LBL. Minimal disseminated disease and minimal residual disease testing appear to be promising tools for future studies. The presence of LOH 6q14-q24 suggests the need for therapy intensification while the presence of activating mutations of NOTCH1 is a marker for improved outcome.

Diffuse Large B-Cell Lymphoma

Pathology

Large-cell lymphomas (LCLs) are a heterogenous group of tumors in which the cells contain nuclei that are larger than those of the surrounding histiocytes. Major subtypes of LCL are diffuse large B-cell lymphoma (DLBCL), anaplastic large-cell lymphoma (ALCL), and the other, rarer, peripheral T-cell lymphomas, so-called because of their mature T-cell phenotype.

DLBCLs comprise about 10% of childhood NHL and are the most common subtype among patients with immunodeficiencies. The cells are of mature B-cell phenotype, express CD20, and show light chain restriction (either κ or λ). Surface expression of immunoglobulin may be absent in up to one-third, however [58]. In keeping with the mature B-cell phenotype, they are TdT-negative. Occasional cases of B-cell large-cell NHL with an extensive T-cell reaction (T-cell-rich B-cell lymphoma) have been described [58].

According to the WHO classification, primary mediastinal large B-cell lymphoma (PMBCL) is a rare distinct entity from DLBCL, and only accounts for 2% of all pediatric NHL [4, 17]. PMBCL with sclerosis is characterized by large lymphoid cells with abundant cytoplasm, a vesicular chromatin pattern, and prominent nucleoli. Sclerosis may vary from thick bands of collagen to fine spider-like sclerosis surrounding small groups of cells. The major differential diagnosis involves nodular sclerosing HL and ALCL.

Molecular Biology

Specific recurrent cytogenetic abnormalities are only seen in a minority of patients with DLBCL, although complex cytogenetic findings are common. Some pediatric large-cell lymphomas show the t(8;14)(q24;q32) translocation, which is identical to that seen in Burkitt lymphoma with a similar mechanism of transformation. Unlike in adults, translocations involving *BCL-2*, such as t(14;18)(q32;q21), are rarely seen in childhood DLBCL [82]. Gene expression profiling of adult DLBCL cases suggests the existence of three subgroups: germinal-center B-cell-like, activated B-cell-like, and intermediate group type 3, of which the best outcome is associated with germinal-center subtype. In the pediatric population, gene expression analysis has shown that DLBCL comprises mainly the germinal-center subtype (CD10+ or CD10−/BCL-6+/MUM-1−). These findings in conjunction with the absence of t(14;18) involving the *BCL-2* gene may explain the favorable outcome in children compared to adults [82]. A study which combined gene expression profiling, comparative genomic hybridization (CGH), FISH, and immunohistochemistry showed that one-third of histologic DLBCL were reclassified as BL and only 1 of 14 non-BL mature B-NHL cases showed *MYC* rearrangements. While no difference in survival was shown between these biologic differences, they may provide targets for future therapies [40].

PMBCL is characterized by expression of CD45, CD20, and CD79a, and a diffusely positive pattern for CD30, and recent gene expression studies show an overlap with Hodgkin lymphoma rather than DLBCL [83].

Clinical Presentation

Diffuse large B-cell lymphoma can present in any anatomic site and may present with abdominal disease similar to Burkitt lymphoma or a mediastinal mass similar to lymphoblastic lymphoma. The mediastinal location of primary mediastinal large B-cell lymphoma and the extensive sclerosis associated with it may result in a clinical presentation of airway compromise or SVC syndrome similar to that of lymphoblastic lymphoma. Bone marrow is less frequently involved than in the other types of NHL, and CNS disease is uncommon.

Treatment

The biologic heterogeneity of this subtype of NHL has made the determination of optimal therapy for this group of patients difficult. This is reflected in the fact that the POG studies have treated all patients with early and advanced-stage LCL on the same chemotherapeutic protocols, irrespective of subtype [84, 85]; in contrast, the COG and European study groups have combined all B-cell lymphomas and treated DLBCL and Burkitt lymphoma on the same short, intensive protocols and showed equivalent results for DLBCL and Burkitt lymphoma (Table 46.7) [31, 48].

For localized disease, three courses of CHOP chemotherapy as per POG 9219 achieved a 5-year EFS of 98% and OS of 98% among 46 patients with stage I and II DLBCL [85]. Similarly, the FAB/LMB 96 study achieved a 4-year EFS of 98% and OS of 99% in patients with localized NHL, 57 of whom had DLBCL, and none of whom had any events [50].

Table 46.7 Outcome for patients with diffuse large B-cell lymphoma

Protocol	Number	Stage or risk group	Outcome (%)	References
Localized disease				
POG 9219	46	I/II	98% 5-year EFS	Link et al. [85]
FAB LMB 96 Group A	57	Stage I/II completely resected	100% 4-year EFS	Gerrard et al. [50]
Advanced disease				
POG 9315	73	III/IV	64% 4-year EFS[a]	Laver et al. [84]
FAB LMB 96 Group B	145	DLBCL	93% 4-year EFS	Patte et al. [48]
	32	PMBCL	72% 4-year EFS	
FAB LMB 96 Group C	21	IV, BM+/CNS + among responders	90% 4-year EFS (reported no different than BL)	Cairo et al. [31]
BFM-95	81	Group R3	85% 3-year EFS	Woessmann et al. [35]
		Group R4	81% 3-year EFS	

[a]Outcome in treatment arm APO (doxorubicin, vincristine, prednisone) was not different from the experimental arm IDM/HiDAC (intermediate-dose methotrexate/high-dose cytarabine), EFS 64% vs. 70%, respectively

In intermediate-risk (Group B) DLBCL, the FAB/LMB 96 trial demonstrated a 4-year EFS of 93% [48] while the BFM group reported a 3-year EFS of 85% and 81% for all patients in risk groups R3 and R4, respectively, indicating no difference between patients with BL and DLBCL [35].

Patients with DLBCL appear to do well with either short, intensive alkylator-based therapy or longer, less intensive anthracycline/steroid-based therapy.

Primary mediastinal large B-cell lymphoma carries a poorer prognosis in pediatrics compared to adults, possibly because of the omission of involved field radiation therapy (IFRT) in children. Within pediatrics, patients with PMBCL treated on three successive BFM studies had a lower 5 year EFS of 70% when compared to DLBCL [4]. In patients with intermediate-risk disease treated on FAB/LMB96, those with PMBCL had a lower 5-year EFS of 66% compared with 85% among those with DLBCL [86]. Adult studies suggest that patients have an improved outcome on intensified chemotherapy protocols compared to CHOP [87, 88]. The NCI dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin, and rituximab (EPOCH-R) protocol has resulted in significantly improved 5 year 93% EFS and 97% OS in adult PMBCL without IFRT [89]. This same regimen is currently being tested in a phase II setting for pediatric PMBCL in the ongoing Inter-B-NHL Ritux 2010 Clinical Trial.

Summary of the Findings of the Cooperative Group Trials

1. Patients with large B-cell lymphomas do well on either a short intensive Burkitt lymphoma-like regimen or a longer, less intensive regimen. Most groups are including DLBCL patients on BL protocols, including the international COG-European B-NHL study (Inter-B-NHL Ritux 2010), which initial results have shown that the addition of rituximab is superior, leading to the early cessation of randomization for mature CD20 positiv e NHL.
2. In the BFM and SFOP studies, intermediate- or high-dose MTX with (BFM) or without (SFOP) intrathecal therapy effectively prevents CNS relapse without cranial irradiation. Local radiotherapy appears to be of little value in DLBCL, even when bulk disease is present.
3. As in Burkitt lymphoma, residual tumor after chemotherapy is usually necrotic, but should be confirmed following resection. If residual lymphoma is detected, intensified, systemic therapy rather than local radiation therapy is indicated.
4. PMBCL appears to have a better prognosis with intensive chemotherapy and the benefit of the addition of rituximab in adults has yet to be confirmed in pediatric studies.

Anaplastic Large-Cell Lymphoma

Pathology

Anaplastic large-cell lymphoma accounts for 10–15% of pediatric NHL. The histopathologic characteristics include cells with eccentric kidney shaped nuclei often with an eosinophilic area near the nucleus. There are currently five morphologic subcategories of ALK-positive ALCL included in the 2008 World Health Organization (WHO) classification system including common, small cell, lymphohistiocytic, Hodgkin-like, and composite [90]. ALK-negative ALCL, a much rarer diagnosis in children is considered a provisional entity in the current WHO system [17].

ALCL is uniformly CD30 positive. T-cell antigens are commonly expressed including CD2, CD4, and CD5. CD3 and CD8 are often negative. Some cases are described as having a “null cell” phenotype with absence of T cell markers however recent studies suggest a T-cell lineage based on gene signature [91]. The “null cell” phenotype is of no clinical or prognostic significance. Epithelial membrane antigen (EMA) is generally positive, and CD25 (IL2-R) is often expressed.

Molecular Biology

Unlike adult ALCL where only 40–50% are ALK positive, in children more than 90% have disease that harbors a

translocation involving ALK The most common translocation, t(2;5)(p23;q35) relocates a promoter sequence of the nucleolar phosphoprotein encoding gene (*NPM*) on 5q35 to the anaplastic lymphoma kinase gene *ALK* on 2p23, results in production of the fusion protein NPM-ALK and accounts for 90% of pediatric ALK-positive ALCL [92]. Other chromosomal rearrangements, such as inv 2 (p23;q35) and t(1;2)(q25;p23), as well as variant traslocations with partner genes on chromosomes 3, 9, 17, 19, and 22 also result in ALK expression through novel fusion partners [93]. The ALK protein can be recognized immunohistochemically on fixed tissue using an anti-ALK1 monoclonal antibody. The pattern of staining is concordant with the specific translocation, with only the NPM-ALK fusion showing both cytoplasmic and nuclear and nucleolar staining, while variant translocations, including t(1;2)(q25;p23) have ALK staining restricted to the cytoplasm [92]. Expression of ALK is normally confined to cells of the nervous system and is not detected in normal lymphocytes. Overexpression of *ALK* leading to inappropriate phosphorylation of intercellular growth regulators and inducing cell transformation has been shown to be essential for lymphoma growth and survival [94].

Clinical Presentation

Most children with ALCL present with advanced-stage disease involving nodal areas, including mediastinum, intra-abdominal and peripheral nodes and extranodal sites such as liver, bone, skin, and soft tissue [95]. Bone marrow involvement detected by morphology occurs in 10–15% of patients whereas detection by PCR for NPM-ALK occurs in approximately half of patients tested CNS involvement is rare occurring in approximately 3% of children. Very rarely ALCL can present in a leukemoid phase which can associated with diffuse pulmonary infiltrates.

Unlike the other lymphomas, lymphadenopathy due to ALCL may be tender to palpation and is more commonly associated with B symptoms, including fever, night sweats, and unexplained weight loss, as well as laboratory findings of, a high leukocyte count and thrombocytosis, all of which are thought to be due to excess cytokine production by lymphoma cells. ALCL must be included in the differential diagnosis of persistent fever and lymphadenopathy, particularly as a waxing and waning course may be seen, followed by rapid progression. This spontaneous regression may be mediated by cytokines such as TGF-β [96], and the rapid progression that may follow is thought to be due to escape from the cytokine-mediated effects.

Primary Cutaneous ALCL

Isolated cutaneous ALCL is usually ALK negative. Pathologically it can be indistinguishable from lymphomatoid papulosis. Primary cutaneous ALCL has a favorable prognosis and can be managed with initial observation only. Surgical excision or low-dose radiation have been used with excellent results for localized disease [97]. Low-dose oral methotrexate and more recently both vinblastine and Brentuximab vedotin have been shown to be of benefit in multifocal cutaneous disease [98, 99]. The presence of ALK protein indicates the necessity to treat as systemic ALCL [100].

Treatment

Treatment of Localized ALCL

The prognosis for the relatively rare patients with low stage disease, and in particular resectable disease, is very favorable. Six weeks of CHOP-based chemotherapy in POG protocol 9219 achieved a 5-year EFS of 84% and OS of 100% in patients with stage 1 and II ALCL [85]. The BFM group reported a 5-year EFS of 100% for nine patients with completely resected stage I and II disease with three courses of inpatient chemotherapy whereas the 5-year EFS was 73% for non-resected stage II and stage III disease with six courses of inpatient chemotherapy [101]. In a report on 36 patients with stage I disease on the ALCL99 study, those who had completely resected disease and received short course chemotherapy had an EFS of 100% whereas those with incompletely resected disease had a relapse rate of 30%, similar to patients with higher stage disease [102].

Treatment of Advanced ALCL

The majority of patients with ALCL present with stage II, III, or IV unresectable disease. Over the last two decades multiple clinical trials employing strategies of varying durations of therapy, specific combinations of drugs, dose intensity, and cumulative doses have demonstrated similar outcomes with EFS rates between 70 and 75% (see table below).

The Pediatric Oncology Group and subsequently the Children's Oncology Group conducted trials in children with ALCL utilizing the "APO" regimen (see Table 46.8 below). This regimen can be given in the outpatient setting with a cumulative anthracycline dose of 300 mg/m^2 an no alkylator therapy. It includes 6 doses of intrathecal methotrexate. The duration of therapy is 52 weeks. Modifications to the backbone with dose intensification of methotrexate

Table 46.8 Doxorubicin–prednisone–vincristine (APO) protocol for anaplastic large-cell lymphoma (COG ANHL 0131)

Phase	Drug	Day
Induction	Doxorubicin 75 mg/m²	1, 22
	Prednisone 40 mg/m²	1–28
	Vincristine 1.5 mg/m²	1, 8, 15, 22, 29
	IT methotrexate	1, 8, 22
Maintenance[a] (every 21 days)	Doxorubicin 30 mg/m²	1[b]
	Methotrexate 60 mg/m²	1[b]
	Vincristine 1.5 mg/m²	1
	Prednisone 120 mg/m²	1–5
	6-Mercaptopurine 225 mg/m²	1–5
	IT methotrexate (cycles 1–3 only)	1

Adapted from Alexander S, Kraveka JM, Weitzman S, Lowe E, Smith L, Lynch JC, et al. Advanced stage anaplastic large cell lymphoma in children and adolescents: results of ANHL0131, a randomized phase III trial of APO versus a modified regimen with vinblastine: a report from the children's oncology group. Pediatr Blood Cancer 2014 Dec;61(12):2236–2242 [104]

[a]Maintenance cycles given every 21 days for a total therapy duration of 1 year

[b]Methotrexate substituted for doxorubicin when the cumulative dose of doxorubicin reached 300 mg/m²

and cytarabine or the replacement of vincristine with vinblastine did not significantly improve outcomes (Table 46.8).

The BFM group during the same time period conducted trials which included patients with ALCL evaluating short course, "pulse therapy" as was used for B-NHL patients with initial therapy duration of 2–5 months based on stage (Table 46.9). The ALCL99 backbone of therapy was adapted from the BFM regimen. It includes dexamethasone, cyclophosphamide, ifosfamide, etoposide, doxorubicin methotrexate cytarabine, prednisone, and vincristine with 6 cycles given over 5 months for all except stage I patients. Cumulative doses of each agent are relatively low and therefore associated with lower long-term risks. The regimen does require inpatient care and is associated with substantial short morbidity including relatively high rates of febrile neutropenia and mucositis. ALCL-99 randomized patients to 1 gm/m² MTX over 24 h vs. 3 gm/m² over 3 h and found equal efficacy but less toxicity with the shorter infusion. The 3 gm/m² over 3 h is thus the current standard [103].

Vinblastine as a single agent has been known to have activity and in some patients be curative in the setting of relapsed disease [107, 108]. As a result, the European consortium study protocol ALCL-99 as well as the COG ANHL0131 protocol were designed to test the addition of weekly vinblastine to the BFM and APO backbones, respectively, in newly diagnosed patients. In both of these trials there was no statistically significant improvement in outcome with the addition of vinblastine.

Table 46.9 Outcome for patients with anaplastic large-cell lymphoma

Protocol	Number	Stage or risk group	Outcome (%)	References
Localized disease

COG 0131	125	III/IV	74% 3-year EFS	Alexander et al. [104]
			84% 3-year OS	

Several factors have been found to be prognostic in children with ALCL. Patients with disease in their mediastinum, visceral disease (defined as lung, liver, or spleen), or skin involvement had a poorer outcome in multivariate analysis [109]. By histology, lymphohistiocytic and small cell variant subtypes are associated with worse outcomes [104, 110].

In the context of patients treated with BFM type therapy the most powerful prognostic data comes from biological markers. The detection of *NPM-ALK* fusion gene transcript by quantitative PCR from blood and morphologically negative bone marrow at the time of initial diagnosis (minimal disseminated disease, MDD) was highly prognostically significant [24]. In addition, persistence of measurable residual disease (MRD) by *NPM-ALK* PCR in the blood following the first course of chemotherapy is associated with a very high risk of disease recurrence [111]. An immunological response at diagnosis has also been shown to be of prognostic significance in ALCL. Antibodies to ALK protein were detected in 95% of all ALK-positive patients at diagnosis. A low antibody titer was associated with advanced-stage, clinical features of mediastinal and visceral organ involvement, male gender and high numbers of

circulating tumor cells by PCR. In addition, antibody levels correlated significantly with the risk of relapse [112].

When considered together, the combination of MDD at diagnosis measured by quantitative PCR and the ALK antibody titer was found to be highly predictive of outcome in a retrospective evaluation of 128 patients from the BFM and Italian groups. In this study high-risk patients (MDD positive and ALK antibody low) had a progression-free survival of 28% compared to those who were low risk (MDD negative and ALK antibody high) of 93% and intermediate-risk group with a PFS of 68% [113].

There are a number of targeted therapies for children with ALCL currently being investigated in clinical trials that may alter the therapeutic landscape. Brentuximab vedotin is an anti-CD30 antibody linked to an antimicrotubule agent, monomethyl auristatin E. In heavily treated adult patients with relapsed/refractory ALCL 57% achieved a CR in a phase 2 trial [114]. As a single agent it is generally well tolerated though with neuropathy in 40% of patients. The use of this agent in newly diagnosed patients together with standard combination chemotherapy is being evaluated in ongoing adult and pediatric studies [115].

ALK inhibitors are very promising agents for the treatment of children with ALK+ ALCL. In a phase I trial which included children with relapsed/refractory ALCL, 7 of 8 patients achieved a CR [116]. Similarly in a retrospective adult trial 9 of 9 patients with refractory ALCL achieved a CR. Unlike adult lung cancer, responses have been durable in some of these patients continuing with single agent therapy [117]. The optimal duration of therapy is unknown. Trials evaluating the safety and utility of adding crizotinib to multiagent chemotherapy for newly diagnosed patients are being conducted through the COG and are being planned by the European pediatric EICNHL group. There are numerous second generation ALK inhibitors in development. Strategies to best evaluate these agents in children with this relatively rare lymphoma will require careful design and cooperation.

Summary of the Findings of the Cooperative Group Trials

1. Children with ALCL treated on different protocols have a similar outcome with an EFS of approximately 75%.
2. Despite the proven efficacy in patients with relapsed disease, the addition of weekly vinblastine to upfront therapy has not been shown to improve outcomes.
3. Patients with ALCL who develop relapse have high response rates to salvage chemotherapy, though the optimal curative therapy in this setting remains unclear.
4. Novel therapies, including monoclonal antibody-drug conjugates and ALK inhibitors, are likely to be important tools in the care of patients with ALCL.

Treatment of Relapsed Disease

Burkitt Lymphoma and Large B-Cell Lymphoma

Children who relapse following modern intensive protocols are difficult to cure. Relapses in BL and DLBCL are uncommon, but usually occur in the first year following therapy and carry a dismal prognosis. A UK-based multicenter study showed less than 30% survival in patients with relapsed BL and DLBCL [118]. Similarly, across three LMB studies, LMB89, FAB/LMB96, and LMB2001, 5% of patients with B-NHL relapsed at a median of 4.8 months for BL and 22 months for DLBCL and PMBCL and had an overall survival of 30% at 6 years [119]. Prognostic factors predicting better survival included Group A or B with LDH <2× ULN, large cell histology, relapse after 6 months, and relapse at only 1 site.

Since an initial response is usually required before referral for HSCT, novel therapies added to chemotherapy are being tested for B-NHL. The use of monoclonal antibodies (MAB) targeted to specific antigens on the tumor cell, for example, has produced compelling results for the treatment of adults with NHL. Reports have included a variety of antibodies, unlinked or linked to toxins such as ricin or to radioisotopes such as tositumomab (iodine-131 labelled anti-CD20 antibody) and ibritumomab (yttrium-90 labelled anti-CD20 antibody) [120, 121]. Radioimmunotherapy with tositumomab was shown to be effective in myeloablative regimens followed by autologous HSCT among adults with relapsed B-cell NHL, resulting in a 3-year OS of 59% and progression-free survival (PFS) of 51% [120]. It has also been demonstrated that adequate stem-cell collections are possible following MAB therapy even when the antibodies are linked to iodine-131 or yttrium-90.

In children with recurrent/refractory B-cell NHL, CYVE chemotherapy was effective in two-thirds of patients initially treated with Group A or B LMB therapy [119]. In a COG prospective phase II study, the addition of rituximab to ifosfamide, carboplatin and etoposide (ICE) chemotherapy achieved a complete plus partial response rate of 60% in 20 patients with BL, B-ALL, and DLBCL [122]. Following salvage chemotherapy, patients proceed to high-dose chemotherapy with autologous stem cell transplantation for consolidation therapy. There was zero percent chance of survival for non-responding patients.

Lymphoblastic Lymphoma

With the current intensive protocols, relapse or refractory disease is seen in about 15–20% of patients with LBL. Relapse occurs most commonly in the mediastinum but may be systemic and the outcome is poor with cure rates of between 15

and 30% [123, 124]. In general, the same salvage protocols used for T-ALL are tried but particularly in T-LBL the chance of obtaining a CR is low and the results of trials with combinations of chemotherapy with new agents such as nelarabine/etoposide/cyclo (NECTAR), carfilzomib plus 4 drug induction and mTOR or NOTCH1 inhibitors are awaited.

In B-LBL new agents that have been shown to be effective in B-lineage ALL may prove to be useful, including anti-CD20 antibody for those who are CD20 positive and the bispecific CD19/CD3 antibody Blinatumomab for the majority of B-LBL who are CD19 positive.

In those patients who do achieve a CR or VGPR, allogeneic transplant is indicated (see below).

Anaplastic Large Cell Lymphoma

Unlike the other lymphomas, ALCL often remains chemosensitive at relapse. The outcome for patients with relapsed ALCL is more favorable than for other NHL types in children with chances of survival approaching 60% [107, 125]. Prognostic features at relapse include time to relapse and CD3 positivity of tumor cells at the time of initial diagnosis. The EICNHL relapsed ALCL protocol stratified patients into risk groups with higher risk patients achieving 3 year EFS of 64% with allocation to allogeneic stem cell transplant, whereas those in the intermediate group treated with autologous transplant had a less good outcome with a 3 year EFS of 41%. The low-risk group was treated with 2 years of weekly vinblastine and has very favorable outcomes with a 3 year EFS of 85% [126].

As discussed above, ALK inhibitors are very promising agents for the treatment of children with ALK+ ALCL and may be valuable for therapy of relapsed/refractory disease. The development of second and third generation ALK inhibitors may prove to be useful in children whose disease recurs post therapy that included crizotinib. The optimal duration of ALK inhibitor therapy is unknown.

The use of novel agents in addition to conventional therapy including stem cell transplant for patients with relapsed and refractory ALCL requires ongoing investigation.

Hematopoietic Stem Cell Transplantation

The value of autologous vs. allogeneic transplant remains controversial and appears to depend on the NHL subtype. A review of data from the Center for International Bone Marrow Transplant Research (CIBMTR) from 1990 to 2005 showed that 5-year EFS for allogeneic HSCT was equal to autologous transplants for patients with DLBCL (50% vs. 52%, respectively), Burkitt lymphoma (31% vs. 27%, respectively), and ALCL (46% vs. 35%, respectively). Only for lymphoblastic lymphoma did allogeneic HSCT demonstrate an advantage compared to autologous transplantation (40% vs. 4%, respectively, $P < 0.01$) [127]. This is in agreement with an earlier study in which the advantage of allogeneic over autologous transplantation for LBL showed a lower relapse rate but at the expense of higher treatment-related mortality [128], as well as BFM data in which the only patients with relapsed T-LBL to survive were those who receive an allogeneic HSCT [123]. A long-term single institution study of pediatric patients with NHL demonstrated an OS and DFS of 55% and 53%, respectively, at a median follow-up of 9.7 years. The most important prognosticator for survival was response to salvage chemotherapy with DFS of 61% for chemotherapy-sensitive disease compared to 25% for nonresponders. The study found a 50% DFS and OS for 11 patients with LBL who received an allogeneic HSCT, with a median follow-up of 12 years [129]. One of the study recommendations was autologous SCT if no matched donor, related or unrelated, was available, but given the recent improvements in results using haploidentical donors, with current knowledge all relapsed LBL patients should be referred for allogeneic SCT.

For relapsed ALCL, the BFM group has used allogeneic transplant with conditioning regimens that include total body irradiation, etoposide, and cyclophosphamide, resulting in a 3-year EFS of 75% [130]. Many of the patients in this trial had failed multiple protocols and all 5 who had failed previous autologous transplantation survived following allogeneic HSCT.

Another potentially important approach involves post-transplantation therapy directed at minimal residual disease, such as approaches aimed at increasing the host immune response to residual lymphoma cells, or using novel targeted anti-lymphoma therapies. Several studies in children with relapsed B-cell NHL have demonstrated that anti-CD20 monoclonal antibody is well tolerated when given after transplantation [131].

In summary, HSCT offers an OS of around 50% for patients with relapsed NHL. The decision regarding autologous vs. allogeneic SCT should be based first on histology as well as risk factors, at least in ALCL. As supportive care measures improve, the balance may swing towards allogeneic SCT given the proven graft vs. lymphoma effect.

For B-NHL, most of whom are CD19 positive irrespective of histology, chimeric antigen receptor (CAR) T-cell immunotherapy with specificity for CD19 has shown major promise for the most treatment resistant pediatric and adult B-cell acute leukemias, even those that have failed HSCT [132, 133]. Second generation CAR T-cells for treatment of adult relapsed B-NHL has recently been reported in a phase I study with 75% 1-year PFS and without any reported cytokine release syndrome usually seen in ALL patients [134]. Further studies are needed to confirm this data.

Table 46.10 Summary characteristics of the four major pediatric non-Hodgkin lymphomas

	Burkitt lymphoma (sporadic type)	Lymphoblastic Lymphoma	Diffuse large B-cell lymphoma	Anaplastic large-cell lymphoma
Immunophenotype	Mature B-cell	Precursor T-cell (80%)	Mature B-cell	Mature T-cell (80%)
		Precursor B-cell (20%)		Null-cell (20%)

[a]Collective results of the cooperative study groups

Conclusion

The survival of children with NHL of all four subtypes (Table 46.10) has dramatically improved, so that the majority of pediatric patients with lymphoma can now be cured. However, several important challenges remain. These include reduction of treatment-related toxicity without sacrificing cure rates, identification of new prognostic factors that will allow therapy to be tailored to specific risk groups, and development of effective treatment for patients who have resistant disease despite modern intensive protocols.

It is unlikely that continued intensification of chemotherapy will achieve further major improvement in responses, although modifications currently being evaluated may improve survival by decreasing therapy-related toxicity. The introduction of therapies targeted to specific molecules on the malignant cell surface membrane or engineered T-cell adoptive immunotherapy has added an exciting new dimension to future therapeutic strategies.

Finally, the importance of coordinated international collaborative efforts to facilitate the development of more effective therapies aimed at tumor-specific targets cannot be overemphasized.

Lymphoma in Other Diseases

47

Jennifer Crombie and Dan L. Longo

Introduction

In the United States in 2016, non-Hodgkin's lymphoma (NHL) comprised 4.3% of all new cancers and 3.4% of cancer related deaths [1]. The incidence of NHL has increased considerably since the early 1970s, though has stabilized in the last 10 years. While the cause of lymphoma is unexplained in the majority of cases, lymphoma is associated with various diseases and their treatments. For example, patients with the human immunodeficiency virus (HIV) have a 60–200-fold risk of developing NHL [2, 3]. Other viruses, such as Epstein-Barr virus (EBV) and HTLV-1, and even certain bacteria, have been associated with the development of lymphoma as well. Patients who have undergone solid organ or bone marrow transplantation have an increased risk of lymphoma, particularly in the setting of iatrogenic immune suppression. Autoimmune disease and the therapies used in their management have also been linked to malignancy. Immune dysregulation, as is seen in patients with genetic immunodeficiencies, also results an increased risk of lymphoma compared to the general population.

Lymphomas that occur in the context of other diseases often have distinct histologic, morphologic, and clinical presentations and require unique therapeutic considerations that will be further addressed here. The vast majority of secondary lymphomas are of B-cell origin. They tend to be aggressive histologically as well as in advanced stage at presentation. Extranodal sites are affected in a high proportion of cases, particularly the bone marrow, central nervous system (CNS), and GI tract. These lymphomas often occur in association with EBV infection and other viruses.

The development of lymphoma in these cases typically results from a multistep process in which a hierarchy of events impinges on the normal control of cell growth. The series of biologic changes that lead to cancer involves the accumulation of discrete genetic alterations that provide the basis for the transition from normal to premalignant to malignant lesions. Although details regarding mechanisms of lymphomagenesis remain to be clarified, three key components appear critical: (1) polyclonal proliferation of B cells; (2) the benign, or premalignant, but extensive B-cell hyperplasia that increases the chances of acquiring critical genetic alterations; (3) the inherent immune deficiency leads to a failure of immune surveillance, allowing the abnormal cell growth of occasional clones to proceed unchecked. The result is ultimately a monoclonal or oligoclonal cellular proliferation that constitutes the observed lymphoma.

Throughout the remainder of this chapter, the ways in which immune dysregulation is thought to predispose to lymphoma as well as the specific clinical presentations and treatment considerations will be further explored.

Infectious Agents in the Etiology of Lymphomas

Epstein-Barr Virus (EBV)

EBV is a transforming DNA virus of the herpesvirus family that targets oro- and nasopharyngeal epithelial cells and human B lymphocytes [4]. Thus, as will be discussed later, EBV appears to be involved in lymphomagenesis in the settings of AIDS, iatrogenic immunosuppression, and inherited immunodeficiency diseases such as X-linked lymphoproliferative disease (LPD) and ataxia-telangiectasia. EBV infection also plays a role in the development of the endemic form of Burkitt's lymphoma, which is primarily seen in children in Africa, as well as a range of malignancies involving B cells, T cells, and natural killer (NK) cells [5].

EBV is shed through oral secretions of infected hosts and is thought to infect up to 90% of the population [6]. Primary infection is usually asymptomatic, though can also result in infectious mononucleosis, a clinical syndrome characterized by fever, pharyngitis, lymphadenopathy, and fatigue. It is thought that the virus initially targets B cells located in oropharyngeal epithelium and mucosa, though ultimately inhabits memory B cells, where it remains as a lifelong inhabitant of the host [7, 8]. The virus is intermittently reactivated in the oropharyngeal epithelium allowing for transmission.

EBV Biology

The EBV viral genome is encased within a nucleocapsid that is surrounded by the viral envelope. The major envelope glycoprotein, gp350, binds to the viral receptor, the CD21 molecule, which is closely related to the receptor for the C3d component of complement [9, 10]. This receptor is present on the surface of epithelial cells, B cells and some T cells [9, 11]. The major-histocompatibility-complex (MHC) class II molecule serves as a cofactor, thus allowing for infection of cells [12].

The EBV genome consists of a linear DNA molecule that encodes nearly 100 viral proteins. These proteins in turn regulate the expression of viral genes, replication of viral DNA, formation of the virion, and modulation of the host immune system. After infecting B cells, the linear EBV genome becomes circular, forming an episome. In this form, the virus remains as a lifelong latent infection.

Of the genes that make up the EBV genome, only specific subsets are expressed during the latent infection of EBV-immortalized cells. These include six EBV nuclear antigens [EBNA-1, -2, -3A, -3B, -3C, and leader protein (LP)], three latent membrane proteins (LMP-1, -2A, and -2B), and two abundant non-polyadenylated, nontranslated small RNAs [EBV-encoded small RNA (EBER)-1 and EBER-2]. Six of these (EBNA-1, -2, -3A, and -3C; LMP-1; and LP) are required for immortalization, whereas two (LMP-2A and -2B) are believed to maintain EBV latency.

At least three types of latency have been demonstrated, each of which is characterized by a specific array of latent gene expression. Furthermore, the different histological types of EBV-related lymphomas tend to fall into specific latency types [13]. EBNA-1 is expressed in all the latency types and is the only viral protein expressed in type I latency (Lat I). Burkitt's lymphoma, whether endemic or AIDS-related, generally displays a Lat I phenotype [14]. Type II latency (Lat II) includes expression of the LMPs in addition to the ubiquitously expressed EBNA-1. The Lat II subtype has been described in a subset of Burkitt's lymphomas as well as in Hodgkin's disease, nasopharyngeal carcinoma, and T-cell tumors [15]. Lastly, type III latency (Lat III) involves expression of all the latent viral proteins. The two small RNAs (EBER-1 and EBER-2) are expressed in all three latency types. AIDS-related large-cell and immunoblastic lymphomas have been shown to fall into all three latency categories.

Following initial infection, EBV primarily resides in the long-lived memory B cells. There are two proposed mechanisms in which the virus inhabits these cells [8]. The first is known as the germinal center model, in which EBV-infected memory B cells are generated through normal B-cell maturation involving germinal centers. Infection of naïve B cells leads to the expansion of cells expressing type III latency proteins [8]. The cells enter the germinal center where they express latency II proteins and ultimately exit as memory B cells. EBV-infected memory B cells downregulate latent gene expression and enter what is known as latency 0, allowing the cells to avoid recognition by the immune system. The cells switch on the EBNA-1 protein when required for cell division during latency 1 and differentiate into plasma cells in order to reactivate the EBV lytic cycle.

The alternative model, known as the direct infection model, suggests that germinal center B cells or memory B cells are directly infected by EBV. In these cases, EBV is able to form a memory phenotype while bypassing the requirement of a germinal center reaction and somatic hypermutation [8].

Two distinct types of EBV isolates, type 1 and type 2, have been described, each of which is subdivided into multiple strains [16]. These strains are distinguished by polymorphisms in the latent genes encoding the nuclear antigens EBNA-2, -3A, -3B, and -3C, and the EBER genes. EBV type 1 has a greater transforming capacity and is the predominant type (90%) in lymphocytes of EBV-infected individuals. While the majority of people harbor a single virus strain, multiple strains have been seen, especially in immunocompromised hosts. For example, EBV type 2, which is relatively rare in the healthy Caucasian population, is observed in over 30% of HIV-positive men who have sex with men (MSM) and in 10% of HIV-infected hemophiliac individuals [16].

Individual EBV type 1 strains do not appear to be restricted to specific EBV-associated diseases or tumor types. While certain polymorphisms have been associated with specific clinical presentations, these associations are believed to reflect the most prevalent circulating EBV strains in the population, rather than the disease presentation. For example, the 3′-terminal of the LMP-1 gene has a characteristic 30-base pair deletion in nasal T/NK-cell lymphomas in a Chinese population and a 69-base pair deletion in Burkitt's lymphoma of Turkish children [17, 18]. This view is supported by the appearance of identical variant strains in other EBV-associated diseases, such as nasopharyngeal carcinoma and peripheral T-cell lymphomas, as well as in healthy virus carriers in the same populations. Specific EBV antigen polymorphisms have been shown to correlate with oncogenic potential in cell culture, though has not been substantiated in vivo [19].

Accumulation of Genetic Lesions

The contribution of the EBV antigens to cellular transformation is complex. EBNA-1, a phosphoprotein that binds to both viral DNA and RNA, maintains the EBV genome as an extrachromosomal plasmid in immortalized cells [20]. EBNA-2 counters transcriptional repression by interacting with the inhibitory transcription factor CBF1/RBP-Jκ [21]. EBNA-2 also activates EBNA-3A, which is essential for initiation of B-cell immortalization. EBNA-3C, which is also necessary for immortalization, has been shown to activate the promoter of the B-*MYB* oncogene, leading to cell cycle progression. EBNA-3C may promote lymphogenesis through interaction with the *RAS* oncogene as well [22]. The products of specific EBV genes may also exert more direct effects on oncogene expression. Even in the absence of a c-*MYC* translocation, the presence of the EBV genome in the Burkitt's lymphoma cells is reversibly associated with increased levels of c-*MYC* messenger RNA, due to stabilization of the c-*MYC* transcript in the late exponential phase of growth [23]. In addition, EBV early protein EB2 has the ability to transform cells, possibly by regulating c-*MYC* expression at a posttranscriptional level [24].

EBV is also thought to promote transformation through expression of LMP-1, which is transcriptionally regulated by EBNA-2 [25]. LMP-1 activates multiple signaling pathways, including mitogen-activated protein kinase (MAPK), c-Jun N-terminal kinase (JNK), phosphatidylinositol 3-kinase (PI3K)/Akt, and NF-κB [26]. LMP-1 also induces transcription of many genes to affect apoptosis, cell cycle progression, cell proliferation, metastasis, and angiogenesis [26, 27]. An association between specific mutational hot spots in the EBV *BNLF*-1 gene that encodes the LMP-1 protein and various lymphoproliferative disorders (e.g., Hodgkin's disease, angioimmunoblastic lymphadenopathy (AILD), B-immunoblastic lymphoma, and peripheral T-cell lymphoma) have also been demonstrated. Similarly, reduction in transcriptional expression of LMP-1 by triptolide in vitro was also found to decrease proliferation of EBV-positive B-cell lymphoma cells [27]. A meta-analysis has also shown that LMP-1 expression appears to be an unfavorable prognostic factor for overall survival for non-Hodgkin lymphoma in Chinese patients [28].

Overall, it is thought that EBV likely provides the initiating insult in the multistep process of lymphomagenesis by increasing growth of affected cells. The ability of EBV to infect cells latently and to immortalize them also leads to expansion of the affected B-lymphocyte population. The ability of the virus to evade the immune system and avoid apoptosis further provides a survival advantage.

Host Response

The normal host displays cellular mechanisms that limit the number of virally transformed B lymphocytes. Healthy, immunocompetent EBV-seropositive individuals maintain a vigorous cytotoxic T-cell response against EBV latency antigens (EBNA-2, -3A, -3B, or -3C). Patients with infectious mononucleosis have cytotoxic T lymphocytes (CTLs) that can lyse EBV-transformed B-cell targets in culture, implying that such cells play an active role in eliminating the infected B lymphocytes in vivo [29]. In severely immunocompromised individuals, however, a deficit of appropriately targeted antigen-specific CTLs may allow EBV-infected B-cell proliferation to go unchecked. This could explain the finding that many posttransplant lymphoproliferative disorders are positive for EBV within tumor cells. Adoptive immunotherapy with healthy donor-derived EBV-specific CTLs modified with specific target EBV antigens has been explored in an effort to reconstitute cell-mediated immunity against EBV infection and thereby to prevent EBV lymphomas in immunocompromised patients [30, 31].

While a deficit of immune surveillance may explain the escape of EBV-transformed cells in immunocompromised patients, in immunocompetent individuals, malignant cells also evade immune control by failing to express virus-induced surface antigens that normally serve as targets for CTLs. EBV-related tumors arising in healthy individuals (including EBV-related Burkitt's lymphoma, Hodgkin's disease, and nasopharyngeal carcinoma) fail to express the majority of EBV latency antigens, in contrast to the viral antigen expression that has been noted in some posttransplantation and AIDS-associated lymphomas. Specifically, CTL responses against LYDMA, the virus-induced lymphocyte-detected membrane antigen, limit EBV-infected B-cell numbers in healthy carriers [32]. In virus-associated Burkitt's lymphomas, the malignant clone is frequently insensitive to such surveillance by effector CTLs derived from healthy virus-immune donors, suggesting that in these cases the malignant cells do not express LYDMA.

In addition to CTLs, EBV can be opposed by interferon-α and -γ, other cytokines, natural killer cells, and antibody-dependent cellular cytotoxicity. Immunologic dysfunction involving these mechanisms can similarly lead to failure of adequate surveillance and control of EBV-induced lymphocyte proliferation. For instance, the EBV-encoded protein BCRF-1 is structurally and functionally homologous to the cytokine IL-10, or cytokine synthesis inhibitory factor (CSIF). BCRF-1 suppresses T cell and perhaps natural killer cell synthesis of interferon-γ and IL-2, resulting in what amounts to functional suppression of T-cell antiviral activity [33].

Other immunologic abnormalities that may impair elimination of virally transformed lymphocytes include upregulation of autocrine factors such as IL-6, a cytokine that stimulates B-cell growth, and soluble CD23, the receptor that promotes immortalization in response to IL-1.

It has also been shown that HLA class I type can impact the immune surveillance of EBV by CD8 + T cells. In western

European populations, HLA-A*01 and HLA-B*37 are associated with an increased susceptibility to EBV, while HLA-A*02 is protective [34, 35]. Specifically, HLA-A*02 seems to mediate a CD8+ T-cell response against latency II antigens that may reduce the incidence of malignant disease [15].

Clinical Features of EBV-Associated Lymphomas

Burkitt's Lymphoma

The prototype of the EBV-related lymphomas is Burkitt's lymphoma. In the endemic (African) form of the disease, the EBV genome is detected in 98% of cases, in contrast to the sporadic form of Burkitt's lymphoma, in which only 15–20% of cases are EBV positive [7, 36]. Both endemic and sporadic Burkitt's lymphoma cells carry a translocation involving chromosome 8q24, which harbors the c-*MYC* gene, and one of the Ig loci. As a result of this translocation, the oncogenic c-*MYC* is upregulated, contributing to transformation of the affected cell. In the majority of cases, the reciprocal translocation exists between chromosome 8q24 and chromosome 14q32, the locus of the Ig heavy chain (IgH) gene, though translocations of chromosome 8q24 to chromosome 22q11 (the Ig-λ locus) and chromosomal 8q24 and chromosome 2q24 (the Ig-κ locus) have also been seen [37]. Although a cytogenetic translocation is demonstrable in all cases of Burkitt's lymphoma, the actual breakpoint on chromosome 8 may be outside the c-*MYC* locus, as is typical for the endemic form of Burkitt's lymphoma [38]. By contrast, sporadic Burkitt's lymphoma generally harbors multiple breakpoints within or close to the 5′-region of c-*MYC* (in the noncoding first exon or the first intron) [38].

Both types of Burkitt's lymphoma result in a histologically similar tumor with round monomorphic cells and surrounding macrophages, creating what is often called a "starry sky appearance" [36]. The endemic form, however, has a unique phenotype typically with the formation of tumors in the jaw or abdomen of children. In these cases, there may be a correlation between malaria infection, as they most commonly occur in areas of equatorial Africa and Papua New Guinea, where malaria is holoendemic. In these regions, asymptomatic EBV infection in children is common. A subsequent acute malarial infection can lead to dysregulation of the immune system and reactivation of the latent virus. EBV-induced polyclonal B-cell proliferation ensues in the absence of a complete T-cell response, allowing for the characteristic 8;14 translocation and dysregulated cell growth.

The surface phenotypes for both the sporadic and endemic forms of Burkitt's are similar (CD10+, CD77+, CD23-, BCL6+, and PAX5+) and are consistent with the likely precursor being memory B cells for endemic and germinal center B cells for sporadic forms of the disease [39]. In endemic Burkitt's lymphoma, the c-*MYC* gene is typically translocated unrearranged into a breakpoint in the V_H-D-J_H recombination region, generally into the J_H segment [37]. This type of translocation appears to result from aberrant functioning of the recombinase enzyme that under normal conditions is responsible for routine Ig gene rearrangement in memory B cells. In the case of sporadic Burkitt's lymphoma, the first exon of the disrupted c-*MYC* gene is sometimes translocated, in inverted orientation, into a breakpoint in the switch region of the heavy chain gene (Sμ) [40]. The presumed error in this case is on the part of isotype switching enzymes that are normally active in more mature B cells that have the capacity to secrete Igs.

While *MYC* overexpression results in increased proliferation, mutated cells must also overcome increased sensitivity to apoptosis signals. Accordingly, approximately 30% of endemic, EBV+ Burkitt's lymphomas carry p53 mutations, and those with wild-type p53 frequently overexpress the p53 antagonist MDM2 [41]. Over the past decade an increased understanding of a second MYC-activated pathway to apoptosis that involves the apoptotic activator of the Bcl-2 family, BIM, has also been described. BIM initiates apoptosis by binding and inactivating pro-survival BCL2 family members (including BCL2 and MCL1) and by activating apoptotic effectors, BAX and BAK [42]. Thus, dysregulated MYC expression can trigger apoptosis through multiple and independent pathways (p14ARF, 19ARF, p53, or BIM) and inactivation of any of these can allow proliferation and lymphoma development.

EBV-Associated Hodgkin's Lymphoma

EBV was first noted to have an association with Hodgkin's lymphoma in epidemiologic studies. A threefold increase in the relative risk of developing Hodgkin's lymphoma was also observed following infectious mononucleosis [43]. This association was further supported by data showing that a prior history of infectious mononucleosis was more likely to correlate with EBV-positive than with EBV-negative Hodgkin's lymphoma [44]. Furthermore, elevated levels of IgG and IgA antibodies against EBV capsid antigen, EBNA, and early antigen D have been seen in individuals who subsequently developed Hodgkin's lymphoma [45]. Episomal, clonal EBV DNA has also been detected in involved lymph nodes of Hodgkin's lymphoma patients, where it is localized to Reed–Sternberg and variant cells [46]. The Reed–Sternberg cells of Hodgkin's lymphoma exhibit a Lat II pattern, in which latent gene expression is restricted to EBNA-1, LMP-1, and LMP-2, differing from the latency type seen in other EBV-associated lymphomas (e.g., Burkitt's lymphoma) but resembling that seen in nasopharyngeal carcinoma [46, 47].

A higher expression of proliferating cell nuclear antigen (PCNA) has been noted in EBV-positive than EBV-negative Hodgkin's lymphoma, suggesting that EBV probably promotes the cell cycling of Reed–Sternberg cells [48]. Interestingly, higher PCNA expression in a tumor appears to confer a survival advantage to the patient.

EBV-specific CTLs have been demonstrated among the tumor infiltrating lymphocytes from Hodgkin's lymphoma biopsies, indicating an ongoing immune response against EBV-carrying cells [49]. Despite this observation, EBV-associated Hodgkin's lymphoma tumor cells have evolved immunologic strategies to evade such ongoing cytotoxic responses. In one study, the cytokine IL-10, an inhibitor of cell-mediated immunity, was shown to be upregulated by the EBV antigen LMP-1 in tumor cells of Hodgkin's lymphoma [50]. EBV also increases the expression of programmed death1 (PD-1) ligands, which when bound to the PD-1 receptor immune cells, can serve as a checkpoint to limit T-cell-mediated responses [51, 52].

Mixed cellularity Hodgkin's lymphoma, commonly found in children and older adults and in developing countries, is the subtype most likely to be associated with EBV (up to 90% of cases). Lymphocyte-depleted tumors are also frequently EBV positive, whereas 30% of nodular sclerosing and only rare cases of the lymphocyte-predominant subtype carry the virus [53]. Finally, epidemiologic studies have shown that 50–70% of cases in Western countries are positive for the EBV genome, with EBV-positive disease being found more often in males than females [54]. Although the evidence for a causal relationship between EBV infection and Hodgkin's lymphoma is not yet considered definitive, the accumulating data continue to strengthen the likelihood of such an association.

Diffuse Large B-Cell Lymphoma

Diffuse large B-cell lymphoma (DLBCL), which is one of the most frequent subtypes of non-Hodgkin's lymphoma in adults, can also be associated with EBV infection. EBV-positive DLBCL of the elderly, for example, has been incorporated into the 2008 World Health Organization classification as a provisional entity [55]. Patients with EBV+ monoclonal B-cell tumors must be greater than 50 years old and have no known evidence of immunodeficiency in order to meet criteria [56]. The malignant B cells are typically positive for the leukocyte common antigen CD45 and B-cell markers CD20, CD19, CD79a, and PAX-5 [57]. This malignancy is most commonly seen in Asian countries, but has been identified in a smaller fraction of Western countries as well. It is aggressive subtype of lymphoma and patients typically have a poorer prognosis as compared to patients with EBV-negative disease. EBV uses a type II latency pattern, as is seen in Hodgkin's lymphoma, or a type III pattern as is seen in post-transplant lymphoproliferative disorder (PTLD).

It has been postulated that EBV+ DLBCL of the elderly may result from the senescence of the immune system that is seen with aging [55]. Specifically, it is thought that B-cell diversity and the absolute number of T lymphocytes decreases [58, 59]. Studies have also implicated activation of the NF-kB signaling pathway by LMP-1 in the pathogenesis [58]. Interestingly, higher levels of EBV DNA in tumor specimens has been shown to confer worse progression free survival and overall survival as compared to tumors with lower quantities [60]. While a dampened immune system may contribute to the development of this disease in older patients, it has been shown that gene expression profiling, microRNA profiling and treatment outcome is similar in younger patients and this arbitrary age cutoff may not be necessary [56].

Other EBV-Associated Malignancies

In addition to Burkitt's lymphoma, Hodgkin's lymphoma, and DLBCL, EBV is thought to contribute to the development of other less common subtypes of lymphoma. EBV is associated with a variety of T-cell lymphomas. While EBV primarily infects B cells, it is also thought to rarely infect T cells and natural killer (NK) cells. EBV infection in seen in all cases of nasal NK-T-cell lymphoma, which is endemic in East Asia. Immunophenotypically, these malignant cells are CD3e and CD56 positive and are almost always infected with clonal, episomal EBV. Quantification of EBV in the plasma can also predict tumor load and confer a poorer prognosis in these patients [61]. T/NK cell lymphoproliferative disease, which is characterized by fever, lymphadenopathy, and splenomegaly in non-immunosuppressed patients, is similarly related to EBV infection and more commonly seen in East Asian countries [62].

Plasmablastic lymphoma (PBL) is a rare type of NHL that arises from B cells that are in transition to plasma cells known as plasmablasts. This is a rare aggressive lymphoma that primarily occurs in the context of immunosuppression with a predilection for the oral and nasal cavity. Infection with EBV in these patients can lead to surge in plasmablast levels and potentially predispose to malignant transformation [63]. Lymphomatoid granulomatosis is another EBV-driven lymphoproliferative disorder that presents in the form of bilateral pulmonary nodules in the lungs. This is an angiocentric and angiodestructive entity defined by the presence of large B cells that are positive for EBER [64]. In primary CNS lymphoma, occurring in both the absence and presence of obvious immunodeficiency, EBV DNA has been identified in the lymphoma but not in the adjacent normal brain tissue [65]. The presence of EBV has been noted in thyroid lymphomas, as well as lymphoepithelial and

non-lymphomatous malignancies of the salivary gland, thymus, tonsil, oral mucosa/hairy leukoplakia of the tongue, esophagus, lung, uterine cervix, and breast. The significance of the EBV findings in many of these malignancies, however, still remains questionable [54].

Acquired Immune Deficiency Syndrome/Human Immunodeficiency Virus (HIV)-Associated Lymphomas

HIV

HIV is a retrovirus that targets CD4-positive lymphocytes through interactions with CD4 and the chemokine receptors, CCR5 and CXCR4. Infection subsequently leads to a progressive reduction in the CD4 T-cell count as well as lifelong latent infection in resting memory T cells. In 2012 an estimated 35.3 million people were infected with HIV [66]. Through a variety of mechanisms, which will be discussed in greater detail, patients with HIV are at increased risk of some forms of malignancy. Approximately 40% of patients with HIV will develop cancer, the majority of which will be lymphoma [67].

In 1985, HIV-associated lymphoma was first incorporated into the Centers for Disease Control and Prevention's definition of AIDS [68]. Despite an improvement in morbidity and mortality with the advent of antiretroviral therapy, patients with HIV remain at risk of developing a variety of malignancies [3]. While there have been reductions in lymphomas associated with lower CD4 counts, such as primary CNS lymphoma and primary effusion lymphoma, other subtypes of lymphoma, including Burkitt's lymphoma and Hodgkin's lymphoma, persist despite improved immune function [69, 70].

Accumulation of Genetic Lesions

Following an initial insult, such as the HIV infection, successive genetic changes can be superimposed on the expanded lymphocyte population resulting in malignant transformation of one or more clones. There are a variety of proposed mechanisms to suggest why this occurs. One theory is that HIV infection leads to chronic antigenic stimulation and persistent immune activation [3]. Additionally, defective immune surveillance in the setting of a reduced CD4-positive lymphocyte count allows for possible expansion of abnormal clones. Support for this model comes from the observation that HIV-related lymphadenopathy often predates the development of lymphoma [71]. Multiple monoclonal B-cell expansions have been documented in biopsies of AIDS–non-Hodgkin's lymphomas, as well as in a significant fraction of lymph nodes with the ostensibly benign polyclonal hyperplasia [72]. The fact that up to 60% of the AIDS–non-Hodgkin's lymphomas but only 10–20% of lesions of AIDS-related benign lymphoid hyperplasia contain oligoclonal B-cell expansions suggests a progression along a spectrum of malignancy, reflecting the accumulation of genetic alterations (Table 47.1) that culminate in the dominance of specific B-cell clones [73]. By contrast, non-Hodgkin's

Table 47.1 Genetic alterations and viral infection in AIDS-related non-Hodgkin's lymphomas[a]

lymphomas in the immunocompetent population only infrequently show multiple clonal B-cell expansions [73].

Cytokine production in the setting of HIV infection also contributes to the production of these clonal populations. Interleukin (IL)-6 and IL-10 are two cytokine regulators of B-cell growth that have been shown to play a role. IL-6, also known as BSF-2, or B-cell stimulatory factor, is produced by a variety of cell types, including monocytes/macrophages, T lymphocytes, and fibroblasts and has been shown to promote the growth and terminal differentiation of B cells [74]. B cells from HIV-infected individuals constitutively secrete high levels of IL-6, which in turn, contributes to polyclonal B-cell stimulation and nonspecific hypergammaglobulinemia. IL-6 serum levels in AIDS patients may also predict the subsequent development of non-Hodgkin's lymphoma [75].

IL-10 also acts in an autocrine fashion as a potent stimulator of B cells. Its B-cell differentiating capability may enhance Ig secretion, contributing to the hypergammaglobulinemia. IL-10 is also thought to inhibit apoptosis, thereby promoting B-cell viability. Finally, IL-10 inhibits the production of IL-2 and the antiviral cytokine, interferon-γ, by T cells, leading to impairment of immunosurveillance.

Among the genetic alterations contributing to B-cell non-Hodgkin's lymphomas in AIDS is activation of the c-*MYC* oncogene by means of its rearrangement into the vicinity of Ig regulatory elements (Table 47.1). All AIDS–small noncleaved cell lymphomas contain t(8;14) or t(8;22) translocations, resembling those found in Burkitt's lymphoma in the non-AIDs population. Single c-*MYC* rearrangements of this nature have been identified less frequently in AIDS–non-Hodgkin's lymphomas of other histologic types as well. At the molecular level, the t(8;14) translocations in AIDS–non-Hodgkin's lymphomas generally resemble the sporadic Burkitt's lymphomas, by involvement of the Sμ region of the IgH gene [76]. Mutations within the first intron as well as the coding region have also been demonstrated in AIDS–non-Hodgkin's lymphomas, primarily in Burkitt's and Burkitt's-like lymphomas [77].

In addition to c-*MYC*, translocations in AIDS–non-Hodgkin's lymphomas have been shown to involve the *BCL*-6 gene (Table 47.1) [73, 78]. *BCL*-6, which is located on chromosome 3q27 and codes for a zinc finger transcription factor, is truncated by virtue of its translocation in 30–40% of DLCL in immunocompetent hosts [73, 79]. Similarly, *BCL*-6 rearrangements in AIDS–non-Hodgkin's lymphomas are restricted to DLCL (occurring in 19% of AIDS–immunoblastic lymphomas and 25% of AIDS–large-cell lymphomas), never being observed in AIDS–Burkitt's or Burkitt's-like lymphomas. *BCL*-6 rearrangements are seen in both EBV-positive and EBV-negative lymphomas. Rearrangements involving c-*MYC* and *BCL*-6 have never been observed in the same biopsy specimen, suggesting that the two genetic lesions contribute to independent pathways to tumorigenesis [73].

The *BCL*-2 gene, whose protein product blocks cellular apoptosis, is rearranged in most low-grade follicular B-cell lymphomas and a smaller percentage of the more aggressive lymphomas. However, no rearrangement or mutation in this gene has been detected in AIDS–non-Hodgkin's lymphomas [80]. Similarly, no alteration has been demonstrated for *PRAD*-1/*BCL*-1, a gene that encodes cyclin D, an active component of the cell cycle machinery, whose translocation from chromosome 11q13 to chromosome 14q32 is associated with mantle cell lymphomas [80, 81].

Inactivation of the suppressor gene *p53* has been demonstrated in approximately 40% of AIDS–non-Hodgkin's lymphomas, including Burkitt's and Burkitt's-like lymphomas (Table 47.1). There is a lower frequency of *p53* mutations in large-cell immunoblastic lymphomas in individuals with and without AIDS [82]. *p53* mutations have been seen in both EBV-positive and EBV-negative tumors, suggesting no correlation between the tumorigenic mechanisms involving these two lesions [73, 83]. Conversely, the functional interdependence of accumulated genetic lesions in achieving tumorigenesis is exemplified by *p53* and c-*MYC* which frequently occur together [83]. In fact, elevated levels of mutant p53 have been shown to result from transcriptional activation of the *p53* promoter by an overexpressed c-MYC protein [84]. Deletion of two discrete regions on the long arm of chromosome 6, representing the sites of two putative tumor suppressor genes, is common in B-cell non-Hodgkin's lymphomas and constitutes a poor prognostic indicator [83]. Such 6q deletions are seen in 25% of AIDS–non-Hodgkin's lymphomas, suggesting a role for these putative genes in AIDS-related lymphomagenesis. Other commonly altered tumor suppressor genes have been examined in AIDS–non-Hodgkin's lymphomas. No mutations have been demonstrated for *RB1*, and the potential involvement of *NF*-1, *APC*, *DCC*, or *WT*-1 seems unlikely based on the lack of cytogenetic aberrations at the corresponding chromosomal regions in AIDS–non-Hodgkin's lymphoma [83].

Contribution of Viruses to AIDS-Associated Lymphomas

HIV and co-infecting viruses are believed to contribute to malignant transformation in the setting of AIDS. Over 90% of HIV-infected individuals are also infected with EBV. In most studies, Burkitt's lymphomas show inconsistent association with EBV (30% in systemic AIDS–Burkitt's lymphoma). Between 70 and 80% of AIDS–diffuse large-cell lymphoma variants (i.e., diffuse large B-cell and immunoblastic subtypes), on the other hand, are EBV positive. Interestingly, results have also shown that systemic AIDS–non-Hodgkin's lymphomas in which the tumor

clone is infected with EBV have a significantly increased risk of CNS involvement at some point during their clinical course, regardless of the molecular features of the EBV strain [85]. Furthermore, detection of EBV DNA in the CSF of patients with systemic AIDS–non-Hodgkin's lymphomas is highly predictive of a diagnosis of localized CNS involvement. A particularly strong association exists between EBV infection and Hodgkin's lymphoma and Ki-1+ anaplastic large-cell lymphomas in HIV patients as well [86].

EBV DNA is detected more frequently in monoclonal than polyclonal AIDS–non-Hodgkin's lymphomas in contrast to the polyclonal lymphomas that characterize other immunodeficient states [87]. The EBV genomes within the lymphoma clones are also clonal, indicating that the B-cell progenitor of each lymphoma was already infected with EBV before expansion. In vitro, HIV has been shown to transform EBV-immortalized B lymphocytes and to upregulate the expression of EBV and c-*MYC* in the transformed cells. Such HIV-transformed B cells are also able to give rise to lymphoproliferations resembling lymphomas when inoculated into nude mice [88].

In addition to EBV, other viruses have also been examined for their potential role in AIDS-related lymphomagenesis. Among these viruses, human T-cell leukemia virus (HTLV)-I and HTLV-II DNA sequences have been detected in lymphomatous tissues of AIDS patients. Herpesviruses other than EBV, namely, human herpesvirus type 6 (HHV-6, or HBLV), which is associated with lymphoproliferative disorders in both HIV-positive and HIV-negative individuals, and HHV-7, have been identified as well [89]. Cytomegalovirus (CMV), an opportunistic pathogen in virtually all individuals with AIDS, has also been shown to induce both T-cell proliferation and B-cell activation.

Given the high frequency of coinfection with HIV and other viruses, the possibility that different viruses interact synergistically to promote tumorigenesis should be explored. As an example, mitogenic stimulation of HIV-infected peripheral blood leukocytes by noninfectious HTLV-I virions results in the production of large amounts of HIV-1 [90]. Furthermore, many of the opportunistic viruses commonly seen in AIDS patients (including CMV, herpes simplex viruses, EBV, and HHV-6) encode transactivator proteins that upregulate transcription from the promoters of heterologous genes [91]. Thus, CMV encodes protein products that can transactivate the HIV long terminal repeat, or LTR [92]. A possible effect of this interaction is noted in cases of fulminant CMV infection, in which high amounts of HIV are also found. However, despite these potential contributing interactions among viruses prevalent in the setting of AIDS, the etiology of most of the AIDS-associated lymphomas is unknown.

Host Response

Host factors may also play a role in HIV patients' predisposition to lymphoma. Just as specific alleles of chemokines and their receptors are known to confer protection against or increased risk of HIV infection, an increased risk of HIV-associated non-Hodgkin's lymphoma, has been observed in association with a particular polymorphism of the stromal cell-derived factor 1 (SDF-1) chemokine gene [93, 94]. The risk is greater for homozygotes of this SDF1–3′A allele than for heterozygotes, with 19% of homozygous and 10% of heterozygous SDF1–3′A carriers developing lymphoma after a median follow-up of 12 years, in contrast to 5% of wild-type HIV-infected individuals.

Clinical Features of HIV-Associated Lymphomas

The most common HIV-associated lymphomas are DLBCL, Burkitt's lymphoma, and Hodgkin's lymphoma. Other subtypes, including primary effusion lymphoma and plasmablastic lymphoma, are also seen but less common. Some authors have noted considerable pleomorphism with frequent overlap between some of these histologic categories, suggesting a morphological spectrum of lymphomatous proliferations [95, 96]. Among the morphologic complexities noted within these larger categories are classical Burkitt's lymphoma (30%) and atypical Burkitt's-like lymphoma (among the small non-cleaved cell lymphomas), as well as lymphomas with features intermediate between Burkitt's lymphoma with plasmablastic differentiation and immunoblastic lymphoma [95]. Although more rare, other histologic types of lymphoma have also been noted in conjunction with HIV, including T-cell lymphomas, T-cell lymphoblastic leukemia, adult T-cell leukemia/lymphoma, peripheral T-cell lymphoma, and Ki-1+ anaplastic large-cell lymphoma.

In contrast to non-Hodgkin's lymphomas in immunocompetent individuals, a very high proportion of AIDS-associated non-Hodgkin's lymphomas present with extranodal disease, with or without nodal involvement. The most frequently involved sites are the CNS (20–40%), bone marrow (25%), and gastrointestinal tract (25%) [97]. Other affected sites include the skin, salivary glands, oropharynx, heart, lungs, liver, rectum, muscles, bones, orbit, mandible, and even the peripheral blood.

Approximately 31% of the AIDS-related non-Hodgkin's lymphomas are systemic. They usually present at advanced stages with up to 95% of cases being in stage III or IV [98]. Those few cases that are early stage are frequently extranodal (Stage IE and IIE disease) [98].

Diffuse Large B-Cell Lymphoma in HIV Patients

DLBCL, which accounts for over 70% of lymphoma cases, remains the main type of cancer that develops in patients with HIV, although the incidence has declined since the initiation of HAART [99]. DLBCLs are variable in their histology in patients with HIV. The centroblastic variant consists of diffuse sheets of large lymphoid cells with round or oval nuclei and prominent nucleoli. They are often positive for CD10 and CD20 and express Bcl-6, suggesting germinal center origin [100]. Alternatively, the immunoblastic variant refers to lymphomas with more than 90% immunoblasts with plasmacytoid features. CNS lymphoma typically falls into this category. These cells have plasma-cell surface markers, such as CD138, while still retaining features of mature B cells [100]. These tumors classically have frequent mitoses and high proliferation rates. The prognostic implications of these subtypes remain unclear.

Burkitt's Lymphoma in HIV Patients

Burkitt's lymphoma accounts for approximately 14% of AIDS-related NHL and is more commonly seen in patients with HIV than other types of immunodeficiency [101]. HIV-associated Burkitt's lymphoma cells typically express CD10, CD20 and have a proliferation rate close to 100%. Morphologically, Burkitt's lymphoma can fall into three categories. The classic type, which accounts for approximately 30% of patients, appears similar to those in non-HIV-infected patients [100]. Burkitt's lymphoma with plasmacytoid features, however, demonstrates pleomorphism in nuclear size and shape, abundant eccentric cytoplasm, and nuclei with a centrally located prominent nucleolus. Lastly, in atypical Burkitt's there is greater pleomorphism with fewer, but more prominent nucleoli [100]. This histologic appearance is typically only seen in patients with HIV [3].

Primary Central Nervous System Lymphoma

The incidence of primary CNS lymphoma of the brain, a rare tumor that accounts for less than 2% of all non-Hodgkin's lymphomas and 1% of all brain tumors, increased threefold from 2.7 to 7.5 cases per 10 million population between 1973 and 1984 [102]. Part of this increase may be attributed to the unusually high proportion, between 19 and 25%, of AIDS–non-Hodgkin's lymphomas that present as primary brain lymphoma (Table 47.1), with a frequency 1000 times greater than that in the general population [97]. Primary CNS lymphoma is the second most common AIDS-associated cerebral mass lesion, after toxoplasmosis. Sites of AIDS-associated CNS lymphomas include the cerebrum, cerebellum, basal ganglia, and brain stem [103]. Furthermore, the association that is generally seen between AIDS–non-Hodgkin's lymphomas and low CD4 counts is even more pronounced in primary CNS lymphomas, which tend to occur in patients with CD4 counts below 50 cells/mm^3 [104]. In contrast to primary brain lymphomas in the immunocompetent host, those occurring in conjunction with AIDS do not have a characteristic radiographic appearance. They can occur in the cortex or deep periventricular structures. Although 50–75% of cases are multifocal on computed tomography (CT) or magnetic resonance imaging (MRI) scan, at autopsy virtually all are multifocal. Twenty to 60% of AIDS-related primary CNS lesions show ring enhancement accompanied by surrounding edema, making them difficult to distinguish from toxoplasmosis and necessitating brain biopsy for accurate diagnosis [105]. Accompanying spinal fluid analysis may be normal or may show a mild pleocytosis that is primarily mononuclear, as well as elevated protein and depressed glucose [105]. It is notable that there has been a clear decrease in the incidence of AIDS-related PCNSLs since the advent of HAART [106].

Pathological evaluation usually shows a high-grade B-cell lymphoma. Although some studies note only diffuse large-cell histologies, especially large-cell immunoblastic lymphoma, other reports demonstrate small non-cleaved cell lymphomas among the primary CNS lesions. Leptomeningeal involvement has also been reported with high frequency. In contrast to the systemic AIDS–non-Hodgkin's lymphomas which show EBV infection in only 30–60% of cases, in situ hybridization has demonstrated EBV expression in up to 100% of primary CNS lymphomas in HIV patients [103]. The latter finding also differs from that in immunocompetent patients, in whom primary CNS lymphomas rarely contain EBV. Finally, primary localized extranodal lymphomas, like primary CNS lymphomas, tend to be immunoblastic, whereas both large-cell immunoblastic lymphomas and Burkitt's lymphomas have been noted in the meninges [107].

Hodgkin's Lymphoma in HIV-Infected Individuals

Although individual cases of Hodgkin's lymphoma in AIDS patients have been reported since 1984, Hodgkin's lymphoma has not been classified as an AIDS-defining illness to date. This omission was attributable to the failure of some studies to demonstrate an increased incidence of Hodgkin's lymphoma in HIV-infected patients. However, there now seems to be a clearer association with HIV, with at least a tenfold increased risk as compared to the general public [108]. This increased risk may even be greater since the implementation of HAART, as there is an increased incidence of Hodgkin's lymphoma in the post-HAART era.

The most prevalent histological subtype of Hodgkin's lymphoma reported among HIV-infected individuals is mixed cellularity. The nodular sclerosis type constitutes the second most common subtype (30%), though its frequency is decreased in comparison with non-HIV-infected patients with Hodgkin's lymphoma [109]. The proportions of both mixed cellularity and lymphocyte-depleted subtypes among HIV-infected individuals with Hodgkin's lymphoma (40–60% and 20%, respectively) are elevated relative to that in the non-HIV Hodgkin's disease population [108, 109]. Interestingly, in the post HAART era, there has also been a shift toward increased incidence of the nodular sclerosis subtype, which is seen more commonly with higher CD4 counts [110].

HIV-infected individuals with Hodgkin's lymphoma present with advanced (i.e., Stage III or IV) disease in as high as 80–90% of cases, often accompanied by B symptoms. Extranodal disease occurs in two-thirds of patients, with bone marrow involvement in up to 50%, in contrast to the 3.5% observed in patients with Hodgkin's lymphoma not infected with HIV [111, 112]. Other reported sites of involvement include lung, liver, bone, paraspinal masses, rectum, and CNS, as well as other unusual sites such as the tongue and skin. A relative paucity of mediastinal disease has been noted in HIV-infected patients—22 versus 50% in the absence of HIV infection—and noncontiguous spread may occur in the setting of HIV [113]. In contrast to patients with seronegative disease, patients with HIV Hodgkin's lymphoma are nearly always associated with EBV [108].

Body Cavity Lymphoma/Primary Effusion Lymphoma

An unusual clinical entity, *body cavity-based lymphoma* associated with lymphomatous effusions (pleural, pericardial, or peritoneal) in AIDS patients was originally described in 1989 and was subsequently designated *primary effusion lymphoma* [114]. Knowles et al. have noted such lymphomatous effusions in the absence of a contiguous tumor mass in MSM patients usually, but not always, in association with HIV infection [115]. The lymphomatous effusions generally constituted the initial presentation of a lymphoma, which in most cases remained localized to the body cavity of origin. Examination of the malignant cells revealed features of both large-cell immunoblastic lymphoma and anaplastic large-cell lymphoma. Despite the absence of B-cell-associated antigens, clonal Ig gene rearrangements placed these lymphomas in the B-cell lineage. A potential etiologic agent for these body cavity-based lymphomas was identified when a DNA sequence homologous to a 233-base pair region of Kaposi's sarcoma-associated herpesvirus-like virus (KSHV) was observed in all AIDS-related body cavity-based lymphomas associated with lymphomatous effusions but in none of the other tested AIDS- or non-AIDS-related lymphomas [116]. Subsequently, KSHV sequences have been identified in body cavity-based lymphomas in patients not infected with HIV, including patients with Kaposi's sarcoma, post-cardiac transplant, and even in immunocompetent individuals. The putative agent, KSHV, named for its original association with Kaposi's sarcoma lesions in AIDS patients, is now classified as human herpesvirus-8 (HHV-8) based on homology of KSHV sequences to members of the Gammaherpesvirinae subfamily of herpesvirus [117]. Similar to EBV, KSHV/HHV-8 exists in the latently infected cells of primary effusion lymphoma as multiple copies of a circularized DNA episome. A KSHV/HHV-8-encoded latency-associated nuclear antigen (LANA) appears to be necessary and sufficient for the persistence of these episomes, tethering KSHV/HHV-8 DNA to chromosomes during mitosis to ensure their efficient segregation to progeny cells [118]. In addition to KSHV/HHV-8, EBV sequences have been identified in well over 70% of body cavity-based lymphomas examined [119]. The combined presence of KSHV/HHV-8 and EBV in this particular presentation of lymphoma supports a synergistic effect in which both agents act as carcinogenic insults contributing to the multistep progression toward malignant lymphoma.

Treatment of AIDS-Associated Lymphomas

Before use of HAART, patients with HIV-associated lymphomas had poor outcomes, given chemotherapy failures and high rates of infection. Prognosis in these patients was determined primarily by their performance status and severity of HIV rather than the type of lymphoma. While a variety of dose and risk adjusted treatments were studied, median survivals remained at approximately 5–6 months [100]. Since the advent of HAART, patients have had dramatic improvements in outcome. Given improvements in immune function, patients are now able to tolerate optimal chemotherapy regimens with outcomes similar to those in non-HIV-infected patients.

The decision about timing of HAART treatment remains incompletely established, primarily because of issues related to potential drug interactions. Components of the HAART regimen, particularly the non-nucleoside reverse transcriptase inhibitors (NNRTIs) and the protease inhibitors (PIs), are extensively metabolized by the cytochrome P-450 (CYP450) enzyme system. These drugs may also be inhibitors or inducers of CYP450. Since many chemotherapeutic agents are also metabolized by the CYP system, concomitant HAART use presents theoretical disadvantages. For example, concomitant HAART and chemotherapy might result in either drug accumulation and possible toxicity, or decreased

efficacy of one or both groups of agents. Nonetheless, there is now considerable experience of concomitant use, even in dose-intense regimens, and most guidelines recommend concurrent use.

There has also been controversy regarding the role of rituximab in addition to chemotherapy in patients with HIV-associated NHL. While there is a clear benefit in patients with non-HIV-related disease, the increased risk of infection in patients with HIV has raised concern about its universal use. One randomized controlled trial did not demonstrate a benefit in survival with the addition of rituximab to cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) for patients with NHL, presumably given an increase in infection related mortality [120]. Subsequent studies, however, have demonstrated safety and efficacy with rituximab use with CHOP and dose escalated cyclophosphamide with etoposide, vincristine, doxorubicin, prednisone (da-EPOCH) in this population [121]. Based on these studies, rituximab use is recommended, though should be used with caution in the setting of CD4 counts <50/uL.

Controlled studies investigating the role of CNS prophylaxis in HIV-positive patients with lymphoma are also lacking. In HIV-negative patients, there is an increased risk of CNS relapse in patients have an elevated LDH, ECOG performance status greater than 1, and extranodal involvement. It is therefore reasonable to provide CNS prophylaxis for patients in HIV-positive patients with these features as well. Options for prophylaxis include high-dose methotrexate and liposomal extended release cytarabine [122].

Incorporation of granulocyte/macrophage colony-stimulating factor (GM-CSF, sargramostim) or granulocyte colony-stimulating factor (G-CSF, filgrastim) into the chemotherapeutic regimens has permitted the use of standard doses with the maintenance of higher mean nadirs of absolute neutrophil count, shorter mean durations of neutropenia, and fewer episodes of neutropenic fever. However, no statistical difference in survival time has been demonstrated as a consequence of CSF use [123]. Furthermore, evidence from elevated mean p24 levels suggests that GM-CSF stimulates HIV replication [123]. However, the elevation is transient and is not consistently observed.

For patients with relapsed or refractory AIDS–NHL, standard treatment remains to be established. Thus, patients are often treated in a manner similar to that of HIV-negative patients, such as with isofamide, cisplatin, etoposide (ICE), or rituximab-ICE or with etoposide, solumedrol, high-dose cytosine arabinoside, and plantinum (ESHAP). Patients responsive to second-line chemotherapy have been successfully treated with high-dose chemotherapy and autologous stem cell transplant. In one report, 84% of such patients (n = 19) were in complete remission at a median follow-up of 27 months (range 6–57 months) [124]. In a multi-institutional study conducted by the AMC, of 20 patients, 10 (50%) were event free and 13 remained alive at a median follow-up time of 23 weeks [125].

While outcomes for patients with HIV Hodgkin's lymphoma have improved dramatically since the advent of HAART, standard therapy in this population has not been defined. Typically, a standard chemotherapy regimen for patients with Hodgkin's lymphoma in non-HIV patients such as doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) is used. Alternatively, a stage and risk-adapted approach, which has been described by German investigators, also seems to be efficacious in this population [126]. With this strategy, patients with early favorable disease are treated with two to four cycles of ABVD followed by intensive field radiation. Patients with early unfavorable disease receive four cycles of bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone (BEACOPP) or ABVD with radiation. Lastly, patients with advanced stage disease receive six to eight cycles of BEACOPP. Given the toxicity of the BEACOPP regimen, ABVD is typically preferred in patients with advanced HIV.

There are limited data to suggest an optimal treatment regimen in HIV-associated Burkitt's lymphoma. Dose intensive regimens used in the treatment of acute lymphoblastic leukemia (ALL) have been applied to HIV-associated Burkitt's lymphoma with outcomes similar to patients without HIV. Other dose intensive regimens such as Hyper-CVAD/HD-MTX and CODOX-M-IVAC regimens that are used in seronegative patients have also been used. Given significant toxicities with this regimen, dose adjusted R-EPOCH may be preferred for some patients [121]. Central nervous system prophylaxis is also typically included in this population.

Other Viruses

In addition to EBV and HIV, HTLV-I, HHV-8, and HCV are also strongly implicated as lymphomagenesis. HTLV-I is a single-stranded RNA virus that integrates randomly into the host cell genome, with one copy of this provirus being detectable per cell. The HTLV-I genome codes for Tax, a viral transcriptional transactivator that upregulates viral and cellular gene products that may contribute to carcinogenesis [127, 128]. In HTLV-I-infected cells, for example, Tax activates *NF-κB* and $BCL\text{-}X_L$, which leads to the inhibition of apoptosis and ultimately results in an increase in cytokine production and cell proliferation.

The majority of HTLV-1-infected individuals remain asymptomatic, though approximately 5% ultimately develop the rapidly progressive T-cell leukemia/lymphoma, ATLL, characterized by uncontrolled clonal proliferation of mature transformed CD25 + CD4+ T cells and a very poor prognosis [129]. Four subtypes of ATLL are seen: acute, chronic,

smoldering, and lymphoma type [130]. All subtypes have viral DNA clonally integrated into the cellular DNA of the neoplastic cells. The acute form of ATLL is an aggressive T-cell lymphoma associated with a high white blood cell count, hypercalcemia, hepatosplenomegaly, and lytic bone lesions. The presence in the peripheral blood of large flower-like cells with lobulated nuclei is pathognomonic for ATLL. The chronic form resembles the acute form in some ways (e.g., hypercalcemia) but lacks the characteristic peripheral blood involvement of ATLL. Smoldering ATLL may resemble mycosis fungoides/Sezary syndrome in that cutaneous involvement occurs in the form of erythema or infiltrative plaques or tumors. Both the acute and the lymphoma-type ATLL have a poor prognosis, with mean survival being only 6 months. They are poorly responsive to conventional chemotherapy, encouraging the use of experimental approaches such as aggressive infusional chemotherapy which has shown some promise, yielding up to 93% overall objective response rate with a median survival of 17.4 months [131]. HTLV-I is endemic in areas such as southern Japan, the Caribbean Islands, and some areas of Brazil, where ATLL accounts for over half of adult lymphoid malignancies. In contrast to HTLV-I, HTLV-II has not been strongly correlated with any disease.

HHV-8/KSHV, in addition to showing an association with body cavity-based lymphomas in the setting of HIV (see earlier discussion), has been observed in the plasma cell variant of multicentric Castleman's disease and in angioimmunoblastic lymphadenopathy (AILD).

As a final example, the prevalence of chronic HCV infection has been shown to be higher in patients with B-cell non-Hodgkin's lymphoma than in controls, suggesting a potential role for HCV in B-cell lymphomagenesis [132]. HCV is a single-stranded, RNA virus that infects liver, and in a subset of approximately 20%, causes irreversible liver disease in the form of either cirrhosis or hepatocellular carcinoma. HCV is implicated in extrahepatic disease as well. For example, it is the primary etiologic agent of type II mixed cryoglobulinemia, which is associated with an underlying B-cell proliferation in 2–11% of cases. Although an association between HCV infection and non-Hodgkin's lymphoma has not been observed by all investigators, in a retrospective cohort study conducted within the Department of Veterans Affairs including 146,394 individuals infected with HCV and 572,293 not infected, there was a 20–30% increased risk of NHL and an almost threefold increased risk of Waldenstrom's macroglobulinemia among those infected with HCV [133]. Furthermore, a meta-analysis which included 15 case–control and three cohort studies revealed a pooled risk ratio (relative risk) of 2.0 (95% CI, 1.8–2.2) for the cohort studies and 2.5 (95% CI, 2.1–3.1) for the case–control studies for the development of B-cell NHL in HCV-infected patients [134]. Although most studies have concentrated on the association of HCV with B-cell lymphomas, a meta-analysis of nine published reports also demonstrated a significant association with T-cell lymphomas [135].

Mucosa-Associated Lymphoid Tissue (MALT) Lymphoma

Of the many lymphomas associated with infectious agents, those that arise in mucosa-associated lymphoid tissue (MALT) provide an excellent model of antigen-driven malignancy in which environmental factors and host immune response are demonstrably involved in the pathogenesis of lymphoma. MALT lymphomas are extranodal marginal zone B-cell lymphomas most commonly arising in the stomach but also occurring in the lung, ocular adnexa, skin, salivary glands, thyroid tissue, and breast. MALT lymphomas occur in the context of chronic inflammation related to infectious disease, including *Helicobacter pylori*, *Borrelia burgdorferi*, and *Chlamydophila psittaci*, or autoimmune disorders including Sjögren's syndrome or Hashimoto thyroiditis.

Helicobacter pylori

For many years, the belief was held that microorganisms could not inhabit the stomach and that gastric juice was sterile. More recently, however, not only was a high prevalence of *H. pylori* shown in the stomachs of the population, but its presence has also been associated with disease. *H. pylori* eradication has become a primary component of the therapy of peptic ulcer disease and non-ulcer dyspepsia, in which it has been shown to play an etiologic role. In addition, infection with the organism appears to be a risk factor for gastric carcinoma and lymphoma, raising the prospect that these cancers could be prevented by treating the infection.

The stomach wall normally contains no lymphocytes. However, in persons infected with *H. pylori*, a lymphoid cell infiltrate, *MALT*, may appear and eventually develop into a lymphoma. MALT lymphoma, the most common type of marginal zone lymphoma, is mucosal based, showing a tropism for the epithelium of the affected extranodal parenchyma [136]. The key histologic feature is the presence of lymphoepithelial lesions, with invasion and partial destruction of the gastric glands or crypts by aggregates of centrocyte-like cells [137]. Although low-grade MALT lymphomas are generally believed to be localized (Stage I_E or II_E) at the time of diagnosis, some studies have demonstrated dissemination in up to a third of cases [136, 138].

The mechanism of the lymphomagenesis is incompletely understood, but the infecting organism, *H. pylori*, is believed to provide an antigenic stimulus to neoplastic B cells in the

lymphoid infiltrates via *H. pylori*-specific T-cell proliferation [139]. In addition, host T-cell regulatory gene polymorphisms could influence T-cell response in gastric MALT lymphoma [140]. The subsequent development of genetic alterations also contributes to carcinogenesis. The loss of chromosome 3 has been suggested as playing a role in the transition from benign MALT to low-grade MALT lymphoma [141]. Similarly, trisomy 3 and, less frequently, trisomy 18 have been observed in most MALT lymphomas.

Three major translocations specific of MALT lymphomas are reported which share a common pathogenic mechanism: activation of the NF-kB signaling pathway. The t(11;18)(q21;q21) is the most common (20–30%) and is associated with *H-pylori* eradication unresponsive gastric MALT lymphoma [142].

Another genetic abnormality encountered in 1–2% of MALT lymphomas is the t(1;14) translocation. The t(1;14) translocation results in truncation of *Bcl*-10, leading to activation of *NF*-κ*B* and absence of apoptosis [143]. Similar to the t(1;18), the t(1;140) MALT lymphoma is usually advanced and unresponsive [144].

The t(14:18)(q32q21)/(IGH-MALT1) translocation occurs in 10–20% of MALT lymphomas, mostly arising in the skin (14%) and ocular adnexa (13%) [145]. This translocation is typically associated with additional chromosomal aberrations including trisomy 18 and with more aggressive clinical behavior.

Although c-*MYC* rearrangements are not generally seen in MALT lymphomas, mutations in exon 1 and the intron 1 regulatory region were observed in 17% of cases examined, implicating this oncogene in MALT lymphomagenesis [138].

Moving along the carcinogenic spectrum, the relationship of low-grade to high-grade MALT lymphomas is complex. One possibility is that low-grade MALT lymphomas progress to diffuse large-cell lymphomas. Such a relationship is supported by epidemiological data linking the much more common high-grade gastric diffuse large-cell lymphoma to *H. pylori* infection. In fact, most gastric MALT lymphoma patients (98.5%) are seropositive for *H. pylori*, although only 58–78% of resected specimens actually contain the *H. pylori* bacteria (63% for low-grade vs. 38% for high-grade lymphomas) [146]. Histologic distinction of grade among MALT lymphomas, however, has posed problems, with many presentations occurring as mixtures of low- and high-grade tumors. Therefore, attempts to determine the existence of a transition from low- to high-grade have relied on documenting changes at the molecular level.

A sense of transition from low- to high-grade MALT lymphoma emerges from comparisons of *p53* mutations (seen in 6%, 12%, and 31% of low-, mixed-, and high-grade tumors, respectively) and *bcl-2* overexpression (seen in 93, 88, and 44% of low-, mixed-, and high-grade tumors, respectively), which are inversely correlated with each other [147]. These data point to a possible association of *p53* mutations with transformation to high-grade lymphoma. Another genetic alteration that appears to correlate with progression to more aggressive histology is mutation of the *BCL*10 gene [145].

Low-grade gastric MALT lymphomas have been successfully treated by eradication of *H. pylori* with antibiotic therapy. Complete regression of low-grade MALT lymphomas occurs in 50–80% of the treated cases. More recently, patients with early stage high-grade gastrointestinal lymphomas experienced complete remission after eradication of *H. pylori* as well [148]. When antibiotic therapy is unsuccessful or is inappropriate, surgical resection or radiation has been administered, since low-grade MALT lymphoma is usually confined to the site of origin. Chemotherapy has also been administered with good results. To date, there is no evidence from controlled trials defining optimal therapy, and none of the modalities has been proven superior to the others in terms of prolonging survival.

Chlamydophila psittaci

The occurrence of ocular adnexal MALT lymphoma (OAML), a marginal zone B-cell lymphoma, has increased in recent years, with its highest prevalence among older women [149, 150]. OAML display typical histopathology and immunophenotype profile of MALT lymphomas with clonal IGHV gene rearrangement in 55% of cases [151]. Although MALT-related chromosomal translocations are uncommon in OAML (<10% of cases) [642], trisomy 3 and 18 occur frequently [152].

Chlamydiae are ubiquitous, obligate intracellular bacteria responsible for a wide range of human diseases, including chronic conjunctivitis. *Chlamydophila psittaci* (CP) has been detected by PCR techniques in 80% of Italian patients with OAML [153]. Retrospective reviews from Korea and Austria reveal similar, but not quite as high, infection rates among OAML patients [154, 155]. Other eye pathogens, such as *C. trachomatis* and herpes simplex viruses 1 and 2 have not been implicated in OAML; however, *C. pneumonia* has been detected in a few cases.

In addition to OAML, *Chlamydophila psittaci* has been detected in a significant portion of DLBCL arising in the skin and Waldeyer's ring, although it does not appear to be involved in the pathogenesis of lymphomas in the gastrointestinal tract or in pulmonary MALT lymphoma.

Borrelia burgdorferi

An association between primary cutaneous B-cell lymphoma (CBCL) and infection with the spirochete *Borrelia burgdorferi*,

the infectious cause of Lyme disease, has been observed in a number of cases. A pathogenetic role for the organism was suggested in part by the clinical observation of B-cell lymphomas arising on skin affected by acrodermatitis chronica atrophicans, a skin lesion known to be caused by *B. burgdorferi*. Raised titers of antibodies to *B. burgdorferi* in the sera of patients with CBCL offered additional evidence supporting such an association [156]. Monoclonality of the lymphomatous skin infiltrate has been demonstrated, and specific DNA sequences of *B. burgdorferi* have been identified in the cutaneous lesions in 18% of cases. The lymphomas are generally low-grade, extracutaneous involvement is rare, and progression is slow, with tumors remaining confined to the skin for as long as 7–15 years. By analogy to *H. pylor*i-associated MALT lymphomas of the stomach, a proportion of *B. burgdorferi*-associated lymphomas have been cured by appropriate antibiotic treatment, with concomitant eradication of the spirochete [156, 157]. Reports have also suggested an association between *Borrelia burgdorferi* and some cases of mantle cell lymphoma, mycosis fungoides, and possibly immunoproliferative small intestinal disease (IPSID).

Lymphomas in the Setting of Transplantation

Lymphomas in the Setting of Solid Organ Transplantation

Epidemiology/Demographics of Lymphomas Associated with Organ Transplants

Organ transplantation and the immunosuppressive therapy that is often essential to prevent rejection of transplanted organs, have been found to contribute to the development of non-Hodgkin's lymphomas. This is especially true of solid organ transplants where patients have a twofold risk of developing cancer compared to the general public [158]. Excluding non-melanoma skin cancers and in situ carcinomas of the cervix, the most frequently encountered malignancy in the transplant setting is lymphoma, which comprises 14% of posttransplant cancers [158]. Up to 25% of transplant patients develop post-solid organ transplantation lymphoproliferative disorders (PTLD), depending on the organ transplanted [159–161]. PTLDs are clinically and pathologically a heterogeneous group of lymphoid proliferations, most of which are of B-cell origin and are associated with EBV [161]. Despite the heterogeneity, PTLD remains a serious complication of transplantation with a 5-year overall survival ranging from 40 to 70% [162, 163].

The average time of occurrence of all cancers following transplant is 61 months. Lymphomas tend to appear earlier, averaging about 36–40 months [163]. EBV-negative PTLD, however, presents later, with occurrences more than 1 year following transplant [163].

Additional demographics point to a higher incidence of posttransplant lymphomas in North America than in Europe among both kidney and heart transplant patients [164]. In the United States, the risk of developing non-Hodgkin's lymphoma is slightly lower among African–American than white patients [164]. Several of these epidemiologic correlates probably reflect two key features of transplantation: the type of transplant and the nature of the immunosuppressive therapy.

Influence of Type of Transplant on Lymphoma Incidence

Risk of PTLD has been linked to pretransplant EBV mismatch, the immune suppression agents used and the type of organ transplanted. The incidence of PTLD is highest following intestinal or multi-organ transplants (up to 20%), followed by lung (2–9%), heart (2–6%), liver (1–2%), and renal transplants (1–3%) [165–167]. It is thought that these differences arise from variation in histocompatibility as well as the amount of lymphoid tissue present in the transplanted organ. For example, the small intestine, which has high rate of PTLD, has significantly more lymphoid tissue and subsequently donor lymphocytes [168]. Interestingly, analysis of sex chromatin, HLA specificities, and DNA restriction fragment length polymorphisms indicates that most posttransplant lymphomas following solid organ transplantation derive from recipient rather than donor lymphocytes.

Influence of Immunosuppressive Therapy on Lymphoma Incidence

A number of immunosuppressive agents, including azathioprine, cyclophosphamide, tacrolimus, and cyclosporine, have been shown to promote tumorigenesis in the transplant setting [161]. It is theorized that the reduction in host cytotoxic T-cell response decreases control of EBV infection of the transplanted graft, thus predisposing to PTLD. While it is difficult to dissect out the tumorigenic effect of a single component, qualitative differences have been demonstrated among these agents with respect to their carcinogenic, and specifically lymphomagenic, potential. In kidney transplant patients, for example, immunosuppression with cyclosporine did not increase risk of PTLD compared to azathioprine and steroids, but treatment with tacrolimus led to an approximately twofold risk [164]. Maintenance tacrolimus has also been associated with increased risk of disease as compared to cyclosporine [169].

The degree of immunosuppression also clearly influences risk of developing PTLD. Thus, the higher incidence of LPD seen in early trials with cyclosporine relative to established immunosuppressive therapy was subsequently traced to the higher cyclosporine doses used at the time [170]. Higher cumulative doses of prophylactic anti-CD3 (more than 75 mg) in cardiac transplant recipients correlate with a higher incidence of lymphomas, 35.7%, compared with 6.2% for

doses less than 75 mg [166, 171]. Anti-CD3 doses higher than 75 mg also correlate with a shorter time interval between transplant and development of lymphoma, averaging only 1–2 months. Furthermore, the variable incidence of malignancy, and specifically lymphoma, in different subgroups of transplant recipients may at least in part be attributable to the intentional implementation of more intensive immunosuppressive regimens in certain settings. Termination of immunosuppressive therapy may also be a reasonable option for management of severe rejection of a kidney transplant, given the non-life-threatening nature of the transplant rejection. However, no such option is available when a comparable threat of rejection occurs in the setting of heart, liver, or lung transplant, necessitating intensification of the immunosuppressive regimen in order to save the patient's life.

In addition to higher doses of individual agents, the use of combinations of immunosuppressive agents to minimize individual toxicities may carry its own risk by undermining different points in the immune system [172]. Doses of cyclosporine used in triple therapy with prednisone and azathioprine, for example, have been lowered in an effort to reduce nephrotoxicity. Despite these reduced cyclosporine doses, the incidence of lymphoma is increased with triple therapy.

Clinical Features and Histopathology

PTLD displays a spectrum of lesions ranging from polymorphic diffuse B-cell hyperplasia to intermediate polymorphic diffuse B-cell lymphoma to true monomorphic large-cell immunoblastic lymphoma [173–175]. The polymorphic presentations, which contain small and large cells of both follicular center and medullary type, have been interpreted as benign reactive hyperplastic or neoplastic lymphomas depending on whether cell marker studies reveal polyclonal or monoclonal B-cell proliferations [176]. Evolution from a polyclonal polymorphic lymphoproliferation to a true monoclonal monomorphic large-cell immunoblastic lymphoma has been demonstrated with individual lymphomatous sites displaying distinct monoclonal derivations. Similarly, PTLD lesions have been described in which polyclonality is suggested by immunophenotyping but that contain either Ig gene rearrangements or clonal cytogenetic abnormalities [177]. This suggests that independent activation of multiple cells is occurring as an early step in tumorigenesis, with occasional early malignant transformation detectable at the DNA or cytogenetic level. Among the true monomorphic monoclonal lymphomas, several histopathologic types have been identified, including large-cell immunoblastic lymphoma, DLBCL, diffuse mixed lymphoma, and small noncleaved Burkitt's and non-Burkitt's lymphoma.

Initially based on morphologic categories, the classification system for PTLDs was subsequently modified to incorporate correlative genetic and molecular analysis [178]. Knowles and colleagues incorporated a series of attributes that jointly define three categories of PTLDs (Table 47.2): (1) plasmacytic hyperplasias, which are polyclonal, associated with multiple EBV infections, and lack oncogene or

Table 47.2 Histopathologic categories of posttransplantation lymphoproliferative disorders[a,b]

Category of lymphoproliferation	Anatomic site(s) at presentation	Clonality by Ig gene	EBV events	Oncogene, tumor suppressor gene alterations	Clinical intervention and outcome
Plasmacytic hyperplasia	Oropharynx, lymph nodes	Most polyclonal	Most with multiple EBV infection events, or only a subset of cells infected by a single form of EBV, or EBV negative	Absent	All responded to reduced immune suppression + surgical resection
Polymorphic B-cell hyperplasia and polymorphic B-cell lymphoma	Lymph nodes, various extranodal sites	Most monoclonal	Most with single form of EBV	Absent	Respond to reduced immunosuppression + surgical resection; or to medical therapy; or no response
Immunoblastic lymphoma, multiple myeloma	Widely disseminated disease	Monoclonal	Single form of EBV	Alteration of one or more oncogenes or tumor suppressor genes: N-*ras*, *c-myc*, *p53*	Medical resolution; or no response—Most

[a]Data from Knowles DM, Cesarman E, Chadburn A et al. Correlative morphologic and molecular genetic analysis demonstrates three distinct categories of posttransplantation lymphoproliferative disorders. *Blood*. 1995;85(2):552–65; and from Chadburn A, Chen JM, Hsu DT. The morphological and molecular genetic categories of posttransplantation lymphoproliferative disorders are clinically relevant. *Cancer*. 1998;82:1978–1987

[b]Based on data from 1 lung, 5 kidney, and 26 heart transplant recipients

tumor suppressor gene alterations; (2) polymorphic B-cell hyperplasias and polymorphic B-cell lymphomas, which are generally monoclonal, manifest a single form of EBV, but still lack genetic changes in oncogenes or tumor suppressor genes; and (3) immunoblastic lymphomas or multiple myelomas, which are monoclonal, contain a single form of EBV, and exhibit alterations in one or more oncogenes or tumor suppressor genes [178]. Additionally, these tumor types tend to have cytogenetic karyotype abnormalities, including trisomy 9, trisomy 11, and rearrangements involving 8q24 [179]. An attempt to validate this system in terms of its clinical relevance has revealed that these categories correlate with clinical presentation, response to therapy, remission, and clinical outcome [180]. Importantly, all lesions categorized as plasmacytic hyperplasia regressed in response to reduction in immunosuppression alone or accompanied by surgery. Polymorphic PTLDs that did not regress with reduction in immunosuppression usually resolved with medical intervention, such as chemotherapy or radiation therapy. Lesions classified as malignant lymphoma/multiple myeloma did not respond in spite of aggressive clinical intervention. These histologic-clinical correlates provide a basis for choosing optimal treatment in the management of PTLDs.

Although about 85% of posttransplant lymphomas are B cell in origin, occasional T-cell lymphomas have been identified, some of which have been linked to EBV infection [181–183]. A rare CD8+ γδ T-cell lymphoma reported in the setting of renal transplant was found to be associated with human HHV-6 infection [184]. B- and T-cell lymphomas have also been observed within a single patient, and T-cell receptor and Ig heavy chain rearrangements have even been detected within the same lymphoid proliferation in a renal allograft, indicating a polyclonal origin to the PTLD [185, 186]. Unusual presentations such as that of a nasal natural killer cell lymphoma associated with EBV have also been reported post-renal transplant [187]. MALT-type lymphomas have been observed in the stomach and parotid gland following cardiac, liver, or kidney transplant [188]. Interestingly, all cases examined were negative for EBV, and the gastric lymphomas were all positive for *H. pylori*, resembling MALT lymphomas in immunocompetent patients rather than lymphomas that occur in association with immunosuppressed states. Hodgkin's disease has only been reported uncommonly following kidney, liver, and heart transplants [189]. Posttransplant leukemias occur but are uncommon, and most of them are granulocytic, particularly monocytic, in phenotype [190]. Other lymphoid-related proliferative diseases that are occasionally observed in the posttransplant setting include monoclonal gammopathies, multiple myeloma, and plasmacytomas [191].

As with lymphomas in other settings of immunosuppression, posttransplant lymphomas frequently present at advanced stages. Thus, in one study 50% were diagnosed as Stage III or IV, while 35% were Stage I [182]. The similarity to other immunodeficiency states extends to the frequency with which the posttransplant lymphomas occur at extranodal sites. Between 26 and 45% occur in the CNS: 14–66% of these are confined to the brain parenchyma with frequent multifocality and virtually no lymphomatous meningitis [161, 182].

The allograft has also been described as a site of involvement by lymphoma in 15–31% of cases, the lymphomatous infiltrate sometimes being mistaken on biopsy for graft rejection [192]. In fact, Opelz et al. noted a strong preferential location of lymphomas in the heart or lung after heart transplantation and in the kidney after renal transplantation [164]. On the other hand, Leblond et al. have suggested that allograft presentation may be less common in heart than in renal transplants [193]. Presentation in the allograft brings to mind the question of whether the tumor or a tumorigenic agent such as EBV (see discussion to come) was in fact transmitted from the donor, having been transplanted with the graft.

Pathogenesis: Mechanisms Underlying Lymphomagenesis in Association with Solid Organ Transplants

Molecular and Immunologic Basis for Posttransplant Lymphomagenesis

PTLD is believed to arise by a series of carcinogenic steps that roughly correspond to those described previously for HIV- and EBV-related lymphomas. Malignant progression is facilitated by a variety of mechanisms, some of which are unique to the setting of organ transplant. Thus, the underlying disease process that necessitates the transplant may predispose the patient to malignancy. As an example, a history of polycystic kidney disease seems to correlate with the development of posttransplant lymphoma [194]. By contrast, the duration of renal disease and length of time on dialysis, both potential contributors to overall immunosuppression, appear to play no role in lymphomagenesis, although they may influence the frequency of other malignancies [172, 195]. Among cardiac allograft recipients, PTLD has been noted primarily in individuals transplanted for idiopathic cardiomyopathy, rather than coronary artery disease [196, 197]. The reasons for this difference are unclear. Idiopathic cardiomyopathy is associated with a defect in mitogen-stimulated suppressor T-cell activity, whereas coronary artery disease is not; however, the relationship of this finding to subsequent lymphomagenesis remains obscure [198].

Initial B-cell proliferation results from exposure of host lymphoid tissue to a number of foreign antigenic stimuli, some of which are peculiar to the transplant setting. Chronic exposure to foreign histocompatibility antigens in the allograft may lead to hyperplasia [199, 200]. Blood transfusions, heterologous ATG or ALG, monoclonal antibodies like anti-CD3, and various infectious agents may elicit proliferative responses in lymphoid tissues. In particular, EBV, which is highly associated with the development of posttransplant lymphomas (see discussion to come), provides a potent antigenic stimulus to lymphoproliferation, as discussed previously. Patients with PTLD also often have decreased levels of interferon-α, a downregulator of IL-4, in turn allowing increased expression of IL-4, a potent stimulator of B-cell proliferation [201].

Within the expanded polyclonal B-cell population, genetic alterations occur that may lead to clonal expansion and malignant transformation. Although these changes have not been as extensively documented as in the AIDS–non-Hodgkin's lymphoma literature, clonal cytogenetic abnormalities suggestive of malignant progression have been identified in posttransplant lymphomas. For example, within polyclonal B-cell proliferations, cellular clones containing a 6q + long marker chromosome, trisomies 3 and 14, t(9;14) involving the IgH locus on chromosome 14, and t(2;19) involving the Ig-κ light chain locus on chromosome 2 have been identified [173, 202–204]. More recently, recurring copy number amplification in 9q24.1 have been seen in EBV-positive disease. Amplification of this locus, which includes programmed death ligand 1 and 2, may contribute to tumorigenesis by suppressing the anti-tumor immune response by T cells [205].

Finally, iatrogenic immune suppression further contributes to multistep tumorigenesis, by permitting the unchecked expansion of malignant clones. Each of the immunosuppressive agents used to prevent organ rejection targets discrete sites along the cascade of T-cell activation. For example, azathioprine plus prednisone abolishes natural killer cell-mediated cytotoxicity [206]. Glucocorticoids inhibit the expression of a number of cytokines, including IL-1, IL-3, IL-6, interferon-γ, and tumor necrosis factor-α, resulting in depression of T-cell proliferation and T-cell-mediated immunity. Cyclosporine blocks IL-2 gene activation, IL-2 receptor expression, and IL-2- and IL-6-mediated proliferation of mitogen-activated T cells [207]. Conversely, cyclosporine induces expression of IL-6, an activator of B-cell proliferation [207]. By thus modulating these two interacting arms of the immune system, cyclosporine may contribute to depressed T-cell surveillance of an expanding B-cell population in transplant recipients.

Role of EBV in Posttransplant Lymphomagenesis

A large volume of data supports the association of EBV infection with PTLD. First, EBV levels seem to increase in patients following transplantation. Renal transplant recipients, for example, exhibit higher levels of EBV oropharyngeal shedding than do healthy seropositive controls [208]. B cells containing EBV genomic DNA, which normally exist in the peripheral blood of seropositive individuals at concentrations of less than $1/10^7$ peripheral blood mononuclear cells (PBMCs), also increase in transplant recipients to more than $1/10^5$ PBMCs 1–3 months after transplant and remain high for about 3 months [209]. Certain studies suggest that the presence of increased levels of EBV DNA or RNA in lymphoid cells correlates with the subsequent development of PTLD, though the data has been conflicting [209–211]. Finally, EBNA-2 and EBNA-3C DNA sequences typifying EBV type 1, the more potently transforming strain (see earlier discussion), have been found in the majority of EBV-positive disease [212].

Transmission of EBV from a seropositive donor via the allograft leads to primary infection in virtually all initially seronegative transplant recipients. Swinnen et al. observed that among patients developing PTLD, 30% had negative tests for EBV before transplantation [171]. This observation, together with those from other studies involving a variety of transplanted organs, suggests that initial EBV seronegativity, with resulting primary EBV infection, is an important risk factor for PTLD [166]. In fact, the simultaneous development of PTLD in two seronegative recipients of kidneys from a single seropositive donor has been reported [213]. In addition to recipient seronegativity, donor EBV positivity has been shown to predict for seroconversion and developing PTLD [214]. The association of baseline seronegativity with conversion via primary infection as a risk factor for PTLD is especially pertinent to transplantation in the pediatric age group, since younger patients are more likely to be EBV seronegative. Data on pediatric transplant recipients bear this out, with symptomatic mononucleosis-like EBV infection and PTLD occurring more frequently in this age group than among adults [214, 215]. Because of the strong association of EBV transmission and primary EBV infection with the development of PTLD, some investigators believe that seronegativity of a potential recipient should preclude transplantation of an allograft from a seropositive donor.

As with EBV-containing AIDS–non-Hodgkin's lymphomas, the EBV genomes within PTLD generally exist as clonal circular episomes, supporting the clonality of these lesions as well as suggesting that EBV infection is an early event that occurs before clonal expansion [216]. In fact, the absence of monoclonality by EBV classification generally correlates with nonclonality by immunophenotyping and is

associated with histologic characteristics of polymorphic diffuse B-cell hyperplasia or intermediate polymorphic B-cell lymphoma. The EBV data therefore support a model in which the biologic spectrum of histologic types actually represents various stages of progression from polyclonal to monoclonal to frankly malignant lymphoproliferations.

The normal containment of EBV-infected B lymphocytes by EBV-specific cytotoxic T cells may also be abrogated by immunosuppressive agents used in organ transplant recipients. EBV may also affect the immune system by modulating levels of key cytokines such as serum IL-10, which is frequently upregulated in association with posttransplant lymphomas, especially those in which EBV is detected, following primary or reactivated EBV infection [217].

EBV latent gene expression is restricted in the PTLD lesions of solid organ transplant recipients. Using Southern blot, Western blot, and immunofluorescence analysis, Cen et al. observed a variety of restriction patterns, reflecting universal expression of EBNA-1, expression of LMP-1 in almost all cases, and only occasional expression of EBNA-2 [218]. In other studies, expression of the EBV-derived B-cell activating proteins EBNA-2 and LMP-1, as well as of their target cellular surface genes, CD23, intercellular adhesion molecule-1 (ICAM-1), and leukocyte function-associated antigen-3 (LFA-3), has been demonstrated by immunofluorescence in infiltrating B lymphocytes from bone marrow transplant recipients with EBV-related PTLD [219].

While there is a strong link between EBV positivity and PTLD, EBV-negative cases do occur. For example, Leblond et al. failed to detect EBV in 31% of the 19 B-cell PTLDs examined [193]. These EBV-negative PTLDs were more often morphologically monomorphic, and, interestingly, all but one of these lymphomas arose late, 1 year or more after transplant. These data suggest that the development of EBV-negative PTLDs in organ transplant recipients may be distinct entities. Further supporting this, EBV-negative PTLD has been found to share many cytogenetic abnormalities and copy number alteration lymphomas occurring in immunocompetent hosts [205]. Despite these differences, EBV status does not seem to be prognostic or predictive of outcome. [220].

Treatment

There is no standard treatment for PTLD given the pathologic and clinical heterogeneity. Reduction of immune suppression has been a critical component of treatment, though responses are typically durable in only 10–20% of cases [67, 221, 222]. The type of organ transplanted also dictates whether this is a feasible option. Similarly, clinical features, such as high LDH, late presentation, extranodal disease, older age, multi-organ involvement, and B symptom, often suggest a poorer response to reduction in immune suppression alone [161, 223].

In an effort to alleviate the confusion regarding therapy for PTLDs, Hanto et al. [173] categorized the posttransplant lymphomas into three histologic groups; a distinct therapeutic approach is recommended for each. For group 1, consisting of polyclonal polymorphic diffuse B-cell hyperplasia, acyclovir has successfully reversed the lymphoproliferation and is recommended with or without a reduction in immunosuppression. In group 2, the polyclonal B-cell lymphomas run the risk of progressing from polyclonal to monoclonal B-cell proliferations. Therefore, they should be treated by reduction or cessation of immunosuppression in most kidney transplant patients, allowing rejection to occur; the parallel approach in heart, heart-lung, and liver recipients, where allograft rejection would be fatal, involves acyclovir therapy and a modest reduction in immunosuppression. Finally, for group 3, the morphologically malignant monoclonal B-cell lymphomas, recommendations include standard chemotherapy or radiation therapy, combined with discontinuation of or reduction in immunosuppression. Combinations of all three modalities, acyclovir, reduction of immunosuppression, and intensive multi-agent chemotherapy, have been used successfully to treat frankly malignant lymphomas in the transplant setting.

Studies investigating the role of single agent rituximab have shown response rates of 34–42% [224–226]. A large prospective study also showed efficacy with rituximab treatment followed by CHOP chemotherapy [227]. There is also ongoing evaluation of the role of risk stratified sequential therapy with either additional rituximab or R-CHOP following rituximab depending on response [161, 227].

Lymphomas in the Setting of Bone Marrow Transplantation

Epidemiology/Demographics of Lymphomas Associated with Bone Marrow Transplants

The risk of cancer among recipients of allogeneic bone marrow transplants (BMT) is 3.8–6.7 times higher than that in the general population [229, 230]. The incidence of LPD in this treatment group ranges from 0.3 to 1.8% in different studies, generally less than the risk observed following transplants of various solid organs [230, 231]. In an overview of the allogeneic BMT experience at 235 centers worldwide reporting to the International Bone Marrow Transplant Registry (IBMTR), the cumulative incidence was 1.0 ± 0.3% at 10 years [232].

Post-bone marrow transplant lymphoproliferative disease (PBMT-LPD) develops earlier (median, 3 months) following transplant than do solid tumors of epithelial origin (median,

99 months) [168, 233]. The highest incidence in the IBMTR overview occurred 1–5 months posttransplant, with a peak at 3 months. This early onset disease (less than 1 year post-transplant) was followed by a gradual but steep decline among patients surviving for a year or more, although the risk of late-onset PBMT-LPD remained significantly higher than expected in the general population [232]. Although most reports of PBMT-LPD pertain to allogeneic transplants, lymphomas have been observed following both autologous and cord blood BMTs [234].

A variety of risk factors for the development of PTLD-LPD have been identified. Predisposition to PBMT-LPD occurs following treatment of acute GVHD with ATG or total-body irradiation and particularly, as discussed previously for solid organ transplants, with CD3-specific monoclonal antibodies [168, 214, 235]. In addition, HLA mismatch between donor and recipient, presumably because of the prolonged antigenic stimulation, contributes to a lesser degree [236]. T-cell depletion of the graft, which may result in increased susceptibility to EBV infection, has also been shown to predispose to PTLD. An identifiable risk factor late-onset PBMT-LPD was extensive chronic GVHD, possibly as a result of long-term treatment with immunosuppressive drugs.

In some studies, the incidence of PBMT-LPD varied with the underlying disease, e.g., 0.6% for treatment of hematologic malignancy versus 0.3% following transplantation for aplastic anemia [230, 237]. The risk for PBMT-LPD is particularly high among patients transplanted for congenital immunodeficiency diseases (see discussion to come). Conversely, no significant association of disease for which the transplant was performed with the risk of PBMT-LPD was seen in the IBMTR study [232].

Clinical Features and Histopathology

Histologically PBMT lymphomas resemble those seen after solid organ transplant, encompassing a large spectrum of morphologic characteristics, ranging from polymorphic B-cell hyperplasia to polymorphic B-cell lymphoma to large-cell immunoblastic lymphoma [206, 237, 238]. They are generally B-cell neoplasms, although T-cell lesions may occur [229, 238]. Interestingly, the two T-cell lymphomas observed in the IBMTR study occurred among the less frequent late-onset cases [232]. Staining for Igs has revealed both polyclonal and monoclonal lesions, although Ig heavy chain gene rearrangements have occasionally been detected within the polyclonal lesions, suggesting the presence of clonal proliferations [237]. Nonidentical monoclonal populations have been observed in separate lesions in the same patient, indicating distinct clonal derivations at the two sites [216, 239].Among PBMT-LPDs, most lymphomas have proved to be of donor origin, with host-derived lymphomas being only rarely observed [168]. Similar to PTLDs following solid organ transplants, the sites of involvement are varied and are often extranodal, involving abdominal and thoracic nodes as well as liver, spleen, gastrointestinal tract, and lungs [237].

Pathogenesis: Mechanisms Underlying Lymphomagenesis in Association with Bone Marrow Transplant

The histologic spectrum observed among PBMT-LPDs suggests the usual multistep progression from antigenically stimulated polyclonal proliferation through genetic alteration and ultimately selective expansion of a malignant clone. Analogous to the situation described for solid organ transplant recipients, potential factors operating in the context of BMT to promote tumorigenesis include the underlying disease, foreign antigenic stimuli such as mismatched HLA antigens and EBV, and the institution of immunosuppressive therapies designed to prevent GVHD. EBV DNA is almost always detected in the lymphoproliferative lesions associated with both BMT and organ transplant [206, 232, 238]. Despite the resemblance of post-BMT and post-solid organ transplant lymphomas with respect to the EBV positivity of their tumor tissue, BMT patients with PTLD fail to mount specific antibody responses to EBV VCA, early antigen, and EBNA. In the setting of BMT, a rapid increase in EBV DNA has been observed within 1–3 months after transplant, paralleling the timing of the peak of EBV-infected lymphocytes in pediatric solid organ transplant patients [240, 241]. Proposed sources of EBV in the BMT population include latently infected donor B lymphocytes, latently infected host B lymphocytes, the host nasopharynx, and blood transfusions. Since most cases of PBMT-LPD are of donor origin, the most likely etiology of EBV infection is via infected B lymphocytes transferred from the donor at the time of transplant or by infection of donor lymphocytes following transplantation into the host [237].

In addition to the clustering of EBV-negative lymphomas among late-onset cases, the two T-cell lymphomas observed in the IBMTR study occurred in the late-onset group [232]. This brings to mind the few T-cell lymphomas seen among PTLDs observed by Leblond et al. following solid organ transplantation, which also were of late onset and also tended to be EBV negative [193]. As pointed out by these authors, these data suggest that the development of EBV-negative PTLDs in organ transplant recipients may represent a morphologically and clinically distinct entity, depending on the accumulation of additional genetic changes and increasing in number with time after transplant.

Treatment of Post-Bone Marrow Transplant Lymphomas

Limited information is available regarding the treatment of PBMT-LPD. Although a strong association exists between EBV and these lymphomas, the data suggesting efficacy of acyclovir or ganciclovir are confined to a small number of cases, and do not support the use of these antiviral agents in either a prophylactic or a therapeutic mode in the setting of bone marrow transplants [237, 242, 243]. Based on the association of PBMT-LPDs with EBV and T-cell depletion of the allograft, together with their tendency to be of donor origin, patients who developed EBV-related lymphoma after receiving T-cell-depleted marrow were infused unirradiated donor lymphocytes [244]. The underlying hypothesis that the infused cell populations would supply missing cytotoxic T-cell precursors presensitized to EBV in the donor's microenvironment, which might control the proliferation of EBV-transformed donor cells in the host, was supported by observed responses in this small set of patients. An additional therapeutic approach has utilized interferon-α which, together with intravenous γ-globulin, has elicited responses in hematological malignancies complicating BMT [206, 243]. Finally, the use of CD21- and CD24-specific B-cell antibodies in patients with severe PBMT-LPD led to complete responses in 16 of 28 patients (57%), similar to the results with organ transplant patients, among whom 20 of 31 had complete responses (64%) [245, 246]. However, only 35% of bone marrow transplant patients survived more than 1 year, significantly less than the 55% survival among solid organ transplant recipients. The CD20-specific B-cell monoclonal antibody rituximab has also been used successfully to induce complete responses in three patients who developed EBV-associated lymphomas following stem cell transplantation [245]. By analogy to the solid organ transplant setting, the absence of firmly established effective treatments for PBMT-LPD, together with the association of this disease entity with EBV infection, has led some to recommend avoiding exposure of seronegative recipients to this virus and to select an EBV seronegative donor whenever possible for such transplants.

Lymphomas in Specific Autoimmune Diseases

The rheumatologic, or autoimmune, disorders offer another disease context in which an increased incidence of LPD is observed. The underlying mechanisms in these disease entities involve dysregulation leading to hyperactivity of the immune system.

The intimate relationship between malignancy and autoimmunity is particularly evident in Sjögren's syndrome, in which a classic histopathologic feature is the benign lymphoepithelial lesion, an infiltration of glandular tissue by B and T lymphocytes and plasma cells. Non-Hodgkin's lymphomas occur in Sjögren's syndrome patients with a frequency between 12 and 43 times that seen in the general population [247–249]. The lymphoproliferative lesions of the syndrome range from benign pleiomorphic lymphoid infiltrates to morphologically malignant lymphoma, resembling the spectrum of lesions described in transplant recipients [250]. The term *pseudolymphoma* refers to the middle portion of this spectrum and applies to those lesions that contain tumor-like aggregates of lymphoid cells but fail to meet the histologic criteria for malignancy [250]. These lesions may be localized to the salivary gland or appear as extraglandular lymphoid infiltrates.

All the morphologically malignant lymphomas are B cell in origin and diffuse in pattern of growth. The predominant histologic types include large cell, particularly immunoblastic, mixed large and small cell, and even small-cell lymphomas, with marked histologic variation within individual tumors. These are probably all lymphomas of the MALT type, similar to gastric MALT lymphoma [251]. The antigenic stimulus within the salivary gland has not been defined. Loss of intracytoplasmic Ig has been noted in association with terminal lymphomas, suggesting dedifferentiation of plasma cells and immunoblasts. Progression from a polyclonal benign lymphoproliferative lesion to monoclonal lymphoma has also been demonstrated. In other studies, however, clonal Ig gene rearrangements have been detected in presumably benign lymphocytic infiltrates [252]. A possible explanation for this apparent inconsistency is that the clonal expansion is due to a generalized defect in immune surveillance that characterizes Sjögren's syndrome, whereas the development of lymphoma reflects additional genetic alterations that promote neoplastic transformation [249].

Accompanying immunologic abnormalities include hypergammaglobulinemia, a high incidence of autoantibodies, organ-specific (anti-salivary duct) autoantibody, and a local excess synthesis of Igs, especially IgM macroglobulins [198]. While increased IgM levels in involved tissues or in serum are suggestive of concurrent Waldenstrom's macroglobulinemia, a low IgM level may herald the appearance of malignant lymphoma and is a poor prognostic sign. A fall in rheumatoid factor may accompany the decrease in IgM, leading to generalized hypogammaglobulinemia and loss of autoantibodies concomitant with the development of lymphoma [198]. The search for a potential viral role in lymphomagenesis associated with Sjögren's syndrome has been limited. However, based on a small number of cases, in which the EBV-encoded small RNA EBER-1 was not expressed in the benign lymphoproliferations of Sjögren's syndrome, EBV infection does not appear to play a key role in the pathogenesis of these lesions [253]. HHV-8 DNA

sequences were detected in a single bilateral MALT lymphoma of the parotid gland associated with Sjögren's syndrome, in contrast to 53 other histopathologic types of salivary gland tumors, but further investigation is required to establish a true pathogenetic association between this virus and the lymphoma [254].

The prognosis of patients with Sjögren's syndrome and LPD is guarded. In some cases, however, therapy with radiation or immunosuppressive agents such as cyclophosphamide, chlorambucil, and prednisone has led to improvement of the primary disease symptoms of xerostomia and conjunctivitis sicca as well as eliciting a diminution in tumor size. Series employing more recent treatment approaches have not been reported.

A variety of lymphoid neoplasms have been noted in individuals with antecedent rheumatoid arthritis and, to a lesser extent, systemic lupus erythematosus (SLE). However, statistical analysis has not consistently proven an increased susceptibility to LPD in these disease states. Evidence from a number of studies suggests that the incidence of cancer among individuals with rheumatoid arthritis ranges from 0.6 to 4.1% [255–258]. Other studies have demonstrated no overall increase, and even a lower incidence, of malignancies in patients with rheumatoid arthritis [255, 256]. The increased risk of lymphoma in association with rheumatoid arthritis is generally reported as modest, only 2–2.5 times that in the general population, although relative risks as high as 24 have been noted [259–261]. Nevertheless, within the 1–2% of rheumatoid arthritis patients who have Felty syndrome (rheumatoid arthritis with neutropenia, splenomegaly, and recurrent infections), the incidence of all cancers is twice that in the control population. The risk of non-Hodgkin's lymphoma in Felty syndrome is increased 12-fold, approximating the increased risk of non-Hodgkin's lymphoma in Sjögren's syndrome, a condition that is sometimes associated with Felty syndrome [247]. The susceptibility of Felty syndrome patients to non-Hodgkin's lymphoma probably derives from their particular array of immunologic alterations, which include bone marrow depression and an increased frequency of the HLA-DQ haplotype, linked to control of suppressor T-cell function. In general, however, rheumatoid arthritis is associated with only minimal immunologic deficits, including failure of PMBCs to respond to recall antigens, a moderate decrease in both B and T cells, and a decrease in CD8 cells, accompanied by an increase in both CD4 cells and the CD4:CD8 ratio [262]. A reduction in natural killer cell activity, observed in some studies in the synovial fluid and whole blood of patients with rheumatoid arthritis, has been suggested as a possible explanation for the increased tendency to develop non-Hodgkin's lymphomas [261]. EBV DNA sequences have been demonstrated in rheumatoid arthritis-associated lymphoma, 80% being type 1 [263]. In contrast to Sjögren's syndrome, there is only a rare association of MALT lymphoma with rheumatoid arthritis.

A positive association between SLE and non-Hodgkin's lymphoma has been observed in some studies. Lewis et al. noted a 4% incidence of cancer among patients with SLE, which is over twice the frequency in their controls [255]. This contrasts with their data on rheumatoid arthritis, in which cancer risk was not increased. Among cancers, lymphomas appear to have the strongest association with SLE [264]. Nevertheless, the question of a genuinely increased risk of cancer, and specifically of LPD, in patients with SLE remains unanswered.

The skin is included in the spectrum of tissues affected by a number of the connective tissue diseases, such as SLE, dermatomyositis, relapsing polychondritis, and lichen sclerosus et atrophicus. Atypical lymphoid infiltrates arising in such autoimmune cutaneous lesions have been categorized as either pseudolymphomas or malignant lymphomas based on a combination of clinical, histologic, immunologic, and genotypic attributes.

Primary non-Hodgkin's lymphoma of the thyroid gland accounts for 5% of thyroid malignancies and less than 2% of extranodal lymphomas [265]. These generally occur in the context of chronic lymphocytic thyroiditis (Hashimoto's disease). The male-to-female ratio in one study was 1:4, with mean ages of 63 and 73 years, respectively [266]. Thus, patients typically are middle-aged females who are euthyroid, lack antithyroid antibodies, and present with a cold nodule in the neck. Most cases are localized, stage IE or IIE. In view of their tendency to remain localized for prolonged periods with late, distant relapses, the thyroid lymphomas, along with those of the breast, lung, parotid, and gastrointestinal tract, are believed to belong the subset of extranodal lymphomas, designated MALT lymphoma [267]. The thyroid antigen that serves as the stimulus is not defined. As in other settings of immunodeficiency, the lymphomas occurring in the thyroid are primarily of the diffuse large-cell type, especially with immunoblastic morphology, although some of the tumors are small lymphocytic in histology.

Histologic differentiation of diffuse chronic lymphocytic thyroiditis from malignant lymphoma may be difficult, recalling the spectrum of histologies observed among the lymphomas found in Sjögren's syndrome, transplant recipients, and other immunocompromised states. Areas of chronic lymphocytic thyroiditis are sometimes present in residual thyroid tissue adjacent to areas of malignant lymphoma, suggesting progression through this spectrum from benign hyperplasia to frankly malignant lesions. The polyclonality together with the predominantly T-cell nature of the lymphoid infiltrates of thyroiditis presents a stark contrast to the monoclonal B cells that make up MALT-type lymphomas, including those of the thyroid [268]. However, the emergence of a monoclonal B-cell proliferation in the midst of a

polyclonal B- and T-cell inflammatory response appears to be a common mechanism for MALT lymphomas involving different organs. Only rarely have T-cell thyroid lymphomas been observed. A role for EBV in promoting the progression from Hashimoto's thyroiditis to malignant lymphoma is suggested by the observation of a small subset of thyroid lymphomas in which strong and homogeneous signals for EBER appeared in the nucleus of most cells by both in situ hybridization and immunohistochemistry [269]. However, larger numbers and demonstration of EBV clonality in tumor cells are necessary before EBV can be definitively regarded as a contributor to lymphomagenesis in the thyroid.

Treatment in early studies of thyroiditis-associated lymphomas consisted of local modalities only, first surgery and later radiation, the latter yielding an overall relapse rate of 37.1%, primarily as distant relapse (30.8%) [265]. Given this outcome, combined modality therapy, which has an overall relapse rate of 7.7% (5.1% distant relapse), is now being espoused as the optimal approach to thyroid lymphoma [265]. Overall, the outcome in more recent studies has been favorable following appropriate therapy.

Autoimmune diseases of the gastrointestinal tract have also been associated with an increased incidence of lymphomas. The risk of malignant lymphoma is elevated in individuals with adult celiac disease (celiac sprue, gluten-sensitive enteropathy, and nontropical sprue), an autoimmune disease in which infiltration of the lamina propria by plasma cells and lymphocytes is believed to mediate damage to the intestinal mucosa that results in villous atrophy and malabsorption. The lymphomas that occur in association with celiac disease represent a specific subtype of primary intestinal T-cell lymphoma, *enteropathy-associated T-cell lymphoma*, confirmed as monoclonal by TCR gene rearrangement [270]. Despite their T-cell origin, they may be somewhat dedifferentiated in immunophenotype [271]. The few B-cell lymphomas that are seen are usually diffuse large-cell or immunoblastic lymphomas [272]. Enteropathy-associated T-cell lymphomas commonly occur in the jejunum, often in areas of ulcerative jejunitis, and they tend to affect patients with a short history of adult celiac disease, rather than those whose disease dates back to childhood [137]. The prognosis is poor, reflecting, in part, late stage at diagnosis and poor performance status. Nevertheless, some evidence exists to suggest that these lymphomas may be prevented by adherence to a strictly gluten-free diet.

Other gastrointestinal disease settings that may predispose to primary small intestinal malignant lymphomas include inflammatory bowel disease, both ulcerative colitis and regional enteritis (Crohn's disease) and Mediterranean α chain disease. Colonic lymphoma has rarely been observed superimposed on chronic ulcerative colitis. One report describes the occurrence of reversible EBV-related polymorphic B-cell lymphoproliferation in a patient with Crohn's disease during treatment with azathioprine therapy, resembling the lymphomas that are observed in transplant recipients [273]. The immunoproliferative small intestinal disease that occurs in α chain disease is a low-grade subtype of MALT lymphoma (see previous discussion), except that plasma cells secreting large amounts of α heavy chain without light chain are prominent in the intestine and mesenteric lymph nodes [137].

Pathogenesis: Mechanistic Basis for Autoimmune Disease-Associated Lymphomagenesis

The immune dysregulation that is inherent in patients with autoimmune diseases is believed to contribute to their tendency to develop lymphoproliferative malignancies. Hypergammaglobulinemia with a high incidence of autoantibodies and excessive local synthesis of Igs in some cases may provide chronic intense stimulation of B-cell proliferation [250]. Superimposed on this, an impaired immune surveillance may allow uncontrolled proliferation of abnormal cells. Lastly, as is the case for patients with PTLD, use of immunosuppressive agents may contribute to tumorigenesis in autoimmune disease. Cyclosporine, azathioprine, and methotrexate, common immune suppressive agents used in autoimmune disease, have been linked to the development of lymphoma [274–276]. More recently, given the growing popularity of anti-TNF (either soluble receptor or monoclonal antibody) agents, there has also been increased attention regarding a possible link to malignancy as well.

TNF-alpha was identified in 1975 as factor released by host cells that mediated endotoxin-induced tumor necrosis [277]. While subsequent studies have not clearly identified TNF-alpha as an anti-cancer agent, it has been found to have other critical affects on immune function. Specifically, TNF-alpha stimulates macrophage activation, monocyte differentiation, neutrophil recruitment, and granuloma formation [278, 279]. Therefore, targeting this proinflammatory cytokine has been an effective strategy in a variety of inflammatory illnesses, such as rheumatoid arthritis, psoriasis, ankylosing spondylitis, and inflammatory bowel disease [228, 280–282].

Five inhibitors, infliximab, adalimumab, certolizumab pegol, golimumab, and etanercept, have been developed and approved by the US Food and Drug administration. The first drug developed was infliximab, a chimeric mouse/human monoclonal antibody. In an effort to improve tolerability, adalimumab and golimumab, fully humanized monoclonal antibodies, as well as certolizumab, a humanized antibody to the Fab fragment of TNF-alpha monoclonal antibody were developed. Etanercept, a recombinant protein composed of the TNF receptor and the Fc portion of the human IgG1, blocks TNF interaction with cell surface receptors.

Since the advent of these drugs, there has been concern regarding an increased susceptibility to malignancies, specifically to lymphoma. Postmarket adverse event surveillance by the FDA revealed 26 cases of lymphoproliferative disorders following treatment with infliximab or etanercept. In two instances, lymphoma regression was seen following discontinuation of the anti-TNF therapy [283]. Subsequently, a meta-analysis of trials including over 3000 patients demonstrated a dose-dependent increased risk of malignancy in patients with rheumatoid arthritis using anti-TNF-alpha therapy [284]. While this data suggests an increased risk of malignancy, other similar studies have shown conflicting data with no clear association between TNF-alpha inhibitor use and malignancy [285, 286]. In regards to lymphoma specifically, results are confounded by the fact that patients with more severe autoimmune disease are more likely to use this therapy than patients with mild disease. However, studies have been performed that do not demonstrate a clear risk of lymphoma as compared to patients using alternative immunomodulatory drugs [287, 288].

The interaction of specific immunodeficiencies in individuals with rheumatoid arthritis with infection by EBV may also predispose toward malignancy. Persistent EBV infection has been documented in a patient with rheumatoid arthritis and a diffuse large-cell lymphoma [262]. EBV DNA, RNA, and LMP have also been detected in malignant cells in patients with autoimmune disease [289, 290]. Furthermore, although B cells from EBV-immune patients with rheumatoid arthritis respond appropriately to EBV stimulation by increasing Ig production, their T cells are deficient in mediating late suppression of this Ig production by the autologous EBV-infected B cells [291].

Lymphomas in the Setting of Congenital Immunodeficiency Diseases

The primary immunodeficiency diseases (CID), i.e., diseases that are either congenital or genetically determined, are rare conditions, seven of which account for 95% of cases (Table 47.3). Among individuals with CIDs, there is an increased risk of malignancy, with the overall cancer incidence in the immunodeficient population varying between 2 and 25% [201, 292]. Although each of the CIDs is associated with a particular incidence and constellation of malignancies, over 50% of the cancers are lymphoid neoplasms, substantially higher than that in the general population [293]. Of these, the majority are non-Hodgkin's B-cell lymphomas, although, in contrast to most other immunodeficiency settings, Hodgkin's disease is also well represented [294]. T-cell lymphoma has only rarely been reported. The non-Hodgkin's lymphomas are clearly the most common neoplasms in five of the seven major immunodeficiency states: Wiskott-Aldrich syndrome (80%), IgM deficiency (56%), ataxia-telangiectasia (46%), severe combined immunodeficiency (74%), and common variable immunodeficiency (46%) [201]. These lymphomas make up a large proportion of the cancers in the other two major CIDs, X-linked (Bruton's) hypogammaglobulinemia (33%) and IgA deficiency (16%). There are even reports of lymphomas in association with rarer CIDs, including B-cell lymphomas in Di George syndrome and Nijmegen breakage syndrome [295–297]. The proportion of non-Hodgkin's lymphomas among cancers (65%) is the same among both adults and children with CID, unlike the general population, in which only 13.5% of pediatric cancers are non-Hodgkin's lymphomas, while leukemias represent 48–76% of cancers in this age group [293].

Clinical Features and Histopathology

The non-Hodgkin's lymphomas are virtually all diffuse. As in the settings of immunodeficiency previously described, the large-cell lymphomas, particularly the large-cell immunoblastic lymphomas, constitute a larger percentage (38%) than in the general population (4.2%), whereas Hodgkin's lymphoma and the small-cell lymphomas are underrepresented [293, 298, 299].

Noteworthy differences exist in the distribution of histological types among the different CIDs. Whereas the relative frequencies of the three histological types of lymphoma (diffuse large-cell, small-cell, and Hodgkin's lymphoma) are similar among patients with ataxia-telangiectasia, combined variable immunodeficiency, and IgA deficiency, IgM-deficient patients exhibit a higher percentage of large-cell lymphomas [300]. This is also true of individuals with Wiskott-Aldrich syndrome, which, interestingly, is associated with impaired IgM responses [301]. A comparison of ataxia-telangiectasia and Wiskott-Aldrich syndrome reveals additional important differences. Patients with the former disease regularly develop both non-Hodgkin's lymphomas and Hodgkin's lymphoma, in contrast to individuals with the latter disease who present with Hodgkin's disease far less often [299–301]. Furthermore, the predominant subtype of non-Hodgkin's lymphoma in ataxia-telangiectasia patients is diffuse large B-cell lymphoma, whereas two-thirds of the non-Hodgkin's lymphomas among Wiscott-Aldrich syndrome patients have a large-cell immunoblastic histology. It is also of interest that among individuals with ataxia-telangiectasia, 50% of the Hodgkin's lymphoma is of the lymphocyte-depleted subtype, and it can occur in very young patients. This contrasts sharply with the general population where lymphocyte-depleted Hodgkin's lymphoma is diagnosed in fewer than 5% of cases and tends to occur in elderly men with advanced stage disease or at relapse after treatment of other histologies [109, 113].

Table 47.3 Congenital immunodeficiency diseases

Immunodeficiency disease	Clinical features/Immune deficiencies	Genetics/epidemiology	% of cancers that are lymphomas, types of cancers, with statistics	Association with EBV	References
Ataxia-telangiectasia (AT)	Cerebellar ataxia, oculocutaneous telangiectasia, recurrent sinopulmonary infections	Autosomal recessive	– Lymphomas—60% of cancers, usually T cell	++	[751, 821, 822, 824, 825, 829, 835, 843–854, 860, 868, 869, 882–884, 939]
	Deficiencies of IgA, IgE, abnormal T-cell-mediated responses, hypoplastic thymus glands	*ATM* (ataxia telangiectasia mutated) gene at chromosome 11q23	– Hodgkin's disease—11% of cancers		
	Defective excision repair of irradiation-induced double-stranded DNA breaks; increased intrachromosomal recombination	Somatic genetic alterations	– Acute leukemia—21% of cancers		
	α-fetoprotein levels elevated	t(14;14) (q11;q32.1)inv.(14) (q11q32),t(x;14),inv.(7) (p13;q35),t(7;7) (p13;q35),t(7,14) (p13;q11),t(7;14)(q13;q11) rarely t(X;14) (q28;q11)	– B-cell lymphoma—12% of AT patients		
		Prevalence: 1:200,000	– Breast cancer increased 3.9-fold in female relatives of AT patients		
		Birth frequency: 1 per 300,000 births	– 13.8% of sporadic breast cancers due to *ATM* mutation		
		ATM mutation carriers: 1% of U.S. population			
Wiskott-Aldrich syndrome (WAS)	Eczema, thrombocytopenia, susceptibility to infections	Sex-linked	– B-cell lymphomas 80% of cancers	+	[751, 822, 825, 829, 838, 840, 842, 870–873, 885]
	Combined B- and T-cell variable immunodeficiency, low IgM, increased IgA and IgE	*WASP* (Wiskott-Aldrich syndrome protein) gene at	– Hodgkin's disease—4% of cancers		
		Chromosome Xp11.22–11.23			
		Birth frequency: 4 per million live male births			
Severe combined immunodeficiency (SCID)	Severe infections beginning in neonatal period	Autosomal recessive or sex linked	Lymphomas B 55–74% of cancers	+	[751, 822, 825, 829]
	Defective stem-cell differentiation to T and B cells, some with adenosine deaminase deficiency		Hodgkin's disease B 9.5% of cancers		
			Acute leukemia		

Common variable immunodeficiency (CVI)	Encompasses several syndromes: Recurrent bacterial infections of the respiratory tract, sinusitis, otitis media, bronchitis, pneumonia due mostly to encapsulated bacteria (*Streptococcus pneumoniae*, *Hemophilus influenzae*)	Autosomal dominant with incomplete penetrance	Lymphomas—49% of cancers	+	[408, 751, 822, 825, 826, 829, 832, 841, 886]
	Normal numbers of B cells with hypogammaglobulinemia, deficits of T-cell immunity in some patients, cutaneous anergy	Associated with mutations of C4-A and C2 gene alleles in the class III MHC region on chromosome 6	Hodgkin's disease—7% of cancers		
			CLL		
			Peripheral T-cell lymphoma—1 case		
			Benign lymphoproliferative disorders: 30% of CVI patients		
			Lymphomas—Increased 30-fold over general population; female CVI patients B increased 100-fold		
IgM deficiency (isolated, selective)	Upper respiratory infections, especially gram-negative bacteria and bacteremia	Frequency: 1/1000 persons	Lymphomas—71% of cancers	NA	[822, 829]
IgA deficiency (isolated, selective)	Recurrent infections, often with autoimmune disease and GI disorders, or asymptomatic	Frequency: 1/500 to 1/700 persons	– Lymphomas B 16–31% of cancers,	NA	[751, 822, 825, 829, 831, 837]
			– Hodgkin's disease—8% of cancers		
			– Gastric adenocarcinoma		
			– Abdominal T-cell lymphoma B 1 case		
X-linked (Bruton's)	Infections with encapsulated organisms (*Hemophilus influenzae*, *Pseudomonas aeruginosa*, *Diplococcus pneumoniae*);	Sex-linked *BTK* (Bruton's tyrosine kinase) gene at	– Lymphomas—33% of cancers	B (no EBV receptors)	[587, 822–824, 826, 829, 841, 874, 940]
Hypogammaglobulinemia/ Agammaglobulinemia	B-cell maturation defect B few B lymphocytes, no Ig-secreting plasma cells	Chromosome Xq22	– Acute lymphocytic leukemia		
			– Chronic myelogenous leukemia		

(continued)

Table 47.3 (continued)

Immunodeficiency disease	Clinical features/Immune deficiencies	Genetics/epidemiology	% of cancers that are lymphomas, types of cancers, with statistics	Association with EBV	References
X-linked	Chronic or fatal infectious mononucleosis with hepatic necrosis	Sex-linked	– B-cell lymphoma	+++	[3, 34, 160, 250, 824, 875–879, 881, 882, 887]
Lymphoproliferative disease (XLP; Duncan's disease)	Variable hypogammaglobulinemia, decreased NK-cell activity, abnormal CD4/CD8 ratios, decreased memory T-cell activity against Epstein–Barr virus	*DSHP/SH2D1A/XLP* gene at	– 35% of males with XLP		
	Induction of *DSHP/SH2D1A* may interfere with inhibition of lymphocyte activation	Chromosome Xq25			
		DSHP/SH2D1A mutated in 70% XLP patients			
Bloom's syndrome	Telangiectatic erythema, stunted growth	Autosomal recessive	– Increased incidence of non-Hodgkin's lymphomas, acute lymphocytic leukemias, solid tumors	NA	[1, 849, 863, 864, 866, 867]
	Decreased immunoglobulins of one or more classes, poor lymphocyte response to certain mitogens	*BLM* (Bloom's) gene at	– Non-Hodgkin's lymphomas—21% of cancers		
	Chromosome breakage and rearrangements, especially quadriradial (Qr) cytogenetic abnormality, usually chromosome 1	Chromosome 15q26.1			
	Increased sensitivity to ultraviolet radiation				
Xeroderma pigmentosum	Skin atrophy, photosensitive dermatitis	Autosomal recessive	– Increased incidence of skin cancer	NA	[1]
	Mild immunodeficiency				
	Defective DNA repair following exposure to ultraviolet light				
Nijmegen breakage syndrome	Small stature, severe microcephaly, bird-like facial appearance, progressive decrease of intellectual function	Autosomal	– 40% of patients develop cancers	NA	[835, 836, 849]
	Deficiency in B- and T-cell function	*Nibrin* gene at	– Leukemias and lymphomas B 85% of cancers		
	Frequent infections, especially paranasal sinuses, lower respiratory tract	Chromosome 8q21	– B-cell lymphomas B most common		
	Chromosomal breakage syndrome, chromosomal hypersensitivity to X-rays, radioresistance of DNA replication				

Fanconi's anemia	Progressive pancytopenia, diverse congenital abnormalities	Autosomal recessive	– Increased incidence of acute myeloid leukemia	NA	[827, 833]
	Mild immunodeficiency	Somatic genetic alterations: t(11;14) (p13;q32)	– T-cell lymphoblastic lymphoma B 1 case		
	Hypersensitivity to the clastogenic effect of DNA cross-linking agents, such as diepoxybutane, mitomycin C				
Diamond-Blackfan anemia	Chronic pure red cell aplasia, macrocytic anemia	Congenital	– Acute myelogenous leukemia	NA	[941, 942]
	Ocular, thumb, craniofacial, genitourinary abnormalities		– Acute lymphocytic leukemia		
			– Hodgkin's disease B few		
			– Non-Hodgkin's lymphoma B 1 case		
Hyper IgM syndrome	Absence of hypoxanthine guanine phosphoribosyl transferase (HGPRT), leading to defective salvage pathway of purine biosynthesis B contributes more to B lymphocytes than T lymphocytes	Sex-linked	Lymphomas—56% of cancers	NA	[751]
	Increased numbers of B cells		– Hodgkin's disease—25% of cancers		
	Increased IgM, decreased amounts of other isotypes				
	Activated T cells have abnormal CD40 ligand, which cannot bind CD40 on B cells and thus fails to stimulate B-cell proliferation and IgE secretion				

NA not addressed

Unlike the large-cell immunoblastic lymphomas that occur in the general population, those observed in patients with CIDs are typically extranodal and often localized. The CNS is frequently involved, as are the liver, lung, and gastrointestinal tract, resembling the non-Hodgkin's lymphomas observed in transplant recipients. Even though chronic benign lymph node enlargement frequently occurs in patients with Wiskott-Aldrich syndrome, who have affected nodes displaying a spectrum of hyperplastic changes, frank lymphoma tends to occur extranodally [302].

Pathogenesis: Mechanistic Basis for Congenital Immunodeficiency-Associated Lymphomagenesis

The disrupted immunoregulation that characterizes the CIDs is believed to contribute to their association with cancer, especially lymphoid malignancies. A number of mechanistic bases for these immune defects are unique when compared with those operating in other immunodeficiency settings.

Several syndromes feature defects in DNA metabolism as well as the accumulation of chromosomal aberrations. Ataxia-telangiectasia, for example, is characterized by cells that are exquisitely sensitive to X-rays and experience excessive chromosomal breakage secondary to defective excision repair of irradiation-induced breaks in double-stranded DNA [303, 304]. The inherited mutation in individuals with ataxia-telangiectasia is in the *ATM* gene, which is located on chromosome 11q22–23 [305]. *ATM* has homology to several cell cycle checkpoint genes, suggesting that a nonfunctional *ATM* may lead to defects in the surveillance and appropriate cellular responses to DNA damage [306]. The contribution of *ATM* alterations to lymphomagenesis is supported by the observation of acquired 11q22–23 hemizygous deletions in sporadic lymphomas of various histologies (follicular, mantle-cell, and diffuse large-cell) and of *ATM* missense mutations in a high percentage of sporadic T-cell prolymphocytic leukemias and occasional B-cell non-Hodgkin's lymphomas and B-cell chronic lymphocytic leukemias [307, 308].

Rates of spontaneous intrachromosomal recombination are also increased in patients with Ataxia-telangiectasia [306]. Approximately 10% of all T lymphocytes circulating in the peripheral blood of these patients contain karyotypically abnormal T cells, typically involving chromosome 7 and 14 rearrangements at specific breakpoints (Table 47.3) [309]. The usual breakpoints, at 14q11 and 14q32.1, encompass the T-cell receptor-α (TCR-α) and IgH loci, respectively [310, 311]. Importantly, the percentage of cells containing a typical monoclonal, cytogenetic abnormality may increase over time, preceding both identifiable TCR monoclonality and an overt malignant phenotype [309, 311]. This defect appears to be unique to ataxia-telangiectasia, since T cells from other immune deficiency diseases, including common variable immunodeficiency and Wiskott-Aldrich syndrome, fail to show such an abnormal T-cell receptor ratio. The lymphomas associated with ataxia-telangiectasia are usually T cell in phenotype, but rare B-cell lymphomas have been described [312].

An additional cytogenetic abnormality, telomeric fusions, is also associated with large pre-leukemic clones. It is thought that these fusions result from the combined effect of the accelerated telomere shortening seen in cells homozygous for *ATM* mutations and the growth advantage of cells in large clones [313]. The picture that emerges is one of sequential genetic alteration, contributing to the progression toward tumorigenesis.

Bloom's syndrome is a rare CID in which cells exhibit increased sensitivity to ultraviolet radiation [314]. It is characterized by a cytogenetic rearrangement involving a quadriradial configuration (Qr), usually of chromosome 1 [315]. Patients with the disease are homozygous for a mutation in the Bloom's syndrome gene, *BLM*, located on chromosome 15q26.1 [316]. *BLM* encodes a protein that is homologous to the ReqQ DNA helicases and, when mutated, leads to genetic instability [317]. Xeroderma pigmentosum (XP) and Fanconi's anemia, both of which show abnormal DNA metabolism and mild immunodeficiency, are also associated with an increased risk of cancer, particularly leukemias and skin tumors [318]. An increased risk of cancer also exists among first-degree relatives of patients with ataxia-telangiectasia, Bloom's syndrome, and Fanconi's anemia [319].

Defects in DNA repair and recombination are not central to all of the lymphoma-associated CIDs. Wiskott-Aldrich syndrome is an X-linked recessive disease that is caused by mutations in the *WASP* gene at chromosomal locus Xp11.22, which encodes Wiskott-Aldrich syndrome protein, WASP, a protein involved in lymphoid cell signal transduction pathways and regulation of actin cytoskeleton rearrangement [320, 321]. The immune deficit in this syndrome appears to result in part from accelerated destruction of lymphocytes, marked by an increased frequency of spontaneous apoptosis, with attenuated Bcl-2 expression [320]. T cells from Wiskott-Aldrich patients show diminished proliferative responses and failure to appropriately upregulate cytokines like IL-2. These immunologic abnormalities may well contribute to the propensity to lymphomagenesis of this patient population.

EBV and Congenital Immunodeficiency Disease Act in Synergistic Fashion to Promote Lymphomagenesis

Although in a number of CIDs EBV is believed to interact synergistically with the underlying immune deficiency to

promote malignancy, this is not universal. At one extreme, individuals with Bruton's agammaglobulinemia, which involves B-cell deficiencies that are due to mutation of the X-linked Bruton's tyrosine kinase (*BTK*) gene, lack EBV receptors and therefore cannot be infected by this virus [322, 323]. By contrast, in the curious condition of X-linked lymphoproliferative syndrome (XLP), EBV has been shown to play a vital role in triggering the onset or exacerbation of immunological deficits [324].

DSHP/SH2D1A, the gene for XLP, maps to chromosome Xq25 and is mutated in approximately 70% of XLP patients (Table 47.3) [325, 326]. The protein encoded by this gene consists of a single SH2 domain that is homologous to the SH2 domain of SHIP, an inositol polyphosphate 5-phosphatase that functions as a negative regulator of lymphocyte activation [327]. Induction of *DSHP* may therefore sustain an immune response by subverting the normal inhibition of lymphocyte activation that is mediated by SHIP [328]. Overall, males carrying the allele for XLP exhibit normal cellular and humoral immunity before EBV infection. However, subtle deficits, such as an elevated CD4/CD8 ratio, a partial IgA deficiency, and failure to switch from IgM to IgG on OX174 challenge, have been documented [329]. During acute EBV infection, they develop vigorous cytotoxic cellular responses against EBV-infected and uninfected autologous target cells, including hepatocytes, often succumbing to a fatal infectious mononucleosis syndrome as a result of fulminant liver failure and hepatic necrosis or hemophagocytic syndrome [330]. Survivors of infectious mononucleosis manifest varying degrees of immunodeficiency, commonly involving hypogammaglobulinemia of different isotypes with absence of the normal post-infectious mononucleosis antibodies to EBNA and usually to VCA [331]. Among the other defects acquired following infection with EBV are loss of natural killer cell activity, abnormal CD4/CD8 ratios, and destruction of the thymic epithelium [324].

Four major pathogenetic outcomes have been described following EBV infection in males with XLP: (1) acquired agamma- or hypogammaglobulinemia with necrosis of lymph nodes in 20%; (2) aplastic anemia, including various gradations of neutropenia and red cell aplasia; (3) fatal and chronic infectious mononucleosis in almost two-thirds of patients, 85% proving fatal; and (4) malignant B-cell lymphoma in about one-third of males with XLP. XLP patients with lymphoma may manifest concomitant hypogammaglobulinemia or fatal infectious mononucleosis, or both [330].

Interestingly, 78% of the primary lymphomas in XLP patients occur in the intestine, frequently the ileocecal region [330]. Most are localized stage I and II tumors. Histologically, Burkitt's lymphomas constitute the largest group (45%), but large cell, immunoblastic, and other types have also been seen. Because of the intimate association between EBV infection and the immunodeficiency observed in XLP, this disease entity has served as a prototype for understanding the interaction of these factors in the development of non-Hodgkin's lymphoma, a frequent outcome. In addition to precipitating or exacerbating a preexisting subtle immunodeficiency in XLP patients, EBV stimulates polyclonal B-cell proliferation. The EBV-suppressed immune surveillance that characterizes XLP is believed to allow such polyclonal cell growth to proceed unchecked, providing more raw material for subsequent genetic mutations that ultimately might lead to malignancy. Despite the overwhelming evidence for intricate synergism between the inherited immunologic abnormality and EBV in inducing lymphomagenesis in XLP patients, rare cases have been reported of boys with documented mutations in the *DSHP/SH2DA1* gene developing non-Hodgkin's lymphomas in the absence of EBV infection [332].

EBV genomes have also been identified in lymphomas associated with ataxia-telangiectasia. Furthermore, patients with this disease frequently display abnormal antibody responses to EBV, characterized by high EBV antibody titers to VCA, an increased incidence of antibodies to early antigen, but low or absent antibodies to EBNA [333, 334]. The immunological basis for such antibody expression undoubtedly contributes to the tendency to develop lymphomas, as in the case of XLP. The immunological dysregulation may, in turn, result from and/or cooperate in a synergistic manner with the DNA repair and chromosomal recombination abnormalities of ataxia-telangiectasia to promote malignant transformation.

Interestingly, EBV DNA has also occasionally been detected in monoclonal B cells from the tumor tissue of malignant lymphomas in the setting of other CIDs such as Wiskott-Aldrich syndrome and common variable immunodeficiency [335, 336].

Treatment of Congenital Immunodeficiency Disease-Associated Lymphomas

Information on treatment strategies addressed specifically to lymphomas that occur in the setting of CIDs is sparse. The use of bone marrow transplantation to reconstitute the immune deficiency fully has been proposed as a means of preventing the development of lymphomas [337]. In patients with XLP, EBV-induced malignant transformation is the result of uncontrolled expansion of infected B cells and proliferation of activated T cells. Therefore, rituximab has been used to control acute EBV infection by eliminating infected cells and preventing subsequent lymphomas [338]. Antiviral agents such as acyclovir could theoretically also decrease viral load, though clinical trials have not been performed.

Radiation therapy and surgery have also been attempted in some cases. Whereas treatment of lymphomas is often successful in settings of potentially reversible immunodeficiency such as organ transplant, the lymphomas in CIDs are generally unresponsive because of the inability to remedy the underlying immunologic deficit.

Summary

Lymphomas that develop in the setting of other diseases exhibit a distinct constellation of clinical features. In general, they tend to be of the non-Hodgkin's type and often have a large B-cell, particularly immunoblastic, histology. Difficulty in establishing histopathologic diagnoses may relate to a spectrum of lesions ranging from polyclonal LPD to frankly malignant monoclonal lymphoma. Extranodal, notably CNS, presentations are common. These non-Hodgkin's lymphomas are aggressive and, although responsive to therapy, often lead to death from treatment-related toxicity, uncontrolled lymphoma growth, or progression of the underlying disease. Within the confines of these common features, the LPDs associated with each disease entity have their own peculiar features regarding histopathology, site, and clonality. However, two phenomena dominate the picture of most of these lymphomas. First, all these disease conditions are characterized by some degree of immunodysregulation. Second, a strong association with EBV has been documented in many of these LPDs. A multistep model of tumor progression has been proposed to explain tumorigenesis in the setting of underlying diseases. The observed associations with EBV and immunodeficiency offer likely mechanistic explanations for the progressive steps involved in lymphomagenesis. Finally, while many patients can be successfully treated with conventional chemotherapy, a variety of novel therapies, including biologically based agents, are being tested in an effort to improve response and survival.

Part V

Supportive Care

48 Supportive Care for Patients with Leukemia: A Historical Perspective

Charles A. Schiffer

Introduction

Once upon a time, the delivery of therapy to patients with acute leukemia was profoundly constrained by problems with venous access, life-threatening infections due to a paucity of effective and nontoxic broad spectrum antibiotics and antifungal agents, hemorrhage due to a lack of readily available high quality platelet transfusions, severe vomiting resulting in weight loss and inanition, and a considerable risk of hepatitis from blood product transfusions. Indeed, the therapeutic nihilism which permeated the medical literature in the late 1960s and early 1970s derived as much from doubts about the ability to keep patients alive following chemotherapy as from skepticism about the effectiveness of the chemotherapy itself. In fact, the current "standard" chemotherapy for acute myeloid leukemia (AML), so-called "3 & 7" (anthracycline and cytarabine), and multi-agent therapy for acute lymphoblastic leukemia (ALL) is essentially identical to what was used and developed in the 1970s.

Forty years later, the situation is profoundly different. As but one example, whereas ~30% of older patients receiving induction therapy for AML experienced early death due to complications of pancytopenia as recently as 20 years ago, a recently published trial in AML patients with a median age of 67 years reported a death rate of only 11% within 30 days of treatment [1]. In this chapter, I will briefly provide my idiosyncratic perspective on the advances in supportive care which contributed to the improved tolerability of induction therapy for acute leukemia.

Transfusion Medicine

Therapies for acute leukemias became more intensive in the late 1960s creating a demand for more sophisticated supportive care and in particular, a need for a reliable source of high quality platelets for transfusion. Much of the initial clinical investigational work was done in specialized units created within cancer centers that focused on leukemia treatment. Subsequently, as the technology became more standardized and mature, regional blood centers adopted these techniques and high quality red blood cell and platelet transfusion products are now readily available throughout the United States. A large and sophisticated subspecialty termed "Transfusion Medicine" has evolved through the years.

Platelet Transfusion

In the early 1970s, platelets for transfusion were obtained as a by-product of whole blood donation and stored as platelet concentrates at 4 °C. Pools of platelet concentrate were administered and, although these platelets stored at 4 °C were hemostatically effective, posttransfusion increments and platelet survival were reduced [2]. The transition to storage at ambient temperature (22 °C) with gentle agitation was facilitated by advances in the plastics industry [3]. Pliable plastic bags which could tolerate centrifugation at high speeds were developed. These plastics permitted transmission of oxygen, necessary for continued aerobic platelet metabolism, as well as egress of CO_2 which was produced as a consequence of ongoing metabolism by platelets and contaminating white cells. The outward diffusion of CO_2 as well as the development of appropriate citrate anticoagulant buffers allowed maintenance of plasma pH permissive of prolonged platelet storage.

Indeed, systems were developed in which platelets could be stored for 7 days or more at 22 °C (equivalent to or actually longer than they would have survived in circulation) [4] but, because of descriptions of platelet transfusion associated

bacteremia, storage has now been limited to 5 days [5]. Studies have shown that under proper conditions, there is minimal effect on platelet recovery with storage up to 5 days [6] with posttransfusion increments considerably higher than what was seen when platelets were stored at 4 °C. Bacteremia from "contaminated" platelet products is rare but should be considered in patients who develop unusually severe, febrile reactions while receiving platelet transfusions. In such circumstances, it is appropriate to discontinue the transfusion, and do blood cultures as well as cultures of the platelet bag, usually in association with beginning parenteral antibiotics, particularly in neutropenic patients.

As transfusions became used more widely, the problem of refractoriness to transfusion due to alloimmunization became a major issue. Approximately 40–50% of patients receiving chronic transfusions developed antibody against HLA A or B antigens resulting in impaired platelet recovery and survival and leaving recipients at risk for hemorrhage [7]. A number of investigators demonstrated that satisfactory increments could generally be obtained by transfusion of platelets from donors whose HLA types were identical to or very similar to those of the recipient, and many centers set up large pools of HLA typed donors for use in alloimmunized patients. A number of interesting observations were made, including demonstration of antigenic similarity of different HLA antigens resulting in the ability to selectively "mismatch" for these antigens [8, 9], as well as discrepancies in the expression of particular HLA antigens on the leukocytes and platelets from the same individual, which also permitted successful transfusion of mismatched platelets, thereby increasing donor availability [8, 10].

In parallel with these findings was the development of sophisticated blood cell separators which permitted the collection of leukocytes and the equivalent of many units of platelet concentrates from single donors. A whole series of different technologies were utilized, all capitalizing on disparities in density of different cellular elements and some evolving from technologies used to separate different components of milk products [11, 12]. The apheresis devices focused originally on platelet and granulocyte collection as well as the occasional therapeutic leukapheresis of patients with leukemia and very elevated white blood cell counts. So-called "single donor" platelets are now used widely, although except in alloimmunized patients, they have not been shown to be preferable to pooled platelet concentrates [13, 14]. Perhaps the most common current indications for apheresis are therapeutic plasma exchange, collection of autologous or allogeneic stem cells from peripheral blood to be used in support of high dose therapy, procurement of autologous T cells to be modified ex vivo and used in a variety of "immunotherapy" treatments, and as part of programs of red blood cell exchange for patients with sickle cell disease.

The creation of large registries of HLA type donors was expensive and never became readily available at many centers, particularly as leukemia treatment evolved to the point where most patients were treated in community rather than subspecialty centers. Over the years, a number of assays for platelet antibody testing were developed, many deriving from research focused on the autoantibodies responsible for platelet destruction in patients with immune thrombocytopenic purpura (ITP). Although initially somewhat cumbersome, a number of these assays can now be done rapidly and in a semiautomated fashion, permitting cross matching of donor platelets with patients' sera, conceptually analogous to cross matching for red blood cell transfusion [15, 16]. Most blood centers do cross matching of single donor units which they have been routinely collecting as part of their platelet inventory and this approach has greatly facilitated the management of alloimmunized patients.

Early studies of the histocompatibility antigen system demonstrated that it was not the platelet, but rather the leukocytes which contaminated the platelet transfusion, which were recognized by the host immune system provoking the development of alloantibody. Apheresis technology was further refined to reduce the number of contaminating leukocytes, but the major advance occurred with the development of "inline" filters through which the platelet transfusions were administered and which produced a 3–4 log reduction in the number of mononuclear cells. The Trial to Reduce Alloimmunization to Platelets (TRAP) study demonstrated that alloimmunization rates, as assessed clinically by the measurement of posttransfusion increments and serologically by the measurement of lymphocytotoxic antibodies [17], were substantially reduced in patients who received either pooled platelet concentrates or single donor platelets which had been filtered, compared to the control standard of unfiltered pooled platelet concentrates [13]. There was no advantage of the single donor compared to the filtered platelet concentrates. Because of this critical observation, filtration of blood products, with most blood centers actually filtering the entire red blood cell collection (so-called "pre-storage" filtration), has become routine practice and has markedly decreased the incidence of alloimmunization and simplified the platelet transfusion support of patients with leukemia, aplastic anemia, and recipients of stem cell transplantation. The incidence of febrile transfusion reactions, which are a consequence of infusion of cytokines activated by leukocyte metabolism and death during storage, has also decreased appreciably due to removal of WBC pre-storage [18].

Lastly, there has been a major change in the practice of prophylactic platelet transfusion in the last decade. An early descriptive study from the National Cancer Institute demonstrated an increased incidence of hemorrhage in leukemia patients at platelet counts less than 20,000/μL [19]. Of importance, however, is that the antibiotics available at the time that study was done had inconsistent activity against gram-negative

organisms, the results of chemotherapy were poor resulting in more prolonged periods of aplasia and, perhaps most notably, aspirin was often used as an antipyretic. Indeed, the authors of that paper stated that: "A 'threshold' concept would be useful for the description of a direct causal relationship. For platelet values above the threshold would be adequate to prevent hemorrhage, whereas at levels below this threshold, hemorrhage would occur. This type of relationship *does not exist* between platelet count and hemorrhage" [19]. Nonetheless, in large part based on this publication, it became routine practice for a couple of decades to provide prophylactic platelet transfusion to maintain counts above 20,000/μL.

Subsequent randomized trials demonstrated that utilizing a threshold for prophylactic transfusion of less than 10,000/μL was as safe as the 20,000/μL threshold and resulted in the use of fewer platelet transfusions [20, 21]. Other studies have suggested that lower thresholds are also safe and have emphasized the point that the transfusion "trigger" needs to be individualized, taking into account the presence (or not) of other complicating clinical problems which could increase the risk of hemorrhage in individual patients [22]. Certainly, many clinically stable patients who are not receiving active therapy, including patients with aplastic anemia or myelodysplasia, can remain stable without significant hemorrhage for long periods of time with platelet counts of 5000/μL or less.

Two recent large randomized trials evaluated the safety of a therapeutic transfusion strategy, administering transfusions should signs of hemorrhage develop, compared to the traditional prophylactic approach. Both trials suggested that the 10,000/μL threshold for prophylactic transfusion is still appropriate for patients with hematologic malignancies receiving active treatment, but that there was no difference in the incidence of > grade 2 hemorrhage in patients undergoing autologous stem cell transplantation, perhaps because of the short duration of count suppression following stem cell infusion [23–25]. It is important to note that whatever strategy is used, the incidence of severe and/or fatal bleeding in patients receiving leukemia induction therapy or undergoing stem cell transplantation is remarkably low, a testament to the resilience of the vascular system even at very low platelet counts and even in the setting of other active inflammatory or infectious complications. Guidelines addressing the common clinical issues related to platelet transfusion were published and recently updated by the American Society of Clinical Oncology [26] and by the American Association of Blood Banks [27].

Treatment and Prevention of Infections

Bacterial Infections

There is a well-described relationship between the depth and duration of neutropenia and the likelihood of acquiring infections during and after treatment of acute leukemia [28]. Perhaps the most critical initial treatment principle was the then heretical recommendation that antibiotics be administered empirically to neutropenic patients with fever, irrespective of whether they had localizing signs of infection and *before* confirmation of infection by culture of blood or body fluids. This practice derived from the recognition that patients with severe neutropenia frequently had delayed onset of the characteristic signs of inflammation and frequently presented only with fever or pain in infected areas without obvious signs of infection on examination or by radiographs. In addition, such infections often proceeded very rapidly with the development of sepsis and bacteremic shock.

Empiric treatment was initially directed at gram-negative organisms such as Pseudomonas aeruginosa or Klebsiella, utilizing combination antibiotic therapy which often included nephrotoxic aminoglycosides [29]. Literally dozens of randomized trials comparing either antibiotic combinations or the use of single broad spectrum antibiotics were conducted in the ensuing decades. In general, it was difficult to demonstrate superiority of one regimen compared to others as long as the broad spectrum antibiotics used were suitable for the flora most prevalent in individual institutions. Currently, most institutions use broad spectrum single antibiotics such as cefepime or imipenem or its family members as empiric therapy, including vancomycin if there is clinical suspicion of skin infection. It is routine to counsel patients to present themselves immediately to their physicians or to emergency rooms for prompt empiric treatment of fever in association with severe neutropenia and this practice has substantially decreased the incidence of catastrophic bacteremia amongst neutropenic patients.

In recent years, bacteremia with gram-positive organisms have become more prevalent, perhaps in part related to the ubiquitous use of indwelling central venous catheters, with the gastrointestinal tract as another major source of these organisms [30]. Although infections with commensal bacteria such as Staphylococcus epidermitis are generally of low virulence without subsequent organ damage, they are often partially or completely resistant to even broad spectrum antibiotics and frequently require treatment with vancomycin after they are identified in blood cultures. The spectrum of infecting organisms continues to change and evolve under the pressure of widespread antibiotic use, with infections with vancomycin resistant enterococcus, *Clostridium difficile*, and multidrug resistant Acinetobacter and Klebsiella species as a few recent examples. There are thus still career opportunities in infectious disease focused on myelosuppressed patients.

Attempts to *prevent* infections in neutropenic patients also proceeded in a step-wise fashion throughout the years. Attention to personal hygiene, dental prophylaxis prior to chemotherapy, and careful care of indwelling venous catheters

remain the most important and simplest modalities of infection prevention. Initial attempts at patient isolation in protected environments failed to produce important reductions in serious infections and were very expensive and isolated patients both emotionally and physically to a generally unacceptable degree [31, 32]. Because the gastrointestinal tract was the most common source of gram-negative organisms, early studies attempted GI tract sterilization using broad spectrum oral antibiotic cocktails [33, 34]. These treatments frequently resulted in severe nausea, vomiting (particularly in the pre-antiemetic era), and diarrhea and quickly fell by the wayside. Later experiments attempted to preserve the anaerobic flora of the GI tract because of evidence that the continued presence of these organisms could prevent subsequent colonization by gram-negative bacteria. A series of studies with trimethoprim/sulfamethoxazole also failed to be of significant benefit, however [35, 36]. These approaches were succeeded by a variety of trials utilizing either partially absorbable antibiotics or more broad spectrum antibiotics such as ciprofloxacin; at this time there remains little consensus about the validity and importance of these prophylactic approaches. Nonetheless, because of overall improvement in the quality of antibiotics and greater attention to the need for immediate empiric therapy, death from bacterial infection is now an uncommon problem limiting the administration of initial induction chemotherapy, a dramatic improvement from the earlier days of anti-leukemia chemotherapy.

Fungal Infections

As the death rate from bacterial infections decreased and as patients remained on systemic antibiotics for longer periods of time, infections with yeast and fungal organisms became a major cause of infectious death particularly in patients with very prolonged periods of neutropenia. As with the approach to bacterial infections, guidelines were developed recommending earlier empiric use of antifungal agents in neutropenic patients receiving antibiotics with persistent fever or signs of infection, and in particular sino-pulmonary infections. Empiric therapy was felt to be necessary in this situation because it was very uncommon for blood cultures to be positive with infections with *Aspergillus* sp. or other molds and it was often difficult to biopsy affected tissues because of thrombocytopenia. For decades, amphotericin B was essentially the only available broad spectrum antifungal agent. Although the development of liposomal preparations somewhat ameliorated the side effects [37], this was very difficult therapy associated with fevers, chills, renal insufficiency, hypokalemia, hypomagnesemia, and exacerbation of cytopenias. Therapy often had to be continued for weeks to months, complicating and sometimes precluding the administration of further chemotherapy.

The landscape has changed dramatically in the past 10–15 years. Newer antifungal agents such as voriconazole and caspofungin and their analogues have almost totally supplanted "shake-and-bake" as initial empiric therapy when fungal or yeast infections are suspected [38, 39]. The importance of the avoidance of the debilitating effects of amphotericin B cannot be underestimated and has profoundly simplified and streamlined the care of patients with leukemia. Recent trials have also shown prophylactic benefit from the use of these agents in selected patient populations [40].

Granulocyte Transfusions

The close relationship between the level and duration of granulocytopenia and the incidence of infections prompted interest in the development of blood cell separators to collect granulocytes from normal blood donors for transfusion. This turned out to be easier said than done. Granulocytes have a density similar to lighter red blood cells and it proved to be difficult to efficiently separate the granulocytes from other blood components, even after the availability of apheresis technology which was highly effective at platelet collection and plasma exchange [41].

The initial experience with leukocyte transfusion used leukocytes procured from patients with chronic myelogenous leukemia (CML) from whom very high numbers of cells could be collected by simple centrifugation as well as by apheresis [11, 42]. Prompt clinical responses were seen in some recipients with otherwise refractory infections [11] and in some patients, the infusion of immature myeloid precursors capable of further division provided sustained circulation of granulocytes for days after a single transfusion [43].

After this "proof of principle," which was quite convincing to many of us at that time, attention turned to procurement of granulocyte from normal donors. A number of small randomized trials, which would be considered historically "quaint" by current design and statistical standards, suggested clinical benefit in patients receiving granulocytes obtained from normal donors compared to controls treated with antibiotics alone [44–46]. Nonetheless, granulocyte transfusion never "caught on" and are now used infrequently. There were multiple reasons for the decline in interest in the use of granulocyte transfusions during the last 30 years including:

- Difficulties in obtaining adequate doses of cells for transfusion with average cell yields <10% of what was obtained from CML donors [12]
- Administrative difficulties in obtaining sufficient donors to provide transfusions for many consecutive days
- Failure to recognize the effects of recipient alloimmunization which prevented migration of nonhistocompatible

granulocytes to sites of infection and which produced sometimes severe transfusion reactions [47, 48]
- Overall improvements in supportive care and the decrease in the number of patients with refractory gram-negative bacterial or fungal infections

Of note is that interest in granulocyte transfusion has been rejuvenated somewhat with the demonstration that higher doses can be collected after pretreatment of donors with granulocyte colony stimulating factor thereby substantially increasing the yield and the number of cells transfused [49]. If the incidence of infections with multidrug resistant bacteria increases or if new chemotherapy is developed which is more effective but with the price of longer periods of aplasia, granulocyte transfusion might return to its previous halcyon days.

Antiemetics

The development of potent antiemetics has been of major benefit to leukemia patients receiving induction and post-remission chemotherapy, and the effects of these advances have been somewhat under appreciated. When mixtures of phenothiazines, barbiturates, and metoclopramide represented the standard backbone of antiemetic therapy, induction chemotherapy was accompanied by severe and often protracted nausea and vomiting, depression and altered cognition due to their CNS side effects, and sometimes intractable diarrhea related to the high doses of metoclopramide needed to produce the antiemetic effect. The latter often resulted in perirectal excoriations sometimes resulting in infection, while the repetitive episodes of vomiting resulted in inanition as well as erosive distal esophagitis. The latter often became secondarily infected with candidal organisms resulting in candidemia and not infrequently the development of disseminated disease and hepatosplenic candidiasis with the need for prolonged treatment with amphotericin B. Nutritional problems were particularly devastating for older patients receiving chemotherapy and the presence of hepatosplenic candidiasis frequently delayed and sometimes precluded the administration of further chemotherapy.

With the availability of the serotonin antagonist ondansetron and its offspring, nausea and vomiting became a bad memory of the past and it is now common to see patients eating regular diets without vomiting during their entire period of chemotherapy. Although the increased use of fluconazole as antifungal prophylaxis may have also been contributory, hepatosplenic candidiasis is now extremely rare and I have not seen a case in many years. Because they are generally nutritionally replete, many patients who are not requiring systemic antibiotics can now be discharged after completion of induction or re-induction chemotherapy and followed closely as outpatients. This is a remarkable and underappreciated change and indeed, this single improvement in supportive care makes it more difficult to compare outcomes of more recent trials with those conducted in the pre-antiemetic era.

Hepatitis Testing

A less appreciated advance occurred as a result of the development of sensitive testing for the presence of hepatitis causing viruses transmitted by blood transfusion. So-called "non-A, non-B" hepatitis was a common occurrence in leukemia patients receiving transfusions from sometimes hundreds of different donors during their induction chemotherapy. Signs and symptoms of hepatitis frequently developed towards the end of induction chemotherapy and often resulted in delay of count recovery as well as important delays in the administration subsequent post-remission chemotherapy because of concerns about the administration of potentially hepatotoxic drugs such as cytarabine during periods of active hepatitis [50]. The identification of the hepatitis C virus with the rapid implementation of universal screening of blood has virtually eliminated this as a complication [51]. Of note is that transmission of cytomegalovirus has also markedly decreased by the elimination of white blood cells by filtration of blood and platelet products, decreasing the frequency of new CMV infections in transplant and leukemia patients [52].

Conclusions

It has been interesting to observe the maturation of what was once considered to be "high tech" to the point where these treatments are now routine and sometimes taken for granted by the current generation of clinicians. These improvements in supportive care have allowed the delivery of curative therapy to tens of thousands of leukemia and transplant patients and it is predictable that further fine tuning of these principles will continue to benefit patients in the future.

Prevention of Infections in Patients with Hematological Malignancies

49

Marcio Nucci and Elias J. Anaissie

Introduction and General Principles: A Risk-Targeted Approach

Infection is a frequent complication and a leading cause of morbidity and mortality in patients with hematological malignancies. Problems associated with the management of infections in these patients include difficulties in early diagnosis because the clinical signs of infection are subtle, the low performance of diagnostic tests, and suboptimal response to treatment because recovery of host defenses is a key factor for resolution of infection. Preventing these infections relies on infection control measures and antimicrobial chemoprophylaxis. While infection control measures are safe (but not always effective), the use of antimicrobial agents for prophylaxis of infection is not devoid of problems. Its wide use may increase the possibility of the development of resistance, select for resistant organisms, and increase toxicity and cost. Therefore, any attempt to administer an antimicrobial agent should be accompanied by a reflection of the potential benefits and risks of prophylaxis.

In general, the higher is the incidence of infection, the more beneficial is likely to be antimicrobial prophylaxis. Likewise, the shorter is the period at risk (and therefore the predicted duration of prophylaxis), the higher is the possibility that prophylaxis will work. However, the prediction of an incidence of infection is not simple, and requires an analysis of various factors including patient's prior exposure to pathogens, underlying disease, previous and current treatment, comorbidities, geographic area, and others. Therefore, three questions are critical in defining the appropriateness of antimicrobial prophylaxis: what is the risk for infection; what are the pathogens that predominate in this setting; and what is the period at risk. In this chapter, we describe various strategies directed at the prevention of infections in patients with hematological malignancies, according to this risk-based strategy.

Table 49.1 provides a risk-targeted approach to prophylaxis of infections in patients with hematological malignancies and Table 49.2 presents the most frequent pathogens responsible for infection according to type of immunodeficiency present.

Table 49.1 Risk factors for infection in patients with hematological malignancies

Risk factor for infection	Risk category	
	Low	High
General condition including organ function		
Performance status	Good	Poor
Renal failure	No	Yes
Liver failure	No	Yes
Lung disease	No	Yes
Diabetes mellitus	No	Yes
Nutritional status	Normal	Impaired
Iron stores	Normal or decreased	Increased
Age	Younger (<40 years)	Older (>65 years)
Smoking	No	Yes
Underlying disease and its treatment		
Tumor burden	None	Large
Likelihood of obtaining control of the underlying disease[a]	High	Low
Disease-related immunosuppression[b]	Absent	Present
Prior chemotherapy	None or minimal	Extensive
Receipt of purine analogues (fludarabine, cladribine, clofarabine) or monoclonal antibodies (rituximab, alemtuzumab)	No	Yes
Exposure to pathogens		
Prior history of infection[c]	No	Yes
Colonization with pathogens (bacteria, fungi)	No	Yes
Nosocomial exposure to potential pathogens (water and airborne pathogens such as *Legionella*, *Aspergillus* spp. and other molds, resistant bacteria, respiratory viruses)	No	Yes
Community-acquired infections, especially respiratory viruses	No	Yes
History of living or visiting areas of endemic infections	No	Yes
Immunogenetics		
Deficiency of MBL	No	Yes
Polymorphism of TLR	Absent	Present
Duration of neutropenia	Short (<7 days)	Long (>10 days)
Severity of oral and gastrointestinal mucositis	Absent or mild	Severe
Chemotherapy regimen	Less intensive	Intensive
Polymorphisms of genes associated with metabolism of chemotherapeutic agents (pharmacogenetics)	Absent	Present
Renal failure[d]	Absent	Present
T-cell immune reconstitution after HCT	Fast	Delayed
Prior chemotherapy	Minimal	Extensive
CMV serostatus	Negative	Positive
Need for additional chemotherapy to control the underlying disease[e]	No	Yes
In vitro manipulation of stem cells[f]	No	Yes
Graft versus host disease and its treatment (in allogeneic HCT)	No	Yes

MBL mannose-binding lectin, *TLR* toll-like receptors, *HCT* hematopoietic cell transplantation, *CMV* cytomegalovirus

[a]Risk assessment in each underlying disease (e.g., age, initial white blood cell count, cytogenetics, immunophenotype, rapidity of cytoreduction in acute lymphoid leukemia; advanced age, de novo vs. secondary leukemia, prior myelodysplasia, cytogenetics, gene mutation profile in acute myeloid leukemia; mutational status of immunoglobulin Vh gene and chromosomal abnormalities in chronic lymphocytic leukemia)

[b]Most common disease-related immunosuppression include: hypogammaglobulinemia (multiple myeloma, low-grade B-cell non-Hodgkin's lymphoma, chronic lymphocytic leukemia), T-cell mediated immunodeficiency (Hodgkin's lymphoma and certain types of non-Hodgkin's lymphoma) and neutrophil dysfunction (acute myeloid leukemia with myelodysplasia)

[c]Infections with higher risk of recurrence include: mycobacteriosis (tuberculosis and others), aspergillosis, pneumocystosis, cytomegalovirus, Herpes simplex and Varicella-zoster virus, toxoplasmosis and strongyloidiasis

[d]Renal failure increases the risk of severe mucositis in patients with multiple myeloma receiving melphalan-based conditioning regimens

[e]Need for additional chemotherapy in lymphoma and acute myeloid leukemia is usually related to relapse of the underlying disease, whereas in multiple myeloma additional chemotherapy is usually part of the treatment strategy

[f]in vitro manipulation of stem cells decreases the content of CD34+ and T-cells, increasing the duration of neutropenia in the early posttransplant period and delaying T-cell immune reconstitution after transplant

Table 49.2 Pathogens likely to cause infection in patients with hematological malignancies according to the predominant type of immunodeficiency

(−): no; (+): occasional; (++): frequent; (+++): very frequent
[a]Most frequent: *Escherichia coli*, *Klebsiella pneumoniae*, *Enterobacter* spp.
[b]Most frequent: *Acinetobacter* spp., *Stenotrophomonas maltophilia*
[c]Most frequent: *C. albicans*, *C. glabrata*, *C. tropicalis*, *C. parapsilosis*
[d]Most frequent: *A. fumigatus* (~90%), *A. flavus*, *A. terreus*, *A. niger*
[e]Most frequent: Respiratory syncytial virus, Influenza A and B, Parainfluenza 1–3, Adenovirus, rhinovirus, coronavirus, metapneumovirus

Infection Control Measures

Patients and health care workers should be educated about the risk of and methods to prevent acquisition of pathogens. These methods include:

Personal Hygiene

Handwashing

Handwashing remains the simplest and most effective measure to prevent the acquisition of organisms by patients [1]. Patients and health care workers should wash their hands before eating, smoking, or inserting or removing contact lenses, and after using the restroom, blowing their nose, coughing, sneezing, handling dirty items such as garbage, and after touching an animal. In addition, health care workers should also wash their hands between patients. All surfaces should be thoroughly cleaned, including wrists, palms, back of hands, fingers, and under the fingernails, preferably with an alcohol-based hand rub [2]. However, if hands are visibly dirty or soiled with blood or body fluids, soap and water are best for cleaning hands [3]. Additional recommendations include the removal of rings prior to handwashing, keeping nails short and clean, and avoiding the use of artificial nails as they may carry pathogens [4].

Skin and Mucosal Care

The skin flora could potentially be a source of infections. Patients should keep their skin clean with daily baths using an antiseptic solution with special attention to potential portals of infection such as the perineum, and catheter sites.

The oral flora can lead to infection especially in the setting of severe mucositis, after radiotherapy, or in patients with graft vs. host disease (GVHD). Recommendations to maintain a good oral and dental hygiene include: (a) oral rinses 4–6 times a day with sterile water, normal saline, or sodium bicarbonate; (b) tooth brushing at least twice a day with a soft or ultrasoft toothbrush. Swabs are less effective, but should be used if the patient cannot tolerate brushings.

Handling Pets

Pet owners should follow the following recommendations [3, 5]: (a) avoid contact with young animals as pets (higher risk of shedding *Salmonella* spp. and *Campylobacter* spp. because of a higher incidence of diarrhea); (b) obtain veterinarian consultation when a new pet is adopted and yearly thereafter; (c) keep pet's vaccinations current; (d) keep pet's feeding areas clean and its litter box away from kitchen and eating areas; (e) feed pets only with high-quality commercial pet foods, cooked egg, poultry and meat products, and pasteurized dairy products, and avoid access to garbage; (f) supervise pets when they are outdoors to prevent contact with other pet's feces; (g) prevent animals from roaming through tick-infested woods; (h) wash hands after handling pets and avoid contact with pet's feces and bird droppings; (i) avoid contact with animals with diarrhea, dogs exposed to shows or kennels, wild birds (especially pigeons), birds with avian tuberculosis, reptiles (high carriage and shedding of *Salmonella* spp.), and swine (source of *B. bronchiseptica*); (j) keep pets away from face and wounds; (k) trim pet's nail short; (l) notify physician immediately if patient is bitten or injured by a pet; (m) instruct kids not to share kisses with the classroom pet; and (n) when cleaning cages, wear a particulate mask and avoid shaking cages.

Other Personal Hygiene Items Including Food Handling

High-risk patients should follow additional precautions to prevent serious infections as summarized in Table 49.3.

Table 49.3 Instructions to give to patients with hematological malignancies

Apply during periods of severe immunosuppression: Maintain precautions for up to 3 months after last dose of chemotherapy or discontinuation of immunosuppression
Personal hygiene
– Bathe regularly using a mild soap and shampoo and rinse well
– Don't share razors (electric or blade) as they may retain particles of blood
– Wash hands frequently, preferably with liquid soap before eating and after contact with contaminated materials. If not washed, keep hands away from eyes nose and mouth
– Maintain good dental hygiene, by brushing teeth with soft bristle toothbrush, after meals and floss daily. Do not share toothbrushes and change toothbrush every 3 months
– Use disposable vaginal douches, and when menstruating, avoid tampons change sanitary napkins frequently
– Use sitz baths or soothing lotion for irritations of the rectum or vagina
– Prevent skin dryness (use moisturizing creams)
– Keep nails short and clean and avoid nail clippers used by others
– Clip toenails straight across to prevent them from becoming ingrown
– Try to avoid trauma to and irritation to the nails
– Wear cotton gloves for chores that don't involve water and rubber gloves for chores involving water
– Avoid unprotected sexual exposure (HIV, *Human papillomavirus*, *Herpes simplex*, *Hepatitis B*)
Environment
– Discourage visits by individuals with respiratory infections
– Avoid crowded places
– Don't share towels with others
– Keep house and rooms well ventilated and change air filters regularly
– Encourage household members to get influenza vaccine
– Avoid swimming (particularly in stagnant water)
– Ask your doctor for preventive measures before travel
– Avoid exploring caves, cleaning chicken coops (histoplasmosis)
Other patients
– Avoid close contact with infected patients (tuberculosis, herpes zoster, herpes simplex, other)
Medication/vaccination
– Before traveling, consult your physician and take all medications
– Have vaccines according to recommendation of your clinician
Food/water
Precautions for food handling
– Cook food thoroughly, wash fruits/vegetables before eating
– Wash dishes and silverware in hot soapy water and dry then very well
– Keep uncooked meats separate from vegetables, fruits and wash hands, knives, and cutting boards after handling uncooked foods and clean kitchen surfaces that have come in contact with raw meat
– Avoid using tap water for drinking or making juices, other food items
– Refrain from skinning animals or cleaning seafood
– Use plastic bags in all trash cans for proper disposal
– At the supermarket, pick up perishables last and take them home promptly
– Defrost meat, turkey, chicken in the refrigerator
– Wash the meat before cooking
– Cook thoroughly eggs and meat (use thermometers)
– Clean your refrigerator regularly discarding food of >3–4 days age, especially salad dressings, sauces, milk and egg products, condiments, processed meats, bacon
– Never use canned foods if the can is swollen dented, or rusted
– Toss out any cheese or food that's moldy. Cut up fresh cheeses into small portions and store separately in the freezer, taking out only what can be used up quickly
– Keep cold foods cold (<40 °F) and hot foods hot (>140 °F)
– When preparing foods, the hands should be kept away from the hair, mouth and nose. If possible, rings and jewelry should be removed, because they may harbor germs. Try to limit touching food with the hands at all; use tongs or a fork if possible. -after cutting up raw meats, soak the cutting board and all utensils for 30–40 min in solution of one part bleach and eight or nine parts water -one ounce of bleach to a cup of water. All foods that are not going to be cooked should be prepared first; only after those are out of the way, can any raw meat and poultry be prepared
– Wash all fruits and vegetables well
– Keep food preparation surfaces clean, and use a good dishwashing detergent on the work surface often, especially while handling raw meat, chicken, or fish
– Never let cats or other animals up on the work surface
– Do not prepares food if you have diarrhea or vomiting, or have an open infected sore
– Put leftover foods into the fridge right away and divide large leftovers into individual containers (to avoid repeated warming)
Food restrictions
– Raw eggs (sometimes used in restaurant-prepared Caesar salad dressing or homemade mayonnaise, eggnog)
– Dried, uncooked or undercooked meats, seafood and poultry (to include medium or rare steaks, game, pickled fish or oysters), or food from delis such as cold cuts, hot dogs, tofu, sausage, bacon, cold smoked fish, and lox
– Unpasteurized commercial fruit and vegetable juices
– Unpasteurized milk or cheese products
– Soft and aged cheeses such as feta, brie, camembert, blue-veined, −Mexican-style cheese, refrigerated cheese-based salad dressings (e.g., blue cheese). *Cream cheese, cottage cheese or yogurt (provided they do not contain Lactobacillus* spp.*) are ok to eat*
– Unwashed raw vegetables and fruits end those with visible mold
– Unpasteurized honey or beer or raw, uncooked brewer's yeast
– All miso products (e.g., miso soup); tempe (tempeh); mate'tea
– All moldy and outdated food products
– Herbal preparations and nutrient supplements

Environmental Precautions

Hospital Environment

Air Precautions

Air quality is important to prevent infections in high-risk patients by airborne organisms such as molds (*Aspergillus* spp. or other filamentous fungi), *Legionella* spp. and *Mycobacterium tuberculosis.* Patients at very high risk for invasive aspergillosis (IA) should be placed in sealed rooms with HEPA filters (central or point-in-use) and positive pressure. Air flow should be direct (air intake at one side of the room and air exhaust at the opposite side), and the system should be able to make ≥12 air exchanges per hour [6]. This group is represented mostly by patients receiving induction chemotherapy for acute myeloid leukemia (AML) and in the pre-engraftment period of myeloablative allogeneic hematopoietic cell transplantation (HCT).

The conidia levels in outdoor air vary widely, from 1–5 cfu/m^3 [7] to 2400 in winter and fall in certain areas [8]. The safe concentration of airborne fungi is not established and probably depends on the patient's immune status. The efficacy of HEPA filters in preventing the entry of contaminated outside air into the hospital was confirmed after the demolition of a building. Despite the increase in the number of conidia of filamentous fungi, no conidia were found in most HEPA filter-equipped areas [9]. Because construction and renovation may increase the concentration of airborne fungi, guidelines have been developed when such activities are taking place close to areas were high-risk patients are cared for [10].

Portable HEPA filters decrease the concentration of airborne fungal spores [11] and their use has successfully prevented the occurrence of fungal infections during building construction [12]. However, it is generally agreed that they are less efficient than central or point-in-use HEPA filters [3].

Airborne fungi have been shown to secondarily aerosolize from a water source [13]. Therefore, preventive measures to limit exposure to water can decrease the airborne concentration of fungal pathogens (see below).

Diet

Although no data exist to support a role for sterile or low-level microbial-content (<1000 CFU/mL of nonpathogenic organisms) diets for patients with hematological malignancy, this practice is generally recommended [3]. A randomized study compared cooked and uncooked diet for patients undergoing induction remission for AML. There were no differences in the rates of episodes of major infection and death [14]. A Cochrane review published in 2016 found only three studies comparing cooked and uncooked food. Since pooling of results was not possible, and serious methodologic limitations were found, the authors could not provide solid recommendations for clinical practice [15].

Water

The hospital water system can be a reservoir for *Legionella* spp. [16], bacteria [17–19], and the opportunistic molds, especially *Aspergillus* spp. [13, 20–22], *Fusarium* spp. [23, 24], and *Exophiala jeanselmei* [25]. Potential modes of acquisition of infection include contamination of intravenous solutions, direct contact with skin breakdowns, and aerosolization of fungal spores. Measures to prevent the occurrence of infection depend on the mode of acquisition. It is generally recommended that patients at risk for such infections should avoid direct exposure to contaminated water. In addition, specific measures have been tested, including the use of point-in-use water filters for *Legionella* spp. [26] and cleaning water-related structures to prevent aerosolization of fungi [27].

Health Care Workers (HCW)

Infections can be transmitted from the HCW to the patient. The risk of transmission is high for Varicella zoster (VZV), viral conjunctivitis, measles, and tuberculosis, and intermediate for influenza, mumps, Parvovirus B19, pertussis, respiratory syncytial virus (RSV), rotavirus, and rubella. Therefore, HCW with any of the abovementioned infections or with HSV lesions in lips or fingers should not be in contact with patients [3].

HCW who care for patients with hematological cancer should be immunized against rubella, measles, mumps, influenza, and chickenpox, in addition to the already recommended tetanus and hepatitis B immunization [3].

Household Exposure

The recommendations for immunization and precautions that apply to the HCW also apply to close contacts of patients with hematological cancer [3]. Immunization against hepatitis A and B is highly recommended for sexual contacts of patients. In addition, immunization against hepatitis A should be considered for all households of patients with chronic liver disease or living in endemic areas. Oral polio vaccine is contraindicated for all households of patients with hematological cancer since live polioviruses can be transmitted to and cause disease in immunocompromised patients, especially during the first month after vaccination [28]. Patients with hematological cancer should also avoid exposure to individuals with vesicular rash secondary to chickenpox immunization to prevent VZV disease [3].

Sexual partners: Sexually active patients should avoid unprotected sex during the periods of significant immunosuppression to reduce the risk of exposure to CMV, HSV, HIV, HPV, HBV, HBC, and other sexually transmitted infections [3].

Invasive Procedures

Procedures that break the integrity of natural barriers such as skin and mucosa should be avoided when possible. Fixed orthodontic appliances and space maintainers should not be worn during any period of neutropenia to avoid oral trauma and infection. Enemas, suppositories, rectal temperature check, or/and rectal examination are contraindicated. Necessary dental procedures should be performed prior to chemotherapy to allow proper healing before neutropenia and mucositis develop [29]. Bone marrow biopsies should be done aseptically to avoid cellulitis and osteomyelitis.

Recommendations for the insertion of indwelling devices include careful cleaning and sterilization of instruments and devices (particularly reusable ones) and guidelines for the prevention of intravascular device-related infections [30]. However, solid evidence to support some of the guidelines for the prevention of intravascular device-related infections is lacking.

Antimicrobial Prophylaxis

Antimicrobial prophylaxis may be primary, when prevention targets an individual that has not been infected in the past, and secondary, when prevention is used to avoid recurrence of infection in an individual who has been previously infected.

Antibacterial Prophylaxis

Bacterial infections occur frequently in two settings: neutropenia and hypogammaglobulinemia. As shown in Table 49.2, common bacterial infections in patients with neutropenia include staphylococci, enterococci, and viridans streptococci among the Gram-positive bacteria, and enterobacteria and non-fermentative bacteria (especially *Pseudomonas aeruginosa*, *Acinetobacter* spp., and *Stenotrophomonas* spp. among the Gram-negative bacteria).

Because Gram-negative bacteremia may be associated with high mortality rates, strategies of antibacterial prophylaxis during neutropenia have been focused mostly to prevent the occurrence of Gram-negative bacteremia, and the quinolones have been extensively studied. A meta-analysis pooling data from 95 trials showed that quinolones reduced the incidence of fever, documented infections, and mortality associated with infection [31]. A major concern is the development of resistance. Another meta-analysis examined the effect of quinolone prophylaxis on microbial resistance. There was no difference in the incidence of colonization by resistant organisms, or in the rates of infection caused by resistant pathogens [32]. These data, however, must be interpreted with caution, because rates of resistance are very different among different institutions, cities, and countries. As a general rule, once the clinician decides to give prophylaxis with a quinolone for neutropenic patients, a careful attention to the development of resistance is advised.

Another concern when using quinolone prophylaxis is the increase in the incidence of infections caused by Gram-positive organism, notably viridans streptococci [33, 34]. A great concern related to such infections is that they may occasionally evolve to shock and respiratory failure [35]. Although most of such infections may be prevented by penicillin or macrolides [36], some strains are resistant to these agents [37]. The use of glycopeptides is not generally recommended for prophylaxis [3]. Table 49.4 shows the usual doses of quinolones in the prophylaxis of bacterial infections in neutropenic patients.

Hypogammaglobulinemia is frequent in chronic lymphocytic leukemia, multiple myeloma, and in allogeneic HCT

Table 49.4 Dosage-schedule of antimicrobial agents used in the prophylaxis of infection in patients with hematological malignancies

Disease	Prophylaxis
Bacterial infections	
Neutropenic	Quinolone[a]
Non neutropenic	TMP-SMX—800 mg/160 mg PO daily Or daily quinolone
C. difficile diarrhea	Consider metronidazole prophylaxis (500 mg PO TID) if prior history of CDAD
Tuberculosis	Isoniazid—300 mg PO daily
Fungal infections	
Invasive candidiasis	Fluconazole—200–400 mg PO daily
Invasive aspergillosis	Posaconazole—200 mg TID for oral solution or 300 mg BID on day 1 followed by 300 mg once daily on day 2 and thereafter for tablet
Oral and/or esophageal candidiasis	Clotrimazole troches (10 mg, ×5/day) or fluconazole—100–200 mg PO daily
Pneumocystis jirovecii pneumonia	TMP-SMX—800 mg/160 mg PO daily or ×2/week, pentamidine—300 mg aerosol monthly, dapsone—100 mg PO daily, atovaquone 1500 mg PO daily
Viral infections	
Herpes simplex	Acyclovir—200–400 mg PO BID or TID, valacyclovir—500 mg PO TID or famciclovir—500 mg PO TID
Herpes zoster	Acyclovir—400 mg PO BID or TID, valacyclovir—500 mg PO TID or famciclovir—500 mg PO TID
Cytomegalovirus	Ganciclovir—5 mg/kg IV BID or valganciclovir—900 mg/d PO or foscarnet—60 mg/kg IV BID
Influenza virus	Oseltamivir—75 mg PO daily for the duration of the influenza season. Zanamivir is more appropriate in the presence of viral resistance

TMP-SMX trimethoprim-sulfamethoxazole, *PO* per os, *TID* three times a day, *QID* four times a day, *BID* twice a day

[a]Includes ciprofloxacin—500 mg PO BID, levofloxacin—500 mg PO daily, moxifloxacin—400 mg PO daily, others

recipients who develop GVHD. These patients are at greater risk of developing bacterial infections, particularly by encapsulated bacteria. Intravenous immunoglobulin (400 mg/kg) every 4 weeks may be effective for the prevention of bacterial infections, and this recommendation is supported by randomized controlled studies [38–40]. However, since its use is costly, intravenous immunoglobulin should be reserved to a selected population of patients with repeated episodes of severe infections. A meta-analysis of nine studies comparing intravenous immunoglobulin with a control group in patients with chronic lymphocytic leukemia or multiple myeloma did not show any survival benefit of immunoglobulin prophylaxis. However, a reduction in the incidence of major infections and of clinically documented infections was observed. The authors concluded that intravenous immunoglobulin should not be recommended routinely [41]. A cheaper alternative to immunoglobulin is to give quinolone prophylaxis with levofloxacin (500 mg/day), moxifloxacin (400 mg/day), or sulfamethoxazole-trimethoprim (TMP-SMX) (Table 49.4) [42].

Antifungal Prophylaxis

Primary prophylaxis against invasive candidiasis is not indicated in all neutropenic patients. In allogeneic HCT recipients, two randomized clinical trials (RCTs) showed that fluconazole reduced the frequency of superficial and systemic candidiasis, as well as infection-related mortality [43, 44]. In one of these trials, fluconazole was given until day +75 posttransplant, and a post hoc analysis of the trial has shown that fluconazole was associated with prolonged protection against invasive candidiasis, even beyond the period of prophylaxis [45].

The benefit of prophylaxis against invasive candidiasis was not as apparent in other settings, such as in patients with acute leukemia [46]. However, the ineffectiveness of fluconazole in non-HSCT neutropenic patients is probably related to the heterogeneity of the populations of neutropenic patients studied (with different incidences of invasive candidiasis) rather than an absence of efficacy. In general, the higher is the risk for the patient to develop severe mucositis during neutropenia, the higher is the risk for invasive candidiasis.

Fluconazole is the drug of choice, usually at a dose of 400 mg daily. Fluconazole is not effective in preventing infection caused by all *Candida* species. *Candida krusei* is intrinsically resistant to fluconazole, and *Candida glabrata* exhibits minimal inhibitory concentrations (MIC) higher than other species. As a consequence, fluconazole is not recommended for the prevention of infection due to these two species.

Other than fluconazole, itraconazole oral solution (but not capsules) [47], voriconazole [48], posaconazole [49], and micafungin [50] effectively prevent the occurrence of invasive candidiasis during neutropenia.

Invasive aspergillosis usually occurs in the context of prolonged (>15 days) and profound (<100/mm^3) neutropenia in patients receiving induction therapy for AML or myelodysplasia (MDS), or after myeloablative conditioning regimen for allogeneic HCT [51]. In addition, HCT recipients with GVHD are at high risk for IA. In these patients, severe T-cell mediated immunodeficiency rather than profound and prolonged neutropenia is the main risk factor [52]. More recently, cases of IA have been diagnosed in patients with other hematological malignancies, including patients with chronic lymphocytic leukemia receiving treatment with alemtuzumab, and patients with multiple myeloma [53–56].

In the setting of AML/MDS, posaconazole (200 mg 3×/day) was superior to fluconazole or itraconazole oral solution in a large randomized controlled trial, and is considered the drug of choice for anti-*Aspergillus* prophylaxis [49]. By contrast, a reduction in the incidence of IA was not observed in trials comparing itraconazole with fluconazole, and itraconazole was associated with more adverse events [47, 57]. A recent meta-analysis of itraconazole trials suggest that there is a reduction in *Aspergillus* infections but only if a certain threshold of bioavailable dosing is used [58]. Its ability to prevent invasive fungal diseases (IFD) has been associated with trough itraconazole concentrations >500 ng/mL, best achieved with the IV formulation (followed by the oral solution if the gastrointestinal function is intact). The oral capsule formulation suffers from erratic bioavailability and is best avoided.

In allogeneic HCT recipients, itraconazole oral solution resulted in a reduction in the frequency of IA in 2 trials, but about 25% of patients discontinued itraconazole because of gastrointestinal side effects [59, 60]. In these trials, prophylaxis was used both in the early pre-engraftment and in the post-engraftment period. Another randomized clinical trial compared posaconazole to fluconazole in allogeneic HCT recipients who developed GVHD. Although the primary endpoint (incidence of IFD from randomization to day 112 of prophylaxis) was not achieved, posaconazole significantly reduced the incidence of IA [61]. Micafungin given during the pre-engraftment period was associated with a trend suggesting ability to prevent aspergillosis. In this trial the incidence of IA was 0.2% among 425 patients receiving micafungin and 1.5% among 457 patients receiving fluconazole ($p = 0.07$) [50].

Two randomized clinical trials evaluated the efficacy of voriconazole as prophylaxis in allogeneic HCT recipients. In the first study, patients received voriconazole or fluconazole from day zero until day +100 (or beyond, in the presence of GVHD) posttransplant. For the primary endpoint (fungal-free survival at 180 days), no differences were observed in the two arms (75% fluconazole vs. 78% voriconazole, $p = 0.49$). There was a trend for a lower incidence of IA in

voriconazole recipients ($p = 0.09$) [48]. The other study compared voriconazole and itraconazole, given for the same period as the previous study [62]. The incidence of IFD (including IA) was similar in the two arms, but tolerability was better with voriconazole.

Taken together, it seems that mold-active azoles indeed reduce the incidence of IA. These findings, however, should be balanced against our significantly improved ability for the early detection of fungal infections and the potential undesirable consequences including toxicities, drug–drug interactions, costs, and emergence of resistance [63]. The application of serial serum galactomannan monitoring has enabled us to make the diagnosis of IA much earlier, with a significant impact in reducing mortality [56]. Indeed, in the trial comparing voriconazole and fluconazole, screening with twice-weekly serum galactomannan was part of the protocol in the two arms, and appropriate antifungal therapy was started based on positive galactomannan tests. The absence of a significant difference in the incidence of IA suggests that giving an anti-mold agent as prophylaxis or giving fluconazole plus serial monitoring with serum galactomannan results in similar outcomes.

Therefore, several factors should be taken into consideration in determining if prophylaxis is appropriate at a specific treatment center, for a given patient or patient population to target a specific infection or if prophylaxis should be withheld and a diagnostic-based preemptive strategy used instead. In general, the higher the risk, the more likely anti-mold prophylaxis should be given. Therefore, risk assessment (Table 49.1) should be performed in order to decide the best strategy. Patients at high risk to develop IFD should receive anti-mold prophylaxis, while low-risk patients can be managed with fluconazole plus active monitoring with serial (3×/week) serum galactomannan and CT scans, provided that these tools are available in the hospital [64]. Clinicians should keep in mind that this risk assessment is dynamic. For example, a patient with AML who was considered at low risk on admission but presents residual blast cells on day 15 of admission should be reclassified to a higher risk and the prophylactic regimen should be changed accordingly [64].

Secondary prophylaxis is indicated for patients who developed an invasive mold infection and will receive treatment for the underlying malignancy that results in immunosuppression, particularly neutropenia and/or T-cell immunodeficiency [65]. Options for secondary prophylaxis include amphotericin B and its lipid formulations, caspofungin, itraconazole, voriconazole and lipid amphotericin B followed by voriconazole [66–70]. In addition to secondary chemoprophylaxis, strategies to abbreviate the duration of neutropenia, such as the use of reduced-intensity conditioning regimens and peripheral blood stem cells, and the use of granulocyte transfusions may be employed [71, 72]. The antifungal agents and doses given as prophylaxis are summarized in Table 49.4.

Antiviral Prophylaxis

Most viral infections that complicate the course of chemotherapy in patients with hematological malignancies represent reactivation of latent infections, while a minority are due to exogenous acquisition (such as respiratory viruses).

Cytomegalovirus (CMV)

Until the early 1990s, CMV seropositive allogeneic HCT recipients had a 70–80% risk of viral reactivation, and one-third of these patients developed CMV disease (mainly pneumonia) [73] with a high fatality rate [74]. The application of preemptive therapy guided by serial monitoring with CMV antigenemia has markedly reduced the incidence of patients who develop overt manifestations and/or die of CMV pneumonia [75]. More recently, quantitative PCR for the detection of CMV DNA and CMV RNA have been introduced as alternatives for the antigenemia [76, 77]. Since these techniques are more sensitive than antigenemia, a threshold for starting preemptive therapy should be established for every group of patients; in other words, a specific number of copies of CMV DNA above which triggers the institution of preemptive therapy in allogeneic HCT may not be the same for patients with less severe immunodeficiency. Indeed, the application of these sensitive biomarkers has revealed that hosts not thought to be at risk for CMV reactivation may indeed have positive CMV PCR quite frequently [78]. Outside the setting of allogeneic HCT, patients at higher risk to develop CMV reactivation include patients with chronic lymphocytic leukemia (CLL) receiving fludarabine or (especially) alemtuzumab [79], patients with multiple myeloma receiving highly intensive therapies [80], and autologous HCT recipients treated previously with rituximab [81].

Two strategies were reported effective for the prophylaxis of CMV disease in allogeneic HCT recipients: universal prophylaxis and preemptive therapy. Universal prophylaxis is not usually given because this strategy may lead to a significant increase in the incidence of bacterial and fungal superinfections associated with ganciclovir-induced neutropenia and immunosuppression [82], and the occurrence of late CMV disease [74]. Ganciclovir, administered intravenously, is the drug most often used for preemptive therapy. The usual duration of therapy is 2 weeks, provided antigenemia (or PCR) becomes promptly negative. Otherwise, a prolonged course of ganciclovir or maintenance therapy is indicated. Alternatives to ganciclovir include foscarnet and oral valganciclovir [3]. Investigational agents include brincidofovir [83], letermovir [84], and maribavir [85].

Herpes Simplex Virus (HSV)

Reactivation of HSV is frequent in patients with hematological malignancies, especially after induction chemotherapy for acute leukemia, and following conditioning

regimens for HCT, and manifests as oral lesions indistinguishable from chemotherapy-induced mucositis [86]. Less frequent manifestations include genital ulcers, esophagitis, hepatitis, and pneumonia. Antiviral prophylaxis against HSV is administered if the patient is seropositive for HSV or conveys a history of recurrent fever blisters, cold sores, or other indications of recurrent HSV infections, particularly if the CD4 counts are low (<50/mm^3). The drug of choice is acyclovir, and should be given prior to or at the time of cytotoxic or myeloablative chemotherapy and continued until bone marrow recovery and/or resolution of mucositis [86]. Alternatives to acyclovir are valacyclovir and famciclovir (Table 49.4).

Varicella-Zoster Virus (VZV)

Patients at highest risk for VZV reactivation are those with severe lymphopenia and/or CD4 cytopenia such as patients with lymphoma, leukemia (mainly CLL), heavily treated myeloma patients, HCT recipients and patients receiving fludarabine or alemtuzumab. Without acyclovir prophylaxis, reactivation of VZV is common and can be complicated with severe post-herpetic neuralgia. Visceral dissemination (pneumonitis, meningoencephalitis, and hepatitis) may rarely occur in severely immunocompromised patients [87].

Patients at high risk should avoid contact with persons with VZV disease, as well as vaccine recipients who develop a rash after vaccination. In addition, contact and airborne precautions are recommended if an immunocompromised patient develops VZV disease, in order to decrease the risk of transmission to other patients and to HCW [3].

High-risk patients with a history of recent contact with any person with VZV disease should receive varicella-zoster immunoglobulin (VZIG) or, as an alternative, acyclovir or valacyclovir [88]. Acyclovir is indicated as prophylaxis against VZV reactivation in allogeneic HCT recipients, usually given for 1 year [89]. In addition, patients with multiple myeloma receiving regimens containing bortezomib should receive prophylaxis because of the high risk of VZV reactivation [80]. The use of VZV prophylaxis in other settings is more debatable and should be reserved for severely immunosuppressed patients, especially if they develop herpes zoster.

Epstein Barr Virus (EBV)

Patients with EBV disease may present with fever and mononucleosis syndrome. In addition, HCT recipients may present with posttransplant lymphoproliferative disease (PTLD). Patients at high risk for PTLD include recipients of matched unrelated, mismatched, or T-cell depleted transplants, recipients of high dose antithymocyte globulin or anti-T-cell monoclonal antibodies, patients with acute and chronic GVHD, and those receiving radiation as part of the conditioning regimen [90].

High-risk patients who are EBV seronegative should be advised to avoid close contact with EBV seropositive individuals. Increases in EBV viral load following PPSCT/BMT are common, and are highest in patients at risk for PTLD. The best strategy to prevent PLTD is to serial monitor high-risk patients with serum quantitative PCR technique and giving rituximab preemptively for patients who present EBV replication [91].

Hepatitis B Virus (HBV) and Hepatitis C Virus (HCV)

Patients with hematological malignancies undergoing cytotoxic chemotherapy while infected with HBV have a higher risk for severe liver dysfunction [92]. During therapy-induced aplasia, the possibility of viral replication increases dramatically resulting in acute HBV infection that may be mild, asymptomatic, or chronically progressive leading to fulminant hepatitis. Fulminant hepatitis usually coincides with discontinuation of immunosuppression [93]. Risk factors for reactivation include male gender, younger age, a diagnosis of lymphoma, and positive HBV e antigen [94]. In HCT recipients, the risk of reactivation is as high as 50% [95]. Although any chemotherapy regimen may result in HBV reactivation, the risk is particularly higher after exposure to corticosteroids, rituximab, and alemtuzumab [96, 97].

Patients with circulating HBV DNA should receive preemptive therapy with lamivudine (100 mg/day). This regimen is effective and relatively nontoxic. However, prolonged exposure to lamivudine may result in the development of resistance. The optimal duration of preemptive therapy is not established, but is usually recommended to be at least 6 months after discontinuation of chemotherapy, to avoid viral reactivation and the development of hepatitis [95, 98].

Patients infected with HCV may receive chemotherapy or HCT without major complications except for a higher risk for sinusoidal obstruction syndrome; the risk for such patients is the development of late cirrhosis, several years after HCT [99]. Patients with HCV should be assessed for the evidence of chronic liver disease. Patients with cirrhosis who are selected for receipt of HCT should not receive conventional conditioning regimens. Although oral ribavirin may clear HCV viremia, its routine use as prophylaxis is not recommended.

Respiratory Viruses

The respiratory viruses Adenovirus, Influenzae, Parainfluenza, Respiratory Syncytial Virus (RSV), Rhinovirus, Coronavirus, and Metapneumovirus may cause infections in patients with hematological malignancies. Most of these infections appear to be self-limited, although progression to severe lower respiratory infection may occur [100–103]. The main strategy for prophylaxis of infections by respiratory viruses is to prevent

exposure of patients with hematological malignancies to individuals with symptoms of respiratory infections.

Vaccination of household contacts and HCWs for Influenza is recommended during each Influenza season [3]. In addition, patients receiving chemotherapy should also receive the vaccine, considering that they may be able to respond vaccination and the intervention is safe [104]. However, considering that the response to vaccination may be suboptimal, chemoprophylaxis with neuraminidase inhibitors during a community outbreak has been recommended [3].

Regarding RSV, parainfluenza virus, and adenovirus, while highly immunosuppressive patients may be at risk for severe pneumonia, no formal prophylaxis is available and approved. Therefore prevention of severe disease is best approached by early diagnosis and therapy.

Other Pathogens

Mycobacteria

The incidence of tuberculosis in patients with hematological malignancies is low, even in highly endemic regions. In a study from Spain, the incidence of tuberculosis was significantly higher than the general population among allogeneic but not autologous HCT recipients [105]. In another study, 917 patients with hematological malignancies from Brazil were retrospectively reviewed for a diagnosis of tuberculosis. The prevalence was 2.6% only; risk factors were an underlying disease associated with significant impairment in CMI (e.g., receipt of fludarabine and corticosteroids) and malnutrition [106]. The problem is that most patients who develop tuberculosis have not had clearly identified risk factors.

Patients should avoid contact with persons with active tuberculosis, as well as environments that may potentially have patients with tuberculosis, such as health care facilities and shelters for the homeless. There are no studies testing antimicrobial prophylaxis in high-risk patients. Recently published guidelines for infection prophylaxis in HCT recipients recommend the use of isoniazid (5–10 mg/kg, maximum, 300 mg/day) with pyridoxine 25 mg daily for >9 months and until immunosuppression dosages are substantially reduced in patients with past history of tuberculosis or exposure to someone with active tuberculosis, patients with positive tuberculin test or interferon-gamma release assays without a history of BCG vaccination [3].

Pneumocystis jirovecii

Reactivation of latent infection is the most common mechanism of pneumonia by *Pneumocystis jirovecii* among immunocompromised patients. Patients at high risk for *Pneumocystis jirovecii* pneumonia (PJP) are those with chronic T-cell immunodeficiency, particularly: children with acute lymphoid leukemia (ALL), HCT recipients, and patients receiving purine analogues, monoclonal antibodies, or corticosteroids for long periods [107, 108].

The most effective drug for prophylaxis is TMP-SMX. Accepted dosages include one double-strength tablet (trimethoprim 160 mg + sulfamethoxazole 800 mg) bid 2 days a week, one double-strength tablet (daily or 3 times a week), and 1 single-strength tablet (trimethoprim 80 mg + sulfamethoxazole 400 mg) daily. The time of initiation and the duration of prophylaxis should be individualized according to the underlying disease and type of treatment. For example, in ALL patients, prophylaxis is usually started at the end of the induction period and discontinued 3 months after completion of maintenance therapy; in HCT recipients it should be started after engraftment and continued as long as immunosuppressive therapy is ongoing, extensive GVHD is present and CD4 count is <200 cells/mm^3. Alternative agents include: aerosolized pentamidine (given with Respirgard II nebulizer 300 mg every month after an initial loading dose given every other week), atovaquone suspension (1500 mg/day), and dapsone (50 mg bid or 100 mg/day) [3, 109].

Toxoplasmosis

Seropositive patients are at risk of reactivation of toxoplasmosis following HCT. When the recipient and donor are seronegative, special precautions should be taken to avoid primary infection. Those precautions include eating only well-cooked meats (>66°C), well-washed vegetables, cooked eggs, pasteurized milk, sterile water, handwashing after outdoor activities or after handling raw meat or vegetables, using gloves for contact with soil or gardening, avoiding contact with cat litter, and having someone change litter box daily and soak it in boiling water for 5 min.

Reactivation of toxoplasmosis is highest among recipients of T-cell depleted allogeneic PSCT/BMT (5–15%) and is otherwise rare among other allogeneic recipients (<1%). The potential toxicities of effective agents preclude routine prophylaxis against toxoplasmosis. However, preemptive therapy of high-risk patients (positive serology prior to transplantation, T-cell depleted allogeneic transplants) with PCR-based tests is recommended. Primary prophylaxis may be considered in patients with history of ocular toxoplasmosis. Effective prophylaxis includes TMP-SMX, one double-strength tablet daily or 3 times a week, or 1 single-strength tablet daily, Clindamycin 300–450 mg thrice daily plus pyrimethamine 25–75 mg/day plus leucovorin 10–25 mg, pyrimethamine-sulfadoxine (Fansidar) 1 tablet (25 mg pyrimethamine/500 mg sulfadoxine)/20 kg weight on day 1 with folinic acid, 50 mg/20 kg on day 2, then daily following engraftment, atovaquone (750–1500 mg/day), and dapsone 50 mg/day plus pyrimethamine 50 mg/week plus folinic acid 25 mg/week. Fansidar is associated with significant toxicities [110].

Other Parasites

Strongyloides stercoralis may cause a fatal disseminated syndrome with intestinal larval invasion and bacterial superinfection. Patients at high risk are those with T-cell immunodeficiency [111]. Patients at risk should avoid contact with outhouses and cutaneous exposure to soil or other surfaces that might be contaminated with human feces. In addition, patients with unexplained eosinophilia, or those who live in, have resided, or traveled to endemic areas should be screened with either stool examinations (≥3 stool examinations), or an enzyme-linked immunosorbent assay (ELISA) [112]. Patients whose screening is positive should receive empiric treatment with ivermectin (200 μg/kg/day for 2 days, repeat after 2 weeks) [113].

Immune Reconstitution

Passive Immunization (IV Immunoglobulin, IVIG)

Intravenous immunoglobulins may benefit patients with CLL, non-Hodgkin lymphoma and myeloma who have severe hypogammaglobulinemia (serum IgG levels <500 mg/dL) and recurrent and/or severe infections despite appropriate antimicrobial prophylaxis and immunizations [38–40]. Doses of IVIG of 250 mg/kg every 4 weeks were shown to be as effective as 500 mg/kg every 4 weeks. However, the role of IVIG in the prevention of infections among patients with hematological malignancies is not clear and is unlikely to be superior to that of antibiotic prophylaxis (see Antibacterial Prophylaxis above). Therefore, IVIG should probably be given to patients with hypogammaglobulinemia and recurrent bacterial infections despite prophylactic antibiotics [114].

Among HCT recipients, the major benefit of IVIG is the reduction of acute GVHD in allogeneic HCT. The administration of IVIG for the prevention of infections among these patients with severe hypogammaglobulinemia (serum Ig G < 400 mg/dL) is commonly practiced but is of unproven value.

Active Immunization

The immunization of patients with hematological malignancies undergoing cytotoxic chemotherapy has three goals: (a) maintaining the appropriate adult immunization schedule; (b) restoring the immunity that could have been lost after the immunosuppressive treatment; and (c) protecting the patient from the receipt of live vaccines. A suggested schedule for immunization in HCT is shown in Table 49.5.

Table 49.5 Immunization after hematopoietic stem cell transplantation (HCT)

Vaccine	Time after HCT (months)	Number and interval of doses	Comments
Diphtheria, tetanus toxoid, pertussis	6–12	3	Acellular pertussis vaccine preferable
Pneumococcal 7-valent conjugate vaccine	3–6	3	The 7-valent pneumococcal conjugate vaccine is preferable; the polysaccharide vaccine can be given subsequently to broaden the immune response
Pneumococcal 23-valent polysaccharide	12	1	
H. Influenzae type B	6	3	
Meningococcal	6–12	1	Follow recommendations for the general population in the country/region
Hepatitis B	6	3	
Influenza	4–6	1	Repeat every fall
Measles	24	2	All children and posttransplant seronegative adults
Mumps, rubella	24	1	
Inactivated polio virus (Salk)	6–12	3	Inactivated polio vaccine should also be used in household contacts
Varicella vaccine	24	1	Limited data regarding safety and efficacy. Should be given only to seronegative patients

HCT hematopoietic cell transplantation
AVOID live vaccines until patient in complete remission, *and* not receiving immunosuppressive therapy for 6 months *and* has a CD 4 + count >400/μL *and* does not have chronic graft versus host disease
Live vaccines:
– Adenovirus, BCG, Measles-Mumps-Rubella, Oral typhoid, Oral polio, Yellow fever, Varicella zoster
– AVOID oral polio in household contacts (the polio virus may spread and cause uncontrolled infection)
AVOID vaccines until CD 4+ counts > 200/μL (unlikely to be effective)
Consider measuring antibody titers after vaccination to ensure efficacy and repeat doses until optimal titers achieved

Colony-Stimulating Factors (CSF)

Granulocyte colony-stimulating factor (G-CSF) has been shown to reduce the incidence of fever, and duration of antibiotic therapy and hospitalization in some studies. However, a significant reduction of culture-proven infections or mortality

has not been shown. The best cost-effective prophylactic use of G-CSF is in settings when the risk of febrile neutropenia is >20% [115–117].

Granulocyte Transfusions

Prophylactic GM-CSF or G-CSF elicited granulocyte transfusions remains investigational and may be considered in patients with a history of a neutropenia-related invasive mold infection (such as aspergillosis or fusariosis) who are expected to be neutropenic for ≥14 days [118].

Summary

Infection is a frequent complication and a leading cause of morbidity and mortality in patients with hematological malignancies. In general, the higher is the risk for a certain infection, the more beneficial is likely to be prophylaxis. Likewise, the shorter is the period at risk (and therefore the predicted duration of prophylaxis), the higher is the possibility that prophylaxis will work. The decision of giving prophylaxis should take into account its potential benefits, but also side effects, costs, induction of resistance, and the potential for drug interactions with antineoplastic h48 drugs. Risk assessment is a key element in defining prophylactic strategies.

Evaluation and Management of Bacterial and Fungal Infections in Patients with a Hematological Malignancy: A 2018 Update

50

Maria Pia Franco, Jaime S. Green, and Jo-Anne H. Young

Introduction

The treatment of hematological malignancies relies heavily on cytotoxic chemotherapy that most often places patients at risk for invasive bacterial and fungal infections due to disruptions in mucosal barrier integrity and impaired myelopoiesis. A weakened mucosal barrier permits translocation of fungi and bacteria present in the oropharynx, gastrointestinal tract, or skin to enter the body and, when this is combined with immune compromise from impaired myelopoiesis, severe infections are not uncommon. Antineoplastic therapy-associated neutropenia frequently results in a muted inflammatory response, with fever often being the sole presenting symptom. In addition to cytotoxic antineoplastic therapy, these patients often receive concomitant glucocorticoids which may altogether blunt even a febrile response [1]. This necessitates a high index of suspicion on the part of the clinician to effectively recognize infection in the neutropenic patient who might only present with hypotension or tachycardia with or without other nonspecific findings. Also known as neutropenic fever (these terms will be used interchangeably throughout this chapter), this clinical entity is defined as a single oral temperature measurement of 38.3 °C, or a temperature greater than 38.0 °C that is sustained for more than an hour in a neutropenic patient [2–4]. The generally accepted definition of neutropenia is an absolute neutrophil count (ANC) of <1500 cells/μL. Severe neutropenia is defined as an ANC of <500 cells/μL, or when there is an expected ANC nadir of <500 cells/μL within the next 48 h.

Bacterial Infections

The pathogenesis of bacterial and fungal infections in the patient with hematologic malignancy is a complex interplay between host factors, effects of antineoplastic therapy, and changes in the host caused by the underlying malignancy (Table 50.1). As mentioned in the introduction to this chapter, the impairment of mucosal barriers and immune system dysfunction create an environment favorable to invasive microbial infections that is often compounded by frequent healthcare exposure and patients' inherent increased risk for exposure to organisms of increased virulence and drug resistance [2]. It is believed that the majority of infections in patients with hematologic malignancies are due to treatment-related muco-

Table 50.1 Risk factors associated with an increased risk of developing febrile neutropenia

Host factors
Age > 65 years
Female gender
Poor nutritional status
Poor performance status based on underlying cardiovascular, pulmonary, and renal comorbidities
Factors related to the underlying malignancy
Advanced stage of the malignancy
Myelophthisis
Lymphopenia
Elevated serum lactate dehydrogenase in patients with lymphoreticular process
Factors related to the antineoplastic therapies
Expected high dose density chemotherapy
Expected intensity of high dose chemotherapy
Lack of administration of prophylactic hematopoietic growth factor stimulants in patients with high-risk chemotherapeutic regimens

sitis and translocation of gastrointestinal tract flora and colonizing organisms that eventually reach the bloodstream. Less common mechanisms include disruption of respiratory, genitourinary, and lymphatic barriers due to the underlying malignancy or associated with medical procedures. Of particular concern are the presence of central venous catheters (CVCs) and other indwelling catheters [5].

Epidemiology

Bacterial infection is a common cause for febrile neutropenia in patients who have received antineoplastic chemotherapy, with approximately 23% of them presenting with fever or neutropenic fever [6]. Of patients who present with febrile neutropenia, an infectious etiology is only identified in roughly one-quarter of cases, and often only through isolation of an organism causing bacteremia, which is found in up to 25% of all patients with neutropenic fever [2, 7]. Of note, the vast majority of organisms causing infections in hematological cancer patients are bacteria, followed by fungi and viruses as distant second and third place culprits. Given the principal factors that predispose to febrile neutropenia (disruption of mucosal barriers and immune suppression), translocation and infection by saprophytic flora explain the overwhelming predominance of these organisms isolated from cultures [8, 9].

The most commonly isolated organisms tend to be Gram positive bacterial organisms, with a predominance of *Staphylococcus epidermidis*, followed by a variety of other streptococci and staphylococci including *Staphylococcus aureus* [10, 11]. There has been a significant shift in the patterns of causative bacterial pathogens over time due to a variety of factors including antibiotic pressure from prophylaxis and/or treatment, the increased use of long-term indwelling catheters, and novel antineoplastic regimens [12]. Prior to the early 1990s, the majority of organisms isolated during evaluation of episodes of febrile neutropenia were Gram negative bacteria, with *Pseudomonas aeruginosa* being especially notorious [13, 14]. This trend began to turn gradually, with a growing predominance of Gram positives being most commonly isolated in the mid-1990s and into the early 2000s, when Gram negative prophylaxis was common. Approximately 80% of all isolates were Gram positive bacterial organisms [15, 16]. Today a reversal in this trend is being noted, this time the cause for the trend starting to turn back to Gram negative bacterial organisms seems to be related to the emergence of multidrug-resistant organisms (MDROs). MDRO groupings commonly referred to in practice include Gram positive bacteria [methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE)], as well as Gram negative bacteria [extended spectrum beta lactamase (ESBL), *Klebsiella pneumoniae* carbapenemase (KPC), and carbapenem-resistant enterobacteriaceae (CRE)]. Currently the overall percentage of infections due Gram positive bacterial organisms has decreased to around 60% [17–21]. Another important point is that outside of bloodstream infections, where Gram positive bacterial organisms are predominant, Gram negative bacterial organisms are the most common pathogens of infections related to the urinary, gastrointestinal, and biliary tracts [22].

The severity of bacterial infections varies due to a number of factors specific to each organism. Among the Gram positive bacterial organisms, MRSA and VRE are some of the most severe [16]. Though infrequent, anaerobes can contribute to severe, life-threatening infections such as necrotizing fasciitis, typhlitis (neutropenic enterocolitis), and sinusitis. Interestingly, though still rare, polymicrobial infections also appear to be becoming more frequent than in prior decades [19, 23, 24].

Risk Factors

Cancer patients undergoing systemic chemotherapy for hematologic malignancies often suffer significant side effects, especially effects on mucosal integrity and myeloid production and function. These will predispose to the development of infections due to translocation of gastrointestinal tract colonizing bacteria and fungi. Concomitant neutropenia results in a blunted immune response to invasion by previously colonizing organisms [25]. A thorough evaluation of the host characteristics, risk for developing febrile neutropenia, and risk assessment for serious complications associated with febrile neutropenia will guide empiric antimicrobial therapy and dictate additional workup and need for hospital admission [2]. Risk factors associated with an increased risk of developing neutropenic fever are best thought of in terms of host factors, factors related to the underlying malignancy, and those related to the antineoplastic therapies (Table 50.1). Host factors include the patients' underlying conditions and comorbidities that may alter their immune function (e.g., drug-induced neutropenia will predispose to bacterial and candidal infections, underlying cellular immunodeficiency will predispose to opportunistic viral

infections, and underlying humoral immunodeficiency will predispose to mycobacterial infections), those that predispose to infection due to anatomic and or functional abnormalities (vesicoureteral reflux, nephrolithiasis, bronchiectasis, etc.) and those that alter patients' flora (prolonged antibiotic use that causes selective pressure favoring more invasive or resistant organisms). Treatment-related factors include mucosal barrier disruption due to cytotoxic therapy's effect on high turnover cells of the lining the gastrointestinal tract, impaired myelogenous production, and decreased neutrophil phagocytic and chemotactic activity.

Patients with hematologic malignancy presenting with neutropenic fever should be risk stratified according to their risk of developing serious complications (Table 50.2), which in turn guides the need for hospital admission, parenteral antimicrobial therapy, and prolonged hospitalization (Fig. 50.1).

Table 50.2 Risk of medical complications of febrile neutropenia

Patient Risk Category	National Comprehensive Cancer Network	Infectious Disease Society of America
High	– Developing fever while inpatient	– Anticipated ANC ≤100 cells/μL for >7 days
	– Significant comorbidity or clinical instability	– ALT >5x normal or CrCl <30 mL/min
	– Anticipated ANC ≤100 cells/μL for >7 days	– Concurrent clinical conditions such as: Hemodynamic instability, intravascular catheter infection, encephalopathy, respiratory failure, mucositis or other gastrointestinal symptoms, underlying chronic lung disease and or hypoxia/ infiltrates
	– ALT >5x normal or CrCl <30 mL/min	
	– Leukemia not in complete remission or non-leukemia cancer with evidence of disease progression after >2 courses of therapy	
	– Presentation with pneumonia or other complex infection	
	– Alemtuzumab in prior 2 months	
	– Grade 3 or 4 mucositis	
	– MASCC score ≤ 20	
Medium	– Expected 7 to 10-day duration of neutropenia	
	– Lymphoma	
	– CML	
	– Autologous HCT	
	– Purine analog therapy	
Low	– No High Risk features and most of the following criteria are present:	– Anticipated ANC ≤100 cells/μL for <7 days
	– Outpatient at onset of fever	– Absence of renal and hepatic dysfunction
	– No associated acute concurrent condition requiring hospitalization or close observation	– No comorbidities
	– Anticipated ANC ≤100 cells/μL for <7 days	
	– Absence of renal and hepatic dysfunction	
	– Good performance status (ECOG 0–1)	
	– MASCC score ≥ 21

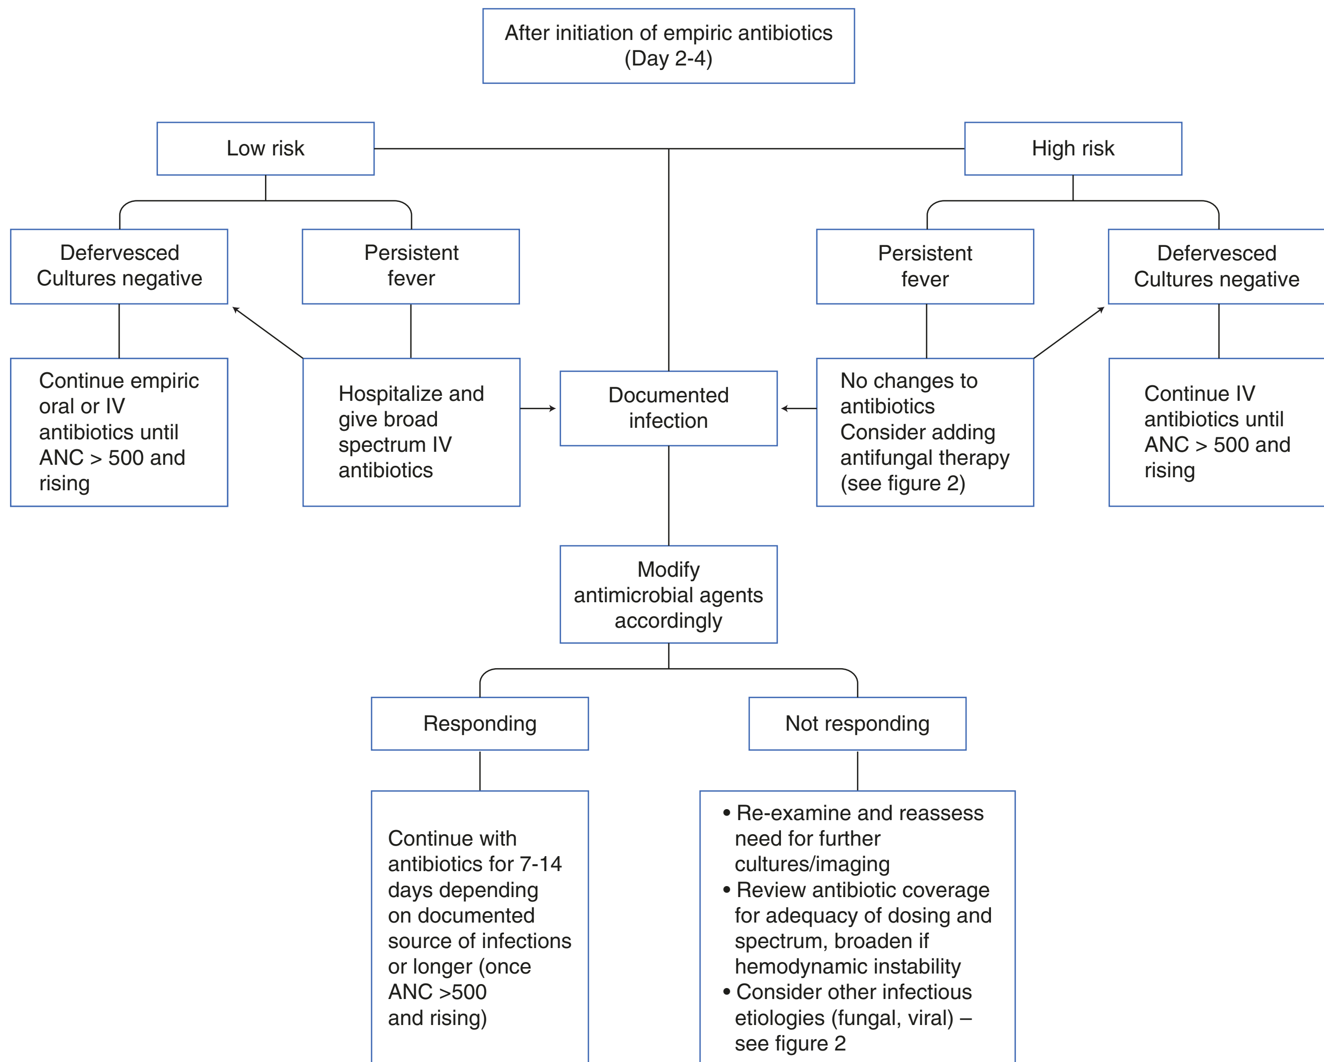

Fig. 50.1 Initial treatment algorithm for febrile neutropenia

Diagnosis

The clinical manifestations of bacterial infections in the patient with hematological malignancies can be very nonspecific due to impaired inflammatory processes. Though much emphasis so far in this chapter has been placed on febrile neutropenia, it is not uncommon for these patients to present with nonspecific findings and be infected despite the absence of fever, or conversely to have a fever as the sole presenting symptom. For the hematological malignancy patient presenting with neutropenic fever, or thought to be otherwise infected, it is imperative to conduct a rapid and thorough workup that focuses on the prompt collection of cultures, especially blood cultures, to enable rapid initiation of broad spectrum empiric antibiotic therapy without compromising their diagnostic yield. The sooner appropriate empiric antimicrobial therapy is initiated the better, as delays in administration correlate with mortality [26, 27].

A thorough history with particular emphasis on pertinent host, underlying malignancy, and antineoplastic therapy factors should be performed in addition to eliciting a listing of careful relevant exposures in the context of the aforementioned factors. The physical exam should be a meticulous head-to-toe examination focused on the skin and mucosal surfaces, oropharynx and teeth, sinuses, heart and lung systems; abdominal, genital and perineal exams should not be overlooked. Peripherally Inserted Central Catheters (PICCs), implanted ports, urinary catheters, old IV sites, procedural sites such as biopsy, aspirate and surgical sites also merit careful visual inspection and palpation. The blunted immune response can manifest in a paucity of inflammatory signs and requires a high index of suspicion.

Peripheral blood counts with white blood cell (WBC) differentials should be obtained as well as at least two sets of blood cultures from the outset when infection is suspected. The hematologic tests serve to both quantify and stratify the

presence and severity of neutropenia, while the blood cultures aim to confirm an infection and identify the causative organism and subsequently determine its antimicrobial susceptibility patterns to tailor anti-infective therapy. When obtaining blood cultures, one should ideally obtain two sets of cultures of 20 mL each in the adult patient. These should be collected from two separate peripheral venipunctures in patients without indwelling venous catheters. In patients with indwelling venous catheters, one set should be from a peripheral venipuncture and one from the indwelling venous catheter. The frequency of subsequent cultures varies depending on the following variables: if fever persists after 24 h on appropriate broad spectrum anti-infective therapy, an additional 2 sets of blood cultures should be obtained and may be repeated a second time after 48 h in the presence of persistent fever. If the fever appears to have defervesced for greater than 48 h and recurs, it is reasonable to repeat blood cultures. Additionally, if initial blood cultures are positive, these should be repeated daily until bacteremia clears regardless of the fever pattern. A study published in 2013 has looked at an alternate single 40 mL sample method from central lines that seems promising, but needs further validation and cost analysis [28].

Treatment

As mentioned throughout this chapter, the prompt recognition and institution of appropriate empiric anti-infective therapy in the potentially infected neutropenic patient with hematological malignancy is life-saving. It is recommended that appropriately selected and dosed antimicrobials are received within an hour of medical contact at a maximum, with administration within 30 min being optimal [23, 26, 29, 30]. The concept of adequate antimicrobial therapy must be highlighted and contrasted with appropriate therapy, and though various somewhat different definitions have been published, we will frame the discussion in terms of the definitions set forth in the joint Infectious Disease Society of America (IDSA) and American Thoracic Society (ATS) guidelines on the management of hospital-acquired, ventilator-associated pneumonia and healthcare-associated pneumonia from 2005 and updated in 2016 [31, 32]. According to these definitions, appropriate antimicrobial therapy is the use of drugs with in vitro activity against the confirmed etiologic agent, whereas adequate treatment implies not only the use of the correct (appropriate) antimicrobial agent, but additionally administering the optimal dose as well as choosing a route for administration that allows for tissue penetration of the drug at the site of infection. In order to provide not just appropriate, but adequate, therapy to the neutropenic patient with hematologic malignancy, host factors as well those related to the underlying malignancy and antineoplastic therapy must be considered in order to determine the patient's risk of developing serious complications of neutropenic fever.

Table 50.3 Key Points: Treatment of bacterial infections

Key points: Treatment of bacterial infections
• Fever may be the only sign of a potentially life-threatening infection in immune-suppressed patients
• Start antibiotics promptly. In high-risk patients, start an antipseudomonal beta lactam agent
• Patients receiving fluoroquinolone prophylaxis should not receive empiric therapy with fluoroquinolones
• Adding vancomycin or an antibiotic with enhanced Gram positive activity empirically is not recommended
• Modifications to empiric treatment should be made based on patient's previous cultures or risks for an infection with a MDRO (e.g., MRSA, VRE, ESBL, CRE, KPC)
• Always tailor antibiotics to the underlying pathogen whenever possible
• Continue with antimicrobial therapy until neutropenia resolves

MDRO multidrug-resistant organisms, *MRSA* methicillin-resistant *Staphylococcus aureus, VRE* vancomycin-resistant enterococci, *ESBL* extended spectrum beta lactamase, *CRE* carbapenem-resistant enterobacteriaceae, *KPC Klebsiella pneumoniae* carbapenemase

In addition to this risk stratification, the patient's drug allergies, prior microbiologic culture data, antimicrobial agent exposures, and the local antibiogram need to be considered [33]. As discussed earlier in the Epidemiology section, the majority of causative organisms in neutropenic fever are Gram positive bacteria, especially skin flora; however, Gram negative bacteria tend to cause more serious clinical disease due to their virulence factors, and they are making a resurgence in terms of their frequency driven in part by the increase in MDROs. Table 50.3 summarizes key points in the treatment of bacterial infections in patients with hematological malignancy.

Those patients who are unable to tolerate oral antibiotics or who are risk stratified into the high-risk category should receive intravenous antibiotics (Fig. 50.1). A number of studies have attempted to find an ideal empiric antibiotic regimen, and no regimen has shown itself to be superior [34–39]. There are a number of acceptable monotherapy options that are as efficacious as combination regimens for empiric therapy in high-risk neutropenic fever syndromes: ceftazidime, cefepime, piperacillin-tazobactam (or other antipseudomonal beta lactam agents), imipenem-cilastatin, meropenem, etc. Combination regimens that use extended spectrum beta-lactams with fluoroquinolones, aminoglycosides, or double beta-lactams have not shown superiority and often increase toxicity [38, 39]. Furthermore, combination regimens that use a second agent to cover Gram positive bacterial organisms do not seem to confer clinical or mortality benefits and also are associated with greater toxicity and bacterial resistance [2, 7, 40–43]. The standard use of vancomycin, linezolid, and other drugs against Gram positive bacteria as part of empiric antibiotic regimens for neutropenic fever should be discouraged. These medications should be reserved for patients with presumed line infections, pneumonia, soft tissue infections, and septic shock.

The importance of knowing the patient's colonization status of resistant bacteria (MRSA, VRE, and other MDROs) and previous culture results cannot be overstated, as many patients with hematologic malignancies are colonized with resistant Gram positive organisms. Once appropriate empiric antibiotic therapy has been instituted in a timely fashion, close attention must be paid to clinical response and the progress of culture (with susceptibility data) to determine adequate therapy. Patients with a persistent unexplained neutropenic fever syndrome, who are clinically stable or improving, do not always require a change in antibiotic therapy for their ongoing fever (Fig. 50.2). Among oncology patients with solid tumors and tumor fever, neutropenic fever usually resolves within 48 h of empiric antibiotics; neutropenic fever among patients with hematologic malignancies can take up to an average of 5 days after initiation of treatment to defervesce [2].

Central line associated bloodstream infections (CLABSIs) are frequently the cause of neutropenic fever in hematologic malignancy patients, and adequate antibiotic administration alone is insufficient to treat these patients, with removal of the offending line being necessary. The exception to this rule is CLABSI due to coagulase negative staphylococci, in which case it may be reasonable to treat through the infection [2]. Catheter removal is recommended for infections with *Pseudomonas aeruginosa*, *Staphylococcus aureus*, fast growing atypical mycobacteria, and *Candida* spp., and with less certainty for other fungal species [2, 44–48]. In these cases, antibiotics should be continued for a minimum of 2 weeks after clearance of bacteremia and removal of the CVC, whichever occurred last. Complicated CLABSIs such as those occurring with deep tissue infections (catheter tunnel tract or port pockets), septic thrombosis or embolisms, endocarditis, or persistent bacteremia (defined as greater than 72 h after initiation of adequate therapy), warrant extended courses of antibiotics in the 4- to 6-week duration range. See Fig. 50.3 for recommendations for management of infected long-term venous access catheters.

In general, the presence of infected material (such as an abscess, a CVC, or a urolith) necessitates both antibiotic penetration and activity to treat the infection. In cases where the drug activity and penetration are suboptimal, removal of the infected material is paramount to achieving control of the infection. Source control requires the removal of infected hardware, drainage of infected fluid collections, or removal of infected tissue or other material. The indications and risk benefit for the interventions already discussed are beyond the scope of this chapter and merit the consultation of infectious diseases specialists, surgeons, or interventional radiologists as clinically dictated.

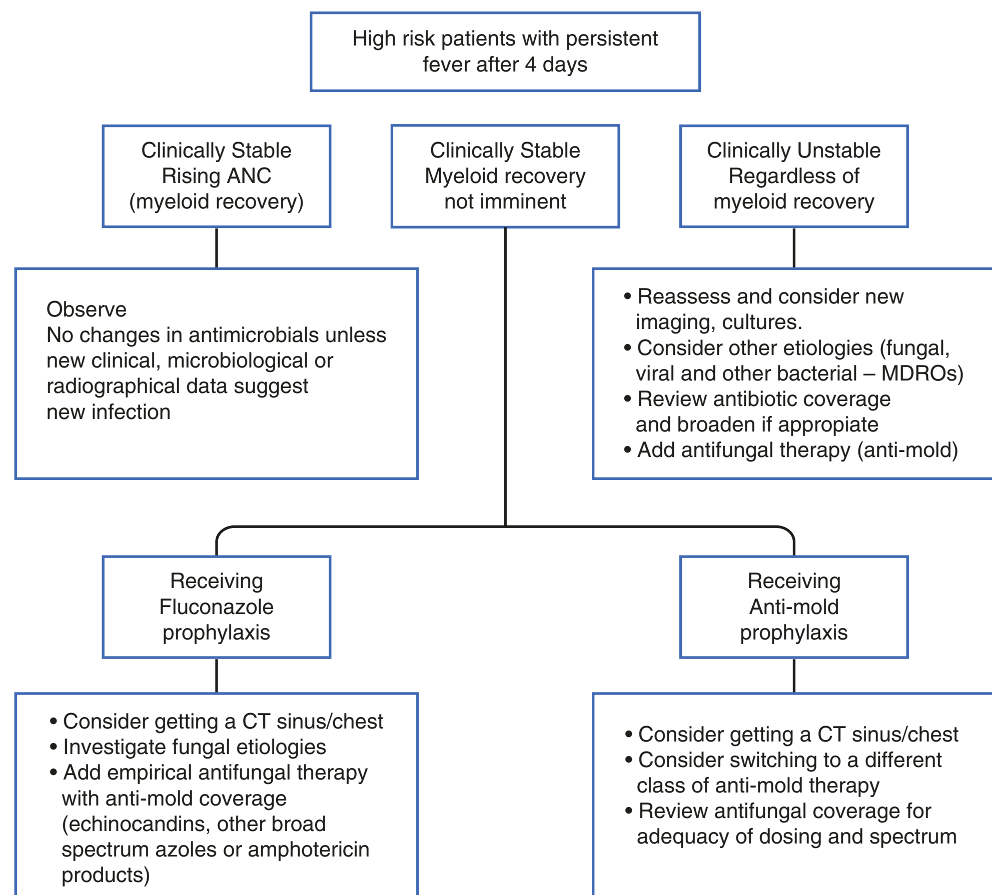

Fig. 50.2 Treatment algorithm for patient with high-risk febrile neutropenia

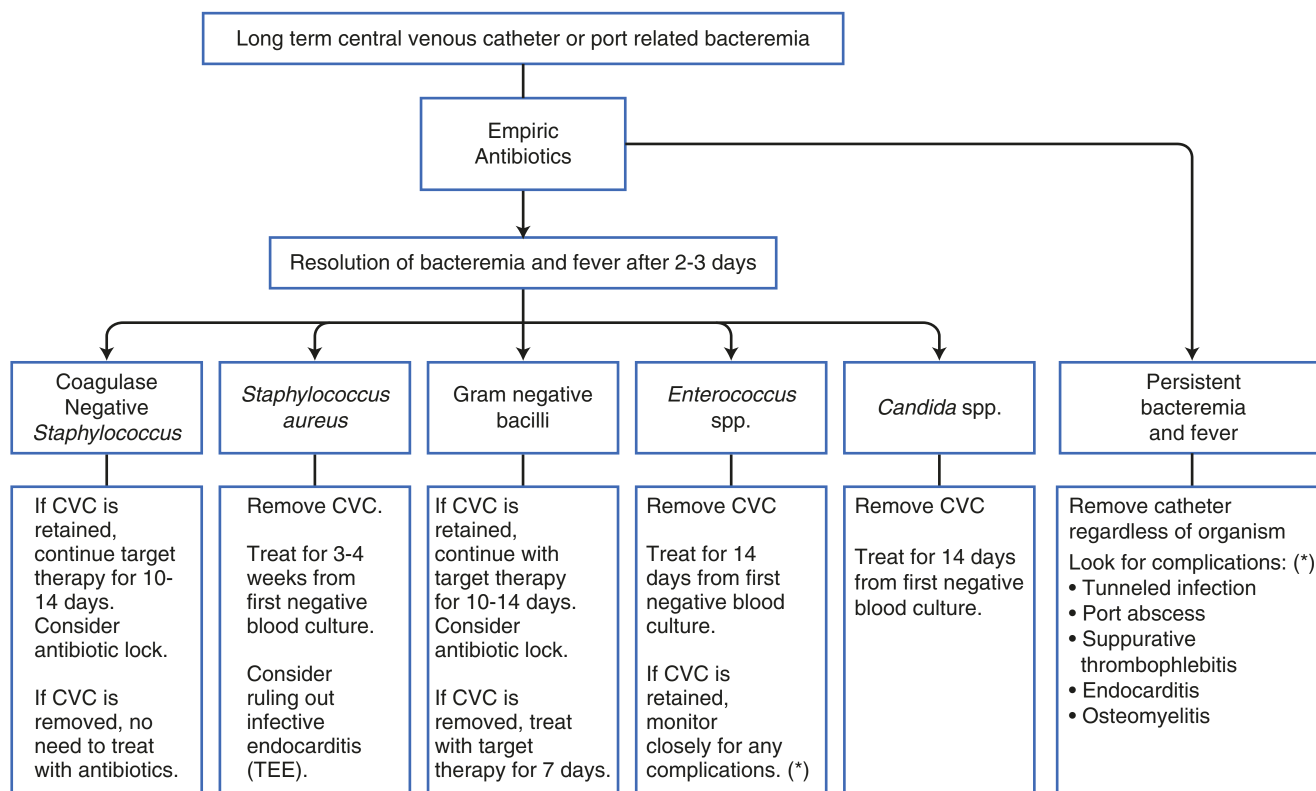

Fig. 50.3 Management of long-term indwelling venous access catheters

Bacterial Prophylaxis

Several studies have demonstrated the utility of antimicrobial prophylaxis to prevent neutropenic fever and infectious complications, especially among high-risk patients [49, 50]. A Cochrane Review meta-analysis in 2012 showed that antibiotic prophylaxis was associated with lower all-cause mortality when compared to placebo or no treatment. Prophylaxis was also associated with significantly reduced occurrence of fever, fewer clinically documented and microbiologically documented infections, and lower risk of infection-related death [49]. Fluoroquinolones (levofloxacin and ciprofloxacin) have been extensively studied given their broad spectrum (covering Gram negative bacteria including *Pseudomonas aeruginosa*, as well as Gram positive bacteria) and good oral bioavailability. Fluoroquinolone prophylaxis reduces the risk for all-cause mortality as well as infection-related mortality [2]. A combination of a fluoroquinolone plus an antibiotic with enhanced Gram positive activity is not recommended [2]. Some studies have shown that this approach may reduce infections caused by *Staphylococcus* and *Streptococcus* spp., but they do not affect infection-related mortality and may increase the rated of resistant bacteria [51–54]. See Table 50.4 for suggested empiric antibiotic regimens for high-risk patients.

There are concerns about toxicities and antimicrobial resistance [52, 55], especially among patients concurrently

Table 50.4 Empiric antibiotic regimens in high-risk patients with febrile neutropenia

Monotherapy options	
Piperacillin/Tazobactam	
Cefepime	
Ceftazidime[a]	
Carbapenems (except Ertapenem since no antipseudomonal coverage)[b]	
Add these antimicrobials based on culture data or specific clinical scenarios	
Vancomycin	If suspected MRSA infection such as cellulitis and/or pneumonia
Linezolid	If suspected VRE infection
Daptomycin	If suspected MRSA or VRE infection, although cannot be used for pulmonary infections as it is inactivated by surfactant
Aminoglycoside/Colistin	If suspected Gram negative MDRO involvement (ESBL, CRE, KPC)
Metronidazole	If suspected intraabdominal infection

[a]Ceftazidime monotherapy has been used for many years, however has less Gram positive coverage than cefepime
[b]Use Carbapenems for patients at high risk of MDROs
MRSA methicillin-resistant *Staphylococcus aureus, VRE* vancomycin-resistant enterococci, *MDRO* multidrug-resistant organisms, *ESBL* extended spectrum beta lactamase, *CRE* carbapenem-resistant enterobacteriaceae, *KPC Klebsiella pneumoniae* carbapenemase

using QT prolonging medications such as amiodarone or voriconazole. In 2016, the Food and Drug Administration (FDA) issued safety warnings about fluoroquinolones causing acute tendonitis, neuropathy, and central nervous system side effects, which has led to a revision of the package inserts for these medications.

The optimal timing for initiation and duration of antimicrobial prophylaxis has not been well studied. Some clinicians will start prophylaxis on the first day of cytotoxic chemotherapy even for those patients not yet neutropenic, while others will do so on the last day of chemotherapy. It is common to discontinue prophylaxis when the neutropenia has resolved.

Fungal Infections

Invasive fungal infections (IFIs) cause significant morbidity in patients with hematological malignancies and stem cell transplants. This section will elaborate on the epidemiology, clinical syndromes, diagnosis, and treatment of the most common IFIs in this population. IFIs are categorized into those caused by yeasts or molds, of which a basic microbiologic understanding is useful when we think about the syndromes and the term "mold active" antifungal agent. Yeasts are single cell organisms that reproduce by budding and include genera such as *Candida* or *Cryptococcus*, among others. Mold organisms have a filamentous growth stage that allows them to elongate by branching with longitudinal extension, and can be further categorized as opportunistic or endemic infections. The morphology of filamentous hyphae on pathology specimens plays an essential part in diagnosis and early management of mold infections. The most common opportunistic mold organisms include *Aspergillus*, *Mucor*, *Rhizopus*, and *Fusarium* species, while *Histoplasma*, *Blastomyces*, and *Coccidioidomyces* species comprise most of the common endemic fungi.

Candida

Candida yeasts are saprophytic organisms commonly found on the skin and mucosal surfaces of humans. Infections with these organisms can cause superficial (oral thrush, esophagitis, dermatitis, and vaginitis, etc.) and/or deep infections (candidemia, visceral organ abscesses, endophthalmitis, and many others). Herein we focus on the invasive forms of candidiasis (IC), which cause significant morbidity and mortality among hematologic cancer patients and stem cell transplant (SCT) recipients. Prior to the use of antifungal prophylaxis, the incidence of disseminated candidemia was approximately 17% among patients with hematologic malignancies [56, 57] and 11% after SCT [58, 59]. Mortality for patients with IC ranged from 39 to 73% [58, 59]. Autopsy studies in SCT patients from the 1980s suggest overall prevalence of *Candida* infections was 28% [60]. Table 50.5 summarizes key points in the management of *Candida* infections.

Table 50.5 Key points: *Candida* spp.

Key points: *Candida spp.*
• The incidence of non-albicans *Candida* is more common than *C. albicans*.
• Non-albicans *Candida* organisms are frequently fluconazole resistant (*C. krusei* and *C. glabrata*)
• Empiric therapy for yeast identified in the blood is an echinocandin, which is then de-escalated pending species identification

Risk Factors and Epidemiology

In addition to the risk factors for IC in the general population (CVCs, broad spectrum antibiotics, and total parenteral nutrition) [61], those with hematologic malignancies are at increased risk of disseminated disease secondary to prolonged neutropenia [62–64], use of antibacterial antibiotics [62, 64], *Candida* colonization [19, 52, 60, 65, 66], and mucosal damage from cytotoxic chemotherapy [62]. Specifically, neutropenia lasting over 15 days is a risk for hepatosplenic candidiasis [62].

Over time the incidence of infection by non-albicans *Candida* spp. is increasing [67, 68], and even surpassing the incidence of *Candida albicans* infections in the United States [68–70]. Hematology patients are at increased risk for specifically *C. glabrata* [63, 67], *C. krusei* [63, 71, 72], *C. tropicalis* [72, 73], *C. guilliermondii* [72], and emerging *Candida* spp. such as *C. dubliniensis* and *C. kefyr* [72]. This evolution of epidemiology is important as these species can be resistant to fluconazole and to a lesser extent voriconazole [72].

Clinical Presentation

The most common clinical presentation of IC in hematologic malignancy patients is fever. Acute disseminated candidiasis can result in severe sepsis and multiorgan failure. Early descriptions of IC from autopsy studies in the 1980s (prior to the use of antifungal prophylaxis in the 1990s) in subjects with acute leukemia report fever refractory to antibiotics or a second episode of fever. At autopsy, often multiple organs were involved [65, 74]. By the late 1990s fever was being reported in 99% patients with malignancies and was most often it was low grade [75].

Chronic disseminated candidiasis or hepatosplenic candidiasis deserves special attention as this entity occurs almost exclusively among patients with acute leukemia. Epithelial damage that occurs along the gastrointestinal mucosa from cytotoxic chemotherapy enables *Candida* to enter the hepatobiliary circulation, resulting in hepatic and splenic microabscesses. Symptoms of disease develop later into the course

of infection, usually just after neutrophil recovery, when neutrophils can migrate to the sites of the microabscesses. As with acute IC, persistent fever is the most common manifestation, sometimes accompanied by right upper quadrant abdominal pain, tenderness, and an elevated alkaline phosphatase. An immune reconstitution-like syndrome has been hypothesized given the timing of symptoms following neutrophil recovery [76].

Diagnosis

There is no true gold standard for the diagnosis of IC, and limitations of culture and non-culture diagnostic tests make this challenging. While diagnosis often relies on positive blood cultures, and blood culture technology has improved over the decades, overall sensitivity of blood culture has been estimated to remain approximately 50% [77]. IC can be divided into three groups: candidemia in the absence of deep-seated infection, candidemia associated with deep-seated infection, and deep-seated candidiasis that is not associated with candidemia. Blood culture systems, while as sensitive as PCR in vitro, may capture 75% of group 1 and 2 above, leading to an overall sensitivity of 50% [77]. The 2- to 3-day turnaround time of blood cultures often delays diagnosis [78]. Of note, in hepatosplenic candidiasis (the third group described above), blood cultures may be positive in only 20% of cases, with tissue culture positivity in approximately 50%.

Non-culture-based techniques include antigen/antibody testing, β-D-glucan, and PCR, which can be used adjunctively with blood cultures. There are several limitations of these non-culture-based tests, some of which include the rapid clearance of antigen/antibody from the circulation and limitations in immunocompromised hosts. β-D-Glucan (a component of the fungal cell wall) is not specific for *Candida*, has poor specificity, and false positivity among immunocompromised patients who are at risk for a number of fungal pathogens. PCR is problematic in that there is a lack of standardization in methodologies and has similar limitations to β-D-glucan testing. Currently these tests are not considered standards in making the diagnosis of invasive candidiasis [77, 78]. There are no guidelines for interpreting these non-invasive diagnostic tests, because they provide adjunctive information to blood cultures and should not be ordered in place of blood cultures.

T2Candida is a newer diagnostic modality that is being implemented into some clinical practices. T2 diagnostic testing involves a miniaturized, magnetic resonance-based diagnostic approach that measures how water molecules react in the presence of magnetic fields. The T2Candida Panel test seems to be capable of improved sensitivity compared to blood culture, using automated systems with a turnaround time of 3–5 h [79]. In some instances, the T2Candida Panel test may be positive up to a week prior to blood culture [79].

Treatment

Treatment of ICs has been extensively reviewed and updated by the IDSA in 2016 [78]. Due to the increase in non-albicans infections, with the potential for fluconazole drug resistance, it has become standard practice that echinocandins (either anidulafungin, caspofungin, or micafungin) are initiated empirically upon microbiologic diagnosis of candidemia until speciation is known. Fluconazole is used in the majority of *C. albicans* infections given the >95% sensitivity of isolates to this drug. Treatment durations range from 2- to 4-weeks on average, depending on the underlying disease [78]. Dilated retinal exams are recommended on all patients with candidemia, but can be delayed until neutrophil recovery in hematologic patients. Removal of CVCs is also widely implemented in clinical practice.

Antifungal Prophylaxis

With the advent of a well-tolerated antifungal drug (fluconazole), initial studies from the 1990s showed that prophylactic fluconazole significantly reduced *Candida* colonization [56], reduced invasive *Candida* infections [80], and decreased the incidence of superficial and systemic IC among SCT recipients, with improvements in survival [81, 82]. A randomized placebo-controlled trial of fluconazole prophylaxis in neutropenic cancer patients identified that patients who benefited most from prophylaxis included those with acute myeloid leukemia undergoing induction with anthracycline-based regimens and those receiving autologous transplants not supported with hematopoietic growth factors [57]. Low dose (200 mg daily) of fluconazole was found to be as efficacious to high dose (400 mg daily) in preventing candidal infections among SCT recipients [83]. Since those pivotal studies, the use of fluconazole prophylaxis has become standard protocol throughout many hematologic and transplant centers and is supported by the National Comprehensive Cancer Network (NCCN) guidelines. Meta-analysis studies of antifungal prophylaxis in neutropenic chemotherapy recipients [84] and stem cell transplant recipients [85] report reduced morbidity, superficial and invasive fungal infections, and fungal infection-related mortality with the use of antifungal prophylaxis [84, 85].

Opportunistic Molds

The term invasive fungal disease (IFD) was coined by the European Organization for Research and Treatment of Cancer (EORTC) Invasive Fungal Infection Cooperative Group and the National Institute of Allergy and Infectious Diseases Mycoses Study Group (NIAID-MSG) in 2008 to describe any disease process dealing with fungi in high-risk patients [86]. The IDSA has now expanded their guidelines

to include other groups of patients at risk such as solid organ transplant and those with primary immunodeficiencies [87]. For the purposes of this section we will refer to IFD as it relates to pathogenic mold fungal infections among hematologic patients, and the discussion will be limited to *Aspergillus*, the agents of Zygomycetes infections (*Mucor*, *Rhizopus,* and *Rhizomucor*) and *Fusarium*, the most common mold infections.

These fungi are saprophytic environmental molds that propagate on decaying soil. Concomitant environmental exposure and host immune deficiency are necessary for invasive disease, of which inhalation of fungal spores is the most common portal of entry. These molds grow by longitudinal extension and branching of filamentous hyphae and are angioinvasive. The morphologic appearance on pathology specimens is pivotal in diagnosing these infections (i.e., *Aspergillus* are seen as branching acute angle septate hyphae, while Zygomycetes are seen as non-septate, broad, ribbon-like hyphae).

Common Features of Invasive Fungal Diseases

There is significant overlap in the clinical and radiographic features of *Aspergillus*, Zygomycetes, and *Fusarium*. Early descriptions of invasive aspergillosis (IA) included persistent fever with pulmonary infiltrates in patients with acute leukemia [74, 88, 89], which also commonly occurs in Zygomycetes [90] and *Fusarium* [91, 92]. The range of pulmonary symptoms includes cough, hypoxemia, shortness of breath, pleuritic chest pain, and (given the angioinvasive character of these fungi) hemoptysis. Risk factors for infection have been extensively studied and include prolonged neutropenia, corticosteroids, and acute leukemia [89, 93–96]. In addition, those patients with active malignancy, persistent neutropenia at the end of treatment, and delayed initiation of treatment are associated with poor survival [97–99]. Delayed therapy for ≥10 days and 6 days has been associated with worse survival in *Aspergillus* [100] and Zygomycetes [99] infections, respectively. Utilization of high-resolution chest computed tomography (CT) scans has allowed earlier diagnosis of IFDs and hence improvement in outcomes with initiation of antifungal therapy.

After entry into the lungs, these mold infections can spread by either direct extension or systemic dissemination via the blood system and angioinvasion [101]. Pulmonary disease is the most common manifestation of infection [102–104], with lung involvement occurring in 90% of cases in one single center study [105]. IA does have a predilection to cause central nervous system disease, either through hematogenous dissemination or contiguous spread from the sinuses, however dissemination into any organ can occur [101]. Table 50.6 summarizes key points regarding invasive mold infections.

Table 50.6 Key points: Invasive fungal diseases

Key points: Invasive fungal diseases
• Invasive aspergillosis is the most common invasive fungal disease among immune-compromised patients
• Rhino-cerebral disease more commonly occurs in Zygomycetes infections
• Ribbon-like non-septate hyphae are characteristic of Zygomycetes histopathology
• Skin manifestations commonly occur in disseminated *Fusarium* infections

Epidemiology

Aspergillus

Invasive aspergillosis is the most common of the opportunistic mold infections occurring in patients with hematologic malignancies and SCT. The actual overall incidence of IA is difficult to estimate; however, the use of non-culture-based diagnostic tests has expanded the number of patients who will be defined as “possible” cases [106]. Among all causes of IFDs among immunocompromised and immunocompetent patients, IA represents approximately 70% of mold infections, with 85% of those occurring in patients with hematologic malignancies and SCT recipients [107]. The majority of IA occurs during the first course of induction chemotherapy for those with AML [108], when mold-active prophylaxis is not routinely employed. A bimodal distribution of IA has been described after SCT, with early disease being related to underlying myeloid deficiencies and late disease (after day 100) related to graft-versus-host disease, steroids, and immunosuppression [108]. *Aspergillus fumigatus* is the most common species isolated [102, 104, 107, 109], followed by *A. flavus*, *A. niger*, and *A. terreus* [102]. A history of aspergillosis during chemotherapy for AML does not preclude progression to transplantation, but the infection should be well controlled unless activity of the underlying transplant condition is the reason why aspergillosis cannot be controlled.

Survival and mortality vary significantly depending on the study and have been reported as 59% survival after hematologic malignances at 12 weeks [102], to 43–62% with hematologic malignancy or after SCT [102, 105, 110]. Factors for poor survival include SCT, progression of underlying disease [111, 112], steroid use [110, 113], neutropenia [112, 113], disseminated disease [113], and extent of pulmonary lesions [105].

Zygomycetes

Common Zygomycetes molds include organisms in the genera *Mucor*, *Rhizopus*, *Rhizomucor*, *Lichtheimia* (formerly *Absidia*), and *Cunninghamella*. Among hematologic malignancy patients, the most common presentation mimics IA; however, Zygomycetes infections do have a greater propensity

to have sinus or rhinocerebral involvement [114–116]. The presence of sinus disease favors Zygomycetes, but does not rule out IA. In the two largest prospective studies on Zygomycetes, the incidence of pulmonary disease ranged from 30 to 46%, with rhinocerebral disease occurring in 27–29% [115, 116]. Single center studies prospectively comparing IA to Zygomycetes infections in those with hematologic malignancies report that sinusitis and rhinocerebral manifestations were significantly more common in those with Zygomycetes infections compared to *Aspergillus* [96, 99]. Other independent predictors for Zygomycetes also included prior use of voriconazole [96, 114], the presence of multiple pulmonary nodules (≥10 nodules), and pleural effusions [114]. Taken together, the two most significant distinguishing factors for Zygomycetes infections include sinus disease and breakthrough IFD on voriconazole prophylaxis.

Worse outcomes have been associated with active malignancy [97, 99], delay in therapy [99], and pulmonary and disseminated disease [93, 116]. A single center retrospective study showed that delay in initiation of an amphotericin product resulted in a twofold increased mortality at 12 weeks [99], which has been confirmed in other studies [115]. Use of posaconazole [99] and neutrophil recovery are associated with favorable outcomes [90, 99]. Mortality ranges from 52% in those with hematologic malignancies to 76% after stem cell transplant [116]. Interestingly, in one small pilot study, radiographic improvement was not predictive of 90-day survival, and 50% who survived did not have improved CT or magnetic resonance imaging at the end of treatment. However, clinical response 30 days after the end of treatment was predictive of survival at 90 days after treatment [97].

Fusarium

Notable characteristics that distinguish *Fusarium* from the above infections is the propensity for disseminated disease (not just pulmonary involvement), skin manifestations that occur in approximately 60% of infections, and the ability to grow in blood cultures in 40–55% of cases [91, 98]. The pulmonary nodules that occur in *Fusarium* infections tend to have more peripheral involvement compared to Zygomycetes or *Aspergillus* infections [117].

Fusarium solani is the most commonly reported isolate representing >50% of the *Fusarium* cases reported in the literature [92, 95, 98]. The most common skin manifestation is multiple painful erythematous papular or nodular lesions with or without central necrosis, and can also manifest as ulcerations, bullae, or ecthyma gangrenosum [118]. Skin lesions have been described to precede fungemia by 5 days [95, 119]. Early descriptions of *Fusarium* in hematologic patients reported fever refractory to antibacterial therapy with painful skin lesions in 91% of infections, with presumed pneumonia and sinusitis occurring in 84% and 26%, respectively [92].

Diagnosis

The EORTC/MSG and IDSA all support a composite definition for the diagnosis of IFD that includes host factors, clinical manifestations, and mycologic evidence of infection. Utilizing these criteria, patients are grouped as either proven, possible or probable IFD, with proven infection necessitating tissue biopsy with pathologic evidence of fungi invading tissue. Probable is the most common category in clinical practice, which includes a host factor (such as allogenic SCT, corticosteroids, T cell immune-suppression, or recent history of neutropenia >10 days), clinical features (such compatible CT imaging), and mycologic evidence (direct or indirect mycologic testing) be present [86].

Use of high-resolution CT imaging and non-culture-based diagnostic testing improves early diagnosis of IFD in hematologic patients, which in turn impacts outcome. There are several classic patterns of IFD on high-resolution CT of the lung, including the halo, air-crescent, or reverse halo sign [120]. The macronodule is the most common manifestation of IA [121]. A macronodule surrounded by ground glass (the halo sign) pathologically represents an area of fungal tissue invasion surrounded by alveolar hemorrhage [87, 120, 122]. The halo sign occurs early in the course of IFD, and while not specific for IA, it commonly occurs among hematologic patients with invasive aspergillosis (92–95% of patients in small series) [120, 123, 124]. The reverse halo sign, a focal area of ground glass opacity surrounded by a ring of consolidation, also occurs early in the course of IFD, but is more associated with infections caused by the agents of Zygomycetes rather than *Aspergillus* [120]. As neutrophils recover, cavitation and gas formation may occur, denoting the air-crescent sign.

Treatment

Azole antifungal agents (fluconazole, itraconazole, voriconazole, posaconazole, and isavuconazole) are the most commonly used class of agents used to treat IFD infection, given their improved tolerability profile over amphotericin products. Table 50.7 expands upon the different antifungal agents, with expanded coverage of the higher generation azole antifungal agents. Echinocandins (micafungin, caspofungin, and anidulafungin) have good *Aspergillus* coverage, but lack activity against the agents of Zygomycetes and *Fusarium*. These are often used along with an azole for dual drug or salvage therapy for *Aspergillus*. Finally, amphotericin products do have a broad spectrum, but are most commonly used to treat Zygomycetes infections. Nephrotoxicity and infusion-related reactions are the most common limiting factors in using these agents. Knowledge of the antifungal spectrum that is used for prophylaxis is essential in making early treatment choices for suspected IFDs and breakthrough fungal infections.

Therapy for *Aspergillus*: In 2002 a randomized clinical control trial showed better treatment responses and improved

Table 50.7 Key points: Commonly used Antifungal agents

Class of antifungal agent	Route of administration	Individual antifungal agent	Characteristic
Azole (Liver metabolism effects)	Water soluble	Fluconazole	– Most activity with *Candida albicans* and *Candida parapsilosis*
	IV and enteral		
		Voriconazole	– Predictable visual side effects
		Isavuconazole	– Zygomycetes activity
			– Administered as a prodrug
	Lipid soluble	Itraconazole	– Absorption variable
	For the most part, used enterally		– Enteral agent only
		Posaconazole	– Zygomycetes activity
			– Extended release form with reliable absorption
Echinocandin	IV only	Anidulafungin	– None of these agents cover *Cryptococcus* or Zygomycetes
		Caspofungin	
		Micafungin	
Polyene	For the most part, used IV	Amphotericin products	– Zygomycetes activity
			– Considered fungicidal
			– Nephrotoxicity common
			– Infusion-related side effects
		Nystatin	Topical agent only

IV intravenous

survival with voriconazole as compared to amphotericin-B [109], which has been confirmed by two superseding studies [105, 113]. Given the high mortality of IA in immune-compromised patients, combination antifungal therapy is often considered for patients with a high risk of death and for critically ill patients. This usually consists of voriconazole plus an echinocandin. A randomized, controlled trial of voriconazole monotherapy versus combination therapy was published in 2015 [125]. There was a trend toward improved mortality at 6 weeks with combination therapy in patients with hematological malignancy or SCT, although statistical significance was not obtained.

Therapy for Zygomycetes: Mold active agents with activity against Zygomycetes include amphotericin, posaconazole, and isavuconazole. Double coverage of amphotericin and posaconazole is the most common regimen used early in the course of therapy. Surgical debridement in those with sino-cerebral disease is an important part of therapy and improves outcomes [90, 93, 126]. Hyperbaric oxygen and granulocyte transfusions are often considered in those with severe disease.

Therapy for *Fusarium*: The most common regimens for therapy include voriconazole with or without amphotericin, and therapy should be based on the isolate's sensitivities. Neutrophil recovery is essential for recovery from *Fusarium* infections [63, 91], with some series reporting 0% survival without recovery from myelosuppression [92]. Granulocyte transfusions can be considered as an adjunct to antifungal therapy, working as a bridge until recovery from myelosuppression. Steroid use is also associated with poor outcome [91].

Summary

The evaluation of potential bacterial and fungal infections in patients with hematological malignancies necessitates a careful understanding of host, underlying disease, and anti-neoplastic therapy factors. The likelihood of infections that one is likely to encounter will influence the types of diagnostic testing and empiric treatment that should be ordered. Additionally, empiric and targeted treatments are influenced by the current knowledge of local microbial prevalence and antimicrobial resistance patterns. Providers managing these patients need to have a good understanding of these concepts and are encouraged to involve infectious diseases experts in the management of these complex patients, especially when facing poor clinical response to anti-infective therapy, MDROs, and fungal infections. To be certain, this is a constantly changing field, if nothing else due to microorganisms' ability to constantly evolve and adapt; therefore, we must remain flexible, observant, and willing to adapt as well.

Viral Infections in Patients with Hematological Malignancies

51

Jack W. Hsu, John W. Hiemenz, John R. Wingard, and Helen Leather

Introduction

Enormous advances in the control of bacterial and fungal pathogens have occurred over the last decade. Although host factors such as impairment of granulocyte function or impaired mucosal barrier integrity are major risk factors for bacterial and fungal pathogens, compromise of cell-mediated immunity, especially of cytotoxic thymus-derived lymphocytes (T cells), appears to be most significant in accounting for susceptibility to viral pathogens. As dose intensity of the chemotherapeutic regimens used in the therapy of hematological malignancies has escalated over the last decade, greater susceptibility to viral pathogens has emerged.

Patients receiving therapy for leukemia or lymphoma and those undergoing bone marrow transplantation are susceptible to a variety of viral pathogens (Table 51.1). The most significant viral infections are caused by members of the herpesvirus family. In recent years there has also been increasing recognition of important manifestations of other viruses. In this chapter various viral infections will be described, and current approaches to treatment and prevention will be reviewed.

Herpesvirus Family

The herpesviruses are large double-stranded DNA enveloped viruses, which commonly infect humans. Typically, the primary infection is mild and self-limited and requires no therapy in the normal host. The human herpesviruses that cause infection are herpes simplex virus type 1 (HSV-1), herpes simplex virus type 2 (HSV-2), varicella zoster virus (VZV), cytomegalovirus (CMV), Epstein–Barr virus (EBV), and human herpesvirus type 6 (HHV-6). Human herpesvirus type 7 (HHV-7) has also been isolated, but its role in illness has not been elucidated. Human herpesvirus type 8 (HHV-8) gene sequences have been identified in tissue specimens of Kaposi's sarcoma and some types of non-Hodgkin's lymphoma, and an association with multiple myeloma has also been proposed.

Following resolution of the manifestations of the primary infection, lifelong latency can occur in normal hosts; the sites of latency are sensory nerve ganglia for HSV and VZV and leukocytes for CMV, EBV, and HHV-6. Endogenous virus can subsequently cause a reactivated infection in both normal and immunocompromised hosts. Generally in the normal host, reactivated infections have milder clinical symptomatology. All have been implicated as pathogens in patients with hematologic malignancies with the capacity to cause more severe clinical manifestations.

Herpes Simplex Virus

Patterns of Infection

Infections with HSV-1 frequently occur in early childhood. Transmission of virus occurs through contact with oral secretions. Transmission of HSV-2 occurs through contact with infected genital secretions, and thus infection generally occurs later in life, after adolescence. Clinical manifestations of HSV-1 include oral or nasolabial vesicles or ulcerations, keratoconjunctivitis, or encephalitis, whereas HSV-2 primarily causes genital vesicles or ulcerations. Serological conversion occurs with the primary infection, and the presence of IgG antibody provides an excellent indicator of prior infection and the presence of latent virus.

HTLV/HIV
West Nile

Immunocompromised patients are more susceptible for reactivation and potentially more severe manifestations [1] than normal hosts. In general, the intensity of chemotherapy regimens used in the treatment of hematological malignancy and the depth of depression of cell-mediated immunity correlate with both the risk for reactivation and the severity of the resulting clinical manifestations (Table 51.2). In seropositive bone marrow transplant (BMT) patients, the risk for recurrence is 70–80% [2, 3]. In adult acute leukemia patients undergoing induction therapy, there is a similar 60–70% frequency of reactivation [4]. In patients receiving ambulatory chemotherapy regimens for non-Hodgkin's lymphoma, the risk is lower, in the range of 40–50% [5, 6]. For comparison purposes, in patients receiving outpatient regimens for solid tumors (which are generally much less intensive than regimens used in the treatment of hematological malignancies), the recurrence rate is generally less than 10–25% [7, 8].

Table 51.2 Rates of herpes simplex virus type 1 (HSV-1) and varicella zoster virus (VZV) infections in different patient groups

	Reactivation	
Group	Rates of HSV-1 infection (%)	Rates of VZV infection (%)
Bone marrow transplant	70–80	20–50
Acute leukemia	60–70	30
Hodgkin's lymphoma	40–50	15–20
Non-Hodgkin's lymphoma	40–50	5–10
Solid tumors	10–25	5

Diagnosis, Prophylaxis, and Treatment

The manifestations of HSV-1 infection in patients with hematological malignancies are generally intraoral. Frequently, the labial lesions typically seen in the nonimmunocompromised host are absent and the oral ulcerations are indistinguishable from stomatitis due to tissue damage from cytoreductive therapy; thus, this distinction can pose a difficult diagnostic challenge. The concomitant occurrences of HSV infection and chemotherapy-induced mucosal damage result in a more severe form of mucositis [9]. The lesions tend to be larger, slower to heal, and more apt to become secondarily infected by bacterial opportunists. Atypical cutaneous satellite lesions may occur by autoinoculation of infected oral secretions into cutaneous abrasions. Extensive and deep oral ulcerations can lead to a greater susceptibility for bacteremia by α-streptococci, especially *Streptococcus mitis*, an organism that normally resides on the buccal mucosa [10]. Typically, HSV-2 infections cause vulval, intravaginal, or perianal ulcerations or vesicles.

Although the oral and genital mucosa are the primary sites of HSV infections, in the immunocompromised host extension to the esophageal and tracheal mucosa may occur [11–15].

Esophagitis can be caused by HSV alone or as part of a polymicrobial infection (especially Candida and CMV) [12, 16]. Endoscopic biopsy is important to distinguish various etiologies. Dissemination and involvement of visceral tissues can occur in profoundly immunocompromised patients [13–15, 17–19]. Herpesvirus pneumonia was noted to account for up to 5% of nonbacterial pneumonias among allogeneic BMT patients [18, 20] in the preantiviral era.

Cultures of infected secretions or lesions permit confirmation of the diagnosis. Rapid methods using the shell vial technique coupled with antigen detection procedures [21] or using antigen detection immunofluorescent or immunoperoxidase assays alone [22–24] offer quicker and easier alternatives but may be less sensitive or specific. Cytologic examination of cells scraped from lesions using the Tzanck procedure can show the multinucleated giant cells caused by

herpetic infection; this is rapid but relatively insensitive and cannot distinguish HSV from VZV. Detection of viral DNA by polymerase chain reaction (PCR) is an alternative to culture with similar sensitivity and specificity [25]. Although as noted serology can identify patients at risk for reactivation, it is not of value for the diagnosis of infection.

Typically the lesions from HSV infection occur 7–21 days after initiation of chemotherapy. This association with active therapy and its predictable temporal occurrence in seropositive patients has led to the development of prophylaxis strategies, as discussed next. In patients who are not being actively treated but who have severe deficiency of cell-mediated immunity due to progressive disease, malnutrition, cachexia, use of high-dose corticosteroids, or severe graft-versus-host disease (GvHD) after marrow transplantation and in patients with the acquired immune deficiency syndrome (AIDS), infection can occur at any time, and chronic progressive infections may occur.

Acyclovir, a purine analogue, is highly active against HSV types 1 and 2. Its phosphorylation by a viral-encoded thymidine kinase is necessary for its activation. Its poor phosphorylation by homologous cellular enzymes offers antiviral specificity. Further phosphorylation by cellular enzymes then occurs. Inhibition of the viral-encoded DNA polymerase provides additional antiviral specificity and accounts for its selective antiherpes activity. Finally, the triphosphorylated acyclic nucleoside is incorporated into the viral DNA chain, leading to chain termination and production of a defective virion.

Acyclovir has been demonstrated to be highly effective in both prophylaxis and treatment of HSV infections in patients with hematologic malignancies (Table 51.3). A variety of oral and intravenous regimens have been evaluated and found to be effective [3, 4, 26–32]. In treatment studies, shortening of the duration of viral shedding, time to pain relief, and interval until healing of lesions have been demonstrated. In prophylaxis studies, excellent control with few breakthrough infections has been noted. Because of its poor bioavailability (only 15% after oral administration), caution should be exercised in patients who may have difficulty in tolerating oral medications, such as patients with severe mucositis or gastrointestinal toxicity, in order to ensure adequate plasma concentrations. Acyclovir is generally well tolerated but may be associated with nephrotoxicity if patients are not adequately hydrated or infusions are given too rapidly. Rare reports of reversible neurotoxicity, including tremulousness, lethargy, agitation, and disorientation, have been reported; these toxicities resolve with discontinuation of the drug [33, 34].

Valacyclovir, the L-valyl ester of acyclovir, is a prodrug that is metabolized to acyclovir within minutes of oral administration [35]. The bioavailability of acyclovir with this prodrug is approximately 50% [36]. Plasma acyclovir levels are substantially higher and approximate those achieved with intravenous acyclovir [37]. Less frequent dosing is thus possible.

It is important to note that acyclovir is virustatic and suppresses viral replication only during the interval of drug administration. Following cessation of acyclovir, reactivation frequently occurs. When used in neutropenic leukemia and BMT patients, a course of therapy is generally given until neutrophil recovery. Recurrences after neutrophil recovery tend to be milder and self-limited and may not require retreatment. Often in nonneutropenic patients, treatment is given for 10–14 days. If severe immunodeficiency persists, lower dose maintenance therapy is sometimes advocated to prevent recurrence after the lesions are healed, to be continued until immunity is more robust.

There is considerable debate as to the relative merits of prophylaxis versus waiting until an established infection is documented before initiating treatment. Factors to be weighed in choosing between prophylaxis and treatment include the likelihood of infection, the depth of host immune deficiency, and the severity of infection if it occurs. Thus, while prophylaxis might be an acceptable strategy for BMT patients, in whom the risk for infections and morbidity are high, it would be of little use in patients with hematological malignancy not on active treatment, in whom the risk and morbidity of infection would be low. In BMT patients, it is currently advised to start acyclovir prophylaxis at the start of conditioning therapy and continue until engraftment occurs, resolution of mucositis, or approximately 30 days after HCT [28].

Table 51.3 Treatment of herpes simplex virus infection with acyclovir

	Viral and clinical response					
Parameter	Acyclovir [30] (IV)	Placebo (IV)	p^a	Acyclovir [29] (PO)	Placebo (PO)	p^a
Median day (range) to						
Negative cultures	3 (1–8)	18 (4–49[b])	0.00005	2	>9	0.0008

[a]Compared by Kaplan–Meier plots and analyzed by Mantel–Cox test
[b]Patient removed from study and given open-label acyclovir

The issue of the emergence of acyclovir resistance is an important consideration in this regard. In BMT patients prophylaxis has been associated with a very low risk for drug resistance [38, 39]. In contrast, repeated treatment episodes of established HSV infection in BMT patients have been associated with progressively increasing rates of resistance [40]. An explanation for this apparent lower risk of resistance seen with prophylaxis has been suggested [41]. Certainly, the gradually improving host immunity that occurs with successful marrow transplantation and the relatively short duration of prophylaxis are contributory, because prolonged acyclovir prophylaxis in advanced AIDS patients, who have relentlessly deteriorating immunity, has been associated with a substantial risk for resistance. Initial reports of acyclovir-resistant HSV infection suggested that virulence had been attenuated and the clinical course was milder [42, 43]. However, reports of resistant isolates causing severe clinical illness have also appeared [44, 45].

For the most part acyclovir resistance has been mediated by alterations in the viral-encoded thymidine kinase production [42, 43, 46]. However, mutations in the DNA polymerase and altered substrate specificity for thymidine kinase are other potential modes of resistance [46]. Risk factors for the emergence of acyclovir-resistant HSV infections include severe GvHD and the lack of ganciclovir prophylaxis [47].

For patients with acyclovir-resistant HSV, treatment with foscarnet, a pyrophosphate analogue that directly inhibits viral DNA polymerase (and does not require thymidine kinase for its activity), may be effective [48]. In a randomized trial that compared foscarnet with vidarabine for acyclovir-resistant HSV infections in AIDS patients, foscarnet was both more effective and less toxic [49]. Another alternative is cidofovir. For patients with mild infection, another alternative approach would be to cease antiviral therapy to allow unassisted resolution. If progressive illness should ensue, then antiviral treatment could be initiated. Currently, there are no vaccines for either HSV-1 or HSV-2.

Cytomegalovirus

Cytomegalovirus infections are common in the general population, with serologic surveys demonstrating latent infection in 40–60% of adults in most industrialized countries. Primary infection is often inapparent, but CMV can be a major cause of congenital malformations and hearing loss, mononucleosis, and sexually transmitted disease. Asymptomatic shedding in saliva and genital secretions is occasionally noted; clinical illness is uncommon unless the patient is immunocompromised.

Different strains of CMV have been identified by using two viral envelope glycoprotein genotypes (gB and gH). Some data suggest that infections by gB type 1 strains may be associated with greater survival than other gB types [50]. In another study, life-threatening myelosuppression was noted with gB3 and gB4 isolates, in contrast to gB1 and gB2 isolates [51]. Further studies are needed to ascertain whether characterization of strains may provide insights as to viral pathogenicity and prognostic information as to outcome from infection [52].

Patterns of Infection

Cytomegalovirus can be reactivated from endogenous latent virus or alternatively can be acquired from transfusion of blood products or from an organ graft. Leukocytes are a reservoir of latent virus; the risk for transmission can be reduced by depletion of leukocytes in blood products [53, 54] and avoidance of granulocyte transfusions [55]. Among seropositive and seronegative BMT recipients, the incidence of CMV infection was similar prior to the routine use of CMV seronegative blood product support [56]. Now infection rates are less than 10–15% in seronegative recipients given seronegative blood products (although higher in the recipients of seropositive marrow grafts) [57].

In immunocompromised patients, CMV can be a cause of fever, leukopenia, thrombocytopenia, esophagitis, enterocolitis, interstitial pneumonitis, hepatitis, mononucleosis-like syndrome, chorioretinitis, and rarely, meningoencephalitis. Infection with CMV may predispose immunocompromised patients to sepsis [58, 59].

Although CMV excretion is a frequent occurrence in patients with acute leukemia undergoing intensive chemotherapy, its relationship to morbidity is poorly defined. However, several small surveys of acute leukemia patients suggest that the morbidity attributable to CMV may be underestimated [60–62]. Among leukemia patients, gastritis and esophagitis occasionally occur, and rarely, pneumonitis can be noted. In contrast, CMV can be the cause of life-threatening illness in BMT recipients.

The most common severe manifestations of CMV in BMT patients are interstitial pneumonitis (Fig. 51.1) and enterocolitis. Less serious manifestations are unexplained fever, esophagitis, gastritis, wasting, and hepatitis. Chorioretinitis is uncommon (in contrast to HIV-infected patients) [56]. Myelosuppression, manifest as delay in the recovery of counts after chemotherapy or unexplained cytopenias weeks to months following engraftment, can occur and can pose diagnostic challenges to distinguish from other causes of myelosuppression.

As with HSV, anti-CMV IgG antibody develops after primary infection. It provides a marker of endogenous latent virus. It does not appear that CMV-specific antibody protects against severe disease because several studies have not found a protective effect of high pretransplant antibody levels against infection [63]. Likewise, there is poor correlation between antibody responses and clinical responses [63]. Thus, while

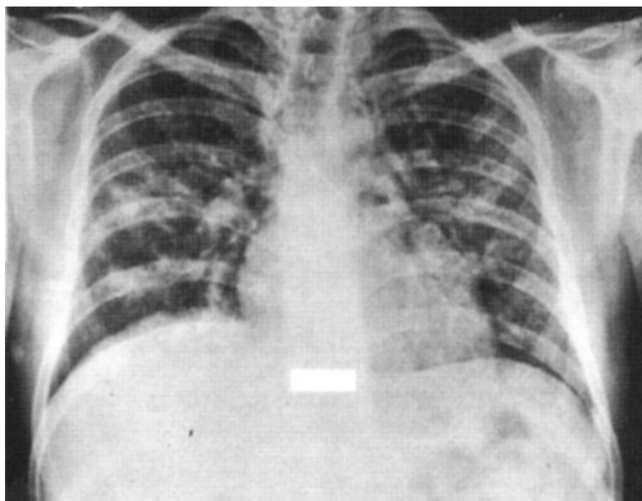

Fig. 51.1 Chest radiograph showing a diffuse mixed alveolar/interstitial pneumonitis due to cytomegalovirus

CMV antibody may have a contributory role in the control of CMV infection, it does not appear to be the most important response. Lymphocytopenia has been noted to be an unfavorable prognostic factor in BMT patients with CMV infection [64], and CMV-specific T-cell and natural killer (NK) responses have been noted following CMV infections [65–68]. The majority of survivors of CMV infection in BMT recipients develop either NK or T-cell cytotoxic responses or both, whereas few of those who succumb from infection develop cytotoxic responses and in the minority in whom cytotoxic responses could be found, the magnitude was much lower [65]. Thus, it appears that the early development of a robust cytotoxic response is crucial to resolution of CMV infection.

Although the development of cytotoxic responses is clearly immunoprotective, animal studies suggest that some cellular responses may be contributory to the pathogenesis of CMV pneumonitis [69–73]. Elucidation of which host immune responses are immunopathogenic and which are immunoprotective is crucial to the understanding of CMV pathogenesis and may permit insights into ways in which augmentation of certain responses and abrogation of others may be possible in future engineering of the constituents of the marrow graft through cell sorting techniques that discriminate various cell populations by their immunophenotypic differences.

Allogeneic BMT recipients are at are at greatest risk for serious illness from CMV infection, in contrast to autologous or syngeneic transplant recipients or nontransplant leukemia patients [74–79]. Among allogeneic recipients, risk factors for CMV-related morbidity and mortality have included HLA disparity between donor and recipient, unrelated donor transplant, T-cell depletion, pretransplant CMV seropositivity, GvHD, older age, the use of immunosuppressive agents other than cyclosporine as GvH prophylaxis, viral excretion, and the intensity of the cytoreductive preparative regimens [20, 56, 57, 75, 79–85]. Detection of viral excretion from blood, urine, or throat secretions is indicative of active infection, and isolation of virus often precedes CMV disease by several days to 1–2 weeks. Viremia is most predictive of subsequent CMV disease [84]. Alternatively, recovery of virus from bronchoalveolar lavage specimens even in patients without any pulmonary symptomatology also identifies patients at high risk for the development of subsequent CMV pneumonitis [86, 87]. In a recent retrospective review of 421 cases that occurred between 1986 and 2011 at the Fred Hutchinson Cancer Research Center, Erard et al. found that female sex, increased bilirubin, lymphocytopenia, mechanical ventilation, and development of grade 3 or 4 graft-versus-host disease increased the risk of mortality from CMV pneumonia as did the lack of treatment with antiviral therapy. In an analysis of 233 cases that occurred in the era of preemptive therapy, only the presence of lymphocytopenia was found to increase the risk of morality from CMV pneumonia [88].

The CMV serostatus of the allogeneic BMT recipient is a significant factor in the long-term outcome. Positive CMV serostatus of the recipient remains a poor prognostic factor, especially in recipients of T-cell-depleted marrow or stem cells. An association of CMV with GVHD and nonviral infections or sepsis has been suggested as a possible mechanism [89]. A large study from the European Bone Marrow Transplant Registry demonstrated the importance of donor serostatus among CMV-seropositive recipients of unrelated grafts, possibly as a result of transferred CMV-specific immunity from the donor to the recipient [90]. In an analysis of a large cohort of T-cell–replete SCT recipients, both donor-positive/recipient-positive and donor-positive/recipient-negative recipients had a higher risk of mortality [91]. After controlling for neutropenia and CMV disease, only donor-positive/recipient-negative recipients had a higher risk of mortality. This was attributed to indirect immunomodulatory effects of CMV because there was an excess mortality due to bacterial and fungal infections when compared with donor-negative/recipient-negative recipients [91]. More recent review of data from 9469 allogeneic transplant recipients transplanted between 2003 and 2010 reported to the Center for International Bone Marrow Transplant Research (CIBMTR) show an increase in nonrelapse-related mortality for all serology groups (donor positive/recipient positive, donor positive/recipient negative, donor negative/recipient positive) compared with the donor negative/recipient negative cohort [92]. Collectively, these studies of the effect of CMV serostatus suggest that CMV infection before transplantation remains an important factor leading to poor outcome after transplantation, especially in recipients of T-cell-depleted transplants.

Although autologous BMT patients are at lower risk for CMV disease, such disease occasionally occurs. Patients

receiving transplants for hematologic malignancy are at greater risk than those receiving transplants for solid tumors. Patients with multiple myeloma undergoing stem cell transplants in one study were at greater risk for CMV disease [93]. In one study, CD34 selection in autologous stem cell transplant recipients was associated with an increased risk for CMV disease [94]. However, this has not been observed by other groups [95].

Of interest, a number of studies have previously evaluated the possible association of early reactivation of cytomegalovirus after allogeneic stem cell transplantation for acute myelogenous leukemia and a decreased incidence of relapse [96]. One study even suggested a similar positive benefit in patients transplanted for chronic myelogenous leukemia. This reduction in incidence in relapse was also suggested to improve overall survival in this group of patients. Unfortunately not all studies have found a positive benefit of CMV reactivation in regard to relapse and/or overall survival [97]. Moreover, an analysis by the European Society for Blood and Marrow Transplantation even suggesting a higher risk of leukemia relapse with a decrease in overall survival in patients who were seropositive for CMV at the time of allogeneic transplantation [98]. With these conflicting findings, the Center for International Blood and Marrow Transplant Research (CIBMTR) recently reported results of analysis of data from 9469 patients transplanted with bone marrow or peripheral blood between 2003 and 2010. Patients were categorized by underlying disease at the time of transplant (AML, ALL, CML, and MDS). The median time to initial CMV reactivation was 41 days. There was no evidence of decrease risk of relapse regardless of underlying disease type in this study. In addition, there was an increase risk of nonrelapse-related mortality. The conclusion of the authors after analyzing this large data set was that CMV reactivation did appear to confer protection against relapse of hematologic disease and remained a risk factor for poor overall outcome [99].

Diagnosis, Prophylaxis, and Treatment

Historically, infection with cytomegalovirus was diagnosed by the use of cultural methods [100]. Unfortunately, this method was not very useful in timely treatment decisions because results may take several weeks. Modified cultural techniques using the shell vial method coupled with a rapid diagnostic antigen assay for the immediate early antigen were then developed to permit demonstration of the virus within several days [101–103].

Newer assays, including the demonstration of the pp65 antigen in circulating leukocytes using immunofluorescence [104–106] or of viral DNA by the PCR [107–110], have replaced the cultural methods of monitoring for active cytomegalovirus infection. Both the leukocyte antigen detection and PCR assays permit detection of virus 7–10 days earlier than shell vial culture. Detection of virus DNA in plasma by PCR appears to be more sensitive than detection in buffy-coat leukocytes. Both the leukocyte antigen assay and PCR assays have the advantage of permitting quantification. Larger virus quantity may be more predictive of subsequent disease than less virus [111]. In one comparison, PCR appeared to be slightly more sensitive than the leukocyte antigen detection assay [112].

Table 51.4 Interstitial pneumonia. Diagnostic procedures

Procedure	Yield (%)	Morbidity (%)
Transtracheal aspirate	5–10	2–5
Bronchoscopy		
Biopsy alone	30–55	5–20
Bronchoalveolar lavage	40–90[a]	5–20
Transthoracic needle		
Aspirate	17–60	10–30
Biopsy	20–60	10–60
Open biopsy	100	5–10[b]

[a]Results include histology, immunofluorescence, and in situ hybridization
[b]100% incidence of pneumothorax requiring chest tube placement

The gold standard for documenting CMV pneumonia in the past had been an open lung biopsy (Table 51.4). Because only half of the episodes of interstitial pneumonitis after marrow transplantation are due to CMV and the treatments are toxic, it is important to confirm the etiology at the outset. Similarly, for gastrointestinal syndromes attributable to CMV, tissue documentation is important to differentiate CMV from GvHD or other etiologies [113]. In contrast to patients with HIV infection, in whom CMV is frequently a pulmonary copathogen of less clinical importance, in BMT patients CMV typically can cause severe illness as a single pathogen. Transbronchial biopsy has not proved to be very reliable, yielding frequent false negatives. In contrast, bronchoalveolar lavage has been found to have a high sensitivity and specificity for documentation of CMV as an etiology of interstitial pneumonitis and is the usual method of diagnosis of CMV pneumonitis today [114]. This less invasive procedure has encouraged clinicians to be more aggressive in the evaluation of patients suspected of having pneumonitis and permits an earlier initiation of therapy.

Untreated CMV pneumonitis after marrow transplantation has an 80–90% mortality. A number of immune modulators and antiviral agents alone and in combination had been tested without success, including vidarabine, interferon, vidarabine plus interferon, acyclovir, acyclovir plus interferon, CMV immunoglobulin, ganciclovir, and ganciclovir with corticosteroids [115–119].

Ganciclovir, a nucleoside analogue similar in structure to acyclovir, differs from acyclovir in that it does not require phosphorylation by a viral-encoded thymidine kinase. Because human CMV does not encode for this enzyme, acyclovir has much less activity than ganciclovir against CMV. Phosphorylation of ganciclovir occurs by the phos-

photransferase product of the viral UL97 gene. Although ganciclovir was shown to have an antiviral effect in BMT patients, most patients initially treated with this agent aloe were felt to have derived little clinical benefit [118]. Several nonrandomized trials which evaluated treatment of CMV pneumonia using a combination of ganciclovir combined with the infusion of intravenous immunoglobulin were felt to show an increase in clinical benefit, with survival rates in the range of 50–70% [120–123]. Although no controlled trials have been performed, this combination has been widely adopted for the treatment of CMV pneumonitis [124]. In a recent review by Erard et al. of 421 cases treated at the Fred Hutchinson Cancer Center from 1986 through 2010, the authors felt their date documented the improvement in outcome of patients with cytomegalovirus pneumonia over the last few decades and was clearly attributed to the availability of specific anti-CMV antiviral therapy. However, the analysis of their data failed to show benefit of the addition of either intravenous pooled or CMV-specific immunoglobulin. If, however, therapy is delayed until ventilatory failure has ensued, outcomes are uniformly poor [88]. Thus, early intervention is crucial. Following control of CMV pneumonia with ganciclovir and immune globulin, there can be occasional recurrences, and some clinicians advocate a maintenance course of ganciclovir for several weeks to several months following an episode of CMV pneumonia.

Although a small prospective randomized clinical trial failed to show statically significant benefit in the use of antiviral therapy with ganciclovir in the treatment of CMV-associated enteritis in marrow transplant recipients in regard to clinical symptoms and endoscopic appearance, the study did show reduction in both orophyngeal and urinary excretion of virus. Four patients on the treatment arm of this study and six on the placebo arm developed pneumonia. All ten of these patients died [125]. Of note, there was less than 20 patients on each arm of the study and it was conducted over 20 years ago before the availability of more sensitive techniques for early viral detection (i.e., detection of CMV viremia in the blood by antigen assay or PCR) as well as the advent of preemptive anti-CMV antiviral therapy as is discussed below. It has, therefore, become standard of practice to treat with appropriate antiviral therapy when CMV enteritis is documented by biopsy. In a subsequent retrospective study by the European Group for Blood and Marrow Transplantation, there appeared to be no improvement in outcome with the addition of intravenous immunoglobulin to antiviral chemotherapy in patients with CMV enteritis [126].

Prior to the availability of effective antiviral therapy for CMV, the onset of CMV-related pneumonitis in the marrow transplant occurred approximately 2 months following transplantation. This was usually shortly after engraftment and frequently after the appearance of acute GvHD. Despite the gratifying improvements in the treatment of CMV pneumonia, many patients still died due to the development of this complication.

Table 51.5 Strategies to cytomegalovirus (CMV) disease in bone marrow transplant patients

Intervention	References
CMV-negative blood products	[50, 82, 115, 131, 132]
Leukocyte filters	[47, 116]
Immunoglobulin or plasma	[117–123]
Acyclovir	[124, 125]
Ganciclovir	[126–129]

A number of investigators have sought ways to prevent either infection or illness from infection (Table 51.5). For CMV seronegative recipients whose donors are also seronegative, the use of CMV-screened blood products has been highly successful in minimizing the risks for CMV infection and disease [57, 104, 127–129]. Alternatively, the use of second-generation leukocyte filters for blood product transfusions similarly reduced the risk and now has become standard of practice in most centers treating patients with hematological malignancies in the United States and Europe [54, 130].

Maribavir has been explored for the prevention of CMV infection in allogeneic stem cell transplant recipients. Despite encouraging results in pilot studies, a subsequent randomized trial showed no significant benefit with maribavir prophylaxis [133].

At present there are no satisfactory preventive measures for seronegative recipients who receive grafts from seropositive donors. Although immune globulin would be appealing in this situation, unfortunately it has not proved to be effective in reducing infection rates [127]. Prophylaxis with acyclovir or valcyclovir in combination with monitoring for viremia and treating viremia with preemptive therapy is advised by recently published consensus guidelines in this population [134].

As noted above, although some centers utilize a prophylactic approach to prevention of CMV disease in their transplant patients, due to the toxicity of the available agents, the "preemptive" approach is most common. The choices of antiviral therapy for the treatment or prophylaxis of CMV disease with several agents. There is clearly an unmet need for antiviral agents with less toxicity as well as enhanced antiviral activity against cytomegalovirus isolates that shows resistance to the currently available agents. Some of the antiviral agents with activity against CMV that show promise and are currently under study include maribavir, letermovir, brincidofovir, and leflunomide [135].

Maribavir, a UL97 protein kinase inhibitor is an orally bioavailable drug with activity agents CMV. In a recent phase III clinical trial utilizing this drug as prophylaxis for CMV infection in allogeneic stem cell transplant recipients,

mirabivir failed to show benefit in prevention of CMV disease. A prior phase II dose range study in hematopoietic stem cell transplant patients had shown activity of the drug against CMV infection or disease at all three different dose levels tested. Since the phase III clinical trial utilized the lowest dose of drug study in the phase II trial (100 mg twice daily), failure of maribavir to prevent CMV disease in the prophylaxis study was considered to be due to suboptimal dosing of drug. Maribavir has also shown activity against CMV resistant to ganciclovir or cidofovir in vitro with small case series suggesting a possible clinical. Further dose ranging studies are currently ongoing utilizing maribavir as preemptive, rather than prophylactic therapy and in transplant recipients with CMV infections that are refractory or resistant to prior antiviral therapy.

Letermovir is a CMV terminase inhibitor with a high level of activity against wild type and drug resistant CMV. Being specific for CMV terminase, it has little activity against other members of the herpes group viruses. The drug is available in both intravenous and oral form and was shown to be superior to placebo at a dose of 240 mg in a phase II dose-escalation study when used as prophylaxis in a group of HLA-matched transplant recipients who were CMV seropositive. As a follow-up of the phase II study, a phase III randomized clinical trial is ongoing. Letermovir has been found to be well tolerated and has been given fast track status by the US Food and Drug Administration and orphan drug status by the European Medicines Agency [136].

Unlike letermovir, brincidofovir is a new antiviral agent with a broad spectrum of activity against herpesviruses other than just CMV, polyomaviruses, adenoviruses, papillomaviruses, and variola virus. It is a lipid analogue of cidofovir which highly bioavailable orally with a long half life. The drug has much less renal toxicity as it is not a substrate for human organic anion transporters. Used a prophylaxis starting at the time of engraftment after allogeneic hematopoietic stem cell transplantation, brincidofovir showed a reduction in CMV infection or disease at a dose of 200 mg per week. Most common side effect was diarrhea. There was no evidence of increased renal or hematological adverse events compared to placebo. A phase III randomized trial for prophylaxis in hematopoietic transplant patients is ongoing [137].

Other drugs which have been studied for the treatment of CMV infection and disease include leflunomide which is FDA approved for the treatment of arthritis. This drug has been shown to have activity against CMV and BK virus. Although it has been reported as being used as a salvage agent for CMV disease with mixed results, no well-controlled studies with this agent for the treatment or prevention of CMV disease have been conducted.

The antimalarial drug arteunate has also been noted to have broad activity against herpes group viruses as well as hepatitis viruses and human immunodeficiency virus due to its ability to downregulate NF-kappB or SP1 pathways. Despite a few reports of efficacy in patients with multi-resistant CMV disease, no formal studies of efficacy and/or toxicity have been performed with this drug [135].

Immune globulin, either CMV specific or from standard commercial lots, has also been shown to be beneficial in reducing CMV infection or disease [138–141]. It is not clear whether there is any advantage to using a hyperimmune globulin preparation compared to commercial lots of immune globulin not specifically selected for high titer anti-CMV antibody. Most of the efficacy from immune globulin has been demonstrated in patients who were seronegative prior to transplant. There does not appear to be any additive benefit of immune globulin to the use of filtered blood products in seronegative patients [126]. The magnitude of benefit from immune globulin has been less in seropositive patients [142], and immune globulin has been found to be of no benefit in autologous marrow transplant recipients [143].

Before the availability of antiviral agents with greater activity against cytomegalovirus, such as ganciclovir and foscarnet, attempts at infection prevention with high-dose intravenous acyclovir were studied. In one such study, seropositive patients receiving high-dose intravenous acyclovir given during the first month after transplantation suggested there was a reduced risk for CMV pneumonia [144]. In a three-arm trial, high-dose intravenous acyclovir during the first month, low-dose oral acyclovir during the first month, and high-dose intravenous acyclovir during the first month followed by 6 months of oral acyclovir were compared [145]. A reduced probability and delayed onset of CMV infection was noted in the group receiving high-dose intravenous acyclovir [145]. In this latter study, the prolonged course of oral acyclovir did not reduce CMV infection but did reduce viremia, and there was an improved survival benefit [145]. Similar acyclovir prophylaxis trials in solid organ transplant recipients had shown efficacy. Why acyclovir as prophylaxis seems to exert an anti-CMV effect whereas its use as treatment provides no effect is puzzling but may be indicative of a mild antiviral effect, which is demonstrable only when the viral burden is low as in the early stages of active infection and not apparent in later stages of infection, when the viral burden is substantially greater.

With the availability of an antiviral agent with greater activity in the early 1990s, however, ganciclovir was also evaluated for prophylaxis (from engraftment to day 100) or as early treatment in BMT patients with active virus infection to preempt disease. As noted previously, asymptomatic patients with virus recovered from bronchoalveolar lavage fluid 35 days after transplantation, as well as those in whom viremia or excretion in urine or throat specimens occurs are at higher risk for CMV disease. Initial studies using ganciclovir as prophylaxis in seropositive patients significantly reduced the incidence of life-threatening CMV disease; how-

ever, the incidence of cytopenias, particularly neutropenia, increased the risk of bacterial and fungal infections in patients receiving this antiviral agent versus placebo controls negated much of the benefit in regard to overall outcome. An alternative approach has been to use viral detection methods (antigenemia assay or DNA titer by PCR) of serial blood samples to detect development of viremia and then "preemptively" start antiviral therapy in attempt to avoid significant marrow suppression with this agent before the development of end organ disease (mainly viral pneumonia). This has become the favored approach in many transplant centers today. An alternative prophylactic strategy is to initiate ganciclovir at the time of engraftment in all seropositive patients [146, 147]. Because of its myelosuppressive toxicity, it is difficult to begin the use of ganciclovir as prophylaxis prior to engraftment. Even when it is begun shortly after engraftment, pancytopenia and interruptions of treatment are common, with an attendant risk of neutropenic infections. Patients with low marrow cellularity, elevated bilirubin, or increased creatinine are at greater risk [148]. The most common practice at present is viral surveillance utilizing polymerase chain reaction with preemptive initiation of antiviral therapy when CMV reactivation is documented. This practice has reduced the risk of death from CMV after allogeneic stem cell transplantation to less than 10% [56].

The use of myeloid growth factors can lower the risk of myelosuppression. There is divided opinion at present as to the relative merits of prophylaxis versus early "preemptive" therapy [39, 149]. Several reviews have discussed the issues related to these strategies [39, 150–153]. It appears that prophylaxis is associated with fewer failures that could occur before or simultaneously with the first detection of active virus. However, the greater morbidity attendant on more frequent and more prolonged pancytopenia with ganciclovir started at the time of engraftment makes ganciclovir less well tolerated than when started later. Moreover, early therapy given only to patients with active infection spares a significant proportion of patients the toxicities and cost of antiviral therapy. The greater use of the leukocyte antigen and PCR assays to detect virus earlier than with the shell vial culture assay may reduce some of the failures associated with early therapy, making this more advantageous than prophylaxis [39]. If ganciclovir is used for prophylaxis or as early therapy, there appears to be no added benefit for acyclovir during the first month [154].

In an attempt to reduce the toxicity of long-term ganciclovir, several variations of daily therapy have been attempted. Ganciclovir three times per week was not found to be adequate to prevent CMV reactivation, at least in T-cell-depleted marrow transplant recipients [155]. On the other hand, a preliminary report suggests that 3–6 weeks of daily ganciclovir may be as efficacious as a longer course while causing less toxicity [156, 157].

Oral ganciclovir is useful in AIDS patients for maintenance therapy to prevent recurrence of CMV retinitis, but because of poor bioavailability, serum concentrations are lower and breakthrough infection rates appear to be higher [158]. Emergence of resistance has also been noted and appears to be greater than with intravenous ganciclovir [159, 160]. Valganciclovir, a prodrug of ganciclovir, is metabolized to ganciclovir and has excellent bioavailability [161–163]. Plasma concentrations are quite high. Valganciclovir has been shown to be an alternative to ganciclovir, which may make prolonged courses of therapy more feasible [164–166].

Resistance to ganciclovir occurs through mutations in the CMV UL97 gene [167–169]. DNA polymerase (UL54) mutations can also occur, resulting in high-level resistance [169]. Although many ganciclovir-resistant CMV mutants have mutations in the UL54 gene (DNA polymerase) as well as in the UL97 gene, susceptibility to foscarnet is retained [169–171]. Although rising CMV antigen titers can be seen in approximately 40% of patients early on with ganciclovir maintenance therapy, most isolates are susceptible to ganciclovir, indicating that host factors and medications, rather than resistance, accounts for the rise in titers. Additionally, no correlation was seen between CMV titers and CMV disease [172].

Foscarnet, a pyrophosphate analogue, targets the viral DNA polymerase. It represents an alternative to ganciclovir both as treatment and as prophylaxis [173–177]. Sparing of the blood counts makes foscarnet an attractive alternative to ganciclovir in patients in whom marrow reserve is marginal. However, nephrotoxicity and renal wasting of electrolytes are prominent side effects of foscarnet. In one small study, the combination of foscarnet and ganciclovir was effective and may have less treatment toxicity [178]. Foscarnet is an option for ganciclovir-resistant CMV [179].

Cidofovir is a nucleoside analogue with potent anti-CMV activity not requiring phosphorylation by the UL97 gene product, which acts against the viral DNA polymerase (UL54). It is an effective treatment for CMV retinitis in HIV-infected patients [180–183]. Advantages include less frequent dose intervals (once weekly at first, then every other week). Limitations include considerable nephrotoxicity (which in some cases was irreversible) and iritis. Concomitant probenecid and intravenous hydration are necessary. There are to date only limited data on BMT patients [171]. Because many ganciclovir-resistant CMV mutants have alterations not only in the UL97 gene but also in the UL54 gene (DNA polymerase), resistance to cidofovir can also be present [169, 170]. Accordingly, foscarnet is the preferred antiviral in the face of ganciclovir resistance.

Historically, most episodes of CMV pneumonitis occurred during the first 100 days after marrow transplantation. However, with the advent of antiviral prophylaxis in recent

years, late-onset CMV pneumonitis has increasingly been noted beyond 100 days [184–190]. In part this is due to the increasing use of unrelated and HLA-mismatched donors, where immune reconstitution is much slower than after allogeneic transplants from genotypically identical siblings. However, delay in the development of cytotoxic anti-CMV responses in patients in whom ganciclovir has been used has also been noted [191, 192]. Most late-onset cases occur in patients in whom CMV infection was documented during the first 100 days [186]. The risk of late-onset CMV pneumonitis appears to be greatest in patients with chronic GVHD. This is a group in whom CMV surveillance may be particularly important. With recognition of the importance of development of cytotoxic cellular responses to CMV for resolution of infection as well as of the ability to clone lymphocyte populations and expand them ex vivo with interleukin-2 and repetitive CMV antigenic stimulation, it has become possible to consider cellular immunotherapy of CMV infection [193–197]. Consideration of donor immunization may also be important because recipients of grafts from seropositive donors may have earlier recovery of cytotoxic responses than recipients of grafts from seronegative donors [191]. Such immunotherapeutic approaches may prove to be increasingly important in years to come as the emergence of ganciclovir resistance among CMV isolates increases [198].

Because the risk of CMV disease is substantially greater in seropositive than in seronegative patients, it has been previously recommended that newly diagnosed leukemia patients who are seronegative for CMV and in whom a transplant is contemplated after induction therapy should receive only CMV-seronegative blood products throughout their induction therapy. The benefit of the routine use of this practice is questionable so long as only leukopoor filtered products are given, particularly if CMV seronegative blood is not available. The value of CMV-negative blood products in autologous transplantation patients, in whom the risk for serious CMV disease is low, is questionable but has been recommended by some [199] This practice, however, has been mostly abandoned with the routine use of leukocyte filtered blood products for transfusion support. Although the use of seronegative blood products and/or routine leukofiltration of donor blood has markedly reduced the risk of transfer of CMV to recipients, newer methods of pathogen inactivation of donor may also reduce the risk of viral transmission to recipient in the near future [200].

Immunization of the donor or recipient by a live attenuated, killed, or subunit recombinant CMV vaccine might be attractive in speeding restoration of immunity [201]. However, although an attenuated vaccine has been found to be immunogenic in solid organ transplant patients, concerns regarding its safety in more severely immunodeficient marrow transplant patients have prevented trials of a live vaccine. A glycoprotein or DNA vaccine would be desirable. Clearly, abrogation of the recipient's immunity by the preparative regimen may mean that prior immunization of the donor as well as repeated boosting of the recipient is necessary to establish meaningful immune responses..

Varicella Zoster Virus

Patterns of Infection

Varicella zoster virus, like the other herpesviruses, can be a significant pathogen in patients with hematologic malignancies. Varicella (chickenpox) is the primary form of infection, and zoster (shingles) is the reactivation form of illness. The initial portal of entry is uncertain, but the respiratory tract, skin, and conjunctiva are candidate sites. After local replication, viremia occurs with dissemination to multiple cutaneous (and visceral) sites. The skin lesions begin as erythematous macules, progress to papules and then to vesicles (with clear fluid), which evolve to pustules (with cloudy fluid containing interferon and leukocytes), and flatten to scabs, until finally healing takes place. The hallmark of infection is the vesicle. Crops of vesicles classically exist on a common erythematous base. Scarring is unusual in varicella, but the inflammatory reaction in zoster may be more severe with greater pain and scarring. Zoster characteristically is dermatomal, and lesions typically stop at the midline. In severely immunocompromised patients extension to adjacent dermatomes may occur, the vesicles may become confluent, and cutaneous dissemination can occasionally occur. Approximately 5–10% of patients with non-Hodgkin's lymphoma, 15–25% of patients with Hodgkin's disease, and 20–50% of patients undergoing BMT develop zoster [202–207] (Table 51.2).

In the normal host varicella and zoster are self-limited. In patients with hematologic malignancies, varicella may be quite severe and life threatening. In the preantiviral era, varicella frequently progressed to visceral dissemination and death [208].

Untreated dissemination occurs in 30–40% of marrow transplant recipients [204, 205] and in up to 20–30% of children treated for hematological malignancy [208]. Visceral dissemination is a severe manifestation and pneumonia can be particularly deadly. In marrow transplant patients an intra-abdominal presentation can occur, with severe abdominal pain [209–211]. This can be particularly challenging to diagnose because it may occur in the absence of cutaneous vesicles. A high index of suspicion should be maintained because if the condition is not treated promptly, it can result in a high mortality. Manifestations of pancreatitis, hepatitis, and peritonitis are frequent, and in patients in whom laparotomy was inadvertently performed, inflammatory changes, vesicles on serosal surfaces, and mesenteric adenitis have been noted.

The onset of VZV infection in the marrow transplant recipient is much later than that of the other herpesviruses,

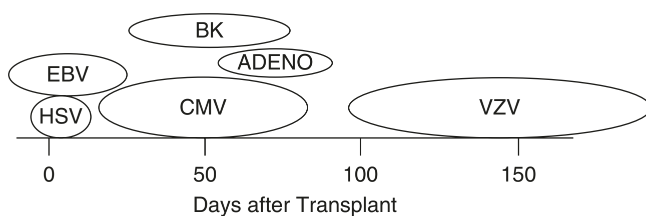

Fig. 51.2 Viral infections and their time course after marrow transplantation. *HSV* herpes simplex virus, *EBV* Epstein–Barr virus, *CMV* cytomegalovirus, *BK* BK virus, *ADENO* adenovirus, *VZV* varicella zoster virus

occurring an average of 5 months following transplantation [204–207] (Fig. 51.2). Susceptibility for reactivation can persist for many months, especially among patients with chronic GvHD [204, 205]. A study of humoral and lymphocytic proliferative responses to VZV in BMT recipients indicated that in approximately 26% of patients a subclinical reactivation occurred [212]. Similarly, in patients undergoing induction therapy for leukemia, 5–10% subclinical reactivation occurred. Thus, when both clinical and subclinical infections are considered, VZV infection is a common occurrence in BMT recipients.

Among patients treated for lymphoma, VZV infection is more common in those with advanced disease, those treated with combined-modality chemoradiotherapy [202], and in patients who have received rituximab [213]. It appears that the frequency of zoster is increasing as more dose intensive therapies are being employed. Risk factors for VZV in allogeneic marrow transplant patients include acute or chronic GvHD, older age, and the posttransplant use of antithymocyte globulin. Among autologous transplant patients, the underlying disease of Hodgkin's or non-Hodgkin's lymphoma is a risk factor [206]. Zoster develops more commonly in dermatomes of prior radiotherapy.

Diagnosis and Treatment

Diagnosis can usually be made solely by visual inspection of the cutaneous lesions. Examination of the cellular contents of a vesicle can demonstrate multinucleated giant cells on Tzanck smear [25]. Culture can be confirmatory but special handling must be used for this heat-labile cell-associated virus. Immunofluorescent staining can also be used [214]. PCR techniques may offer yet another alternative [25].

Acyclovir is highly active against VZV [215–217]. Higher concentrations are required to inhibit VZV in vitro as compared to HSV-1 and HSV-2. Generally, plasma levels achieved with standard doses of acyclovir given orally are insufficient to achieve inhibitory plasma concentrations. High doses of oral acyclovir (800 mg given five times daily) achieve peak plasma concentrations that approximate in vitro inhibitory concentrations for most isolates of VZV and have been found to be useful in nonimmunocompromised patients in whom treatment is initiated early after onset of infection [218]. The adequacy of this dose in compromised patients has not been well demonstrated, although one small trial in BMT recipients suggested that a beneficial effect was achieved [219]. However, because only a small number of patients have been studied, intravenous acyclovir is preferable as initial therapy unless the infection is mild and the patient can be closely monitored to institute parenteral therapy if there is progression or no response.

Vidarabine in the past was an alternative treatment [220], although controlled trials have shown acyclovir to be superior [217]. Interferon-α has also been shown to be efficacious [221], although it has been evaluated only in localized disease and there is no published experience of its use in disseminated disease [222].

Several oral agents are effective therapies in nonimmunocompromised patients. These include famciclovir and valacyclovir, prodrugs of penciclovir and acyclovir, respectively [223–225]. These agents have greater bioavailability and longer half-lives than oral acyclovir, which make them excellent candidates for outpatient treatment. Their efficacy has not been shown to be suitable for zoster therapy, including in immunocompromised patients [226, 227]. They seem to be suitable for mild to moderately severe cases of zoster when the patient can be observed carefully or as a change from intravenous acyclovir once an initial response to therapy is achieved.

The risk for acyclovir resistance in VZV is much less than in HSV. However, several reports have noted the emergence of drug resistance [228, 229]. As with HSV, the mechanism of resistance appears to be an altered thymidine kinase, and thus foscarnet is a suitable alternative for resistant pathogens [229].

Immunization and Prophylaxis

A live attenuated vaccine has been evaluated in normal and immunocompromised children with leukemia and found to be beneficial in reducing the risks for VZV infection in patients with ALL in remission for more than 1 year [230–233]. Because of the risks of dissemination by the vaccine strain in patients with severe immunocompromise, its role in such patients is limited [234]. On the other hand, family members of seronegative children with leukemia could be immunized to reduce the risk of the patient contracting a primary infection [235].

Because of the high mortality of VZV-associated disease among severely immunocompromised HCT recipients and the lack of clinical data, passive immunization with either VZIG or VariZIG is advised under very specific circumstances [134]. For VZV-seronegative immunocompromised HCT recipients, VZIG or VariZIG should be administered within 96 h after close or household contact with a person with chickenpox or shingles. VZV-seropositive patients who

are highly immunocompromised can be given VZIG or VariZIG after exposure to VZV, including after exposure to a VZV vaccine and developing a varicella-type rash. Postexposure acyclovir or valacyclovir may be used as an alternative if VZIG or VariZIG is not available [236, 237].

Acyclovir given orally in intermediate doses for a number of months has been shown to reduce the risks for VZV infection following marrow transplantation [212, 238–242]. Administration of acyclovir for 1 year in BMT recipients has been shown to be effective without a rebound of zoster disease after discontinuation [243]. In one study, the possible transfer of VZV-specific T-cell immunity from donor to recipient in the marrow transplantation setting was evaluated [244].

Unfortunately, simple transfer of immunity was not evident. Whether boosting the donor immunity prior to adoptive transfer might improve on this remains to be seen. Currently, it is advised that autologous and allogeneic transplant recipients receive acyclovir prophylaxis for 1 year after transplantation [134]. In patients who have cGVHD or are on chronic immunosuppression, a longer duration of prophylaxis is required.

Epstein–Barr Virus

Pathogenesis and Immunity

Epstein–Barr virus is an ubiquitous organism with the majority of adults being infected. Transmission is usually via oral secretions. Sites of virus replication include the oropharyngeal epithelium and B lymphocytes, the latter being the major reservoir of endogenous latent virus [245–248]. Primary infection is often subclinical, but in adolescence EBV can cause the syndrome known as infectious mononucleosis. It can also cause acute or protracted fever, malaise, fatigue, autoimmune hemolytic anemia, cytopenias, rash, or adenopathy [248–250].

Rarely, it has been associated with several varied neurologic syndromes. It has been implicated as a factor in the pathogenesis of African Burkitt's lymphoma, central nervous system lymphomas, polyclonal and monoclonal lymphoproliferative disorders in solid organ transplant patients, nasopharyngeal carcinoma, and lymphoproliferative disorders associated with the X-linked lymphoproliferative syndrome; in addition, a possible role in Hodgkin's disease has been proposed [248, 251–254].

Primary infection elicits both humoral and cell-mediated immune responses [248, 255–258]. During the acute illness, the production of heterophile antibody and autoantibodies occur. The heterophile antibody (antibody to sheep erythrocytes not absorbed by guinea pig antigen) is most commonly used to document acute infection. Early after infection, IgM antibody and IgG antiviral capsid antibody (VCA) appear, along with antibodies to the early antigen (EA). IgM antibody disappears generally within 2–4 months, but anti-EA antibody may persist for several months or longer. Anti-EBNA antibody appears late, several months after the acute infection, and persists for life. Host cellular responses include natural killer cells and EBV-specific cytotoxic and suppressor T cells. The atypical lymphocytosis characteristically seen during infectious mononucleosis is primarily made up of the responding T-cells rather than the infected B lymphocytes, and these represent the host attempt to control B-cell lymphoproliferation.

Within the B lymphocyte, the EBV genome persists as episomes or occasionally becomes integrated into the host cellular genome. In latently infected cells EBV gene expression is restricted to nuclear protein genes (EBNA), a membrane protein (LMP), and EBV-encoded RNAs (EBERs), which have roles in maintenance of latency, transformation, and prevention of apoptosis [258]. Although latent EBV infection confers a proliferative advantage to B cells, by itself it does not appear to be sufficient for oncogenesis. Rather, other events involving alterations in oncogenes such as c-myc or N-ras or mutations in tumor suppressor gene such as p53 or RB appear to be necessary for the transition from polyclonal proliferation of B lymphocytes to a monoclonal B-cell malignancy [259, 260].

Diagnosis and Treatment

Culture of EBV is problematic because of the lack of readily available assays in diagnostic virology laboratories. However, in research laboratories EBV can be identified by its ability to transform cord lymphocytes [261]. Today, assays for viral DNA detection are mostly straightforward and monitoring by quantitative PCR is readily available [262, 263].

Epstein–Barr virus can be detected in salivary secretions in 15–20% of the general population [261]. Excretion rates are higher in immunocompromised patients. Patients receiving immunosuppressive therapy have excretion rates of about 35%, patients with malignancies have excretion rates in the range of 40–50%, renal transplant patients 45–60%, leukemia patients 75–100%, and HIV-infected patients 45–70% [264–269]. In adults, most infections occur in previously seropositive patients, whereas in children both primary and reactivated infections occur. The number of EBV genomes detected in peripheral blood leukocytes is increased in immunocompromised patients.

Excretion rates vary considerably according to the intensity of immunosuppressive therapy and the extent of depression of host cell-mediated immunity. Thus, patients with repeated organ graft failure, those who receive multiple immunosuppressive drugs, and those who receive antithymocyte globulin are especially vulnerable for reactivation. Similarly, depending on the immunologic defect, the serologic responses to EBV infection may be more or less pronounced than in immunocompetent individuals. Frequently,

serologic responses are exaggerated [270], whereas the more important cell-mediated immune responses are generally suppressed.

Although EBV shedding may be asymptomatic, several EBV-associated syndromes have been identified in patients with hematologic malignancies. Oral hairy leukoplakia commonly found in AIDS patients is also noted in patients with hematologic malignancies, especially those undergoing marrow transplantation [271–273]. There has been increasing recognition of EBV-associated lymphoproliferative syndromes in transplant recipients [264, 274–276]. Children appear to be at greater risk than adults, and seronegative patients are at substantially greater risk than seropositive patients. The risk also varies according to type of transplant, with heart–lung transplant recipients appearing to be at greater risk than those with renal, liver, or cardiac transplants. The evidence for a role of EBV as a causative agent includes the presence of EBV DNA and EBV-specific proteins within tumors, the presence of activation markers consistent with latent EBV infection (CD23 and adhesion molecules), the association with primary infection, and the analysis of terminal repeats indicating monoclonality. Several types of posttransplant lymphoproliferative disease (PTLD) have been described. A mononucleosis syndrome that is localized and self-limited is the least serious. A more widespread mononucleosis syndrome, which can be progressive, and lymphoma, which can be extranodal involving the gastrointestinal tract, brain, and other organs, can also occur. Several classification schemes have been proposed, including one which incorporated molecular genetic analyses with morphology [259].

In BMT recipients, EBV infection has been characterized both serologically and by EBV detection [277, 278]. Reactivation of EBV in seropositive recipients is frequent and generally occurs 2–4 weeks following transplantation. Clinical manifestations have not been associated with viral reactivation, however.

Infrequently, PTLD has been noted in marrow recipients, generally in the setting of severe GvHD, the use of antithymocyte globulin or anti-T-cell antibody, or after T cell-depleted, cord blood, or haploidentical donor transplantation [279–286]. In a comprehensive review of more than 18,000 patients who had undergone allogeneic BMT, PTLDs were noted with a cumulative incidence of approximately 1% at 10 years [287]. Most cases occurred between 1 and 5 months posttransplant with few cases occurring after 1 year. In a multivariate analysis, lymphoproliferative disorders within 1 year of transplant were associated with unrelated or mismatched donor transplants, T-cell depletion of the donor marrow, the use of either antithymocyte globulin or antiCD3 monoclonal antibody as part of the GvHD prophylaxis regimen, acute GvHD, and conditioning regimens that included radiation. T-cell depletion methods that did not remove B cells (the target cell of EBV infection) were associated with a substantially higher risk than methods that depleted both B and T cells. The only risk factor for late-onset PTLD was the occurrence of chronic GvHD [287].

Although most EBV-associated lymphoproliferative disorders have been described in solid or BMT recipients or in HIV-associated immunodeficiency, the increasing use of potent purine analogues, such as fludarabine or cladribine in combination with corticosteroids, has created a new population of oncology patients with profound cell-mediated immunodeficiency. A recent study of EBV DNA load in leukemia and lymphoma patients receiving fludarabine, cyclophosphamide, and dexamethasone indicated a substantial increase in viral load in some patients [288]. Although no EBV-associated lymphoproliferative disorders have been noted to date, these are cautionary observations, which warrant further study.

Acyclovir is active against EBV both in vitro and clinically [289–292]. Its clinical efficacy in nonimmunocompromised patients with infectious mononucleosis, however, has been only slight [282], which is perhaps related to the initiation of therapy late during active viral replication. However, acyclovir has been useful in the clinical management of oral hairy leukoplakia [293], and viral shedding has decreased in compromised patients [272, 278].

Ganciclovir and interferon have also been noted to be active against EBV [294–299]. The activity of acyclovir in the treatment of EBV lymphoproliferative syndromes has not been particularly salutary, although at least some individual patients with polyclonal disorders may have benefited [252, 274]. However, in a more comprehensive compilation of cases, there did not appear to be any difference in survival of those receiving acyclovir therapy for EBV-associated lymphomas [276]. More important in the overall management is reduction of intensive immunosuppressive therapy, which can have salutary effects early in the evolution of the lymphoproliferative disorders [248, 268]. Once mutations in oncogenes or tumor suppressor genes have taken place, attempts to reduce immunosuppressive therapy may be futile [259], and cytotoxic therapy may be more appropriate. Soluble CR-2 (the EBV receptor of B lymphocytes) has been proposed as a therapeutic agent that can block EBV infection [300].

In solid organ transplant patients, the number of EBV-infected lymphocytes in the peripheral blood has been noted to correlate with the risk for posttransfusion lymphoproliferative disorder (PTLD) [301]. After BMT, high levels of circulating EBV detected by quantitative PCR have similarly been shown to be associated with the subsequent development of PTLD [302–304]. This affords an early opportunity to intervene "preemptively" by reduction in the immunosuppression if possible.

Rituximab, an anti-CD20 monoclonal antibody, has also been used to treat lymphoproliferative disorders either by itself

or in combination with lymphocytes, and in anecdotal reports it has demonstrated efficacy [305–307]. Administration of rituximab can be used preemptively to prevent PTLD in BMT patients with high levels of circulating EBV [308]. In healthy seropositive individuals, the population of EBV-cytotoxic T-cell precursors in the peripheral blood is much higher than populations of cells sensitized to other herpesviruses. Thus, buffy-coat leukocyte infusions or ex vivo expanded EBV-specific cytotoxic lymphocytes can be used as therapeutic modalities for EBV-associated PTLD [309]. Infusions of EBV-specific cytotoxic T lymphocytes have been given to patients with high levels of virally infected lymphocytes at high risk for PTLD, resulting in a reduction of viral load [302, 310–313]. Antiviral agents have not been successful in preventing the development of PTLD [281, 283, 286]. Gene-marked infused cells can persist for as long as 18 months [314]. Such “preemptive” lymphocyte transfusions offer promise for prevention of PTLD in at risk patients.

Human Herpesvirus Types 6, 7, and 8

Human herpesviruses types 6 and 7 have only been recognized in the last decade. However, infection in humans is common [315, 316]. Both have a preference for CD4-positive T lymphocytes but can infect a variety of T- and B-cell lines. Seropositivity is present in 50–90% of normal adults, and infection generally occurs during the first decade of life. Both appear to share clinical manifestations. Although usually subclinical, exanthem subitum, a self-limited, mild, febrile illness, can occur. Viral antigens to HHV-6 have been noted in tissues from lymphoma, but their significance is as yet unknown [317–319].

Reactivation of HHV-6 is frequently detected in the blood of BMT recipients [320–323]. For the most part this has not been associated with clinical manifestations. However, suggestions have been made that rash [322], GvHD [323, 324], and marrow suppression in the posttransplant setting [325–327] may be associated. Other reports have suggested a role for HHV-6 in interstitial pneumonitis [328, 329], encephalitis [330], and lymphocytopenia [331]. The precise role in pathogenicity of this virus has been debated [332–334].

The true impact of antiviral therapy for the treatment of clinical disease due to reactivation or primary infection with HHV6 remains unknown due to the lack of well-controlled, prospective clinical trials. Antiviral agents including ganciclovir and foscarnet appear to be active against HHV-6 in in vitro assays [335] and have been used anecdotally [336–344].

Much less is known regarding human herpesvirus 7. It has been implicated as a possible cofactor in human herpesvirus 6 infections [344] and has been implicated in a case of acute myelitis in an adult BMT recipient [345].

Human herpesvirus type 8 has been associated with several human malignancies, including Kaposi’s sarcoma (giving rise to its other name, Kaposi’s sarcoma-associated herpesvirus), some forms of lymphoma, and multiple myeloma. This virus has been found in saliva, semen, and peripheral blood mononuclear cells and is thought to be transmitted sexually. Tissue samples from most Kaposi’s sarcomas contain gene sequences in common with HHV-8 [346–348]. Serologic prevalence studies have revealed contradictory findings. Certain forms of B-cell lymphomas have also been described, especially AIDS-associated body cavity lymphomas, as containing HHV-8 sequences [349, 350]. It is thought to be the cause of Casteman’s disease [351]. Several laboratories have reported detection of HHV-8 DNA sequences in patients with multiple myeloma [352]; however, other groups have disputed such claims [353, 354].

Intestinal Viruses

Enteric viruses cause sporadic infections in patients with hematologic malignancies, which generally occur in conjunction with outbreaks within a given community. Common pathogens include coxsackievirus, rotavirus, the Norwalk virus, and other caliciviruses and astroviruses. But other viruses, including adenoviruses, present in the wider community may also cause illness. Coxsackie A1 is an enterovirus that has been reported to cause severe diarrhea in marrow transplant recipients [355]. In one series, episodes of gastroenteritis were clustered temporarily and caused high mortality [355]. At autopsy foamy vascularization of the mucosal epithelium was noted, with patchy sloughing of intestinal mucosal epithelium. This outbreak coincided with diarrheal illness in nonimmunocompromised children in the community from whom coxsackievirus was isolated from stool. Isolated cases of disseminated infection from enteroviruses have been reported [356, 357]. Isolation of the virus from stool is confirmatory of the diagnosis. Coxsackievirus infection must be distinguished from GvHD by intestinal biopsy because the manifestations may be quite similar.

Rotavirus is a double-stranded RNA virus and member of the Reoviridae family. Its target tissue is the small intestinal mucosal epithelium. Fecal–oral transmission is the usual mode of contagion. There is considerable seasonal variation of infections, most occurring between January and April in temperate climates. Rotavirus gastroenteritis can vary in severity from mild, short-lived diarrhea to overwhelming and occasionally fatal gastroenteritis. A cluster of cases has been reported in BMT patients [358]. In another study, frequent stool isolation of rotavirus has been found in autologous and allogeneic marrow transplant recipients with diarrhea [359]. At present there is no specific antiviral therapy; electrolyte and fluid replacement are important adjunctive measures. To

date there have not been cases of Norwalk and related viruses reported in patients with hematologic malignancies, probably because of the lack of widely available diagnostic assays. Humoral immunity is felt to be an important host protective response for these viral pathogens. The administration of oral immune globulin or breast milk has been suggested for the treatment of severe rotavirus infection.

Adenovirus

Adenoviruses are double-stranded DNA viruses. Forty-nine antigenic serotypes (divided into six subgroups, A through F, based on their antigenic properties and hemagglutination properties) have been identified, each associated with different clinical syndromes. For example, serotype 3 has been associated with keratoconjunctivitis, serotype 11 with hemorrhagic cystitis [360–362], serotypes 40 and 41 with gastroenteritis, and serotypes 3, 4, and 7 have been documented in epidemics of acute respiratory diseases in military facilities. Serotype 35, although uncommon in the general population is common in immunocompromised patients.

The means of transmission of adenovirus is uncertain but has been reported to occur via direct contact, aerosols, contact with respiratory or fecal secretions, and contaminated water. The virus is capable of at least three types of interactions with cells. These include a lytic infection, a chronic persistent or latent infection, and oncogenic transformation.

Patterns of Infection

Adenovirus is endemic in the pediatric population, with approximately 80% of children between the ages of 1 and 5 years having antibody to one or more serotypes [363, 364]. Adenovirus is a relatively common cause of respiratory tract infections in children less than 5 years of age, causing 2–7% of respiratory tract infections and 5–11% of viral pneumonia and bronchiolitis cases [365]. These infections are rarely severe and typically manifest as upper respiratory tract infections. Other presentations include keratoconjunctivitis, gastroenteritis, cystitis, myocarditis, and lower respiratory tract infections.

Adenovirus infections are well documented in immunocompromised patients, including BMT recipients (4–21%), solid organ transplantation patients (liver transplants 8–18%, renal transplants 12%), and patients with AIDS (28%). The frequency with which adenovirus infection and disease is reported among BMT patients is increasing. This is due in part to increased intensity of immunosuppression and to the use of T-cell-depleted cell products. In the mid-1980s, approximately 5% of all marrow transplant recipients were reported to have adenovirus recovered [360, 366], and that number increased to 12–21% in the mid-to-late 1990s [367, 368].

In the BMT population, approximately 33% of infected patients develop severe and prolonged symptoms, such as (1) gastrointestinal infection, manifested as diarrhea, hemorrhagic colitis, or hepatitis; (2) urinary tract infections, manifested as hemorrhagic cystitis often associated with renal failure; and (3) pulmonary infections, resulting in interstitial pneumonia. Adenovirus infections in hematopoietic stem cell transplant (HSCT) recipients are often disseminated, which is defined as isolation of the virus from two different sites or from the blood [358, 365, 367, 369–373].

The BMT programs at both the University of Kentucky and the University of Wisconsin have reviewed the incidence of adenovirus infections in their transplant population [371, 373]. Using different definitions for infection and disease, these programs have established risk factors for adenovirus disease in BMT recipients. First, the age of the BMT recipient is predictive for infection, with pediatric patients more likely to have a positive culture for adenovirus than a similar adult population (23% vs. 9%, $p < 0.0001$). The reasons for this remain unknown, and the type of transplant procedure does not explain this finding. Second, the type of BMT predicts for infection. The Kentucky program demonstrated that allogeneic BMT recipients are more likely to develop infection as compared to autologous recipients (16% vs. 3%, $p < 0.0001$) [368]. Differences have been shown in some series among allogeneic patients, depending on the degree of HLA disparity. A higher incidence of both adenovirus infection and disease was seen in patients undergoing unrelated HLA-mismatched grafts compared with related HLA-matched grafts, although the difference was not statistically significant [363, 366]. Finally, adenovirus disease developed in a greater number of patients with moderate-to-severe GvHD (15 vs. 5 $p < 0.05$). The development of moderate-to-severe GvHD was found to be an independent risk factor predictive for adenovirus disease on multivariate analysis ($p < 0.01$; odds ratio = 5.4; 95% confidence interval 1.6–17.9). The other major risk factor for progression of infection to disease is isolation of adenovirus from multiple sites. Isolation of adenovirus from more than two sites strongly correlates with an increased risk of invasive disease compared to isolation from one site; adenovirus disease occurred in 63% of patients with more than two positive sites compared to 11% with only one positive site.

The development of invasive disease is associated with a shorter median survival. The median survival for all patients who had a positive adenovirus culture was 208 days. Patients with evidence of invasive infection had a median survival of 100 days, compared to 998 days for those with noninvasive adenovirus infection [373]. Of those patients who develop invasive infection, 50% die.

Treatment

Clearance of adenovirus has been shown to correlate with recovery of adenovirus-specific T-cell immunity [374, 375]. When possible, rapid tapering or withdrawal of immunosup-

pression is felt to be the best way to prevent progression of adenoviral infection [376–379]. Currently, there is no reliably effective antiviral therapy for the treatment of adenovirus infections. There are numerous case reports in the literature reporting success with ganciclovir [380–382], intravenous ribavirin [383–390], vidarabine [391, 392], and cidofovir [383–395]. The key to successful treatment is prompt initiation of therapy in high-risk individuals. A risk-adapted approach, similar to that taken with CMV, may in fact prevent progression to disseminated disease, which is typically associated with a dismal outcome. An alternative strategy that has been exploited is adoptive immunotherapy. There are data supporting the use of donor leukocytes to treat posttransplant EBV-associated lymphoproliferative disease, as discussed previously. This principle has been extrapolated to the treatment of life-threatening adenoviral infection following T-cell-depleted HSCT and has met with success, although there are only published data on one patient [396].

Clearly there is an absence of adequately controlled studies on treatment of adenovirus infections with the currently available antiviral agents. Cidofovir and ribavirin appear to offer most promise and should be further investigated in a prospective multicenter trial.

Prevention

In the allogeneic transplant population, patients can be stratified according to their risk of adenoviral disease:

Low. autologous HCT recipients [368, 397, 398]

Intermediate. T-cell replete, related-donor allograft recipients without GVHD

High. T-cell depleted (2–3 log) related or unrelated-donor transplants [383, 384]; HLA-mismatched transplants (other than DRB1 mismatch) [399]; patients with GVHD on systemic steroids [369, 370, 398], pediatric patients

Highest. refractory GVHD; unrelated cord blood or haploidentical stem cell graft, T-cell depleted (>2–3 log), use of anti-T-cell antibodies (antithymocyte antibody, alemtuzumab) [383, 400]

It is currently advised that patients in the highest risk category undergo weekly PCR monitoring for active adenovirus for either the first 6 months after transplant or for the duration of immunosuppression [399, 401]. Unfortunately, there is no definitive data on a critical value for viral load in the peripheral blood to indicate initiation of treatment.

Respiratory Viruses

Respiratory viral infections are a common cause of morbidity and mortality among patients with hematological malignancies. Despite significant advancements that have been made in our understanding of the pathophysiology, epidemiology, and laboratory diagnosis of these infections; improvement in available treatment regimens for established disease has been limited. A major focus has therefore remained on prevention. Along with adenovirus (already discussed previously) which can also present as an upper respiratory infection, respiratory syncytial virus, influenza, and parainfluenza are the most commonly encountered and will be discussed next [402–404].

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV), a member of the paramyxoviruses, is a single-stranded RNA virus related to parainfluenza virus and is a well-recognized cause of upper and lower respiratory tract illness in children [405–408]. Outbreaks of RSV infection are seasonal and usually occur in the community during November to April, the fall and winter months in the Northern Hemisphere [409, 410]. Repeated infections are common in all age groups, and previous infection does not confer immunity and prevent subsequent infections, even in sequential years [411, 412].

The virus can be transmitted by three possible mechanisms [413]. The first is transmission by small-particle (less than 10 μm diameter) aerosols, which are typically produced by coughing or sneezing. These are able to traverse distances of 1.8 m or greater. Second is transmission by droplets or large particles. This type of transmission necessitates person-to-person contact, usually at distances of less than 0.9 m for infection to occur. Finally, transmission can occur via contact with contaminated surfaces. Typical winter conditions enable RSV to remain viable on nonporous surfaces for longer than 6–12 h. Therefore, assuming virus viability, there is great potential for self-inoculation and transmission of infection to surrounding patients and medical personnel. This is particularly worrisome for medical personnel and nursing staff, who may unwittingly spread the virus during high-risk months. Prevention using good infection control practices is of paramount importance. Nosocomial transmission has been implicated in some groups of immunocompromised patients [414]. Respiratory secretions are contagious and the portal of entry is through the nasopharyngeal mucosa and conjunctivae. The incubation period of RSV is 3–5 days. The target tissue is the respiratory epithelium. Proliferation and necrosis of bronchiolar epithelium with lymphocytic peribronchiolar infiltration and edema are characteristic pathologic findings. Both humoral and cell-mediated immunity are important protective responses [415], and those individuals with inherited or acquired immunodeficiency have more severe and long-lasting RSV infections than normal individuals [408].

RSV infections in BMT patients have been increasingly described since 1988, with several outbreaks being reported

in large BMT centers [399–408]. The reported incidence of RSV infections in hospitalized BMT patients ranges from 7 to 20%. High-risk groups for the development of RSV infections include premature infants; children with bronchopulmonary dysplasia, congenital heart disease, or cystic fibrosis; immunosuppressed patients, including bone marrow and solid organ transplant recipients and those with underlying disorders of cellular immunity; elderly people; and those living in institutions [409]. Children with hematologic malignancies are susceptible to RSV infection, which has the potential to cause more severe illness in these patients than in nonimmunocompromised patients [407, 416], and can result in extension to the lower respiratory tract, pneumonia, and death. Adults with hematologic malignancy are also susceptible [417, 418], especially those profoundly immunosuppressed after marrow transplantation.

In immunocompromised children and adults, RSV infections usually present as an upper respiratory tract illness with cough, fever, sinus and nasal congestion, rhinorrhea, and dyspnea but rapidly progress to severe and often fatal lower respiratory tract viral pneumonia, with marked radiographic changes [419]. A review of 600 children with RSV infection revealed 47 patients with compromised immune function over a 10-year time span. On analysis of the data, those children with primary immunodeficiency disorders and those receiving chemotherapy were more likely to develop RSV pneumonia (60–80% admitted to intensive care units) and had a higher mortality rate (15–40%) compared with those with normal immunity (5% intensive care unit admissions; fewer than 1% died) [407]. In the BMT population, lower respiratory tract pneumonia develops in approximately 50–60% of RSV-infected patients [410, 419]. The development of pneumonia is associated with a higher mortality rate (66–100%), and therefore rapid treatment and prevention of progression are important [409, 417, 420, 421]. The M.D. Anderson Cancer Center has produced data demonstrating that those patients treated earlier (1 day or less from symptoms) had an overall mortality rate of 22% versus 100% in patients who had delayed treatment or who did not receive treatment [417]. This confirms that the mortality rate increases as the time to diagnosis and treatment increases. The other known predictor of outcome in BMT recipients is engraftment status. The risk of pneumonia is greater in patients who have not engrafted than in those who have (79 vs. 41%) [419]. There are also data demonstrating that the frequency of progression from an upper respiratory tract infection to pneumonia is higher in patients in whom engraftment has not occurred or who are less than 1 month posttransplant, compared to those who are more than 1 month posttransplant/engraftment (70–80% vs. 25–40%, respectively). However, once pneumonia develops, engraftment status does not alter overall mortality [410, 420]. Other risk factors that have been identified as causing progression of RSV infections from an upper respiratory tract to a lower respiratory tract infection include older age and HLA-mismatched or unrelated donor transplants (relative risk 2.8.1) [422].

Diagnosis

Nasopharyngeal aspirates or washes are among the most common specimens used for the diagnosis of RSV. Wash specimens are preferred to swabs because they have increased sensitivity. Diagnosis can be made by molecular and nonmolecular methods. Specimens may be tested for RSV by culture or by use of a rapid detection assay such as enzyme-linked immunoabsorbent assay (ELISA) or immunofluorescence [408]. More sensitive methods such as PCR analysis for the presence of viral-specific nucleic acid have been more utilized with more recent attention to the quantitation of viral load. Specimens from sputum or bronchoalveolar lavage also contain the pathogen, and in the immunocompromised patient, bronchoalveolar lavage has an increased sensitivity for virus detection

Treatment

Currently there are a number of available treatment options for RSV pneumonia which include ribavirin, intravenous immunoglobulin rich in RSV titers, RSV immune globulin (RSV-IG [Respigam, MedImmune, Gaithersburg, MD]), and palivizumab (Synagis, [MedImmune, Gaithersburg, MD]). Unfortunately there are no large randomized controlled trials in patients with hematological malignancy supporting the efficacy of any one of these treatments alone or in combination. The most commonly employed agent, ribavirin is a synthetic purine nucleoside derivative [423]. Its antiviral effects result from three mechanisms of viral inhibition, namely, suppression of viral nucleic acid synthesis; blocking of the formation of the terminus of mRNA, leading to inefficient translation of mRNA into viral structural proteins; and suppression of viral polymerase, resulting in interference with viral mRNA expression and subsequent protein synthesis. Ribavirin has activity against a broad spectrum of both RNA and DNA viruses and has been investigated as a potential treatment in influenza A and B, disseminated adenovirus, parainfluenza virus, herpesvirus, and RSV infections. Ribavirin may be given orally (15–20 mg/kg/day divided into 2–3 doses) or aerosolized (6 g administered continuously or 2 g three times per day). Its role in RSV infections is controversial with much of the data on treating RSV infections come from the pediatric literature, as this is one of the populations most at risk for this infection. Conflicting results are reported on the use of ribavirin to treat RSV infections in infants and children. Several studies of infants and children on ventilators have examined the effect of ribavirin on days of ventilation and hospitalization. The results are variable, with one study showing a reduction in days of ventilation

and hospitalization [424], one study demonstrating no difference in hospitalization [425], and two studies showing prolonged hospitalization and ventilation compared to placebo [426, 427]. A meta-analysis of studies in infants with RSV lower respiratory tract infections demonstrated an overall trend in favor of ribavirin but no evidence of a significant benefit; unfortunately, the studies lacked the power to detect reductions in mortality [428]. Based on these data, ribavirin is not often used for infants and children with RSV infections and is reserved for immunocompromised and critically ill patients.

An abundance of case reports and small series report the effectiveness of aerosolized ribavirin in the treatment of RSV in both adult and pediatric BMT recipients [409, 417, 429–432]. It is important to remember that the number of patients treated is small and the studies are uncontrolled and noncomparative. One of the largest studies of RSV infection in BMT recipients reported 31 cases of RSV infection diagnosed among 199 transplant recipients [409]. Of the 31 patients, 18 were diagnosed with RSV pneumonia and the remaining 13 had upper respiratory tract infections. Ribavirin was administered to 13 (72%) of the patients with pneumonia but to none of the patients with upper respiratory tract infections. Survival among patients who developed pneumonia was poor, with a mortality rate of 78%. The mortality rate was 70% in the 13 patients treated with aerosolized ribavirin monotherapy and 100% in the untreated patients. Responses appeared to be better in those patients receiving more than 5 days of ribavirin therapy. An earlier study also documented a mortality rate of 66% in BMT patients with radiographically documented RSV pneumonia treated with aerosolized ribavirin monotherapy [421]. Based on these findings and the results outlined in case reports in the literature, it is difficult to justify monotherapy with ribavirin for the treatment of RSV pneumonia in immunocompromised individuals. If ribavirin is to be effective, early diagnosis is essential and treatment should be instituted prior to progression to pneumonia. In a randomized controlled trial, the efficacy and tolerability of aerosolized ribavirin for preventing the progression of RSV upper respiratory tract infection (URI) to a lower respiratory tract infection (LRTI) was studied in 14 patients who had undergone myeloablative conditioning and were 90 days post-HSCT [433]. Patients were considered to be infected if they had upper respiratory signs, respiratory rate greater than 150% of baseline, increasing cough, wheezing, sputum production, or pleuritic chest pain and oxygen saturation less than 90% on 2 consecutive measurements and a documented RSV infection. Patients randomized to drug therapy received aerosolized ribavirin 2 g (over 2 h) three times each day for 10 days. The primary outcome was progression to clinical pneumonia. Following randomization, 9 patients were allocated to treatment and 5 patients received supportive care. Clinical pneumonia after randomization occurred in 1/9 (11.1%) ribavirin patients and 2/5 (40%) of control patients ($p = 0.51$). There were no deaths in the trial. Overall, this study did not reveal any differences in outcomes despite trends in lower viral loads among ribavirin recipients.

In a study by Chemaly et al., the effect of aerosolized ribavirin on preventing pneumonia in 107 HSCT or hematologic malignancy patients with RSV upper respiratory infection was reported [434]. Patients received 6 grams of aerosolized ribavirin through a face mask inside a scavenging tent for 18 h/day (duration of therapy not defined). In this study, the authors identified 107 RSV patients, 61 were treated with ribavirin and 46 were provided supportive care. Progression to pneumonia occurred in 12/61 (20%) and 27/46 (59%) of patients, respectively ($p < 0.005$). On multivariate analysis, patients who developed pneumonia were older (OR, 1.037; 95% CI, 1.001–1.074; $p = 0.042$) and did not receive RSV-directed antiviral therapy (OR, 4.67; 95% CI, 1.20–18.10; $p = 0.025$). In addition, degree of lymphopenia (absolute lymphocyte count <200 cells/mL) was associated with poor outcomes and should be included in the treatment algorithm.

A number of small studies have suggested improved response rates and improved survival rates with combination therapy [435]. Whimbey et al. [436] studied aerosolized ribavirin 20 mg/mL for 18 h/day in combination with IVIG 500 mg/kg every other day in BMT patients who were RSV positive. The IVIG product was chosen based on the presence of neutralizing antibodies against RSV subtypes A and B. Of 42 patients who presented with upper respiratory tract illness, 19 were RSV positive. Pneumonia developed in 16 patients, of whom 12 (75%) were treated with combination therapy. The overall mortality rate among those with pneumonia was 42%, a significant improvement over mortality rates associated with ribavirin monotherapy. As seen with ribavirin monotherapy, responses were more likely to occur with fast implementation of treatment. The same group from Texas used the same combination of drugs (ribavirin plus IVIG) in a trial evaluating efficacy in preventing progression of RSV upper respiratory tract infection to pneumonia [420]. Fourteen patients were treated for a mean of 13 days with combination therapy. The upper respiratory illness resolved in 10 patients (71%). Four patients (29%) developed pneumonia, which was fatal in two. In this study, two different methods of administering ribavirin were evaluated. Traditionally, aerosolized ribavirin is administered at a daily dose of 6 g, delivered at a concentration of 20 mg/mL for 18 h/day in a scavenging tent to prevent environmental contamination with the drug [420]. Although it produces very high drug levels in bronchial secretions with little systemic absorption [437, 438], this method of administration is cumbersome and is often difficult for patients to tolerate for long periods. In an attempt to improve compliance and ease of

administration, short-duration aerosolized ribavirin at a daily dose of 6 g, administered at a concentration of 60 mg/mL for 2 h every 8 h was evaluated. This method of administration has been attempted in the past with limited success [419], but the favorable results reported by the Texas group offer promise and should be further evaluated in a larger group of patients.

The doses of standard IVIG necessary to achieve the required in vivo RSV-neutralizing activity are large, and frequent dosing is required. This, coupled with wide variations in RSV antibodies between batches and commercial sources, led to the development of a commercial RSV hyperimmune globulin. RSV-IG, a polyclonal hyperimmune globulin containing high titers of RSV antibodies (over 19,200 MU/mL) against RSV [439]. The product is commercially available as Respigam (MedImmune, Gaithersburg, MD).

The only available data in immunocompromised patients are in the BMT literature. The results of a compassionate use protocol of RSV-IG in the treatment of lower respiratory tract RSV infections in pediatric BMT patients showed that 55% of patients had resolution of lower respiratory tract infections following one dose [439]. Importantly it must be noted that of the patients enrolled in the program, 82% had previously received aerosolized ribavirin and 91% were receiving concurrent aerosolized ribavirin with RSV-IG. Despite concomitant treatment, the mortality rate was only 9%, and this offers promise for the future. Clearly, further studies using RSV-IG as monotherapy and comparing outcomes to those obtained with ribavirin are warranted in the immunocompromised patient population.

In addition to RSV-IG, a humanized RSV monoclonal IgG1 monoclonal antibody that is highly active against RSV types A and B is commercially available [440]. Palivizumab is approved by the US Food and Drug Administration for the prevention of serious RSV lower respiratory tract disease in pediatric patients at high risk for RSV disease. In the pediatric population it has been shown to reduce hospitalizations as a result of RSV infection by 55%, reduce the total number of days in hospital as a result of RSV infection (36 vs. 63 days), reduce the number of ICU admissions (1.3% vs. 3%), and reduce the total number of days hospitalized overall (191 vs. 242 days) [441]. In view of these promising data and the increasing incidence of RSV infection among immunocompromised patients, the use of palivizumab has been evaluated in a small number of BMT patients. There are two small studies in this patient group, one examining the pharmacokinetic profile of palivizumab in patients without RSV infection, and the other in patients with documented RSV infection. In the pharmacokinetic study, the mean serum concentration after 30 days was 41.9 μg/mL [442], which was within the limits necessary to produce a two-log (99%) reduction in pulmonary RSV infection, based on animal data [443]. Patients were also monitored for the development of antipalivizumab antibodies. No antibodies were detected, which is consistent with the pediatric literature [442]. The second study evaluated the response to palivizumab in 15 patients with proven RSV infections. At enrollment, 12 patients (80%) had lower respiratory tract involvement and 3 (20%) received mechanical ventilation. Palivizumab 15 mg/kg was administered in combination with ribavirin therapy. The survival rate was 87%, similar to results seen with RSV-IG. Palivizumab is an interesting addition to the therapeutic armamentarium against RSV and offers the advantage of being administered once and producing high concentrations that are sustainable and protective over a 30-day dosing interval. To date there are no comparative studies of RSVIG and palivizumab, so which one is superior remains to be seen.

McCoy et al. recently reported their single-center experience with a RSV algorithm developed by interdisciplinary team for managing RSV infections in 26 patients with hematologic malignancies [444]. Practice guidelines were used to stratify patients by disease severity, time post-HSCT, and degree of lymphopenia. Patients with URI and less than 1 month post-HSCT and/or absolute lymphocyte count <300 cells/mm^3 received aerosolized ribavirin (6 g over 12 h for at least 3 days). If patients presented with LRTI, ribavirin and palivizumab (15 mg/kg for one (1) dose) were administered. Upon review of the data, 13 patients presented with URI and 13 patients presented with LRTI. The average number of ribavirin doses was 5 ± 2.1. No mortality occurred within 30 days of RSV diagnosis. No other variables were addressed regarding the efficacy of the regimen.

Khanna et al. also published the experience from their center along with a review of the literature focusing on the treatment of RSV infections in patients with hematological diseases [445]. The authors of this study identified 780 RSV-infected patients from 1981 through 2007. Aerosolized ribavirin was administered to 337 patients with URI and LRTI. In patients with URI, 30/95 (32%) and 76/112 (68%) progressed to LRTI for ribavirin treated and untreated patients, respectively. In patients with LRTI, death occurred for 39/102 (38%) of patients treated with aerosolized ribavirin, 50/116 (43%) treated with combination ribavirin and IVIG, 15/36 (42%) of untreated patients. These data suggest that early treatment may play a role in reducing progression to LRTI and that treatment may have minimal benefit once disease has progressed beyond URI. RSV infections are not only amenable to aerosolized therapy but may be treated with oral therapy. Oral ribavirin is rapidly absorbed and has been evaluated in several reports. Khanna et al. performed a retrospective analysis on the efficacy of oral ribavirin ± immunoglobulin (IVIG) and/or palivizumab antiviral agents in 34 patients with RSV infection and hematological diseases. Patients were stratified based on degree of immunosuppression and the presence of URI or LRTI. Patients were strati-

fied into moderate or severe immunosuppression based on time from transplant, time from T- or B-cell depletion, presence of lymphopenia, or GvHD grade ≥ 2. Patients with moderate immunosuppression received oral ribavirin (1200–1800 mg/day) plus IVIG (once a week). Patients with severe immunosuppression with URI or LRTI received oral ribavirin plus IVIG plus palivizumab. At the time of RSV diagnosis, 22/34 had URI and 12/34 had LRTI. In patients with URI, 10/22 had moderate immunosuppression and none of the 10 progressed to LRTI. In 12 patients with severe immunosuppression and URI, 2/12 progressed to LRTI. In patients with LRTI and severe immunosuppression, five (5) out of 10 died. For those patients who died, degree of immunosuppression and the presence of LRTI were associated with a poor outcome. RSV loads in nasal secretions were evaluated in 19 patients. A greater than 2 log10 copies/ml drop from baseline was seen in 11/19 within 7 days. None of these patients went on to develop LRTI. Overall, oral antiviral therapy was most effective in preventing disease progression in those patients with moderate immunosuppression and URI.

Avetisyan et al. evaluated the role of systemic ribavirin (intravenous or oral at 15–20 mg/kg/day) therapy in 28 HSCT recipients with laboratory verified RSV infection [446]. No adjunctive therapy was administered (e.g., palivizumab). Following treatment, all patients with URI did not progress to LRTI and survived. For patients with LRTI, 5/14 died directly from RSV. Overall mortality was approximately 20% most of which was in those patients with LRTI. Of note, these data are similar to other reports in which broader antiviral therapy was applied. Overall, these data speak to the fact that degree of immunosuppression and presence of LRTI are associated with poor outcomes and may not be amenable to combination therapy.

With mortality rates approaching 40–60% in patients with lower respiratory infection, ribavirin has become an option for treating patients with upper respiratory disease in the hope of minimizing disease progression. Currently available data suggest that early recognition of infection with RSV, supportive care measures, such as oxygenation and hydration, and reduction of immunosuppressive therapy if possible may be beneficial in improving outcome in improving outcomes. Antiviral therapy appears to be most effective when it is started within 48–72 h of symptom onset, although there are no large randomized controlled trials available to help determine the optimal treatment regimen. With low-level evidence, most data suggest that ribavirin is probably beneficial in preventing disease progression in patients with symptoms of upper respiratory infection. Unfortunately, the initiation of antiviral therapy once lower respiratory infection has developed has not shown a significant benefit in reducing the risk of RSV-related mortality with or without an additional immunotherapy in the form of IVIG or monoclonal antibody.

Although it appears that patients undergoing therapy for hematological malignancy with upper respiratory infection with RSH may benefit from treatment with ribavirin by preventing disease progression, a number of questions regarding treatment remain. One such question is the appropriate route of administration of the drug, particularly in light of the challenges in delivery of the aerosolized formulation of ribavirin. In the US, aerosolized ribavirin is the only FDA-approved agent available for the treatment of RSV approved in 1985. Therefore, most early studies in patients with hematologic malignancies utilized this form of the drug. Since then, aerosolized administration optimized drug concentrations at the site of infection interest stayed with the aerosolized product. There are reasons, however, to consider that oral ribavirin could replace aerosolized therapy in managing respiratory viruses in patients with hematological malignancy. Ribavirin is rapidly absorbed with a reasonable bioavailability at 64% (extensive first pass metabolism), has a large volume of distribution due to tissue and intracellular penetration, and has data to support its role in reducing disease progression (similar to inhaled). In addition, oral therapy is safer for healthcare workers (avoids environmental exposure) and significantly less expensive (Avetisyan). Well-controlled clinical trials to better define the appropriate antiviral management of infection with RSV in this patient population are warranted.

Prevention

Patients presenting for BMT during the RSV season with respiratory symptoms should receive workups for conventional respiratory viruses (CRVs), including RSV, adenovirus, and influenza and parainfluenza viruses. If any of these viruses are isolated, the BMT should be placed on hold until resolution of the acute process if possible. Similarly, patients with cancer undergoing chemotherapy should have therapy temporarily suspended if possible [134].

If any hospitalized BMT patient develops signs and symptoms of CRV infection while an inpatient, appropriate specimens should be obtained for viral culture and rapid diagnostic tests for RSV [437]. If the patient continues to display respiratory signs and rapid testing is negative (two diagnostic samples more than 2 days apart), a bronchoalveolar lavage should be considered. These patients should be placed under contact precautions to prevent spread of infection.

Healthcare workers (HCWs) handling respiratory symptoms of infected patients should wear gowns, surgical masks, and eye protection to avoid contamination from secretions. Protective clothing should be put on when entering the patient's room and discarded before leaving the room. HCWs should change gloves between contacts with patients. All visitors of an infected patient should wash their hands after contacts with the patient or with secretions from the patient. In addition, visitors with upper respiratory tract infections

should defer visiting until resolution of symptoms, and HCWs with respiratory symptoms should be reassigned to duties other than patient care. Unfortunately clinical trials with inactivated and attenuated vaccines have not proven benefit. Further study of subunit vaccines are under development.

Influenza Viruses

Influenza A and B viruses are members of the Orthomyxoviridae family. These enveloped single-stranded RNA viruses are important causes of recurrent epidemics of respiratory disease in both normal and immunocompromised patients. Four genera exist. Influenzavirus A, influenzavirus B, influenzavirus C, and thogotovirus [438]. Influenza A viruses are further divided into subtypes on the basis of serological and genetic differences in their surface glucoproteins [438]. Fifteen subtypes of hemagglutinin (H1 to H15) and nine subtypes of neuraminidase (N1 to N9) have been identified. Considerable antigenic variations can occur; this property has made control by vaccine difficult because these antigenic changes can permit the organism to evade established immunity. Influenza viruses are named by type, location of isolation, number of isolates, year of recovery, and for influenza A, the subtype (e.g., A/Texas/36/91[H1N1]) [447]. Three influenza A virus subtypes, H1N1, H2N2, and H3N2, have caused extensive human diseases during the last century.

Infected respiratory secretions are generally the mode of transmission to a susceptible individual. The target cells are those of the respiratory tract epithelium, particularly the columnar epithelial cells, where the influenza virus replicates [447]. Desquamation of epithelial cells, sloughing and in more severe cases, hemorrhage, hyaline membrane formation, and neutrophilic infiltration are notable findings pathologically. Influenza typically presents clinically as fever with associated chills. Other common presenting symptoms include sore throat, headache, myalgias, and fatigue. In more severe cases patients may present with fulminant pneumonia, a common presentation in the elderly in influenza season. The incubation period for influenza viruses is between 1 and 4 days. Secondary bacterial infections (mainly *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae*) are well-recognized complications. Humoral immunity is an important protective host response, especially neutralizing antibody.

Influenza infections in immunocompromised patients occur, concomitant with outbreaks in the community. For example, an influenza A epidemic in 1991–1992 in Houston was evaluated [448]. Among adult BMT patients, approximately 40% developed acute respiratory illness, and influenza A was isolated from 30%. All had upper respiratory tract illness, but this was complicated by pneumonia in 75%. The case fatality was 17%. Nosocomial acquisition of influenza is also common in hospitalized adults with leukemia or those undergoing BMT [448–450]. Influenza infections in immunocompromised patients have been studied regularly over the past decade and a review of CRVs recovered from 785 consecutive immunocompromised patients with suspected respiratory tract infections has been published [451]. Diagnosis of CRVs was made following bronchoalveolar lavage in all cases, and 199 viruses were isolated from these specimens (23%). Influenza virus was isolated in 11 of 37 patients with CRVs and was the most common CRV isolated. Pneumonia was present in 82% of these patients, and the overall mortality rate was 27%. These results are similar to those previously published in the literature [418, 452] and indicate the need for stringent preventive measures during influenza season and community outbreaks.

In April 2009, an outbreak of a novel H1N1 influenza A virus was noted in Mexico which had a reportedly high mortality rate in an otherwise “low-risk” patient population [453]. This virus was noted to be a reassortment of DNA including genetic components of Swine and human influenza [454]. As opposed to the seasonal influenza virus, mortality from the newly designated Influenza A/pandemic 2009/H1N1 appeared to be higher in infants, young adults, those with obesity, and pregnant women. It was postulated that older individuals may have had some cross reactive immunity to prior exposure of to strains of influenza A not shared by younger individuals [455]. Shortly after infection with this virus was noted in the United States [456], and two cases of infection with the novel H1N1 (“Swine flu”) virus in allogeneic hematopoietic stem cell transplantation recipients were reported [457]. In those cases, prolonged viral shedding with eventual development of resistance to oseltamivir was noted. One patient improved without change in antiviral therapy and one was treated with zanamivir and ribavirin with persistent illness and prolonged hospitalization. Additional cases have been reported in patients with hematological malignancy and/or undergoing hematopoietic stem cell transplantation with varying outcomes [458]. Although pandemic in its spread across the globe, significant increase in influenza-related mortality like that seen in the 1918 outbreak was not noted; however, this outbreak was a warning to healthcare officials and the general public as to how rapidly a contagion can spread globally.

Detection

There are four broad potential targets in diagnosing influenza [459]: virus isolation, detection of viral proteins,detection of viral nucleic acid, and serological diagnosis. The gold standard diagnostic procedure for influenza is isolation in cell culture. This procedure requires 2–4 days to produce a result. The shell vial technique is much faster, enabling detection of influenza antigens following overnight culture, although the

sensitivity of this test is only approximately 80% as compared to standard cell culture [459]. A new area of emerging diagnostics is the detection of viral proteins. There are several rapid tests now on the market, which are easy to perform and do not require skilled technicians. Point-of-care rapid diagnostic tests that are currently available or under development include the Directigen Flu A test, which detects only influenza A in nasopharyngeal, nasal, or throat specimens. This is an enzyme immunoassay test and can be completed in eight steps in approximately 15 min. The sensitivity of the test is variable, ranging from 50 to 99%, with a specificity of 52–97% [438, 447]. The other tests are the ZstatFlu, FLU OIA, and QuickVue. Each of the three latter tests can detect both influenza A and B. The ZstatFlu is a colorimetric neuraminidase enzyme assay that has only three steps but takes 12 min to produce a result from a throat specimen. It has a sensitivity of 62% and a specificity of 99%. The FLU OIA assay method is an optical enzyme immunoassay, which can be completed in seven steps. It is rapid, with a 17-min turnaround, a sensitivity of 62–88%, and a specificity of 70–80%. The QuickVue takes the longest of all the new techniques; it is able to produce a result from a nasopharyngeal or nasal specimen in 30 min and has a sensitivity of 73–82% and a specificity of 96–99%. These tests are rapid and provide quick answers to assist therapeutic decisions, although they are not as sensitive as culture or PCR techniques. In addition, these tests have not been evaluated in the immunocompromised population and the sensitivity and specificity parameters listed are based on studies performed in healthy children and adults. Although these rapid diagnostic tests assist in early treatment, they will not replace the need for viral culture because only culture isolates can provide specific information on circulating influenza subtypes and strains [460]. This information is necessary annually to compare circulating influenza strains and vaccine strains and to formulate vaccines for the coming year.

PCR techniques detect viral nucleic acid in a very sensitive manner, and results can be generated within 24 h. This diagnostic tool is best used in outbreak situations, in which molecular typing and analysis of samples is necessary. Finally, serological diagnosis is based on the detection of a fourfold or greater increase in antibody titers. The test requires two samples, one collected at the onset of symptoms and another 14 days later, and this limits its usefulness in guiding treatment [418]. This test is not as reliable in the immunocompromised population.

Treatment

Amantadine and rimantadine are agents that inhibit an early stage of viral replication and appear to be useful in the prevention and treatment of influenza A in young adults, children, families, and the elderly at risk for exposure [461–465]. Both these drugs act to inhibit the uncoating of the influenza A virus (no activity against influenza B virus) by blocking the activity of the viral M2 protein [460]. Both agents are similarly efficacious (70–90%), although rimantadine may be associated with fewer side effects [466]. These compounds exert maximal benefit when administered within 48 h of the onset of influenza symptoms. They have been shown to reduce the duration and severity of symptoms when administered in this way, although they have not been shown to prevent serious influenza-related complications such as bacterial or viral pneumonia or exacerbation of chronic diseases. One of the main concerns with the use of amantadine and rimantadine is the emergence of drug resistance. Resistance to these agents has been well documented in the laboratory and in humans [467–470], but the frequency and importance of drug-resistant influenza in immunocompromised patients was uncharacterized until recently. It has since been shown to occur in approximately 30% of severely immunocompromised patients with influenza and in 83% of patients with symptomatic disease who shed virus for more than 3 days [467]. In patients who do not respond to treatment, resistant strains must be suspected. Toxicity is also a concern with this class of agents.

A second class of antiviral drugs, the neuraminidase inhibitors, is also available for the treatment of influenza A and B [471–475]. Zanamivir and oseltamivir are both commercially available and FDA approved for the treatment of influenza A and B. They are oral agents and are better tolerated than amantadine and rimantadine. They are not approved for, nor are there currently sufficient data to support their use in the prophylactic setting. Despite this lack of data, in time of community or nosocomial outbreaks of influenza B infections it may be prudent to prophylactically administer these agents to high-risk individuals; this approach certainly deserves further study. These drugs act by selective inhibition of viral neuraminidase. Neuraminidase, essential for viral replication in vitro, promotes the release of progeny virus from infected cells [461]. By inhibiting neuraminidase, zanamivir and oseltamivir block the active site of neuraminidase and leave uncleaved sialic acid residues on the surface of host cells and influenza viral envelopes [461]. Viral hemagglutinin binds to the uncleaved sialic acid residues, resulting in viral aggregation and a reduction in the amount of virus released [460].

Zanamivir is available for use by inhalation only, using the Diskhaler provided in the package. It is approved for the treatment of influenza in patients 12 years and older who have had symptoms for no longer than 2 days. The recommended dose is two inhalations (10-mg dose) twice daily for 5 days. Following inhalation, approximately 7–21% of the administered dose reaches the lungs, with 70–87% of the dose being deposited in the oropharynx [460, 472]. A small amount of the drug is absorbed systemically (4–17%). Zanamivir has an advantage in that the dose does not need to

be modified in renal impairment. Oseltamivir is available as an oral capsule. It is approved for the treatment of influenza A and B virus in adults 18 years of age or older within 2 days of the onset of influenza symptoms. The recommended dose for adults is 75 mg by mouth twice daily for 5 days. Doses need to be reduced in patients with creatinine clearances less than 30 ml/min to 75 mg daily Approximately 80% of a dose is systemically absorbed [460]. Both of the commercially available neuraminidase inhibitors have favorable side effect profiles. The most common side effects seen include nausea, sinusitis, nasal signs and symptoms, diarrhea, cough, dizziness, and headaches. The majority of these side effects could be attributed to the underlying influenza infection and were seen with a similar incidence in the placebo groups of the earlier trials. Both neuraminidase inhibitors have been shown in clinical trials in healthy volunteers to reduce the symptoms associated with influenza by approximately 1 day. There is currently a lack of data supporting the use of these agents in immunocompromised patients, patients who are hospitalized, or patients with severe influenza including pneumonia.

As seen with amantadine and rimantadine, resistance to neuraminidase inhibitors can be induced. The emergence of resistance, however, is much less likely to happen, requiring several passages in cell culture [460], whereas resistance to amantadine and rimantadine requires far fewer passages in cell culture. Resistance to zanamivir has already been documented in a BMT recipient [476], and therefore the use of these agents in this population warrants close surveillance. In addition, osteltamivir-resistant novel influenza H1N1 virus infection has also been reported during the recent outbreak [457].

Machod et al. described the benefit of early administration of antiviral therapy in HSCT recipients with the administration of oseltamivir within 48 h of initial symptoms likely to prevent more serious disease [477]. The optimal duration of therapy for patients who develop influenza infections, however, remains unanswered. Prolonged viral shedding leads to the potential of development of drug resistance. In a report by Khanna et al., 18 of 21 episodes of influenza in allogeneic transplant recipients were treated with 75 mg of oseltamivir twice daily for a median of 11 days (8–14) and all survived [478]. Recurrent viral shedding and need for retreatment has also been described [479].

Prevention

Previously, amantadine and rimantadine were used primarily as chemoprophylaxis for community and nosocomial outbreaks of influenza A. Their use has largely been supplanted by the neuraminidase inhibitors. It is currently advised that during community or nosocomial outbreaks, the following stem cell transplant populations should receive chemoprophylaxis with a neuraminidase inhibitor [134]:

1. Transplant recipients less than 6 months after transplant.
2. Transplant recipients who have not received a current influenza vaccination and are greater than 4 months after transplantation.
3. Transplant recipients who are less than 24 months after transplant or who are greater than 24 months after transplant and substantially immunocompromised who have been exposed to influenza. Additionally caregivers and close contacts of transplant recipients should also receive chemoprophylaxis if an outbreak occurs with a strain of influenza not contained in the available influenza vaccine [134].

Inactivated vaccines are available, and community immunization programs in the fall and early winter can reduce the spread within communities. The efficacy of the influenza vaccine in cancer patients and the severely immunocompromised host is reduced as compared to normal controls. Several attempts to overcome poor immune responses, including administering additional injections, have been made although they have not met with much success. Patients with mild underlying immunodeficiency have been able to mount an antibody response. The scenario in BMT patients is somewhat different. In an evaluation of antibody responses to a two-dose regimen of influenza vaccine in allogeneic T-cell-depleted and autologous BMT patients, the likelihood of response was significantly related to a longer interval between transplantation and immunization [480]. Vaccination during the first 6 months unfortunately was ineffective. Similarly, patients with GvHD were less likely to undergo seroconversion. Thus, early after transplant an agent such as a neuraminidase inhibitor may be more useful in protecting susceptible patients than immunization. It is currently advised that all stem cell transplant candidates and recipients receive a seasonal trivalent inactivated vaccine [134]. In addition, vaccination of family members and close or household contacts is recommended during each influenza season. This immunization schedule should start the year prior to the BMT and continue for at least 24 months after BMT, generally for as long as the patient is immunosuppressed [134]. If the immunization occurred during an influenza outbreak, chemoprophylaxis, if feasible, should be provided for 2 weeks after influenza vaccination while the immunologic response to the vaccine develops.

Recommendations for vaccination and chemoprophylaxis are identical for autologous and allogeneic transplant recipients.

Parainfluenza Viruses

Human parainfluenza viruses (PIVs) are enveloped, single-stranded RNA viruses, which are members of the Paramyxovirus family (along with RSV, measles, and

mumps). Of the four major antigenic serotypes, three are common respiratory pathogens frequently causing upper (type 1 and 2) and lower (type 3) respiratory illness in the general population. Infections are seasonal, especially during the fall. The target tissues are the mucosal epithelium of the nasal and oropharyngeal passages, but infection can extend to bronchi and bronchioles in more severe cases. Neutralizing antibody and cytotoxic T-cell responses are immunoprotective. The virus can be isolated from infected secretions by cell culture techniques coupled with immunofluorescence.

Incidence and Outcomes

Parainfluenza virus is a frequent cause of respiratory illness in children less than 6 years of age. The disorder presents with a variety of symptoms, ranging from upper respiratory tract infections to croup and pneumonia [481]. By 30 months of age, nearly every child will encounter this virus, but immunity is incomplete and reinfection occurs throughout life. When reinfection occurs in later life, the infection course is generally less severe. Parainfluenza virus infections have been reported following BMT [481–484]. The reported incidence among BMT and cancer patients has ranged from 2 to 5% of patients. The largest review of PIV in BMT patients was conducted over 16 years from 1974 to 1990 at the University of Minnesota. Over 1200 patients were screened for common respiratory viruses, and PIV was isolated in 27 patients by either nasopharyngeal cultures or bronchoalveolar lavage. Approximately 30% of patients had respiratory symptoms localized to the upper respiratory tract, characterized by fever, cough, coryza, wheezing, and shortness of breath. The remaining 70% developed lower respiratory tract infections, of which 32% developed respiratory failure. Diffuse pulmonary infiltrates on chest X-ray and sinus opacification, in addition to cough, fever, wheezing, and shortness of breath characterized lower respiratory tract infections. As with other CRVs, development of pneumonia is associated with a poor outcome, with the majority of patients dying. This is in contrast to infection localized to the upper respiratory tract, which all patients survived. Unlike other CRVs such as RSV, infection with PIV was not seasonal but occurred in nearly every month of the year. The most common subtype identified was parainfluenza type 3, which is consistent with other reports in the literature.

The M.D. Anderson group has also reviewed the frequency and outcomes of PIV infections in their cancer and BMT population. Parainfluenza was isolated in 3% of 265 adult BMT patients during 1991. Again, PIV type 3 was identified in all patients. Progression to lower respiratory tract infections was associated with a 50% mortality. More recently, this group published updated results spanning a 5-year period. Parainfluenza was isolated in 61 patients (5.2% of the total screened population). Almost half of the patients evaluated with PIV developed pneumonia, with an associated mortality rate of 34%.

Based on these studies, it is apparent that patients at greatest risk for PIV infection are those who have recently undergone BMT, that is, who are less than 100 days from BMT, and those undergoing allogeneic BMT. In addition, patients with pneumonia were more likely to be lymphopenic than patients with localized upper respiratory tract infections (78% vs. 55%, $p < 0.005$). Other risk factors evaluated but not found to be statistically predictive for PIV pneumonia were patient age, presence of GvHD, type of immunosuppression, and the presence of neutropenia [484].

Treatment

There is no known effective antiviral treatment, although ribavirin may have some activity [401–403, 433, 485]. Ribavirin has been used with mixed results in PIV infections. The Minneapolis group treated nine patients (33% of the total PIV-infected population) with aerosolized ribavirin for a median of 10 days. The survival among those patients (78%) was no different from that patients not treated with ribavirin. This study was uncontrolled and was not intended to test the value of ribavirin therapy. The Texas group also treated some patients with ribavirin, achieving success in 60% of patients. At this juncture the role of ribavirin in PIV infections is unclear. Its role should preferably be in those patients with upper respiratory tract infections to attempt to prevent progression to a lower respiratory tract infection. However, in patients who have already developed a lower respiratory tract infection and are critically ill, it is also worth attempting. There are also limited data supporting intravenous ribavirin in the management of PIV infection [486].

Metapneumovirus

Human metapneumovirus is a single-stranded RNA paramyxovirus that causes respiratory tract infections in children, the elderly, and immunocompromised adults [487–490]. It has been identified as the cause of upper and lower respiratory tract infections worldwide during the late winter months (January to April). In one study of lung transplant recipients, infection was found in bronchoalveolar lavage fluid of 5% of symptomatic patients [487].

Infection manifesting as acute pneumonia with diffuse alveolar damage and hyaline membrane formation has been described in lung and heart lung transplant recipients [491, 492]. In BMT recipients, one study isolated human metapneumovirus by RT-PCR in 26% of symptomatic patients undergoing bronchoscopy and was associated with an 80% mortality rate [493]. Infection usually occurred within the first few weeks after transplant and was characterized by fever, nasal congestion, cough and the rapid development of

hypoxia, hypotension, and a rapidly worsening pneumonia. Pleural effusion and nodular infiltrates can be seen, which can help differentiate the infection from RSV. Prolonged asymptomatic infection after BMT has also been described [494]. Ribavirin has been demonstrated to decrease human metapneumovirus replication in the lungs in a mouse model [495]. Intravenous ribavirin has been effective in the treatment of metapneumovirus infection in lung transplant recipients [496].

Hepatitis Viruses

Hepatitis viruses are RNA (hepatitis A, C, and G) or DNA (hepatitis B) enteric pathogens, which can be transmitted via the fecal–oral route or sexual contact. Transmission through infected blood products is also problematic and represents a serious challenge for the management of patients with hematologic malignancies requiring blood product support. A summary of recommendations for the management of the various hepatitis viruses are listed in Table 51.6.

Hepatitis A

Hepatitis A is a member of the Picornaviridae family. This nonenveloped single-stranded RNA virus replicates in the intestinal tract and then is transported to the liver, which is the major target tissue. It can cause acute hepatitis characterized by jaundice or can present subclinically. In contrast to hepatitis B and C, only rare cases of hepatitis A transmission by blood products have been described, and therefore routine screening of blood products for hepatitis A virus does not occur. Transmission of the virus is thought to occur via the oral–fecal route. In addition, hepatitis A has a long incubation period of 15–50 days, with the virus excreted in the feces for 1–2 weeks prior to the onset of clinical illness and for at least 1 week afterwards [497], which emphasizes the need for good hygiene practices. The typical presentation of hepatitis A virus infections includes fever, malaise, nausea, vomiting, arthralgias, and anorexia [498]. In some patients flu-like symptoms may also be present. These symptoms tend to abate with the onset of jaundice. Rarely, acute liver failure, cholestatic hepatitis, or relapsing hepatitis can occur.

Table 51.6 Recommendations for screening, surveillance, and treatment of Hepatitis viruses

Virus	Screening	Surveillance	Prophylaxis	Treatment
A	Recipient	N	N	IVIG, Hep A vaccine
B	Donor/ recipient	Y	Y	Lamuvidine, famciclovir
C	Donor/ recipient	Y	N	Direct acting antivirals
G	N	N	N	Unknown

Management of acute hepatitis A infection is primarily symptom control. In otherwise healthy patients, resolution of the infection will occur in 3–6 months. The primary control measure is prevention. Patients traveling to hepatitis A endemic areas should receive either IVIG prophylaxis or hepatitis A vaccination. Similarly, immunocompromised patients who come into contact with hepatitis A-infected patients should consider prophylaxis. Passive immunization with IVIG has been the primary treatment of choice for over 50 years. Intravenous immunoglobulin is most effective when given within 2 weeks of exposure and is the fastest way to achieve hepatitis A antibodies. The alternative to IVIG is hepatitis A vaccine, of which there are two types used around the world, including the live attenuated vaccines and the inactivated vaccine. In the United States there are two commercially available inactivated vaccines, Havrix (Glaxo Smith Kline) and Vaqta (Merck). These vaccines produce very high levels of antihepatitis A virus, significantly higher than can be achieved with IVIG [498]. Following the first dose, antihepatitis A virus is detectable in the serum within 15 days in most patients. In the majority of patients, seroconversion is complete 1 month following injection, and persisting antibodies can be detected at 1 year. As with other vaccinations, immunosuppressed patients tend to be less responsive.

Indications for immunization include travel to endemic areas, chronic liver disease, and clotting factor disorders likely to require concentrate replacement. At this time, routine hepatitis A immunization is not recommended for BMT patients [446]. There are limited data on the safety of the vaccine in this population; however, consideration can be given to administration of the hepatitis A vaccine to patients older than 2 years who are at least 12 months post-BMT and who are at increased risk of for hepatitis A and its adverse consequences (e.g., persons with chronic liver disease, including chronic GvHD, and children living in areas with consistently elevated hepatitis A incidence) [497].

Testing for Hep A IgG in candidates and donors is generally not recommended as it has no impact on transplant outcomes. However, testing for Hep A IgM is generally indicated as part of the workup for acute hepatitis in HCT candidates because of the increased risk for sinusoidal obstruction syndrome following myeloablative conditioning regimens. Donors who test positive should have the transplant delayed because of a high risk of transmission and increased morbidity and mortality.

Hepatitis B

Hepatitis B, a member of the Hepnaviridae family, is a small DNA virus, which can cause acute self-limited primary infection and resolve or can become a persistent infection

for years or even a lifetime. The virus can be transmitted by percutaneous inoculation via needles, blood transfusion, or contact of mucosal surfaces with blood and other body fluids, including sexual contact. Persistent infection may be accompanied by no hepatic dysfunction, but chronic hepatitis is common and can be associated with a risk for hepatocellular carcinoma. Persistent viremia can pose a risk for transmission by blood transfusion. With routine donor screening for hepatitis surface antigen (HbsAg) and hepatitis B core antibody (anti-HBc), the risk for hepatitis B from a blood transfusion has diminished tremendously. In addition, increasing immunization with hepatitis B vaccines in the community has led to a decrease in the number of patients infected with hepatitis B and hence a decrease in the number of contaminated transfusions. Less than 5% of post-transfusion hepatitis today is caused by hepatitis B.

The overall incidence of hepatitis B has declined from a peak of 11.5 cases per 100,000 in 1985 to 0.9 cases per 100,000 in 2014, with an estimated 850,000 to 2.2 million chronically infected Americans [499, 500]. The prevalence of hepatitis B virus (HBV) is geography dependent. In the United States approximately 0.1–0.5% of the population are hepatitis B carriers [500] compared ≥8% in all of Africa, the Middle East (except Israel), South and Western Pacific islands, the interior Amazon River basin, and certain parts of the Caribbean (Haiti and the Dominican Republic) [501]. Based on these data, the chance of a patient undergoing chemotherapy also being a chronic hepatitis B carrier is increasing. Similarly, the likelihood of a BMT candidate having hepatitis B or being exposed to an HbsAg positive donor is increasing.

Chronic hepatitis B carriers who undergo chemotherapy or BMT have been shown to have an increased risk of liver-related morbidity and mortality [502–512]. At the completion of chemotherapy or BMT conditioning, the patient becomes immunosuppressed. At this time there is an increase in hepatitis B virus replication in the liver, leading to an increased viral load. On recovery postchemotherapy, there is immune reconstitution, which is associated with an acute hepatitis flare. Immune recovery causes an immune-mediated destruction of liver cells containing HBV. The severity of hepatocyte destruction is directly proportional to the viral load in the liver [500, 503, 506]. This results in an acute exacerbation of hepatitis and may progress to fulminant liver failure.

Studies have been performed in lymphoma patients with concomitant HBV undergoing standard chemotherapy. In this population, the development of impaired liver function (as assessed by increased liver function tests) occurred in more than 50% of patients studied. Liver-related mortality was 5%, with reactivation of HBV thought to be the cause of death [506]. Similarly, there are data characterizing an increased risk of HBV morbidity and mortality in HBsAg-positive BMT recipients [513–520].

In the solid tumor population, prediction of who will reactivate HBV is difficult. The most useful marker of reactivation is HBV viral DNA level [495]. Close monitoring of hepatitis markers is essential. Management strategies in the HBV-positive patient undergoing chemotherapy include as the first step removal of those agents likely to potentiate HBV reactivation. Corticosteroids are a common component of chemotherapy regimens and are known to stimulate viral reactivation [521]. If possible, steroid therapy should be avoided, but this may not always be possible. Continuous low-dose corticosteroids have been attempted and are generally no better than pulse steroids [19]. Similarly, daily or weekly schedules have not been shown to be better than schedules calling for administration every third to fourth week. Other drugs that increase the risk for reactivation/exacerbation of hepatitis B include rituximab [213] and alemtuzumab [522].

The alternative approach is to prophylactically administer antiviral agents to prevent HBV reactivation. Interferon has demonstrated efficacy in hepatitis B carriers (but is less effective in Asian hepatitis B carriers). One of the important side effects of interferon is myelosuppression, and for this reason it is often contraindicated in the already myelosuppressed cancer patient. Alternatives include the nucleoside analogues lamivudine and famciclovir. Both of these agents interfere with viral DNA replication, leading to inhibition of serum HBV viral DNA levels, with consequent improvement in liver function tests (LFTs) [523–529].

The most effective treatment strategy is targeting those patients at greatest risk (identified by screening patients for past and current infection with HBV) and administering prophylaxis to prevent viral reactivation [530]. Patients with evidence of disease at the time of chemotherapy, as demonstrated by viral replication (HBV-DNA-positive) should receive an antiviral agent such as lamivudine (100 mg orally daily) or famciclovir (500 mg three times daily). Unfortunately, on many occasions the viral load in the liver is too great to be affected by this treatment. Carriers of HBV can either be treated prophylactically with the nucleoside analogues or closely monitored postchemotherapy for evidence of viral replication. In those patients receiving prophylactic therapy with the nucleoside analogues, therapy should be continued for at least 6 months following completion of chemotherapy [530].

Management of patients undergoing autologous BMT is similar to conventional chemotherapy. Delayed immune reconstitution may lead to a greater risk of reactivation, but the risk is not as great as that seen in allogeneic BMT recipients. Allogeneic BMT in the HBsAg-positive patient is somewhat more complicated. At the time of transplantation, the patient may be actively infected with hepatitis B virus (HBsAg-positive) or alternatively latent HBV may be reactivated following transplantation (HBsAg-negative) [530]. In

the allogeneic setting, the hepatitis B status of the donor must also be considered; otherwise, liver failure secondary to hepatitis B infection is a possible consequence.

The mechanism of viral reactivation is very similar to that seen after chemotherapy. BMT-conditioning chemotherapy causes ablation of both the bone marrow and the immune system, leading to increased viral replication. On recovery of the immune system, an acute flare may occur. Similar flares have been documented when tapering cyclosporin A immunosuppression [502]. 43 hepatitis B virus carriers undergoing autologous or allogeneic BMT with similar preconditioning regimens, none of the autologous BMT patients developed fulminant hepatitis, compared to five allogeneic patients. Impaired LFTs correlated with cyclosporin A withdrawal [502] and could not be controlled by cyclosporin A dose escalation. Potential signs of a hepatitis flare include increases in LFTs, particularly serum aspartate aminotransferase and alanine aminotransferase (ALT). Hepatitis serology should also be monitored. Ominous signs for the development of fulminant hepatitis include changes in serology from HbeAg-negative to HbeAg-positive, the presence of HbcAb IgM, or detection of HBV-DNA [502].

Approaches to the prevention and treatment of HBV in allogeneic BMT patients are complicated and depend on both the donor and recipient hepatitis profiles. Prior to BMT, all patients and donors should have a hepatitis workup, including HBsAg and HBcAb. If the HBsAg is positive, HBeAb, anti-HBe, and HBV DNA (including quantification) should be assessed. Recommendations for management depending on the results of hepatitis screening have been reviewed [134, 531]. The key to management of BMT patients is comprehensive upfront screening and prophylaxis with a nucleoside analogue if infected.

In addition to lamivudine and famciclovir, newer agents, including adefovir dipivoxil, entecavir, telbivudine, and tenofovir, are effective in suppressing viral reactivation [532, 533]. Unfortunately, the emergence of drug-resistant variant viruses with mutations in the HBV polymerase gene has occurred with their use [534–536] and it is unclear whether any of these newer agents should be used for first-line preemptive therapy. An inactivated hepatitis B vaccine is highly protective. In non-immunized exposed individuals, hyperimmune globulin can afford protection. Interferon can suppress hepatitis B replication although the magnitude of benefit is not great and is frequently temporary [537]. In one study an attempt to immunize BMT and leukemia patients against hepatitis B was unsuccessful [538]. In one case persistent hepatitis B was ablated in a patient who received a marrow transplant from a hepatitis B-immune donor [539]. Similar experimental data in mice have also been supportive of the concept that donor immunity can be adoptively transferred to BMT recipients [540].

In conclusion, when managing BMT recipients, consideration should be given to HBV infection in the differential diagnosis in post-BMT patients with abnormal hepatic transaminases not explained by the typical causes of hepatitis, for example, medications, GVHD, or other viral infections (CMV, HSV, VZV). Increases in hepatic transaminases are most likely at the time of immunosuppression tapering. Provided treatment and prophylaxis recommendations and guidelines are adhered to, the risk of developing HBV infection is low.

Hepatitis C

Hepatitis C is a lipid-enveloped single-stranded RNA virus related to members of the Flaviviridae family. Hepatitis C virus (HCV) can be transmitted via blood transfusions, intravenous drug abuse, and needlestick injuries, as well as by vertical transmission. The risk of transmission of HCV by a blood transfusion has decreased significantly following the introduction of screening processes in 1991. The magnitude of the decrease is such that the risk of transmission in donated blood that has passed all screening tests is now 1 in 103,000 [541] compared to 0.19–0.45% prior to 1991 [542]. The seroprevalence of antibody to HCV in most developed countries is approximately 1–2%. As with hepatitis B, there is significant geographical variation in seroprevalence rates, with higher rates of infection in Eastern Europe and Africa than in the United States. The Centers for Disease Control estimates that 2.7–3.9 million people are infected with HCV in the United States [543]. There are six genotypes of HCV, each having a different geographical predominance. The most common genotypes in the United States are 1a and 1b; genotype 1b is also common in Europe. In Asia genotype 6 is most common, in South Africa genotype 5 is most common, in the Middle East and North Africa genotype 4 is most common, and among intravenous drug users the prevalence of genotype 3 is rising. Differences have been seen in the various genotypes in terms of responses to therapy, but there is currently no clear correlation of disease outcome and severity with genotype [544].

Hepatitis C can cause an acute, self-limiting, primary infection and resolve, or it can become a chronic infection. Approximately 85% of HCV-positive patients develop chronic HCV infection (as documented by persistence of HCV RNA in serum) [544]. There are data demonstrating that cirrhosis develops in more than 20% of chronically infected adults an average of 20 years after diagnosis of the acute infection [545]. Like hepatitis B, hepatitis C has been linked to hepatocellular carcinoma. Hepatocellular carcinoma occurs most commonly in those individuals who develop cirrhosis. Other complications seen commonly in HCV-infected people include elevated transaminases; symptoms of terminal liver failure, that is, portal hypertension and hepatic encephalopathy; and hepatic fibrosis. Hepatitis C has

also been reported to cause extrahepatic manifestations, for example, porphyria cutanea tarda, mixed cryoglobulinemia, and glomerulonephritis [546].

Hepatitis C virus infection can be documented serologically by the detection of antibody directed against HCV in serum (anti-HCV) using enzyme immunoassay (EIA) methodology. These tests have been shown to detect anti-HCV in more than 97% of infected individuals. The test is useful for demonstrating past or present infection but is not able to differentiate among acute, chronic, and resolved infection [547]. The EIA technique occasionally produces false positive results, and therefore confirmatory testing with a supplemental assay is often performed. In cancer patients and the immunocompromised, it is prudent to test for HCV RNA, as this population may produce a false negative result due to inability to produce sufficient antibodies for detection by EIA. The virus itself can be detected in blood through the use of reverse transcriptase polymerase chain reaction (RT-PCR) amplification of HCV RNA. This test enables detection of circulating HCV RNA early in the course of HCV infection, that is, 1–2 weeks following exposure. The presence of HCV RNA indicates an active infection. The final test is a quantitative assessment of the concentration of HCV RNA in the blood (viral load assessment). This test is only useful for determining response to therapy and does not correlate with the severity of hepatitis or overall prognosis.

Hepatitis C infection is relatively common in the cancer (prevalence up to 70%) [529, 548–557] and BMT (3–70%) [558–562] population, particularly those who were treated prior to 1991. These patients have been at greater risk of developing HCV infections than the general population because of the large number of blood products they received during or following therapy. Since the introduction of routine screening tests, the proportion of infected patients has decreased. Because of the large number of people infected with hepatitis C worldwide, the chance of a BMT patient or donor being hepatitis C positive is relatively high. Therefore, appropriate diagnostic and subsequent precautionary measures should be taken to avoid fulminant liver failure. Patients thought to be at risk for hepatitis C (i.e., those with increased ALT pretransplantation that is not explained by other likely diagnoses, those with a history of intravenous drug abuse, with a history of blood transfusion prior to 1991, or with multiple sexual partners) should be evaluated for hepatitis C infection by HCV RNA PCR detection technology prior to transplantation.

Patients who are infected with HCV and undergo BMT are at increased risk for multiple hepatic problems in addition to that seen in immunocompetent patients. Sinusodial obstruction syndrome (SOS, previously known as veno-occlusive disease [VOD]) occurred more frequently in patients who were HCV-RNA positive prior to transplant compared to HCV-negative patients (87% vs. 66%, respectively, $p < 0.004$) [562]. Severe SOS was also increased in patients who were HCV positive prior to transplant compared with HCV-negative patients (48% vs. 14%, $p < 0.0001$) [562]. Hepatic inflammation may be seen 3–6 months after transplantation, which is coincident with immune reconstitution and discontinuation of immunosuppressive medications [562]. Patients who have cirrhosis at time of transplantation are at increased risk of developing hepatic decompensation post-HCT [563, 564]. Finally, patients receiving mycophenolate mofetil may develop a firbrosing cholestatic hepatits, which is an aggressive form of viral hepatitis that usually occurs before day 100 [565]. The impact of HCV infection in long term survivors after HCT was initially studied by Ljungman et al. [556]. The diagnosis was based on the HCV positivity either by PCR for HCV RNA or by second-generation ELISA and RIBA or EIA supplemental assay. Of 161 surviving patients transplanted between 1978 and 1991, 28 (17.4%) were found to have chronic HCV infection. No signs of severe progressive liver disease were shown among the patients included in this study with a follow-up median time of 6.1 years [556]. Thomas et al. with an average follow-up of 6 years found no evidence of cirrhosis [566]. In 1999, the Seattle group reported a cohort of 355 patients that underwent HCT between 1987 and 1988 from which 113 (32%) were HCV RNA-positive by day 100 posttransplant. During 10 years of follow-up, no patients developed clinical evidence of liver disease, and HCV infection did not impact the actuarial survival of long-term survivors over this time period [562]. It was thus concluded that HCV infection was not associated with excess mortality over 10 years of follow-up. However, the same group observed the development of cirrhosis leading to hepatic decompensation and hepatocellular carcinoma in HCV-infected, marrow transplant recipients, surviving beyond 10 years. Among 3721 patients who survived 1 or more years after HCT, 31 developed cirrhosis. Cirrhosis was attributed to HCV in 15 of 16 patients presenting more than 10 years after HCT [567]. HCV infection ranked third, behind infection and GVHD, as a cause of late death [568]. Moreover, cirrhosis was diagnosed beyond 10 years after transplantation in 13 of 15 patients and 3 cases of hepatocellular carcinoma was observed in this cohort. Ivantes et al. also found cirrhosis on a smaller group of patients followed up more than 10 years after HCT [569]. Thus, HCT recipients with HCV infection present a higher risk of earlier cirrhosis.

The presence of HCV is not an absolute contraindication to transplantation. In general, the course of chronic liver disease is insidious, and progress is slow for at least 10–20 years. The determination of whether transplantation should proceed and of when to transplant is dependent on the degree of underlying liver dysfunction, which should be established prior to transplantation. It is recommended that all candidates for HCT with HCV infection must be assessed for evi-

dence of chronic liver disease [134]. Liver biopsy is advised in the setting of associated iron overload, history of excessive alcohol intake, history of hepatitis C > 15 years, and clinical evidence of chronic liver disease [530]. Patients with evidence of cirrhosis should avoid conventional Cy or TBI containing conditioning regimens as they are associated with a 9.6-fold increase in fatal sinusoidal obstruction syndrome [562]. However, even with reduced intensity conditioning regimens, there is a significant mortality risk for patients with cirrhosis [570].

In the allogeneic BMT setting, the HCV status of the donor must also be evaluated. Hepatitis C virus transmission to recipients of HCV RNA-positive allogeneic and syngeneic marrow products [571] occurs universally. Within days of marrow reinfusion, patients develop viremia, although evidence of clinical and biochemical hepatitis may take weeks to months to develop. Damage to hepatocytes in HCV infection is mediated predominantly by HCV-specific cytotoxic T cells, and therefore biochemical abnormalities will only become apparent on engraftment and reconstitution of cell-mediated immunity [562, 563, 572]. If time permits, the best action is to treat the donor in an attempt to render the donor's serum HCV RNA undetectable at transplantation. However, treatment of HCV infection may take 6–12 months, time which is not always available in transplantation because of the underlying nature of the malignant disease. Again, donor HCV seropositivity is not a contraindication to transplantation, priority being allocated to an HLA match, whether donor and recipient are HCV-positive or -negative.

Historically, the standard HCV treatment for the general population was interferon-α, either alone [573–579] or in combination with ribavirin [580–582]. Interferon (3 million units subcutaneously three times per week for 12 months) is active and has been shown to reduce the level of HCV viremia and improve hepatic transaminase abnormalities [583–585]. Long-term remissions can occasionally be seen (in 15–25% of cases) [547]. Unfortunately more than 50% of patients who respond initially relapse after treatment cessation. Predictors of a poor response to interferon include a high HCV RNA titer and HCV genotype 1 (the most common genotype in the United States). The combination of ribavirin (1000 mg/day divided into two doses for patients weighing less than 75 kg; 1200 mg/day divided into two doses for those over 75 kg) and interferon has significantly improved response rates compared to monotherapy (36% vs. 18%, $p < 0.047$) [581], and the responses were sustained over 12 months. In most clinical situations, combination therapy is preferred. The combination of pegylated alpha interferon and ribavirin produced a sustained virological response rate of approximately 55% [583, 584]. Responses were better in genotype 2 or 3 infections versus genotype 1 infections (approximately 80% response with a 24-week treatment duration vs. 50% with a 48-week duration, respectively). There is concern about the use of combination therapy in allogeneic BMT patients as interferon is associated with an increased risk of GvHD and mortality within 6 months of transplantation [585–587], and ribavirin monotherapy has been shown to be ineffective in the general population [588–590], although there is one small case series that demonstrates efficacy in BMT patients [591]. However, a large cohort study showed no increased risk of GVHD among allogeneic HCT recipients treated with interferon with or without ribavirin [592]

Direct acting antivral (DAA) agents are oral agents that target various HCV-encoded proteins vital to the replication of the virus (Table 51.7). When used in combination in normal individuals, they have demonstrated favorable safety profiles and have demonstrated excellent sustained viral repression with the possibility of cure of HCV. Unfortunately, the efficacy and safety of DAAs have not been extensively studied in infected HCV recipients. Current guidelines by the ASBMT are extrapolated from recommendations by the American Association for the Study of Liver Diseases (AASLD) and Infectious Disease Society of America (IDSA) [593].

One of the issues that has yet to be addressed in a large study is how to manage the long-term survivor of cancer or bone marrow transplantation. As supportive care technologies improve, the length of overall survival is increasing, which will lead to a population of patients with the potential to develop cirrhosis. As mentioned, blood transfusion products were not screened for HCV prior to 1991. With the insidious nature of the disease, the implications of cancer treatment and transplantation in this group may not have been truly realized before mid-2000. Common sense tells us that those patients developing signs of cirrhosis and liver failure should be treated in the same manner as the general HCV-infected population. Currently, routine monitoring of HCV-RNA is

Table 51.7 Direct acting antiviral (DAA) agents for hepatitis C

Direct acting antiviral (DAA) agents

Dasabuvir
Nucleoside polymerase inhibitor
Sofosbuvir
Nucleoside analogue
Ribavirin

not advised in HCT recipients with chronic HCV infection. However, viral load monitoring should be considered in patients who have an unexplained elevation in ALT or are receiving active therapy for HCV. In addition, all long-term survivors of cancer with chronic viral hepatitis should be offered vaccination because of the increased risk of fulminant hepatitis should they develop acute hepatitis A [594, 595].

Hepatitis G

Hepatitis G virus (HGV) is a RNA virus that belongs to the Flaviviridae family [596, 597] and is closely related to the GB virus-C (GBV-C) [598]. It prevails worldwide, and the viral RNA has been detected in 1–5% of volunteer blood donors [598, 599]. The prevalence of HGV in patients undergoing BMT ranges from 18 to 61% [600–605]. Following BMT, immunosuppressed patients have been reported to have an increased risk of HGV infection after transfusion-related exposure [601, 606]. This has not translated into accelerated HGV-RNA replication [605].

Currently, the clinical relevance of HGV infection and its long-term effect on BMT patients remain unresolved. HGV has not been shown to affect engraftment kinetics, which indicates no direct effect of HGV on hematopoietic progenitors [607]. The data on the effect of HGV on liver function are conflicting. There are data demonstrating no effect of HGV on the clinical and biological diagnosis of hepatitis in immunosuppressed patients in several studies [604, 606]. However, there are also data in pediatric patients demonstrating increased ALT levels in the absence of other known causes [600]. The maximum ALT levels were statistically higher than those of uninfected patients, although the mean values of ALT showed no difference. This suggests that the effect of HGV on ALT is transient and self-limiting [600].

At present blood for transfusion is not routinely screened for HGV, which is not considered to be a serious pathogen nor a significant cause of hepatitis. Clearly, additional large studies of HGV-infected immunocompromised patients are needed to definitively characterize the effect of HGV on engraftment and hepatotoxicity.

Other Viruses

Papovaviruses

Infection by JC and BK viruses occur early in childhood and are widespread. In most individuals it is asymptomatic, but the viruses persist in the kidney and urogenital epithelium. Asymptomatic virus excretion increases in immunocompromised patients [608, 609]. The JC virus has been associated with progressive multifocal leukoencephalopathy and has been described in patients with chronic lymphocytic leukemia or lymphoma and following BMT [610–612]. Dissemination with involvement of multiple visceral organs, including the lungs, has also been noted [608]. The BK virus has been associated with hemorrhagic cystitis, especially in allogeneic BMT patients, in whom the risk is three times as high as in similarly treated autologous BMT recipients [613–617]. Occasionally adenovirus type 11 can also be associated with hemorrhagic cystitis [614]. Both humoral and lymphoproliferative responses to active viral shedding have been noted, but whether these are immunoprotective remains uncertain [618]. At present, there is no known effective therapy, although cases of response to vidarabine, ribavirin, ciprofloxin, or cidofovir have been reported.

Parvoviruses

Human parvovirus B19 is a small DNA virus, which causes erythema infections during childhood. It is an occasional cause of arthritis and in patients with chronic hemolytic anemia can be a cause of a transient aplastic crisis. It is a potential cause of pancytopenia, rash, or chronic anemia in immunocompromised patients, including leukemia and BMT patients [619–627].

Intranuclear lesions within erythroid precursors in bone marrow specimens have been noted in acutely infected patients [628].

Marrow recipients with GVHD may have chronic infection. The infection can be documented by detection of virus-specific antibody against the B19 antigen by ELISA or of viral DNA by PCR. The virus has been detected in respiratory secretions, bone marrow, and blood. There is no specific antiviral treatment, but reducing the intensity of chemotherapy can be helpful [623], and immune globulin may also be of benefit.

Retroviruses

Human immunodeficiency virus is a retrovirus that is the causative agent of AIDS. Sexual transmission and transmission via blood transfusion or organ transplantation has been well documented. During the early 1980s, prior to the development of a screening serologic test for blood products, patients with hematologic malignancies receiving blood product support were susceptible for contracting HIV infection. Subsequent to 1985 with routine screening, the risk of transmission via a blood product is 1 in 500,000 or lower. Several cases of AIDS in patients with hematologic malignancies have been documented [629]. It is uncertain that the course of illness in immunocompromised patients is substantially different than in nonimmunocompromised patients.

The association of HIV infection with Kaposi's sarcoma and aggressive non-Hodgkin's lymphoma has been noted, especially among those with low CD4 counts for more than 1 year [630–633]. There has been limited experience performing bone marrow transplantation in patients with HIV-associated malignancies [634–636]. In some patients, cytoreductive therapy to ablate all lymphohematopoietic-derived cells (the reservoir of latently infected cells) combined with antiviral therapy has had a marked antiviral effect, whereas in others in whom the virus is not very susceptible, the effect has been marginal. Most of the beneficial effects have been transient, and generally patients have succumbed from transplant-related complications or opportunistic infection. With the development of better antiviral agents and the engineering of donor marrow stem cells with genes that confer resistance to viral infection, this might be more promising in future investigations.

In the era of highly active antiretroviral therapy (HAART), there has been a drop in the rates of opportunistic infection and Kaposi's sarcoma. Of interest, however, is that there has not been a concomitant fall in the incidence of AIDS-related lymphomas, at least so far [637–640], with the exception of a decline in central nervous system lymphomas [630, 631]. Unfortunately, most cases present at an advanced stage and have a very poor prognosis, which also has not changed in the era of HAART [637, 641]. In a subset of patients with CD4 counts above 100/ml, higher response rates and longer survival have been noted [642]. Since HAART therapy may preserve immune function for long intervals, diagnosis of lymphomas at an earlier stage may in the future lead to improved treatment outcomes.

Currently, the presence of HIV in patients with a malignancy treated by transplantation does not automatically exclude the patient from this potentially life-saving procedure. In patients with controlled HIV disease, autologous transplantation is a reasonable, with transplant-related mortality similar to non-HIV-infected patients [643–647]. The data for allogeneic transplant, however, is limited although it is feasible [648]. Management of these patients should be coordinated with a HIV specialist and preferably on a clinical trial.

Human T-cell lymphotropic viruses (HTLV)-1 and -2 are type C oncoviruses present in widely scattered populations, including those of the islands of southwestern Japan and the Caribbean basin, where infection is endemic. Screening of blood donors in the United States indicates a small but detectable seroprevalence. Transmission is by blood transfusion, sexual contact, and in utero. Although most infections are asymptomatic, HTLV-1 is the etiologic agent of adult T-cell leukemia/lymphoma [649–651]. There have also been associations between HTLV-2 and malignancy [651], but its role in pathogenesis is uncertain. Adult T-cell leukemia/lymphoma occurs in only a small minority of HTLV-1 carriers. The lifetime risk is estimated to be between 2 and 5% [649].

West Nile Virus

West Nile virus is a flavivirus first detected in the northeastern United States in 1999 and since then has caused over 2.5 million cases of infection in outbreaks of infection in the late summer and early fall throughout the Unites States [652, 653]. In humans, most infections are asymptomatic. However, 20% of infected patients develop West Nile fever, manifested by malaise, anorexia, nausea, myalgias, headache, and occasionally lymphadenopathy [654]. One in 150 symptomatic patients develop meningitis or encephalitis, presenting as photophobia, phonophobia, and meningismus [655]. Patients with encephalitis develop altered mental status, cranial nerve palsies, seizures, and movement disorders. A minority of patients abruptly develop asymmetric weakness that may progress to flaccid paralysis associated with hyporeflexia or areflexia, mimicking poliomyelitis [653, 656, 657]. Acute neuromuscular respiratory failure may develop, with a mortality rate of more than 50% [655]. Hemorrhagic fever has been described as well, similar to syndromes seen with other flaviviruses [658].

Diagnosis of West Nile virus infection in immunocompetent hosts may be made serologically or by reverse transcriptase PCR. An IgM antibody capture assay is available and becomes positive in CSF 3–5 days after onset of symptoms in nonimmunosuppressed hosts [659, 660], before serum antibody develops; CSF IgG is seen approximately 5 days later. Antibody presence may be confirmed with viral neutralization studies. IgM antibodies may persist in serum for up to 12 months after infection resolution, and IgG may persist for years. Immunocompromised patients demonstrate delayed seroconversion, making diagnosis of acute infection difficult at times. Nucleic acid testing in plasma or CSF is the most useful diagnostic test in this setting [661].

Several cases of West Nile virus infection have been reported in recipients of BMT [659, 662]. In most well-described cases, infection occurred 3–5 months after engraftment while on calcineurin-based prophylaxis against or treatment for chronic GVHD. Fever, lethargy, and progressive bilateral extremity weakness were noted. Hyporeflexia or areflexia were present, and CSF contained 0–6 white blood cells/μL. Serologic studies were negative in CSF and blood in most cases (including IgM assays). Diagnosis of West Nile virus infection was made by PCR performed on serum and CSF. All of the described patients died.

There are no antiviral agents that have proven efficacy in the treatment of West Nile virus infection. Ribavirin possesses in vitro activity but demonstrates poor clinical efficacy [663, 664]. Intravenous immunoglobulin with high titers of anti-West Nile virus antibodies were demonstrated to have significant clinical benefit in animal models. However, immunoglobulins derived from US donors has been ineffective in treating acute infection [652, 665, 666]. Overall mor-

tality from West Nile virus are 4–20% with significantly higher rates in immunosuppressed patients [655, 667].

Summary

The clinical significance of viral infections in patients with hematological malignancies has assumed greater importance during the last two decades. In part, this is related to more frequent recognition of viral syndromes due to improved techniques of documenting various viral pathogens by more accurate and more accessible diagnostic assays. It is also attributable to increasing use of dose-intensive or immunosuppressive treatment regimens, which have greater attendant immunosuppression and susceptibility for viral infection. With increasing awareness of the substantial morbidity due to these viral pathogens, it has become extremely important to recognize these infections. With the expanding array of antiviral agents, vaccines, and immune modulators, it has now become possible to intervene therapeutically to prevent infection, reduce morbidity, or prevent death from these pathogens. With continuing investigations it is likely that a number of unexplained syndromes encountered in patients with hematologic malignancies will be identified in the future as having a viral etiology. These advances hopefully will further improve our supportive care in this patient population and permit further strides in the control of hematologic malignancy.
