The editors of the sixth edition of this book dedicate it to our families; to our mentors; to the hundreds of fellows we have trained over the years, many of whom have gone on to lead major cancer research and treatment programs on several continents; and to the thousands of patients we have had the privilege to care for and learn from over the decades. We also honor the continuing influence on this edition by former editors of previous editions, Drs. George P. Canellos, John M, Goldman, Robert A, Kyle and Charles A. Schiffer.

Preface

The sixth edition of *Neoplastic Diseases of the Blood* is long overdue despite the fact that the fifth edition was published only five years ago, due to the fact that major progress in our understanding of the nature of hematologic malignancies and their treatment has occurred in the interim. This edition is current and up to date, drawing heavily on recent references, and is designed to be a readable, encyclopedic resource for established hematologists and oncologists as well as for trainees in our disciplines.

The chapter structure of the book follows essentially that of the fifth edition, with the addition of some new chapters in the myeloma section. This edition is also divided into five sections like previous editions, each developed and managed by an editor: Chronic Leukemias and Related Disorders (Peter H. Wiernik), Acute Leukemias (Peter H. Wiernik), Myeloma and Related Disorders (Morrie Gertz), Lymphomas (Peter H. Wiernik), and Supportive Care (Janice P. Dutcher). Over 100 authors, many new to this edition, have contributed their expertise to this work.

Our sincere hope is that patients with hematologic malignancies will directly benefit from our work. This hope drove us to take on and complete this huge task that is the creation of this book.

We thank the publisher, Springer Medicine, for invaluable assistance during all phases of the development of the book. Special thanks to Maureen Alexander, Developmental Editor at Springer, for her highly professional continual interactions with the editors and all authors that was instrumental in bringing this project to a close in a timely manner, and to Andy Kwan, Editor, Clinical Medicine for Springer, for overseeing the project from beginning to end.

The Editors

Peter H. Wiernik, M.D.

Janice P. Dutcher, M.D.

Morie A. Gertz, M.D.

Contents

Part I Chronic Leukemias and Related Disorders

1 A History of the Chronic Leukemias. 3
George P. Canellos and Matthew S. Davids

2 Epidemiology and Etiology of Chronic Myeloid Leukemia 9
Maren Rohrbacher and Joerg Hasford

3 Pathology of the Chronic Myeloid Leukemias 19
Barbara J. Bain

4 Molecular Biology and Cytogenetics of Chronic Myeloid Leukemia. 29
Marina Konopleva, Alfonso Quintás Cardama, Hagop Kantarjian, and Jorge Cortes

5 Diagnosis and Treatment of Chronic Myeloid Leukemia 49
Charles A. Schiffer

6 Etiology and Epidemiology of Chronic Lymphocytic Leukemia 69
Helen E. Speedy, Daniel Catovsky, and Richard S. Houlston

7 Morphology and Immunophenotype of Chronic Lymphocytic Leukemia 79
Mir Basharath Alikhan and Girish Venkataraman

8 The Genomic and Epigenomic Landscape of Chronic Lymphocytic Leukemia. 99
Jonathan C. Strefford, Renata Walewska, and David G. Oscier

9 Treatment of Chronic Lymphocytic Leukemia and Related Disorders. 117
Deepa Jeyakumar and Susan O'Brien

10 Hairy Cell Leukemia. 135
Sonia Ali and Alan Saven

Part II Acute Leukemias

11 History of Acute Leukemia 155
Emil J Freireich

12 The Etiology of Acute Leukemia 161
J. N. Nichol, M. Kinal, and W. H. Miller Jr.

13 Epidemiology and Hereditary Aspects of Acute Leukemia 179
Logan G. Spector, Erin L. Marcotte, Rebecca Kehm, and Jenny N. Poynter

14 Classification of the Acute Leukemias: Cytochemical and Morphologic Considerations 197
N. Nukhet Tuzuner and John M. Bennett

15 Immunobiology of Acute Leukemia 237
Elisabeth Paietta

16 Cytogenetics of Acute Leukemia 281
Nyla A. Heerema and Susana Catalina Raimondi

17 Diagnosis and Treatment of Childhood Acute Lymphoblastic Leukemia 307
Melinda Pauly and Lewis B. Silverman

18 Diagnosis and Treatment of Adult Acute Lymphoblastic Leukemia 337
Nicola Gökbuget and Dieter Hoelzer

19 Diagnosis and Treatment of Acute Myeloid Leukemia in Children. 359
Brenton G. Mar and Barbara A. Degar

20 Diagnosis and Treatment of Adult Acute Myeloid Leukemia Other than Acute Promyelocytic Leukemia 375
Peter H. Wiernik

21 Acute Promyelocytic Leukemia 409
Peter H. Wiernik, Robert E. Gallagher, and Martin S. Tallman

22 Therapy-Related Acute Myelogenous Leukemia. 465
Hyung Chan Suh and H. Phillip Koeffler

23 The Myelodysplastic Syndromes 483
Kenneth Miller and Monika Pilichowska

Part III Myeloma and Related Diseases

24 History of Multiple Myeloma. 511
David P. Steensma and Robert A. Kyle

25 Monoclonal Gammopathy of Undetermined Significance 525
Malin Hultcrantz and Ola Landgren

26 Smoldering Multiple Myeloma 531
María-Victoria Mateos and Jesús F. San-Miguel

27 Frail Patients with Newly Diagnosed Multiple Myeloma 539
Alessandra Larocca and Antonio Palumbo

28 Newly Diagnosed Multiple Myeloma in Transplant-Eligible Patients 551
Rajshekhar Chakraborty and Morie A. Gertz

29 Role of Hematopoietic Cell Transplantation for Myeloma 573
Heather Landau and Sergio Giralt

30 Solitary Plasmacytomas and Soft-Tissue Involvement in Multiple Myeloma. 585
Joan Bladé and Laura Rosiñol

31 Supportive Care in Multiple Myeloma 595
Simit Mahesh Doshi, Tom T. Noff, and G. David Roodman

32 POEMS Syndrome 609
Angela Dispenzieri

33 Waldenstrom's Macroglobulinemia 617
Steven P. Treon, Giampaolo Merlini, and Meletios Dimopoulos

34 Plasma Cell Leukemia 639
Nisha S. Joseph and Sagar Lonial

35 Prognosis of Myeloma/Genetics of Myeloma 645
Sébastien Robiou-Du-Pont, Jill Corre, and Hervé Avet-Loiseau

36 Immunoglobulin Light Chain Amyloidosis (AL) 651
Morie A. Gertz, Francis K. Buadi, Taimur Sher, and Angela Dispenzieri

Part IV Lymphoma

37 Historical Landmarks in an Understanding of the Lymphomas 675
Marshall A. Lichtman

38 Genetics in Lymphomagenesis 723
James R. Cerhan, Esteban Braggio, Susan L. Slager, and Anne J. Novak

39 Epidemiology and Hereditary Aspects of Hodgkin and Non-Hodgkin Lymphomas 755
Seymour Grufferman

40 Pathology of Non-Hodgkin and Hodgkin Lymphomas 773
Mariko Yabe and L. Jeffrey Medeiros

41 Immunology of the Lymphomas 827
Christopher Sequeira and Howard Ozer

42 Cytogenetics of Lymphomas 853
Meaghan Wall and Lynda J. Campbell

43 Diagnosis and Treatment of Hodgkin Lymphoma 903
Peter H. Wiernik

44 Radiotherapeutic Management of Lymphomas 939
John P. Plastaras and Eli Glatstein

45 Diagnosis and Treatment of Non-Hodgkin's Lymphoma of Adults 951
David G. Crockett, James O. Armitage, and Julie M. Vose

46 Non-Hodgkin Lymphoma of Childhood 975
Tony H. Truong, Sarah Alexander, and Sheila Weitzman

47 Lymphoma in Other Diseases 999
Jennifer Crombie and Dan L. Longo

Part V Supportive Care

48 Supportive Care for Patients with Leukemia: A Historical Perspective 1039
Charles A. Schiffer

49 Prevention of Infections in Patients with Hematological Malignancies 1047
Marcio Nucci and Elias J. Anaissie

50 Evaluation and Management of Bacterial and Fungal Infections in Patients with a Hematological Malignancy: A 2018 Update 1063
Maria Pia Franco, Jaime S. Green, and Jo-Anne H. Young

51 Viral Infections in Patients with Hematological Malignancies 1079
Jack W. Hsu, John W. Hiemenz, John R. Wingard, and Helen Leather

52 Therapeutic Cytapheresis, Plasmapheresis, and Plasma Exchange in Neoplastic Diseases of the Blood 1129
Janice P. Dutcher

53 Red Cell Transfusions in Patients with Hematologic Malignancies 1139
Karen E. King and Paul M. Ness

54 Platelet and Granulocyte Transfusion 1153
Janice P. Dutcher

55 Alternative Sources of Hematopoietic Stem Cells and Their Clinical Applications 1179
Filippo Milano, Shelly Heimfeld, and H. Joachim Deeg

56 HLA Typing in Support of Hematopoietic Cell Transplantation from Unrelated Donors 1193
Effie W. Petersdorf, Claudio Anasetti, Paul J. Martin, and John A. Hansen

57 Special Care of Blood and Marrow Hematopoietic Cell Transplant Recipient 1211
Syed A. Abutalib and Hillard M. Lazarus

58 Hematopoietic Growth Factors in the Supportive Care and Treatment of Patients with Hematologic Neoplasms 1247
Ryan W. Jacobs, Omotayo Fasan, Edward A. Copelan, and Belinda R. Avalos

59 Bleeding and Thrombosis in Hematologic Neoplasia 1263
Joseph J. Shatzel, Robyn Scherber, and Thomas G. DeLoughery

60 Psychological Aspects of Hematological Neoplasms 1291
Tomer Levin T. Levin and Judith Cukor

Index 1307

Part I

Chronic Leukemias and Related Disorders

1 A History of the Chronic Leukemias

George P. Canellos and Matthew S. Davids

Introduction

Leukemias, both chronic and acute, were not described separately. Historically, the state of excessive quantities of blood cells and secondary organ involvement is attributed to Velpeau in 1827 [1]; although initial observations suggested that the excess of corpuscles in the blood was related to suppuration, it appeared that those cases were more likely to be what is now known as chronic leukemia because of the duration of disease and systemic enlargement noted [2]. Virchow in 1845 introduced the term of white blood of "leukaemie." He accumulated nine cases and doubted that infection was an explanation for the process [3]. The first reported case in America was in 1852. Virchow also differentiated the leukemias according to "splenic" or "lymphatic" leukemia [4]. By 1870, Neumann proposed that splenic leukemias were derived from cells originating in the bone marrow [5]. Further separation of acute versus chronic leukemias was made by Ebstein (1889) introducing the term "acute leukemia," a disease with a very short survival [6]. It remained for Ehrlich to begin staining cells to separate granulocytes from lymphoid cells. This provided a test to classify leukemia even further than prior unstained descriptions [7]. The primitive cells, known as blasts, were further clarified by Naegeli in 1900 separating to some extent myeloblastic from lymphoblasts [8]. However, Turk in 1903 assembled all the "lymphoid" diseases under one classification known as lymphomatoses [9]. However, the true neoplastic nature of these disorders was confirmed when they could be induced in experimental animals by toxic chemical injection.

Chronic Myeloid Leukemia

Chronic myeloid leukemia remained as defined by early investigations until 1960 when Nowell and Hungerford using the new technology of cytogenetics described a marker chromosome with deletion of genetic material known as the Philadelphia chromosome. This provided a test which defined CML as a clonal disorder [10]. This was further supported by studying patients who were heterozygous for isochromosomes of glucose-6-phosphate dehydrogenase which further defined the clonal origins of a number of other disorders [11]. In the 1970s, a greater understanding of the Philadelphia chromosome evolved. It was demonstrated by DeKlein that the human analog of the murine v-abl oncogene was translocated from its normal location on chromosome 9 to chromosome 22 and soon after that the reciprocal translocation of genetic material from chromosome 22 to chromosome 9 was described, resulting in a fusion gene BCR-ABL on chromosome 22 [12]. Two molecular rearrangements on BCR-ABL are possible but both result in a hybrid messenger RNA and thus a protein kinase [13, p. 210]. Modern molecular technology now allows for reassessment of minute quantities of the gene and facilitates the assessment of new therapeutics in assessing remission of the disease. A number of other features of CML have been attributed to the gene including proliferation, less apoptosis, and diminished cellular adhesion. The early therapeutic history of CML probably began with the use of arsenic trioxide (1% solution known as Fowler's solution). It was used on occasion in the nineteenth century with some transient benefit until the discovery of X-rays which were used to radiate the enlarged spleens. This resulted in significant improvements in signs and symptoms as well as blood counts [14]. The modern chemotherapy era for CML began with the demonstrations of the cytotoxic effects of nitrogen mustard [15]. An oral derivative of alkylating agent research was busulfan, which was introduced in 1953 and was, for a considerable period, the standard oral therapy of CML [16]. Other agents, such as chlorambucil and thiopurines as well as colchicine

P.H. Wiernik et al. (eds.), *Neoplastic Diseases of the Blood*, DOI 10.1007/978-3-319-64263-5_1

derivatives, were used. Because of the unpredictable and sometimes extensive bone marrow suppression with busulfan, another antimetabolite, hydroxyurea, was introduced and shown to be active [17]. The blastic phase of CML was quite refractory to effective treatment regimens used for acute myeloid leukemia and almost never resulted in a remission. Transient, but complete, remissions were however achieved when the blastic phase assumed lymphoid characteristics [18]. Vincristine and prednisone could produce remissions lasting months. The lymphoid nature of the blastic cells was confirmed by immunologic and cytologic tests [19]. Treatment also included interferon for a period before the introduction of the specific tyrosine kinase inhibitors directed at the BCR-ABL protein tyrosine kinase [20]. There was an initial success in producing hematologic as well as molecular remissions, and resurrecting the suppressed normal hemopoietic elements resulting in prolonged remissions [21]. The initial agent was imatinib but new mutations resulted in disease relapse and other more potent ABL inhibitors such as nilotinib, dasatinib, and ponatinib were introduced [22, 23]. The actions of these agents have dramatically altered the natural history and resulted in prolongation of survival obviating the need for allogeneic transplantation which was also a component of the treatment plan for some prior to the introduction of the tyrosine kinase inhibitors. Allotransplantation in its time was potentially curative, providing that there was a compatible donor, tolerance to graft-versus-host disease, and a survival from septicemia. Nonetheless, this could be curative and basically a manifestation of effective immunotherapy by allogeneic T cells against leukemic stem cells. Few patients are now candidates for this treatment as the new kinase inhibitors have had an overwhelming effect on the natural history of CML. It remains an effective therapy for those intolerant to all tyrosine kinase inhibitors (TKI) or with mutations conferring resistance to effect TKI therapy [24]. Allogeneic transplants were successful in the past when performed in the chronic phase with 12-year survival of 60–70%. The introduction of tyrosine kinase inhibitors, such as imatinib, has resulted in 8-year survivals of over 90% when used in the chronic phase. However, although uncommon, point mutations can occur and confer resistance to at least generations of inhibitors. The gatekeeper mutation, T3151, is the offender, but even for this mutation a recent TKI, ponatinib, has been introduced.

Chronic Lymphocytic Leukemia

The early histories of treating CML and CLL have much in common due to the limited availability of treatment options and the inability to distinguish the diseases with any degree of accuracy. In the 1940s and 1950s, Osgood [25–27] tested the hypothesis that whole-body external irradiation or administration of radioactive phosphorus could be titrated to control the leukocyte count at a level below 30×10^9/L. He claimed that this strategy was effective in patients with slowly progressing disease and that it could increase the chance of survival to 20 years. However, his results were not confirmed in later randomized trials comparing irradiation with chlorambucil and other alkylating agents [28, 29].

Progress in the clinical management of patients with CML has relied on improved understanding of the different types of disease and on improved prognosis. In the past, diseases diagnosed as CLL would have included a mixture of T- and B-cell leukemias, hairy cell leukemia, and a variety of other conditions associated with lymphocytosis. In contrast, the cells can now be identified accurately by cellular morphology, immunophenotype, cytogenetics, and other features [30] so that subtypes of disease can be grouped together and informative clinical trials can be designed.

It has been recognized for many years that cases of CLL have variable clinical courses [31]. The wide range of survival times for patient with CLL, from a few years to more than a decade, made treatment decisions difficult, particularly because some patients remained well even if they were not treated. This led to the development of staging systems, based on prognostic indicators and other criteria, to facilitate the choice of therapy for individual patients. The long list of prognostic indicators in CLL now includes age, sex, lymphocyte doubling time, cell morphology, and cytogenetic abnormalities [30]. In particular, patients with del(17p), del(11q), or complex cytogenetics have a poorer overall survival, whereas those with del(13q), trisomy 12, or normal cytogenetics have a better prognosis [32]. Patients whose CLL cells are positive for ZAP-70 tend to have a shorter time to treatment [33]. Testing for the mutational status of the immunoglobulin heavy-chain variable region (*IGHV*) also has significant prognostic impact, as patients with <2% similarity to germline DNA ("mutated") have a more indolent course and longer survival compared to those with >2% ("unmutated") [34, 35]. Recently, the presence of somatic mutations such as *TP53, NOTCH1, SF3B1*, and others has allowed further subgrouping of CLL [36, 37].

With regard to CLL therapy, most patients can be observed for a prolonged period of time after diagnosis without the need for treatment. This has been studied in several randomized clinical trials of early intervention with chemotherapy versus delaying therapy until patients meet treatment indications [38]. These indications as per the 2008 IW-CLL criteria include progressive cytopenias due to bone marrow infiltration by CLL, progressive organ-threatening, bulky lymphadenopathy, or progressive constitutional symptoms in the setting of progressive disease [39]. In the absence of these signs or symptoms, an overall survival advantage to early intervention with chemotherapy has never been demonstrated.

Once patients do meet treatment indications, numerous therapeutic options are available. Long-term low-dose treatment with the oral alkylating agent chlorambucil was a mainstay of CLL therapy for decades. For patients with more indolent forms of CLL, this approach regulated the size of the malignant B-cell clone without inducing major cytopenias or other toxicities [40]. The purine analog fludarabine was subsequently found to induce a higher rate of complete remission and a longer progression-free survival than chlorambucil, but as monotherapy it did not confer an overall survival advantage in a randomized trial [41]. Fludarabine plus the intravenous alkylating agent cyclophosphamide (FC) became a new standard of care when it was shown to induce deeper and more durable remissions than fludarabine alone [42]. In the 2000s, rituximab was added to FC to make the FCR regimen, which was pioneered by Keating and colleagues at MD Anderson Cancer Center [43, 44]. The promising results of their initial studies were subsequently confirmed by the German CLL Study Group in their CLL8 trial, which showed an overall survival advantage to FCR over FC as initial therapy for younger, fit patients with CLL [45]. This trial is notable for being the first randomized trial to demonstrate an overall survival benefit in CLL. More recently, a regimen comprised of the alkylating agent bendamustine with rituximab (BR) has become popular for frontline CLL therapy due to its high level of efficacy and generally favorable tolerability [46]. CLL10 is a large, randomized phase III trial that randomized previously untreated patients to FCR vs. BR [47]. The results demonstrated that FCR induced a higher rate of complete remission, more minimal residual disease (MRD) negativity, and a longer PFS than BR. However, an overall survival benefit has not yet emerged, and BR also provided excellent efficacy and tolerability. In particular, older, frailer patients had less severe cytopenias and infectious complications with BR compared to FCR, and therefore BR can be considered a standard regimen in this population. In patients under 65, FCR provided deeper and more durable remissions with relatively comparable toxicity, making it still the standard of care for this group. Recently published data by both the MD Anderson and German CLL groups on the long-term results of FCR treatment suggest that a substantial number of patients with mutated IGHV CLL will be cured by initial therapy with FCR [48, 49].

Patients who become refractory to chemoimmunotherapy and those with high-risk disease markers such as del(17p) or unmutated *IGHV* typically have less durable responses to chemoimmunotherapy. Several approaches have been used to manage these high-risk patients. The monoclonal antibody alemtuzumab (Campath I-H, anti-CD52) was shown to have a high rate of response in patients with del(17p) CLL and was found to be particularly useful in patients with the bulk of disease in the blood and bone marrow and minimal lymphadenopathy [50]. High-dose methylprednisolone was shown to induce a high rate of remission in high-risk patients and was most useful in those with bulky lymphadenopathy [51, 52]. The UK group attempted to combine these two approaches in their CLL206 trial, which gave concurrent alemtuzumab and methylprednisolone to TP53-deleted CLL [53]. Although their response rates, PFS, and OS were substantial for this population, the toxicity of this highly immunosuppressive approach was also apparent, with grade 3–4 infections occurring in half of the patients.

Given the significant unmet medical need for patients with high-risk CLL, particularly those who became refractory to chemoimmunotherapy, there was an urgent need for the development of novel agents to treat this disease. Years of laboratory research had revealed that two of the “Achilles heels” of CLL pathophysiology were the B-cell receptor (BCR) pathway and the intrinsic mitochondrial pathway of apoptosis, with its key anti-apoptotic protein B-cell leukemia/lymphoma-2 (BCL-2). The first effort to target the BCR pathway in CLL examined the Syk inhibitor fostamatinib. CLL patients treated with fostamatinib had significant shrinkage of lymphadenopathy while at the same time showing a rising lymphocyte count, which was initially concerning for disease progression [54]. Fostamatinib also had several off-target effects which led to significant toxicities and the development of this drug in CLL did not move forward. Shortly after this, two drugs entered into clinical trials which would forever change the history of CLL treatment, ibrutinib, the oral inhibitor of Bruton’s Tyrosine Kinase (BTK) [55], and idelalisib [56], an oral inhibitor of the delta-isoform of phosphoinositide-3-kinase (PI3K), which is selectively expressed in lymphocytes. In early-phase clinical trials, both of these drugs demonstrated an initial lymphocytosis and as with fostamatinib, at the same time nodal disease and cytopenias were improving. This phenomenon was later named “lymphocyte redistribution,” as it was recognized that through disruption of integrin signaling in the stromal microenvironment, CLL cells were being released from the lymph nodes and marrow and into the blood of patients and then subsequently undergoing apoptosis. The recognition that this epiphenomenon was not disease progression but quite the opposite—a sign of disease response—led to a consensus statement that lymphocyte redistribution should not constitute progression and a new category of response known as partial response with lymphocytosis (PR-L) or nodal response should be used to classify these patients [57].

Both ibrutinib and idelalisib were found to be highly active in early-phase trials, and remarkably patients had equivalent response rates irrespective of traditional high-risk markers such as del(17p) or unmutated IGHV [58, 59]. In phase III randomized trials, ibrutinib was found to have an overall survival benefit compared to the anti-CD20 antibody ofatumumab, leading to its FDA approval in relapsed/refractory

CLL [60]. Idelalisib plus rituximab was found to have an OS benefit compared to rituximab alone, leading to its approval in relapsed/refractory CLL [61]. Ibrutinib went on to receive frontline approval for CLL based on an overall survival benefit demonstrated in a phase III study comparing it to chlorambucil for initial therapy in older, frail patients [62]. Idelalisib was also being studied in several frontline trials in CLL and other indications, but due to an increased risk of mortality due to infectious complications as well as significant autoimmune toxicities, its development for frontline CLL therapy came to a halt in 2016 [63].

The other key pathway for CLL cell survival is the intrinsic mitochondrial pathway of apoptosis. CLL is well known to express high levels of the anti-apoptotic protein BCL-2, on which the malignant cells depend for their survival. An early attempt to target this pathway was the oral BCL-2/BCL-XL/BCL-w inhibitor navitoclax [64]. Although substantial efficacy was seen with navitoclax in CLL, there was also significant thrombocytopenia observed, which was thought to be on target toxicity due to inhibition of BCL-XL, which is important for platelet survival [65, 66]. A second-generation BCL-2 inhibitor was developed known as venetoclax, which is highly selective for BCL-2 with minimal activity against BCL-XL [67]. In the phase I first in human study, venetoclax was found to be so active against CLL cells that there were several cases of tumor lysis syndrome including one mortality due to this [68]. After lowering the initial starting dose and doing a gradual intrapatient dose ramp-up, the rates of tumor lysis syndrome dropped substantially and there were no further clinical sequelae. As with the BCR inhibitors, venetoclax induced a high rate of response even in patients refractory to fludarabine or harboring ominous prognostic markers such as del(17p). Unlike the BCR inhibitors, the responses induced by venetoclax included a significant number of patients achieving complete response with some patients achieving minimal residual disease negativity. A subsequent pivotal phase II study of venetoclax in patients with del(17p) confirmed these initial results [69] and led to FDA approval of venetoclax for relapsed/refractory CLL with del(17p) in 2016.

Although an exciting development, the novel therapies recently developed for CLL are unlikely to be curative on their own and therefore must be continued for ongoing therapy. Current clinical trials are looking at combination strategies to facilitate time-limited therapy, in some cases with curative intent. These promising trials involve novel agents plus chemotherapy, novel agents plus a monoclonal antibody, and novel agent-only combination approaches, all of which appear to be promising.

To date, the only consistently curative strategy for CLL has been allogeneic bone marrow transplantation. Many CLL patients are older and frail with significant comorbidities and do not tolerate myeloablative conditioning regimens well. Non-myeloablative conditioning regimens (also known as reduced-intensity conditioning) for transplantation have substantial efficacy with less toxicity, and appear to be equally effective for patients with high-risk disease [70]. Rates of success for allotransplant appear to be highest in patients who are maximally cytoreduced prior to transplant. Overall there is about a 40% rate of long-term progression-free survival in CLL patients treated with reduced-intensity allogeneic transplantation, although rates of graft vs. host disease and treatment-related mortality remain substantial. To build on this immunologic approach to treating CLL with less toxicity than allotransplant, several groups have recently presented data on a novel approach known as chimeric antigen receptor (CAR) T cell therapy. This approach utilizes autologous T cells from the patient and ex vivo introduces a CD19 antigen receptor. The T cells are then reinfused back into the patient where they can proceed to eradicate residual CLL. Several dramatic responses have been observed in refractory CLL patients treated with CAR-T cells, and some of these responses have had substantial longevity [71]. Toxicities include a cytokine release syndrome and neurotoxicity. Ongoing studies of this promising new approach in CLL will help define the optimal use of this technology in CLL.

Although there have been many exciting developments in CLL research over the last several years, there are several areas of unmet medical needs. These include patients with high-risk disease such as del(17p) or complex cytogenetics, whose responses to novel agents are less durable, patients who develop Richter's syndrome for which therapy remains inadequate, and patients who desire time-limited therapy with curative potential. Many clinical trials have launched recently to answer these questions, and these promising new approaches suggest that the future outcomes for patients with CLL will only continue to improve in time.

Epidemiology and Etiology of Chronic Myeloid Leukemia

2

Maren Rohrbacher and Joerg Hasford

Introduction

Epidemiology can be defined as the study of the frequency, distribution, and causes of diseases in populations, mainly with observational designs. In recent years the traditional spectrum of epidemiology was extended to a variety of so-called hyphenated epidemiological subdisciplines like genetic, environmental, pharmaco, and healthcare epidemiology. Epidemiology has become an important multidisciplinary science and is essential for the identification of risk factors, assessment of the burden of disease, development of preventive actions, and promotion of public health. Chronic myeloid disease has been identified as a disease entity for the first time in 1845 independently by Virchow and Bennett [1, 2]. In 1973, Rowley published that the so-called Philadelphia (Ph) chromosome, which is pathognomonic for Ph-positive (Ph+) chronic myeloid leukemia (CML), is the result of a translocation between the chromosomes 9 and 22 [3]. From a commonly fatal disease CML has become, with the introduction of tyrosine kinase inhibitors (TKIs) since 2001, for most patients a kind of chronic disease. More recent studies report that the life expectancy of patients with CML approximates the one of the normal population [4, 5].

As CML is a very rare disease and the diagnosis requires elaborate diagnostic tools like cytogentic tests, FISH, or PCR techniques, it remained outside of the focus of most cancer registries and epidemiologists. Thus, reliable epidemiological information on Ph/BCR-ABL-positive CML is still limited, but much better compared to the situation 15 years ago. The aim of this chapter is to review the current knowledge regarding etiology, incidence, prevalence and survival rates, secondary malignancies, health care, and issues of the daily CML practice.

Etiology

CML is caused by a chromosome abnormality, the BCR-ABL fusion oncogene [Philadelphia chromosome (Ph)] [6, 7]. This oncogene is imperative for a Ph/BCR-ABL-positive CML. Specific genetic or environmental factors can result in the fusion of breakpoints of chromosome 9 in the ABL gene with certain breakpoints on chromosome 22 in the BCR gene [7].

No evidence for genetic predisposition in individual persons has been provided, and case reports of familial CML are rare [7–12]. Lifestyle factors such as smoking and a high body mass index have been identified as possible risk factors for CML [13–16].

An association between chemical exposure to benzene, organic solvents, alkylating agents, topoisomerase II inhibitors or other chemotherapeutic agents, and de novo CML has been shown repeatedly, but the evidence was not entirely consistent [7, 17–21]. An increased CML incidence has been seen among workers exposed to benzene or benzene-containing solvents [17, 20]. Benzene itself is not considered genotoxic, but its major hepatic metabolites, phenol, hydroxyquinone, and 1,2,4-benzenetriol and their metabolic products (e.g., 1,4-benzoquinone and semiquinone) are suspected to induce DNA damages in bone marrow cells as well as alkylating agents and topoisomerase inhibitors [22–25]. The benzene metabolite, trans-muconaldehyde, although genotoxic, seemed to get inactivated in the liver by glutathione. Thus, the active form could not reach sufficient levels in the marrow to harm hematopoietic cell chromosomes [7]. In cell line cultures, benzene-related metabolites, alkylating agents, or topoisomerase II inhibitors caused abnormalities of chromosomes 5 (monosomy or del(5q31)), 7 (monosomy), and 8 (trisomy), often causally associated with secondary acute

myelogenous leukemia after cytotoxic therapy [7, 17, 22–24, 26–28]. Neither relevant breaks in chromosomes 9 or 22 nor the formation of the BCR-ABL fusion gene were observed in in vitro tests [7, 22, 24, 27–29]. Studies of late effects of chemotherapy for a variety of malignancies did not show an increased risk for secondary CML [7].

In comparison to chemical exposures, leukemogenic effects of acute, high-dose ionizing radiation exposure have been identified by the Atomic Bomb Casualty Commission in Japan after World War II in extensive epidemiological studies [20, 30–32]. The latest published data indicated that 20% of all leukemias were classified as CML based on an analysis between 1950 and end of 2001 [33, 34].

Also the incidence of CML among the Chernobyl cleanup workers increased in the last 20 years after the Chernobyl Nuclear Power Plant accident [35]. In the United States, CML represents about 17% of the potentially radiation-induced new cases of leukemia per year [7]. Biological plausibility further strengthened the compelling epidemiological evidence for radiation-induced CML by hematopoietic cell line cultures: The BCR-ABL oncogene could result from high-dose X-ray or gamma irradiation and the subsequent transcription of BCR-ABL message in such cells [36, 37]. High-dose radiation exposure can directly generate leukemia-specific fusion genes [37].

Incidence

Knowledge on clinical and molecular features of Ph/BCR-ABL-positive CML is extensive, but the epidemiology has still not been studied in detail [34, 38]. Sources of these data are mortality statistics [39], cancer population-based registries such as the Swedish Cancer Registry [40, 41], the Saarland Registry [42, 43] in Germany, the database of the Surveillance, Epidemiology and End Results (SEERs) Program of the United States National Cancer Institute [44, 45], or surveys such as the European Treatment and Outcome Study CML-Registry (EUTOS) [46].

Worldwide CML incidence rates vary from 0.6 to 2.8 cases per 100,000 inhabitants with an obvious increase in age [38, 40–52] (Table 2.1). CML occurs with greater frequency in men than in women as shown in male-to-female ratios ranging between 1.2 and 1.8 [34, 38, 40–47, 49, 53, 54].

The most recently published results from the EUTOS population-based CML-registry which collected incidence data from 20 European countries reported a raw incidence of 0.39/100,000/year in people 20–29 years old, and of 1.52 in those >70 years old, showing a maximum of 1.39 in Italy and a minimum of 0.69 in Poland [46]. Here, the median age at the time of diagnosis was about 56 (range 50–64) years. With a male-to-female ratio of 1.16 men were more often affected. Interestingly, a majority (53.5%) of the patients presented no palpable spleen at diagnosis, and 88.2% were classified as EUTOS score low-risk patients [46]. Some geographic and/or ethnic variations and different diagnostic accurateness might contribute to the variability of the reported incidences.

Table 2.1 Crude and standardized CML incidences of population-based registries and surveys

[a]World Standard Population
[b]United States Standard Population
[c]CML cases with known Ph/BCR-ABL-positive status

A crude incidence of Ph/BCR-ABL-positive CML of 0.6 per 100,000 is available from the Scotland Leukaemia Registry [48] and from a survey in the Southwest of Germany [54] (Table 2.1). Both studies covered a population size of about 9 million inhabitants. In the German study the incidence of all reported 218 CML cases including negative and unknown Ph/BCR-ABL status was 0.8, and of CML and CMML (0.2) combined 1.0 [54]. As the Ph/BCR-ABL status was only available for 87.2% of the German CML patients and not for any of the 61 patients with a diagnosis of CMML, incidence estimates provided there probably represent the lower margin of the true CML incidence. The variations of incidences seen might indicate geographic and/or ethnic variability beyond technical artifacts [34, 38, 55]. Some registries try to increase data comparability by standardization according to the age structure of the world standard population (WSP). WSP weighs age-specific incidences in

populations with higher proportions of younger people than in the European standard population [56].

All publications considered in Table 2.1 are from northern Europe [40–43, 46–49, 54] or the United States [44, 45]. There seems to be variability of incidences of geographic areas even in the same country as exemplified by the Swedish National Cancer Registry [49] and the Goteborg Central Disease Registry [57] which reported incidences for polycythemia vera and primary myelofibrosis differing by a factor of up to more than two [38]. This is of interest, as differences in the CML risk group composition between southern (Italy) and northern European countries (Poland, the United Kingdom, Austria, Germany) were reported [46, 58, 59]. However, the recently observed data of the EUTOS registry could not identify a particular regional clustering of high and low incidences among Europe [46].

Between 1993 and 2004 the second Edition of the International Classification of Diseases for Oncology (ICD-O) (WHO Geneva 1990) for coding CML cases was commonly used, which did not differentiate true CML, Ph- and BCR-ABL-negative CML, chronic myelomonocytic leukemia (CMML), or subacute myeloid leukemia [38]. Since 2005, the discriminate coding of the molecular BCR-ABL-negative and -positive status has been possible on the basis of the new third Edition of ICD-O (WHO Geneva 2000) [38]. Basic data, stratified for BCR-ABL status, have not been shown in the latest cancer reports (Table 2.1). Consequently, the published incidences for CML may be higher than the true ones as BCR-ABL-negative cases are included. Up to 5% of patients with chronic myelogenous leukemia do not have the Ph-translocation t(9;22)(q34;q11) or a BCR-ABL molecular rearrangement [60].

Prevalence and Survival Rates

Prevalence of chronic, life-threatening, and costly disease has a major impact on the healthcare systems [61–63]. By the targeted treatment with TKIs a long-term survival is observed [62, 63]. An 8-year overall survival (OS) of 89% was recently published which approximates a normal life expectation [64]. Thus, this improved life expectation under the treatment of TKIs directly increases prevalence rates.

CML prevalence data itself remain scarce as population-based registries mostly provide “CML” data in a general category of “Leukemia” [41, 43, 45]. Nevertheless, some estimations are available from France, Sweden, the United States, and Germany: Within a French survey 906 newly diagnosed CML cases were identified in a population of about four million inhabitants for the period of 1985 to 2006 [51]. The calculated prevalence rate had increased from 5.8/100,000 during 1998 to 6.8 (2002) to 7.3 (2003) and to 10.4 in 2007. In another French survey based on 781 CML patients from population-based registries, the following data were presented [52]: The 5-year relative survival (RS) rates among patients with (Ph+) CML were 44% when diagnosed in 1980–1986, 64% in 1987–1999, and 89% in 2000–2009. The 8-year RS rate of patients with Ph+ CML diagnosed was 83% in 2000–2009.

For the Swedish population, prevalence data from 1985 to 2012 showed an increase from 3.9 to 11.9 per 100,000 inhabitants, and as an assumption 22.0 per 100,000 inhabitants by 2060 [5, 62]. The 5-year OS increased from 0.18 to 0.82, and the 5-year RS between 2006 and 2012 was close to a normal 40-year-old, but lower for 80-year-old CML patients (0.95 and 0.63).

For the US population the following data were available [63, 65, 66]: Estimated prevalence was about 70,000 CML patients in 2010, 112,000 in 2020, 144,000 in 2030, 167,000 in 2040, and 181,000 in 2050 against the backdrop of an annual incidence of 4800 CML patients [63]. A mortality ratio of CML patients (in their first 10 years since the diagnosis of CML) vs. the general population with the same age distribution was calculated to be 1.53 [63]. Using the SEERs database, the 5-year OS was improved for all patients between 2000 and 2005 [65]. Compared with patients who were diagnosed in 2000, the 5-year survival improved among patients aged 15–44 years (hazard ratio (HR) for mortality 0.43), aged 45–64 years (HR 0.716), and aged 65–74 years (HR 0.692), and patients aged 75–84 years had an increased 5-year OS rate from 19% in 2000 to 36% in 2005 (HR 0.568). These data were retrieved from 5138 patients [65]. SEERs data were also used to compare ethnic survival rates among Caucasian, African-Americans, and other races and within each race to see survival differences from the pre-imatinib (1973–2000) to post-imatinib eras (2002–2008) [66]. Here, the RS was significantly improved in the imatinib era, but these improvements were modest in the population-based data compared to those reported from clinical trials [66]. Interestingly, young (<50-year-old) female African-American CML patients have a lower RS in the imatinib era compared to young female Caucasian CML patients.

Considering the situation in Germany, the authors based their study on population-based data of about 10.5 million people in the statutory health insurance system in Bavaria for the years 2008–2013 [67]. Survival rates were adapted from the literature. The mean estimated age-standardized (Old European Standard Population) incidence rates per 100,000 inhabitants were 1.300 and 1.768 for women and men. Based on the population data, a total number of about 9000 CML patients was estimated in Germany for 2012, and it was expected that the number of CML patients would increase further until at least 2040 to 2050 with a maximum of more than 20,000 CML patients as the most probable scenario [67].

As a consequence of this considerable increase of the CML prevalence, the burden for the healthcare systems will rise with respect to costs and clinical services used.

Secondary Malignancy

The observed rise of the prevalence rates, associated with a long-term survival for the patients with TKI treatment, is still under investigation especially focusing on the risk of secondary malignancies [68, 69]. So far, a significant higher occurrence of secondary solid tumors such as gastrointestinal, nose, and throat cancer was observed in the imatinib era than in the pre-imatinib era [69].

Population-based data from 868 CML patients diagnosed between 2002 and 2011 in the Swedish Cancer registry and from 5511 CML patients in the SEERs database indicate that CML patients treated in the TKI era had an increased risk of developing a second (non-hematological) malignancy compared to the general population [68, 69]. In detail, the risk of second malignancies was higher in the CML cohort ($N = 868$) compared to the general population, with a standardized incidence ratio (SIR) of 1.52 (95% CI 1.13–1.99). Here, the SIR before and after the second year following diagnosis of CML was 1.58 and 1.47 [68]. Among the 8511 adult CML patients, 446 patients developed 473 secondary malignancies. The SIR for secondary malignancies in CML patients was significantly higher with the observed/expected ratio 1.27 ($P < 0.05$) and absolute excess risk of 32.09 per 10,000 person years compared to the general population [69]. The rate of secondary malignancies of all sites in the post-imatinib era was significantly higher compared to the pre-imatinib era with the observed/expected ratio of 1.48 versus 1.06 ($P = 0.03$) [69]. The authors assumed that the estimated elevated risk is more likely linked to the underlying CML disease than to the TKI therapy [68].

The occurrence of these secondary cancer entities in TKI-treated CML patients in comparison to the general population is the focus of ongoing research.

Health Care and Daily Practice

Patient's survival depends on the available national healthcare system [70–77]. There, aspects of medicines' costs play an important role in treatment decisions, and may also be the reason behind different treatment recommendations in different countries [77]. The growing life expectancy is in addition an influencing factor for the daily clinical practice. Especially, an age disparity for elderly patients in the administration of TKI therapy has been observed as an issue.

For the approved TKIs such as imatinib, dasatinib, and nilotinib, there are high healthcare costs noticed [76, 77]. In the United States the price for imatinib has been increased threefold from initially $30,000 per year in 2001 to $92,000 per year in 2012 [76, 77]. At the same time in 2012, three new drugs were approved by the US Food and Drug Administration (FDA) with pricing levels at $28,000 (omacetaxine), $118,000 (bosutinib), and $138,000 (ponatinib) per year.

The reason for the high TKI therapy prices can be the expensive developmental costs for new targeted, effective, safe, and tolerable medicines, but the negative clinical aspects of the pricing have also to be discussed. A forum of CML experts emphasized that this economic model of high therapy costs can cause a comprised access of needy patients to the targeted drugs with the clinical consequence of a less effective therapy and a poorer survival outcome [77]. Additionally, this pricing model can potentially harm the sustainability of healthcare systems [77].

Examples of the pharmacoeconomic/epidemiologic associations between national healthcare systems, patient's individual access to targeted CML treatment, and patients' survival rates are shortly described in the following: US patients have to pay an average of 20% of the drug prices out of their own pocket (about $20,000–$30,000 per year) which may induce a personal bankruptcy depending on the private household budget. These circumstances can be reasons for poor compliance, drug discontinuation, and worse outcome: It was observed that 10% of the US patients failed to take prescribed drugs mostly due to costs. By evaluating the survival rates in the United States, the estimated 5-year survival rate is currently still 60% although there was an improvement since the imatinib release in 2001 [77]. This suggests a lower TKI treatment penetration rates in the United States compared to higher TKI treatment penetration and compliance rates in Europe, e.g., in Sweden with an estimated 10-year survival rates of 80% where patients have an access to lifesaving CML drugs via the national healthcare policy [77].

Consequently, there are further discussions needed whether lowering the TKI prices would improve treatment penetration rates, increase compliance, and expand CML patient population living longer and continuing on TKI therapy. This concept would paradoxically increase revenues to pharmaceutical companies from sales of TKIs [77].

Focusing on the clinical practice, CML experts from, e.g., the European LeukemiaNet (ELN) (http://www.leukemia-net.org) have developed recommendations for the medical management of patients of all ages with CML including the definition of CML phases, the appropriate use of TKIs, the evaluation of cytogenetic and molecular responses, and optimized treatment strategies [78–82]. The patient's age at the time of diagnosis and the individual concomitant comorbidities are factors influencing treatment decisions. It was observed that especially elderly patients received either a reduced dose of imatinib in case of concomitant comorbidities or another therapy but not the targeted TKI treatment with the benefit of a better

survival [80–84]. This was confirmed by the validated EUTOS score demonstrating that under TKI treatment increasing age did not play a significant negative role for the probability to achieve a complete cytogenetic remission and a long progression-free survival [85, 86].

However, based on published data, there seems to be an age disparity in imatinib-containing treatments being probably associated with a worse survival for especially elderly CML patients: The use of imatinib was inversely associated with patient's age: 90, 75, and 46% for patients aged 20–59, 60–79, and ≥80 in a study based on SEERs and population-based data with 423 CML patients diagnosed in 2003 [84]. Elderly patients who received imatinib survived significantly longer than those who did not. After adjusting for the patient's age, the imatinib use did not vary significantly by race/ethnicity, socioeconomic status, urban/rural residence, presence of comorbid conditions, or insurance status [84].

Further examples for age disparity in CML treatment: In Lithuania, survival data and the TKI treatment penetrance from 601 CML patients were analyzed [87]. The patients' data were retrieved from the national haematological disease-monitoring system being diagnosed between 2000 and 2013 [87]. The reported median age at diagnosis was 62 years. A 5-year RS rate increased from 0.33 (95% CI, 0.27–0.40, in 2000–2004) to 0.55 (95% CI, 0.47–0.63, in 2005–2009), but the 5-year RS survival rates for patients aged 65–74 years and ≥75 years were only 0.33 (95% CI, 0.24–0.42) and 0.18 (95% CI 0.07–0.23). The TKI penetrance rate for the patients grew from 1.5% (in 2000–2004) to 30.6% (in 2005–2009) and 69.1% (in 2010–2013); however, the TKI penetrance rate was lower in the older age groups (60% for the 65–74, and 19% for the ≥75 years patient group, in 2010–2013). Hence, the RS for elderly patients remained poorer as this patient population rarely received TKIs for their CML treatment [87].

In Sweden, the cancer registry provided data from 779 CML patients for an observed period between 2002 and 2010 [5]. The population's median age here was 60 years. Regarding the TKI penetration rate, nearly 50% of the patients received a TKI, a proportion that increased to 94% for younger (<70 years) and 79% for older (>80 years) patients during 2007–2009. The estimated 5-year RS was close to 1.0 for patients younger than 60 years, 0.9 for those aged 60–80 years, and only 0.6 for elderly patients (>80 years) [5]. Despite respective treatment recommendations, the majority of elderly CML patients received non-imatinib-containing regimens as first-line treatment during 2002–2004. From 2006 a change in imatinib therapy for elderly patients was observed, but nevertheless, this population was less likely to be treated with TKIs than younger patients.

Besides the described TKI treatment age disparity in daily practice, it is known that elderly patients are underrepresented in most investigational clinical trials. This was shown in a comparison between multicenter trials and population-based registries during the last decades [38]: The median age in multicenter trials [58, 88–109] (Table 2.2b) is 49 years, even in trials without age limitation as an inclusion criterion [89, 95, 104]. In contrast, the median age is up to 67 years in population-based registries [44–46, 110–112] (Table 2.2a), concluding that data of clinical trials underestimate the true age of the CML population. Within a German survey it was determinated that the chance for a CML patient <65 years to be enrolled in a clinical study was 3.8 times higher than for a CML patient ≥65 years [54].

[b]This study comprises mostly elderly patients since younger patients were recruited for transplantation studies
[c]The referenced publications [95, 98, 103] retrieved their data from the CML IV Study

Another practical aspect in daily CML management is the association between the frequency of molecular monitoring and the risk of progression and progression-free survival (PFS). This was evaluated in a US study with 402 CML patients being on first-line imatinib therapy [113]. There, it has been shown that patients who had on average three to four qPCR tests per year had a lower risk of progression and longer PFS compared to patients who had no qPCR monitoring. These results were also observed in in those patients being monitored with one to two qPCR tests per year compared to those without any molecular monitoring [113]. Thus, patients can benefit from regularly scheduled qPCR testings which is in accordance to current CML recommendations.

Furthermore, it seems that patients treated in teaching hospitals achieve better outcomes: Based on 1491 patients of the German CML Study IV, the authors compared the outcomes of patients from teaching hospitals with those from municipal hospitals and office-based physicians [114]. Adjusting for age, EUTOS score, Karnofsky performance status, year of diagnosis, and experience with CML, a significant survival advantage for teaching hospital patients (HR 0.63–0.61) was found. In particular, when treated in teaching hospitals, patients with blast crisis showed a superior outcome (2-year survival rate: 47.7% vs. 22.3% vs. 25.0%) [114].

Some of the current issues in CML health care and daily clinical practices have been highlighted. More efforts are necessary that all CML patients get access to the targeted TKI treatment and benefit from the reported better survival associated with regular molecular monitoring. Especially, for the population of elderly patients the age disparity in TKI-containing treatment and the exclusion in investigational trials should be reduced by continuous education and implementation of the proposed recommendations.

Summary

Epidemiological information on Ph/BCR-ABL-positive CML is still limited. Available CML incidence rates vary from 0.6 to 2.8 cases per 100,000 inhabitants with an obvious increase in age. Some geographic and/or ethnic variations might contribute to this variability, but there are also differences in diagnostic accurateness. The observed prevalence rates increase with the widespread use of TKIs improving patients' survival and quality of life. Consequencently, an estimated 8-year OS of 89% has recently been determinated indicating an almost normal life expectation for the CML patients.

This outstanding therapeutic achievement asks for further research on the occurrence of secondary malignancies, other therapy-related risks, the treatment of elderly patients, the economic impact on healthcare systems by the expensive long-term treatment, and the chances to stop treatment with TKIs in patients with complete remission without risking relapse of CML.

3 Pathology of the Chronic Myeloid Leukemias

Barbara J. Bain

Introduction

The chronic myeloid leukemias are a group of hematological neoplasms resulting from mutation in either a pluripotent (lymphoid-myeloid) stem cell or in a multipotent myeloid progenitor or stem cell. The former group of leukemias are actually, or potentially, of mixed phenotype while the latter have a purely myeloid phenotype.

Diagnosis of these conditions is based on clinical and hematological features with genetic analysis being crucial for the recognition of some categories. Genetic analysis has been incorporated, as far as current knowledge permits, into the classification of the chronic myeloid leukemias, in the 2016 update of the 2008 World Health Organization (WHO) *Classification of Tumours of Haematopoietic and Lymphoid Tissues* [1]. Depending on their typical hematological features and any relevant genetic abnormality, they are assigned to the categories: (a) myeloproliferative neoplasm; (b) myelodysplastic/myeloproliferative neoplasm; and (c) myeloid or lymphoid neoplasm with rearrangement of *PDGFRA*, *PDGFRB*, or *FGFR1*or with *PCM1-JAK2*.

In making a morphological diagnosis, the peripheral blood features are often of critical importance. The bone marrow aspirate and trephine biopsy sections give useful supplementary information. Flow cytometric immunophenotyping is only of diagnostic importance when there is presentation with acute-phase disease or when acute transformation subsequently occurs. Immunohistochemistry on trephine biopsy sections can be useful, particularly in the recognition of dysplastic megakaryocytes and for confirmation of the presence of dysplastic mast cells. Cytochemistry is now of little importance in diagnosis; the neutrophil alkaline phosphatase score is redundant when genetic analysis is available and immunophenotyping is superior to cytochemistry for the recognition of the lineage involved in acute transformation.

Chronic Myelogenous Leukemia

Chronic myelogenous leukemia (CML) results from a mutation in a pluripotent hematopoietic stem cell that leads to formation of a *BCR-ABL1* fusion gene [2]. The associated acquired cytogenetic abnormality is usually t(9;22)(q34.1;q11.2), but there are other mechanisms, including variant and complex translocations (see Chap. 6). The derivative chromosome 22 is known as the Philadelphia (Ph) chromosome. Alternative designations of this condition are chronic granulocytic leukemia and chronic myeloid leukemia, but it should be noted that the latter term, although very widely used and now favored by the WHO, is open to misinterpretation since it is also used as a generic term for all the chronic myeloid leukemias.

This disease occurs at all ages, but incidence increases steadily with age and is somewhat higher in men than in women. Common clinical features are weight loss, low-grade fever, sweating, splenomegaly, and, when disease is advanced, hepatomegaly [3]. Lymphadenopathy is only a feature when acute transformation occurs. Patients with a very high white cell count can have features of leukostasis, such as blurred vision and priapism. Many patients are now diagnosed as a result of an incidental blood count when they are asymptomatic.

The natural history of CML is that the chronic phase of the disease is followed by acute transformation (myeloid, lymphoid, or mixed), which may be preceded by an accelerated phase. The abrupt onset of acute transformation without a preceding accelerated phase is more common in lymphoid transformation.

Peripheral Blood Count and Cytology

The peripheral blood count in *chronic-phase CML* typically shows leukocytosis and anemia. Usually there is also

B.J. Bain, M.B.B.S., F.R.A.C.P., F.R.C.Path

P.H. Wiernik et al. (eds.), *Neoplastic Diseases of the Blood*, DOI 10.1007/978-3-319-64263-5_3

thrombocytosis although the platelet count can be normal or reduced. Some patients have thrombocytosis without leukocytosis. Such *BCR-ABL1*-positive cases should be recognized as a variant of CML [2]. The blood film characteristically shows a particular increase in myelocytes and neutrophils (Fig. 3.1). Basophils are almost invariably increased and eosinophils usually so [4]. Eosinophil and basophil myelocytes may also be present. The absolute monocyte count is increased but not in proportion to the increase in granulocytes. The number of blast cells and promyelocytes is proportionate to the number of myelocytes. Cells of the granulocyte lineages do not show dysplastic features. Platelets show anisocytosis with some giant forms. There may be occasional circulating megakaryocyte nuclei with scanty cytoplasm ("bare" megakaryocyte nuclei). Red cells may show nonspecific abnormalities, such as anisocytosis and mild poikilocytosis. There may be circulating nucleated red blood cells. Neutrophil alkaline phosphatase is reduced in the great majority of patients, but this test is redundant when cytogenetic and molecular analyses are available.

Peripheral blood features of the *accelerated phase* of CML may include leukocytosis or thrombocytosis that is refractory to treatment; an increasing basophil count; a disproportionate increase in blast cells; the appearance of dysplastic features such as hypolobulated neutrophils and circulating micromegakaryocytes; thrombocytopenia; and increasing anemia. A disproportionate increase in eosinophils can occur but is much less common than marked basophilia. Poikilocytosis may become more marked and there may be teardrop poikilocytes.

In *blast transformation* there is usually an increase in blast cells in the peripheral blood (Fig. 3.2). Usually these are myeloblasts, megakaryoblasts, or lymphoblasts. When transformation is megakaryoblastic, there may also be circulating micromegakaryocytes. Less common forms of transformation (determined by the underlying further mutations that have occurred) include mixed phenotype, monoblastic, eosinophilic, erythroblastic, and hypergranular promyelocytic.

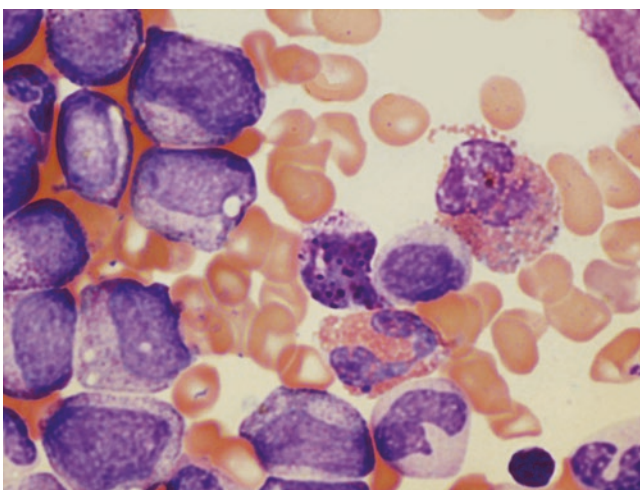

Fig. 3.1 Peripheral blood (PB) film from a patient with chronic myelogenous leukemia with an unusually high white cell count showing an increase of neutrophils, eosinophils, basophils, and granulocyte precursors. May-Grünwald-Giemsa stain (MGG), high power

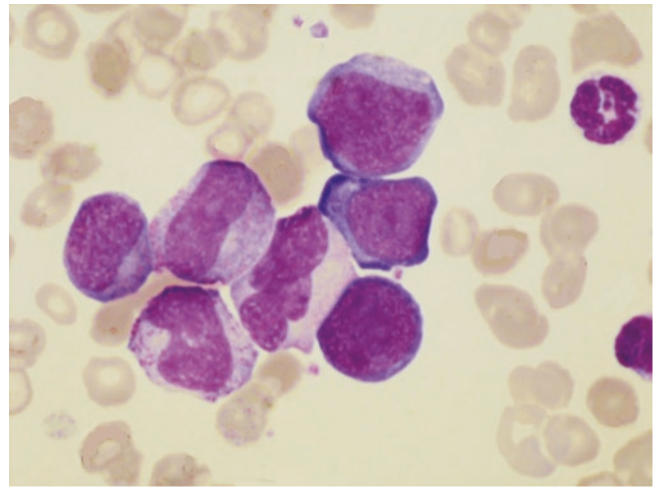

Fig. 3.2 PB film from a patient with transformation of chronic myelogenous leukemia showing three blast cells, granulocyte precursors, and several dysplastic cells of neutrophil lineage. MGG, high power

Bone Marrow Cytology

The bone marrow aspirate in *chronic-phase CML* shows marked hypercellularity due to an increase in granulocytes and their precursors (Fig. 3.3). The myeloid:erythroid ratio is almost always greater than 10:1 and often of the order of 25:1. Megakaryocytes are usually increased with a tendency to be smaller than normal with reduced nuclear lobulation, reflecting a decrease in ploidy. However, micromegakaryocytes, such as those seen in the myelodysplastic syndromes, are not a feature of chronic-phase disease. Sometimes there is an increase in storage cells—pseudo-Gaucher cells and sea blue histiocytes.

In the *accelerated phase*, the aspirate may show increased blast cells, increased basophils, and dysplastic features in the cells of any lineage.

In *blast transformation*, the bone marrow shows increased blast cells, except in the minority of cases in which transformation is first detected at an extramedullary site. Myeloblasts are often agranular and Auer rods are usually absent. In the case of myeloid or mixed lineage transformation, there are usually dysplastic features, particularly in the megakaryocyte lineage (Fig. 3.4).

Flow Cytometric Immunophenotyping

Immunophenotyping is not diagnostically useful in chronic-phase disease.

Genetics

Cytogenetic and genetic features are discussed in Chap. 6.

Histology

In *chronic-phase CML*, trephine biopsy sections show an increase in cells of all granulocyte lineages but, apart from the loss of fat cells, with retention of normal bone marrow architecture (Fig. 3.5) [5–7]. There is an expansion of the band of myeloblasts and promyelocytes that is usually detected against the bony spicule and around arterioles. Eosinophils are readily detected, but basophils are not specifically identifiable on hematoxylin and eosin (H&E) stains as granules are dissolved during processing. Megakaryocytes are increased in number with a reduction in average size and nuclear lobulation. They are normally located and do not form large clusters. Erythropoiesis is decreased. Mast cells and plasma cells are often increased. Increased storage cells may be apparent (Fig. 3.6). Bone marrow vascularity is increased (neoangiogenesis). Reticulin is usually normal or only mildly increased.

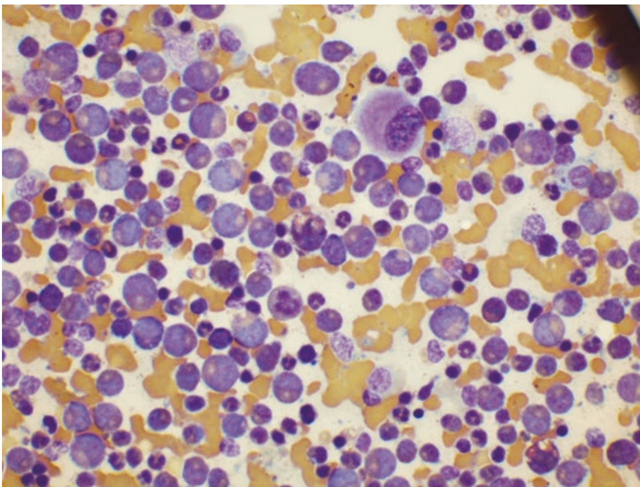

Fig. 3.3 Bone marrow film from a patient with chronic myelogenous leukemia showing increased granulopoiesis and a hypolobated megakaryocyte. MGG, low power

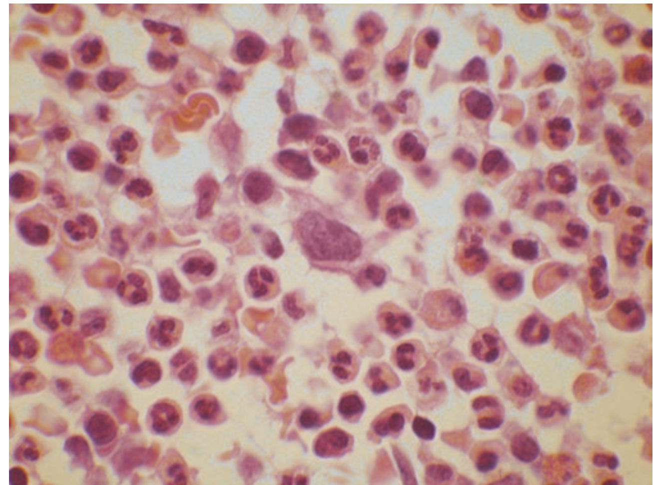

Fig. 3.5 Bone marrow trephine biopsy section from a patient with chronic myelogenous leukemia showing increased granulopoiesis and a relatively small, hypolobated megakaryocyte. Hematoxylin and eosin stain (H&E), low power

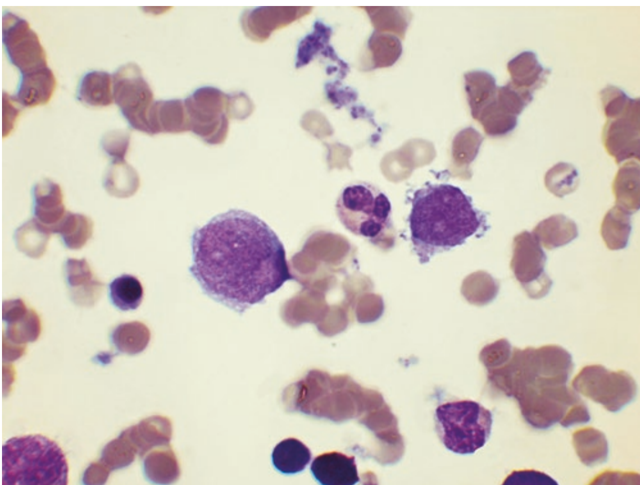

Fig. 3.4 Bone marrow film from a patient with megakaryoblastic transformation showing a neutrophil flanked by a blast cell (*left*) and a micromegakaryocyte (*right*). MGG, high power

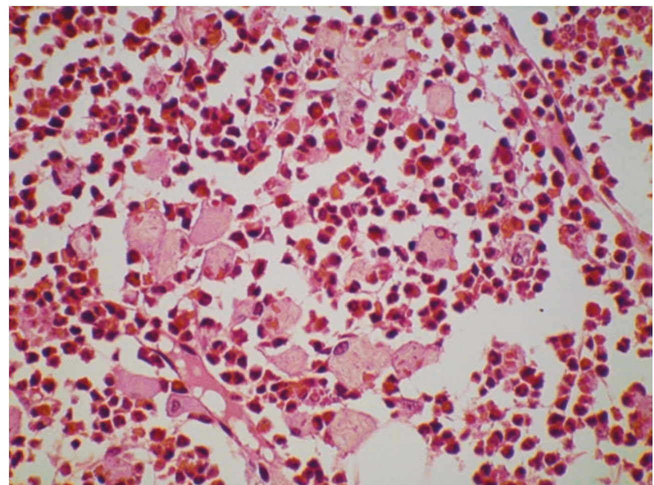

Fig. 3.6 Bone marrow trephine biopsy section from a patient with chronic-phase myelogenous leukemia showing numerous pseudo-Gaucher cells. H&E, low power

In *accelerated phase*, the changes that would be expected from the bone marrow aspirate are present. In addition, the bone marrow architecture may be abnormal, e.g., with megakaryocytes located adjacent to bony spicules or forming large clusters. Intravascular hemopoiesis and bone marrow necrosis can occur. Reticulin may be increased. Sometimes the increase in reticulin is marked and there is also collagen fibrosis and osteosclerosis (Fig. 3.7).

Immunohistochemistry with CD42b or CD61 monoclonal antibodies can be used to identify dysplastic megakaryocytes. CD34 antibodies can identify blast cells and endothelial cells of new vessels.

In *blast transformation*, there is an increase in the blast cells of one or more lineages. In myeloid transformation, there can also be a marked increase of dysplastic megakaryocytes, often in large clusters or sheets. The pattern of blast infiltration may initially be random focal, but subsequently blast cells obliterate maturing hematopoietic cells. Reticulin and collagen fibrosis are common, particularly when there is an increase in megakaryoblasts and dysplastic megakaryocytes.

Immunohistochemistry can be used to identify myeloblastic crisis (CD68, lysozyme), megakaryoblastic crisis (CD42b, CD61), erythroblastic crisis (antiglycophorin—CD235a or CD236R), and B-lymphoblastic crisis (CD79a is more generally positive than CD20). CD34 immunohistochemistry can help in the quantification of blast cells.

In extramedullary transformation, there is initially infiltration of another tissue or organ, e.g., a lymph node, with subsequent spread to the marrow. In extramedullary transformation, immunohistochemistry is useful for confirmation of the diagnosis.

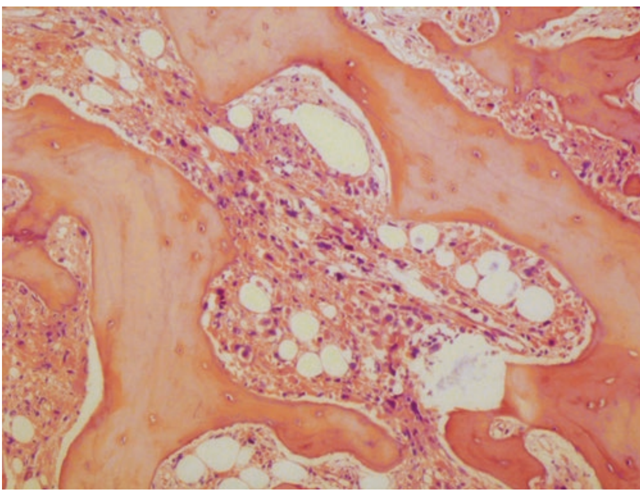

Fig. 3.7 Bone marrow trephine biopsy section from a patient with accelerated phase of chronic myelogenous leukemia showing myelofibrosis and osteosclerosis. There are numerous dysplastic megakaryocytes embedded in the loose fibrous tissue. H&E, low power

Atypical (Ph-Negative) Chronic Myeloid Leukemia

Atypical chronic myeloid leukemia (aCML) is an uncommon, Ph-negative, *BCR-ABL1*-negative chronic myeloid leukemia, which is categorized in the WHO classification as an MDS/MPN [8–10]. Clinical features are similar to those of CML, but the prognosis is worse. Death may result from bone marrow failure or evolution to acute myeloid leukemia (AML). Atypical CML is mainly a disease of adults, particularly elderly adults with a similar incidence in men and women.

Peripheral Blood Count and Cytology

The peripheral blood shows leukocytosis and anemia (Fig. 3.8). The WHO classification has a white cell count (WBC) of at least 13×10^9/L as a diagnostic criterion. There may be anisocytosis, poikilocytosis, macrocytosis, or dimorphism. The platelet count is often reduced but may be normal or increased. In comparison with CML, anemia tends to be more severe and thrombocytopenia more common. There is an increase in neutrophils and their precursors. Eosinophils and basophils are often increased but less consistently than in CML. Basophils are usually less than 2% of leucocytes. However, some patients have prominent eosinophilia. The monocyte count is relatively higher than in CML; it may be more than 1×10^9/L, but monocytes are less than 10% of leucocytes. Granulocyte precursors are also present. In comparison with chronic myelomonocytic leukemia, promyelocytes, myelocytes, and metamyelocytes are at least 10% of leukocytes and

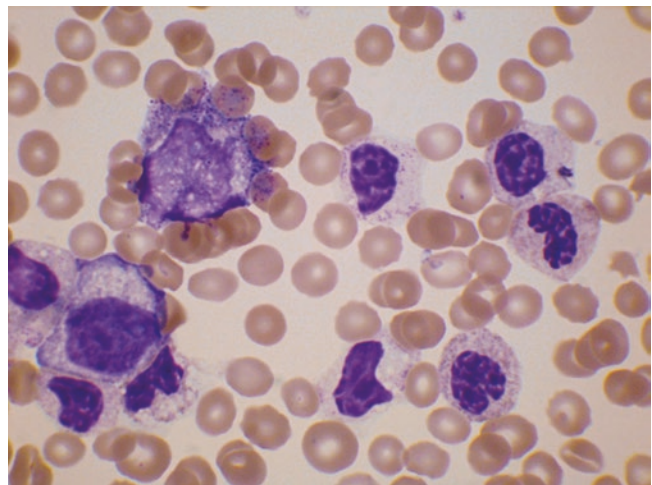

Fig. 3.8 PB film from a patient with atypical chronic myeloid leukemia showing neutrophil precursors and dysplastic neutrophils (hypolobated, nuclear clumping, and hypogranularity). MGG, high power

sometimes 15% or higher. These may include blast cells but, by definition, blast cells (plus promonocytes) are less than 20% in the blood (and the bone marrow). Dysplastic features are present in neutrophils; hypolobation, abnormal nuclear shapes, increased chromatin clumping, and reduced granularity may be seen. Monocytes may also be dysplastic, showing hyperlobation or hypolobation, increased cytoplasmic basophilia, and increased granularity. The neutrophil alkaline phosphatase score is variable and is not diagnostically useful.

Bone Marrow Cytology

The bone marrow aspirate shows increased cellularity with an increase mainly in neutrophils and their precursors. Monocytes and their precursors may be increased and a nonspecific esterase stain can help in their detection. Megakaryocytes may be present in normal numbers or may be decreased or increased. There is dysplasia, which is often of trilineage. Dysgranulopoiesis is usual, but there may also be ring sideroblasts and other features of dyserythropoiesis, hypolobated megakaryocytes, and micromegakaryocytes.

Flow Cytometric Immunophenotyping

Immunophenotyping is not known to be diagnostically useful.

Genetics

Karyotypic abnormalities are common and can include trisomy 8, 20q–, and i(17q) and abnormalities of chromosomes 12, 13, 14, 17, and 19. *SETBP1*, *ETNK1*, *NRAS*, *KRAS*, *CBL*, and *TET2* may be mutated. *CSF3R* mutation has been reported but its presence favors a diagnosis of chronic neutrophilic leukemia. Patients with *BCR-ABL1,* rearrangement of *PDGFRA*, *PDGFRB*, or *FGFR1*, or *PCM1-JAK2* are specifically excluded from this diagnostic category.

Histology

Cellularity is increased as a result of an increase in neutrophils and precursors and a variable increase in monocyte precursors. There is dysplasia and the architecture is disorganized. Reticulin may be increased and collagen fibrosis and osteosclerosis occasionally occur. Immunohistochemistry is useful to highlight dysplastic megakaryocytes (CD42b and CD61) and increased monocytes (CD14 and CD68R).

Chronic Myelomonocytic Leukemia

This is Ph-negative chronic myeloid leukemia that is categorized in the WHO classification as an MDS/MPN [11, 12]. The most prominent clinical features are anemia and splenomegaly, but skin and lymph node infiltration and pleural, peritoneal, and pericardial effusions can also be seen. It is mainly a disease of the middle aged and elderly and shows a male predominance. Transformation to AML occurs in up to a quarter of the patients.

Peripheral Blood Count and Cytology

The peripheral blood shows a normocytic or macrocytic anemia. Red cells are sometimes dimorphic. Leukocytosis is usual but not invariable. There is monocytosis with, by definition, a monocyte count of more than 1×10^9/L (Fig. 3.9). Neutrophils may be increased, normal, or decreased. Neutrophil precursors may be present but, in contrast to aCML, they are less than 10% of the cells and usually less than 5%. There may be small numbers of blast cells and promonocytes; by definition, they total less than 20% of leukocytes, but they are usually much less. The number of blast cells (plus promonocytes) in the blood is of prognostic significance and the presence of 5% or more leads to a classification as CMML-2. A minority of patients have prominent eosinophilia. The platelet count is often reduced but can be normal or high.

Dysplastic features may be present, but are usually less prominent than in aCML. Monocytes may be immature (cytoplasmic basophilia, reduced chromatin condensation, or reduced nuclear lobulation).

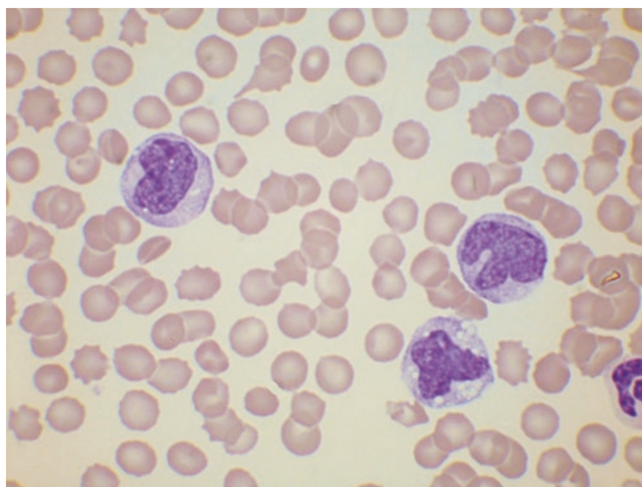

Fig. 3.9 PB film from a patient with chronic myelomonocytic leukemia showing thrombocytopenia and three immature, abnormal monocytes. MGG, high power

Bone Marrow Cytology

The bone marrow shows increased cellularity due to an increase of neutrophils and monocytes and their precursors but a nonspecific esterase stain may be necessary to demonstrate the increase in cells of monocyte lineage. Blasts plus promonocytes are less than 20%. The number of blast cells (plus promonocytes) in the marrow is of prognostic significance and the presence of 10% or more leads to the classification as CMML-2. Auer rods are rarely present but, when present, also lead to classification as CMML-2; a myeloperoxidase or Sudan black B stain is useful for their detection. Some patients have an increase of eosinophils and precursors. There is variable dysplasia, which may include ring sideroblasts.

Flow Cytometric Immunophenotyping

Immunophenotyping may show monocytes to be phenotypically abnormal with reduced, increased, or aberrant expression of various antigens. An abnormal phenotype may be the result of immaturity of monocytes (e.g., reduced CD14 expression) or of aberrant antigen expression (e.g., expression of CD2).

Genetics

Karyotypic abnormalities are detected in a quarter to a half of patients. They include trisomy 8, monosomy 7 and 7q–, and rearrangements with a 12p breakpoint. Common molecular changes include mutations of *RAS* group genes, *RUNX1*, *TET2*, *SRSF2*, *ASXL1*, *SETBP1*, and *CBL*. By definition, *BCR-ABL1*, rearrangement of *PDGFRA*, *PDGFRB* and *FGFR1*, and *PCM1-JAK2* are absent.

Histology

Trephine biopsy sections show the changes that would be expected from the aspirate. Hypercellularity is usual and results from an increase in the cells of both neutrophil and monocyte lineages. Immunohistochemistry (CD14, CD68R, or CD163) may be necessary to demonstrate the increase in the cells of monocyte lineage. Erythropoiesis may be quantitatively normal or increased. There may be nodules of plasmacytoid dendritic cells, confirmed by immunohistochemistry for CD4, CD14, CD68R, and CD123 [13, 14]. Reticulin deposition is often increased.

Chronic Eosinophilic Leukemia

Chronic eosinophilic leukemias, in the WHO classification, are categorized either as chronic eosinophilic leukemia (CEL), not otherwise specified [15], or as chronic myeloid or lymphoid neoplasm associated with rearrangement of *PDGFRA*, *PDGFRB*, or *FGFR1*, or with *PCM1-JAK2* [16–18]. Diagnosis and categorization require both cytogenetic and molecular analyses, the latter to detect the most frequent rearrangement of *PDGFRA*, a *FIP1L1-PDGFRA* fusion gene resulting from a cryptic deletion at 4q12. Diagnosis of CEL requires an eosinophil count of at least 1.5×10^9/L and some evidence that the process is leukemic in nature, such as a clonal cytogenetic or molecular abnormality or an increase in blast cells.

Leukemias with rearrangement of *PDGFRA* can present as CEL, AML with eosinophilia, or T-lineage acute lymphoblastic leukemia (ALL) with eosinophilia [17, 19]. Leukemias with rearrangement of *PDGFRB* can present as CEL or as either CMML or aCML with eosinophilia. Leukemias with rearrangement of *FGFR1* can present as CEL, AML with eosinophilia, or acute lymphoblastic leukemia/lymphoma (ALL) with eosinophilia; ALL is most often of T lineage but can be of B lineage [17]. Leukemias with *PCM1-JAK2* can be CEL or aCML but some patients have had the features of primary myelofibrosis [18]. In all these disorders, patients who present with chronic phase disease can subsequently suffer acute transformation.

Clinical presentation can be with features suggestive of leukemia (such as anemia, splenomegaly, and sometimes lymphadenopathy) or features reflecting tissue damage by eosinophils (such as cardiac, respiratory, and neurological symptoms). CEL associated with *FIP1L1-PDGFRA* shows a remarkable male predominance. Cases with *PCM1-JAK2* also show a marked male predominance [18]. CEL associated with *PDGFRB* or *FGFR1* rearrangement is also more common in males. CEL associated with rearrangement of *PDGFRA* or *PDGFRB* is sensitive to imatinib and making these specific diagnoses is therefore important. Cases with *PCM1-JAK2* show some responsiveness to ruxolitinib.

Elevation of serum vitamin B_{12} and serum tryptase is usual in patients with CEL associated with *FIP1L1-PDGFRA*.

Peripheral Blood Count and Cytology

The peripheral blood shows an increase in eosinophils, which may be cytologically fairly normal or may show reduced or increased nuclear lobulation, loss of granules, darkly staining (purple) granules, or cytoplasmic vacuolation (Fig. 3.10). There may be eosinophil precursors and blast cells. By definition, blast cells are less than 20%. Some patients also have an increase in neutrophils or monocytes, anemia, or thrombocytopenia.

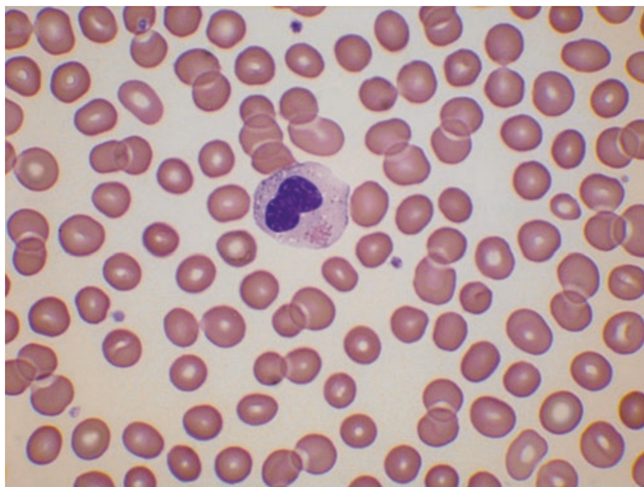

Fig. 3.10 PB film from a patient with chronic eosinophilic leukemia associated with *FIP1L1-PDGFRA* fusion showing an eosinophil with a poorly lobulated nucleus, a few vacuoles, and only a small cluster of granules. MGG, high power

Bone Marrow Cytology

The bone marrow shows an increase in eosinophils and their precursors plus a variable increase in precursors of monocytes and neutrophils. Blast cells may be increased but are less than 20%.

Flow Cytometric Immunophenotyping

Immunophenotyping is occasionally needed to show the lineage of blast cells and thus distinguish CEL and related conditions from ALL with reactive eosinophilia. It must be noted that in the case of CEL associated with rearrangement of *PDGFRA* or *FGFR1*, there may be either presentation as ALL or a lymphoblastic transformation; usually but not invariably the lymphoid component is of T lineage.

Genetics

Karyotypic analysis may show t(5;12)(q31~q33;p12) or another translocation with a 5q31-32 breakpoint involving *PDGFRB*. Rarely there is a translocation with a 4q12 breakpoint involving *PDGFRA*, but usually rearrangement of this gene is cryptic, resulting from an interstitial deletion. *FGFR1* rearrangement most often results from t(8;13)(p11;q12), leading to a *ZMYM2-FGFR1* fusion gene. *PCM1-JAK2* fusion results from the t(8;9)(p22;p24.1) translocation. Other nonspecific chromosomal abnormalities may be found including trisomy 8, 20q–, monosomy 7, and i(17q). The demonstration of t(8;21)(q22;q22.1), inv(16)(p13.1q22), or t(16;16)(p13.1;q22) excludes a diagnosis of CEL and leads to a diagnosis of AML regardless of the blast percentage.

The most important molecular abnormality that must be sought in suspected CEL is the *FIP1L1-PDGFRA* fusion gene, which can be demonstrated either by fluorescence in situ hybridization (FISH) analysis or by PCR (nested PCR often being needed) [16]. Occasionally patients with *FIP1L1-PDGFRA*-associated CEL develop a further mutation in the fusion gene, sometimes associated with imatinib resistance or transformation to AML [19].

Histology

Trephine biopsy sections show the expected increase in eosinophils and precursors and a variable increase in the cells of neutrophil or monocyte lineages. Charcot–Leyden crystals are also sometimes seen [20]. Cases associated with rearrangement of *PDGFRA* or *PDGFRB* may show an increase of mast cells, which are sometimes spindle shaped and clustered. Their presence can be highlighted by immunohistochemistry for mast cell tryptase. The mast cells may show aberrant expression of CD25 and sometimes of CD2, whereas the neoplastic cells of systemic mastocytosis usually show aberrant expression of both CD2 and CD25.

Chronic Neutrophilic Leukemia

Chronic neutrophilic leukemia is a rare myeloproliferative neoplasm that occurs mainly in adults [21]. It is characterized by increased neutrophil production, splenomegaly, and sometimes hepatomegaly. Transformation to AML can occur and at this stage the neutrophil count may fall [22]. Older adults are mainly affected with no gender difference.

Peripheral Blood Count and Cytology

There is leukocytosis and neutrophilia (Fig. 3.11). The WHO classification requires a white cell count of at least 25×10^9/L for this diagnosis. Neutrophils may be heavily granulated and Döhle bodies are sometimes present, but there are no dysplastic features and there are only small numbers of neutrophil precursors [23]. With disease progression there may be anemia and thrombocytopenia.

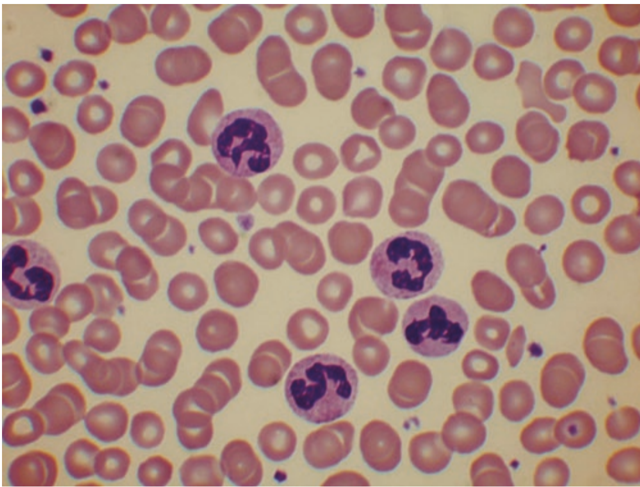

Fig. 3.11 PB film from a patient with chronic neutrophilic leukemia showing cytologically normal neutrophils. MGG, high power

Bone Marrow Cytology

The bone marrow aspirate shows an increase of neutrophils and their precursors without dysplastic features or any increase in the blast cells. The bone marrow must be carefully examined to exclude a plasma cell neoplasm since reactive neutrophilia due to multiple myeloma or monoclonal gammopathy of undetermined significance is an important differential diagnosis [23].

Flow Cytometric Immunophenotyping

Immunophenotyping has no role in diagnosis.

Genetics

Cytogenetic analysis is usually normal. A minority of patients have karyotypic abnormalities typical of myeloid neoplasms such as trisomy 8, trisomy 9, trisomy 21, 11q–, 12p–, or 20q–. Nullisomy 17, a complex karyotype and several nonrecurrent translocations have also been reported. Sometimes an initially normal karyotype becomes abnormal, with acute transformation [22]. There is a strong association with an activating mutation in the proximal membrane domain of *CSF3R* [24]. There is also often an associated mutation of *SETBP1* or *ASXL1*. Occasional patients have a *JAK2* V617F mutation, which may be homozygous [23]. By definition, there is no *BCR-ABL1* fusion gene.

Histology

Trephine biopsy sections show increased granulopoiesis.

Juvenile Myelomonocytic Leukemia

This is a rare myelodysplastic/myeloproliferative neoplasm of children [25–29]. Peak incidence is under the age of 3 years and the condition is twice as common in boys. Predisposing conditions include neurofibromatosis type 1 (*NF1* mutated), Noonan syndrome (*PTPN11* mutated), and *CBL*-mutation associated syndrome. Clinical features can include fever, cough, splenomegaly, hepatomegaly, often lymphadenopathy, skin lesions (an eczematous or maculopapular rash or xanthomas), and a bleeding tendency. Respiratory tract infections are common. In patients with underlying neurofibromatosis there may be café-au-lait spots whereas patients with Noonan syndrome have facial dysmorphism and congenital cardiac anomalies. A hallmark of the disease is increased sensitivity in vitro to granulocyte-macrophage colony-stimulating factor as a result of increased signaling through the RAS-MAPK pathway. The rate of disease progression is quite variable, but prognosis is generally poor unless hematopoietic stem cell transplantation is carried out. Transformation to AML occurs in about 15% of the patients [28]. Occasional patients have had transformation to B-cell precursor ALL and the same acquired genetic lesion has sometimes been found in T-lymphoid and myeloid cells, suggesting that the leukemic clone may be derived from a pluripotent lymphoid-myeloid stem cell [28].

Peripheral Blood Count and Cytology

The peripheral blood shows leukocytosis, monocytosis, and neutrophilia with a lesser increase in granulocyte precursors (Fig. 3.12). Eosinophilia and basophilia are less common than neutrophilia. WHO criteria include a monocyte count of at least 1×10^9/L. There is a variable degree of dysplasia. Blast cells (plus promonocytes) are usually

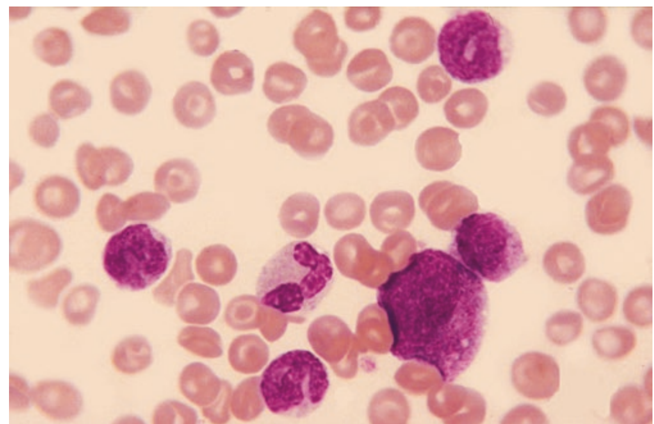

Fig. 3.12 PB film from a patient with juvenile myelomonocytic leukemia showing a neutrophil, a promyelocyte, and dysplastic cells, mainly of monocyte lineage. MGG, high power

low and, by definition, never more than 20% in the blood or bone marrow. Anemia and thrombocytopenia are usual. There may be circulating nucleated red blood cells or neutrophil precursors and some patients have macrocytosis. There is often increased rouleaux formation.

Blood tests show other abnormalities. Polyclonal hypergammaglobulinemia is common and the erythrocyte sedimentation rate is increased. There may be autoantibodies including anti-erythrocyte antibodies. The hemoglobin F percentage is usually increased in comparison with age-matched healthy children and there may be other features suggesting reversion to fetal-type erythropoiesis, such as increased expression of the i antigen and decreased expression of the I antigen, carbonic anhydrase, and hemoglobin A_2.

Bone Marrow Cytology

The bone marrow is hypercellular as a result of increased granulopoiesis. Blast cells (plus promonocytes) are less than 20%. Megakaryocytes are often reduced.

Flow Cytometric Immunophenotyping

Immunophenotyping is not diagnostically useful.

Genetics

There is no specific chromosomal abnormality and cytogenetic analysis is often normal. Some patients have monosomy 7, trisomy 8, or a complex karyotypic abnormality. Chromosomal analysis may be initially normal but become abnormal during the course of the illness. Genetic analysis shows four nonoverlapping groups of patients with loss-of-function mutation in *NF1* (inherited or acquired) or mutation in *PTPN11* (inherited or acquired) [30], *CBL* [31], or a *RAS* group gene (*NRAS* or *KRAS*) [32]; a mutation in one of these genes is found in 85% of cases. In children with neurofibromatosis there may be homozygosity for the mutant gene as a result of acquired uniparental disomy or there may be somatic mutation in the initially normal allele [33, 34]. Similarly, patients with an inherited *CBL* mutation usually show loss of heterozygosity.

Histology

The bone marrow is hypercellular as a result of increased granulopoiesis and a variable increase in monocytopoiesis and erythropoiesis. Reticulin may be increased.

Conclusions

The chronic myeloid leukemias are a heterogeneous group of hematopoietic neoplasms, some with mainly proliferative features and others with myelodysplastic/myeloproliferative characteristics. Origin may be in a pluripotent lymphoid-myeloid stem cell or in a committed myeloid cell. Since leukemias with a *BCR-ABL1* fusion gene or rearrangement of *PDGFRA* or *PDGFRB* are sensitive to tyrosine kinase inhibitors, precise diagnosis is of considerable importance.

Introduction

Chronic myeloid leukemia (CML) is a clonal myeloproliferative neoplasia characterized by the t(9;22)(q34;q11) balanced reciprocal translocation that causes the fusion of a portion of chromosome 9 to chromosome 22 (der22), thereby replacing a fragment of chromosome 22 which fuses to chromosome 9 (der9). The resultant minute chromosome der22, designated as the Philadelphia chromosome (Ph), is the hallmark of CML [1]. The molecular event resulting from this translocation is the hybrid *BCR-ABL1* oncogene, which encodes the constitutively active BCR-ABL1 protein kinase [1]. The BCR-ABL1 oncoprotein can transform cells through phosphorylation of tyrosine residues on a variety of intermediary proteins that transmit signals from the cytoplasm to the nucleus. The ultimate proof that BCR-ABL1 kinase expression can induce CML was provided by experiments in which murine bone marrow was transfected with a retrovirus encoding *BCR-ABL1* and transplanted into irradiated syngeneic recipients. Transplanted recipients developed several hematologic malignancies, most frequently a myeloproliferative syndrome that resembles very closely chronic-phase CML [2]. The demonstration that BCR-ABL1 kinase activity played a critical role in cellular transformation provided the rationale for developing molecules aimed at targeting such activity. Kinase-based assays demonstrated that imatinib, the first tyrosine kinase inhibitor (TKI) developed for the treatment of CML, potently inhibited ABL1 kinase [3, 4]. This inhibitory activity translated into impressive clinical activity [5]. The remarkable clinical success of imatinib propelled the rational design and development of other TKIs (e.g., nilotinib, dasatinib, bosutinib, ponatinib) aided by structural biology and high-throughput medicinal chemistry methods. Despite these agents' clinical activity, many patients with CML receiving TKI therapy frequently manifest measurable amounts of residual disease, and in some the TKI therapy eventually fails. Among patients with accelerated-phase (AP) or blastic phase (BP) CML, responses are less frequent and often short-lived [6]. These shortcomings of TKI therapy have resulted in research efforts aimed at understanding the behavior of CML stem cells, the molecular basis of transformation to AP and BP, and the mechanisms of resistance to TKIs.

The *BCR-ABL1* Oncogene

The breakpoints within *ABL1* map either upstream of exon Ib, downstream of exon Ia, or, more frequently, between exons Ib and Ia [7]. In most patients with CML and in one-third of adults with Ph-positive B-cell acute lymphoblastic leukemia (Ph + B-ALL), the breakpoints within *BCR* map to a 5.8-kb area spanning exons e12–e16 (formerly b1–b5), referred to as the *major breakpoint cluster region* (M-*bcr*). Alternative splicing produces fusion transcripts with either e13a2 or e14a2 junctions that give rise to a 210 kDa protein ($p210^{BCR\text{-}ABL1}$) [8]. In two-thirds of adults with Ph + B-ALL and in occasional cases of CML, the *BCR* breakpoint localizes to a 54.4-kb area between exons e2′ and e2 (*minor breakpoint cluster region* or m-*bcr*), which produces an e1a2 transcript that translates into $p190^{BCR\text{-}ABL1}$ and is associated with a more aggressive CML course. A third breakpoint cluster region (μ-*bcr*) gives rise to a 230 kDa fusion protein ($p230^{BCR\text{-}ABL1}$) that is associated with a very indolent course of CML [9].

Several experimental models, such as *BCR-ABL1*-expressing CD34+ cells in culture [10, 11] or retrovirally transduced *BCR-ABL1*-positive mouse cells [2, 12], have helped establish a direct causality between BCR-ABL1 and CML. A lysine-to-arginine substitution at residue 1176 (K1176R) in the ATP-binding pocket of ABL1 inactivates

the kinase activity of BCR-ABL1 and prevents the development of leukemia in mice, even when *BCR-ABL1*^{K1176R} is expressed in hematopoietic stem cells (HSCs) [13]. Further proof of the central role of *BCR-ABL1* as the pathogenetic driver in CML was provided by developing transgenic mice in which the tetracycline-responsive element (tet-O) inducibly drives *BCR-ABL1* expression specifically in HSCs. SCL-tTA/BCR-ABL-tetO mice, resulting from crossing *BCR-ABL1* tet-O mice with mice expressing the tetracycline transactivator (tTA) under the control of the murine stem cell leukemia (SCL) gene 3′ enhancer, developed a myeloproliferative disease that recapitulated multiple features of human CML upon tetracycline withdrawal [14]. The clinical success of imatinib, a small molecule that inhibits the kinase activity of BCR-ABL1, has further confirmed the oncogenic role of this protein kinase.

Autoregulation of the *BCR-ABL1* Protein Kinase

BCR-ABL1 kinase is a multidomain protein (Fig. 4.1). The N-terminus of BCR-ABL1 includes the “Cap” region, present in two different isoforms, 1a and 1b, as a consequence of alternative splicing of the first exon. The ABL1b isoform contains a C_{14} myristoyl moiety covalently linked to the N-terminus and is expressed at higher levels than type 1a, which is not myristoylated. ABL1 also contains highly conserved Src-homology-2 (SH2) and SH3 domains and a tyrosine kinase domain [15]. The SH2 domain interacts with and phosphorylates signaling proteins, including p62dok, c-Cbl, Rin-1, Tub, and mDab1. Mutations within the SH2 domain have been found to delay the onset of, but fail to prevent, BCR-ABL1-induced myeloproliferation [16]. The last ABL1 exon region contains several distinct domains, including four proline-rich SH3 motifs (which act as docking sites for SH3 domains of adaptor proteins such as Crk, GRB2 [growth-factor-receptor-bound 2], and Nck) [17, 18], a DNA-binding domain, an actin-binding domain, three nuclear localization signals, and one nuclear export signal, which determines the subcellular localization of ABL1 (Fig. 4.1). BCR also exhibits a complex spatial modularity that includes a coiled-coil oligomerization domain, a serine/threonine kinase domain, a Dbl/CDC24 guanine–nucleotide exchange factor homology domain, a pleckstrin homology domain, a calcium-dependent lipid-binding site, and a RAC guanosine triphosphatase-activating protein domain. Tyr177 at BCR serves as docking site for GRB2, GRB10, 14-3-3, and ABL1 proteins through its SH2 domain [19]. The myristoyl modification at the end of the N-terminal segment of ABL1b engages the C-terminal lobe of the ABL1 catalytic domain and facilitates the docking of the SH2 and SH3 domains onto the kinase domain [20, 21]. The absence of the myristoyl group results in constitutive tyrosine kinase activity [15]. In the inactive conformation of the kinase domain, the rotation of the helix αC displaces critical catalytic residues out of the active site, thus hampering ATP access to the active site [15]. The X-ray crystal structure of the oligomerization domain of BCR-ABL1 (residues 1–72 or BCR_{1-72}) showed that two monomers associate in an antiparallel

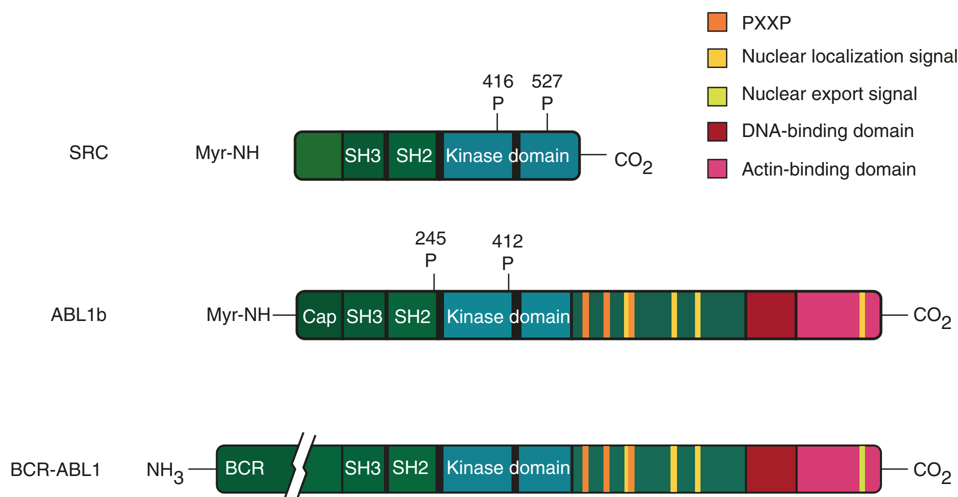

Fig. 4.1 Modular structure of the BCR-ABL1 protein. The modular structure of BCR-ABL1 is lined up against those of SRC and ABL1b kinases, which share a common central core that includes a tyrosine kinase domain, a SRC-homology-2 (SH2) domain, and an SH3 domain. The NH2 terminus in ABL1 and BCR-ABL1 kinases is the “Cap” region. Alternative splicing of the first ABL1 exon yields two ABL1 isoforms (a and b). ABL1b contains a myristate site (Myr-NH) at the extreme end of the amino-terminal segment, which binds to the kinase domain and keeps the SH2–SH3 autoinhibitory structure in place (i.e., in the “off state”)

dimer, which in turn stacks to form a tetramer [22]. Mutations at the coiled-coil domain impairing BCR-ABL1 oligomerization drastically compromise the kinase activity and the leukemogenic potential of BCR-ABL1 [23].

Signaling Pathways Stemming from BCR-ABL1 Kinase

BCR-ABL1 activates numerous downstream signaling pathways (Fig. 4.2). Such activation stems from a multiprotein complex formed by BCR-ABL1 kinase and an array of substrates and adaptor proteins, which include GRB2, CrkL, c-CBL, and p62(DOK). Signaling emanating from this complex leads to cellular transformation. The phosphorylation of the tyrosine residue 177 (Tyr177) of BCR is essential for BCR-ABL1-mediated leukemogenesis [24]. A tyrosine-to-phenylalanine substitution at this residue (Tyr177Phe) impairs GRB2 binding and markedly diminishes BCR-ABL1-induced RAS activation [25], which impedes the transformation of primary bone marrow cultured in the presence of ABL1 kinase activity [25]. Transfection of a mutant *BCR-ABL1* isoform carrying the Tyr177Phe mutation prevents the induction of a myeloproliferative disorder in a murine stem cell transplantation model of CML [25]. Tyr177 functions as a high-affinity docking site for the SH2 domain of GRB2, which in turn recruits SOS (a guanine–nucleotide exchanger of *RAS*), resulting in activation of RAS [19] and the scaffold adapter GRB2-associated binding protein 2 (GAB2) [19]. The importance of GAB2 is illustrated by the fact that BCR-ABL1 fails to transform primary myeloid cells from *GAB2*$^{-/-}$ mice [26]. The GRB2/GAB2 complex activates phosphatidylinositol 3-kinase (PI3K)/AKT [27] and ERK in primary CML cells. Interestingly, MEK-ERK activation is cytokine dependent in chronic phase (CP) but becomes constitutively activated in CML BP and is readily detectable in CD34+ progenitors [28]. Mutation of BCR-ABL1 protein at any of three of the direct binding sites for GRB2, namely CBL, p62(DOK), and CRKL, resulted in defective transformation of primary hematopoietic cells in a mouse model of CML because of decreased activation of the MAP kinase and PI3K pathways but not of the transcription factor signal transducer and activation of transcription 5 (STAT5) [29]. Overall, these data indicate that disruption of the interaction between BCR-ABL1 and BCR-ABL1 substrates may result in abrogation of leukemogenesis.

Other important proteins phosphorylated by BCR-ABL1 kinase are the SRC family kinases (SFKs) HCK, LYN, and FGR. LYN kinase is activated indirectly upon activation of JAK2 kinase by BCR-ABL1. Inhibition of JAK2 reduces the level of the SET protein and increases serine/threonine phosphatase 2A (PP2A) and tyrosine phosphatase 1 (SHP1) activities, which decrease the levels of activated LYN [30]. In turn, phosphorylated HCK recruits STAT5 [19, 31], which upregulates cyclin D1. This in turn induces cell cycle progression from G_1 to S

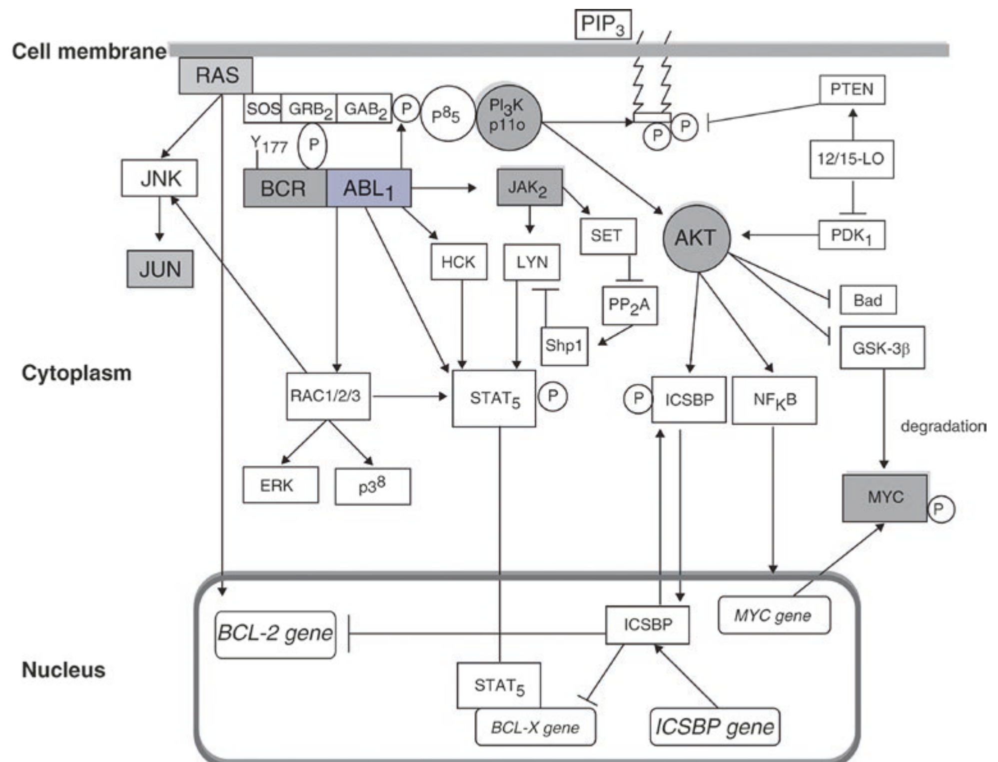

Fig. 4.2 Signaling pathways stemming from BCR-ABL1 kinase. BCR-ABL1 kinase phosphorylates a series of intracellular substrates, thus activating several signaling pathways that promote cell proliferation and inhibition of apoptosis

phase [32]. However, whether Src kinases are indispensable for BCR-ABL1-mediated leukemogenesis remains controversial, since *BCR-ABL1* can cause a CML-like picture in bone marrow of mice lacking *Lyn, Hck, and Fgr* [33]. In turn, the generation of acute lymphoid disease is mitigated in the same model [33], and knocking down LYN by siRNA impairs survival of CML lymphoid blasts [34], indicating that the requirement of SFKs is greater in CML lymphoid transformation than in CP.

STAT5 is constitutively activated in CML. STAT5 downregulation mediated by siRNA in primary CML samples markedly impairs Ph + myeloid colony formation. Fetal liver hematopoietic progenitors from *STAT5a*$^{-/-}$:: *STAT5b*$^{-/-}$ mice retrovirally transduced with BCR-ABL1 failed to induce leukemia in recipient mice [35]. Conditional deletion of STAT5 in purified stem cells from p210$^{BCR/ABL}$ mice failed to initiate CML in mice [36]. Furthermore, the anti-apoptotic protein BCL-X, which is repressed by the transcription factor interferon consensus sequence-binding protein (ICSBP) [37], is transcriptionally activated by STAT5 [38].

Although the individual contribution of some BCR-ABL1 downstream pathways may appear negligible when evaluated individually, a cooperative interplay may be necessary for the full realization of the leukemogenic potential of BCR-ABL1. For instance, when *BCR-ABL1*-positive K562 cells were induced to express dominant negative forms of RAS, PI3K, or STAT5, marked apoptosis was observed in cells expressing two of the three dominant negative mutants in any combination [39].

RAC guanosine triphosphatases (GTPases) are activated in primary CML cells [40]. In a murine model of p210$^{BCR-ABL1}$-induced myeloproliferative disease, targeting of *RAC1* and *RAC2* genes, which encode the GTPases RAC1 and RAC2, markedly delayed myeloproliferation and abrogated the phosphorylation of the BCR-ABL1 downstream signaling molecules CrKL, JNK, ERK, and p38 [40]. This suggests that BCR-ABL1 signaling is highly dependent on RAC GTPases. This contention is supported by experiments using NSC23766, a specific RAC1/RAC2 inhibitor [41].

JUNB is a transcription factor that belongs to the activator protein 1 family. It functions as a tumor suppressor in myeloid cells [42]. JUNB exerts its tumor-suppressor activity by abrogating cell proliferation and survival through inhibition of the RAS downstream target JUN. Transgenic mice lacking the *JUNB* gene in the myeloid lineage (*JunB*$^{-/-}$Ubi-*JunB* mice) develop myeloproliferation that closely resembles CML; a fraction of these animals progress to BP [43, 44]. Granulocyte-macrophage colony-stimulating factor (GM-CSF)-mediated proliferation and survival of *JUNB*-deficient granulocyte/macrophage progenitors (GMPs) are associated with changes in anti-apoptotic proteins such as Bcl2 and Bclx and in cell cycle regulators p16ink4a and *c-Jun* [43].

Mice lacking the enzyme 12/15-lipoxygenase (12/15-LO) develop a myeloproliferative disorder with 100% penetrance that progresses to transplantable leukemia independent from ABL1 dysregulation [45]. Cells isolated from chronic-stage 12/15-LO-deficient mice (*Alox15*) exhibit increased PI3K/AKT activation as well as ICSBP, which results in decreased direct DNA binding, limiting the ability of ICSBP to repress BCL-2 gene transcription and promoting leukemic cell survival (Fig. 4.2) [45]. ICSBP is a negative regulator of granulocyte differentiation. *ICSBP*$^{-/-}$ and *ICSBP*$^{+/-}$ mice exhibit deregulated hematopoiesis manifested as a CML-like myeloproliferative disorder [46]. Forced expression of ICSBP inhibited *BCR-ABL1*-induced CML-like disease in vivo [47]. All the effects observed in *Alox15* mice were reversed upon treatment with a PI3K inhibitor. This suggests that 12/15-LO is an important suppressor of myeloproliferation [45]. Additionally, the arachidonate 5-lipoxygenase (5-LO) gene (Alox5) was identified as a critical regulator for CML LSC. BCR-ABL failed to transform bone marrow from Alox5-deficient mice, and both genetic or pharmacologic inhibition of Alox5 impaired the function of leukemic stem cells (LSCs) [48].

Progression to Advanced-Phase CML

The understanding of the mechanisms associated with the progression from CP to AP and BP has been dramatically hampered by the lack of animal models that faithfully recapitulate the process of CML transformation in vivo, which is almost invariably preceded by a protracted "chronic" myeloproliferative phase. However, several factors have been identified in samples from patients with AP CML as central to the process of transformation (Fig. 4.3). Genome-wide analysis of gene expression profiles may aid in characterizing gene candidates responsible for disease progression. Unfortunately, most studies have failed to provide clear-cut answers, likely because of differences in types of samples, array platforms, and/or statistical methodologies employed [49–54]. DNA microarray analysis comparing the gene expression in 91 cases of CML in all phases found striking similarities between gene expression in AP and BP. This suggests that CML might conform to a biphasic rather than a classic triphasic model of progression [54]. Genes potentially involved in AP/BP compared to CP included cytokines (IL3RA, SOCS2), alternative RAS pathways (Rras2), DNA-damage response genes, and genes involved in HSC self-renewal and interaction with the bone marrow stroma, such as those that encode effectors in the Wnt pathway (e.g., β-catenin) [54]. A genome-wide screening using single-nucleotide polymorphism (SNP) arrays identified only 0.47 copy number alterations per CML CP case (range 0–8), suggesting that *BCR-ABL1* is sufficient to induce CML. In contrast, a mean

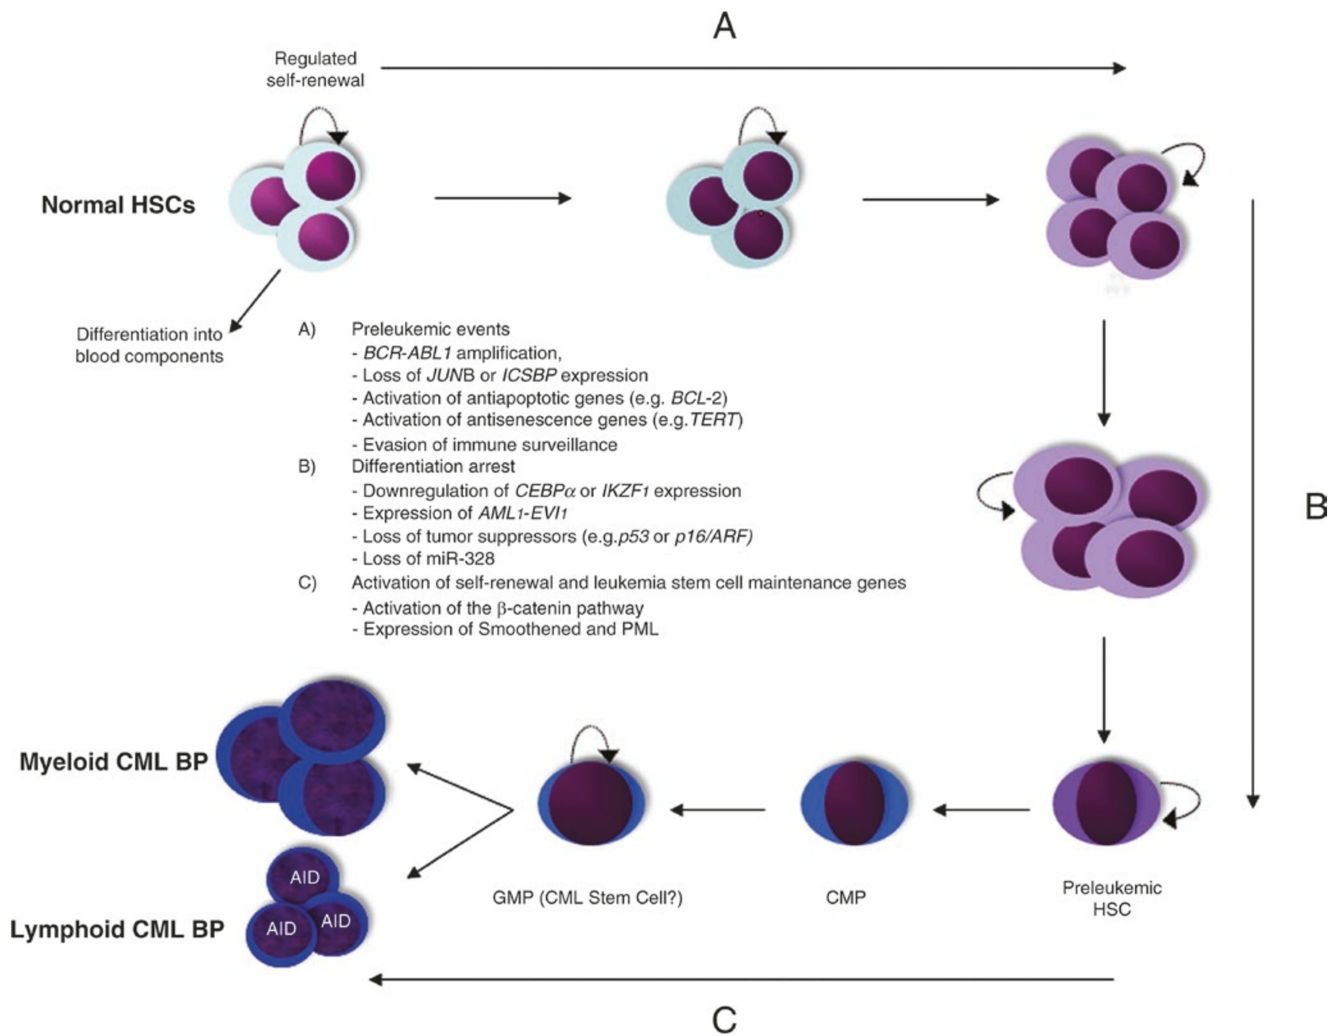

Fig. 4.3 Progression to blastic phase. In CML, hematopoietic stem cells (HSCs) accumulate genetic abnormalities that result in enhanced proliferation, survival advantage, cytokine independence, immune evasion, decreased apoptosis, and differentiation arrest. Granulocyte–monocyte progenitors (GMP) carrying such abnormalities are endowed with self-renewal potential, feed the leukemic pool during disease progression, and facilitate the emergence of clonal leukemic stem cells (LSCs) that drive the transition to blast-phase (BP) CML. Expression of activation-induced deaminase (AID) drives CML progression toward the lymphoid lineage

of 7.8 copy number alterations were detected per CML BP case (range 0–28), indicating that progression requires the acquisition of additional genomic alterations [55].

Blastic Phase Arises from Primitive CML Progenitors

In CML, CD34^{+}CD38^{-}Lin^{-} LSCs express high *BCR-ABL1* transcript levels [56]. LSCs acquire additional genetic and/or epigenetic abnormalities during the transition from CP to BP that confer resistance to apoptosis, extended replicative life span, and consequently a survival advantage [57, 58]. Mice genetically null for the *JUNB* [43] or *ICSBP* alleles develop a CML-like myeloproliferative disorder that, in the case of *JUNB*, arises from the HSC compartment and in some cases progresses to BP. JunB inactivation increases the proliferation of long-term repopulating HSCs in vivo without impairing their self-renewal potential [59]. Whether *BCR-ABL1* directly abrogates or cooperates with JunB expression to promote myeloproliferation during CML progression warrants further investigation, as does the determination of the cell of origin from which the BP clone arises. While transforming clones appear to arise from the HSC compartment in *JUNB*$^{-/-}$ mice, some reports suggest that the acquisition of self-renewal properties by a subset of committed progenitors may result in a CML-like phenotype that includes progression to BP in a mouse model in which the hMRP8p210$^{BCR\text{-}ABL1}$ transgene is expressed specifically by GMPs and their myelomonocytic progeny but not by HSCs [60]. These data suggest that BP may result from the progressive acquisition of genetic alterations within progenitors downstream of the

HSC that acquire self-renewal properties [60]. Importantly, GMPs have also been proposed as candidate LSCs in human CML BP [56].

CML BP Cells Overexpress BCR-ABL1

The continuous and unrestrained activity of BCR-ABL1 kinase is central not only for CML maintenance but also in the progression from CP to BP. *BCR-ABL1* mRNA and protein levels are consistently higher in BP than in CP [61, 62]. *BCR-ABL1* transcript levels may be 200-fold greater in CML CD34+ progenitors than in more differentiated *BCR-ABL1*-positive cells [63]. *BCR-ABL1* has been shown to promote clonogenicity [63, 64], growth factor independence [63], protection against apoptosis [64], cell motility [63], and disease latency in a dose-dependent manner [63]. The reason for the increment of *BCR-ABL1* transcript levels is not well understood, but this phenomenon is likely a consequence of the proliferative advantage resulting from high BCR-ABL1 kinase activity and therefore from selective pressure favoring the expansion of highly proliferative/poorly differentiated leukemic clones. Experimental evidence has demonstrated that levels of *BCR-ABL1* mRNA in the CD34+ GMPs were higher in CML BP than in CML CP [56]. *BCR-ABL1*-positive GMPs have been demonstrated to be expanded in CML BP [56]. Alternatively, it has been proposed that the BCR-ABL1 oncoprotein promotes the expression of *BCR-ABL1* transcripts and/or that *BCR-ABL1* transcript degradation may be selectively downregulated in CD34+ CML progenitors [65]. *BCR-ABL1*-independent mechanisms may also play an important role in CML progression. For instance, overexpression and/or activation of the SFKs HCK, LYN, and FYN has been linked to CML progression and imatinib resistance [66–69]. *BCR-ABL1* retrovirally transduced into bone marrow cells derived from *LYN*$^{-/-}$*HCK*$^{-/-}$*FGR*$^{-/-}$ mice efficiently induced CML but not B-ALL in recipient mice, which suggests that SFKs may play an important role in the pathogenesis of Ph + B-ALL and lymphoid CML BP [33, 70]. BCR-ABL1-independent activation of LYN was noted in patients with imatinib-resistant CML expressing unmutated *BCR-ABL1* [71]. Anti-SFK therapy may therefore be beneficial in advanced-phase CML [70].

Arrest of Differentiation

Progressive corruption of the differentiation program characterizes CML progression. BCR-ABL1 modulates the activity of transcription factors that regulate the expression of several differentiation-related genes (Fig. 4.3) [72, 73]. The *IKZF1* gene, which encodes the transcription factor Ikaros, is essential for lymphoid lineage specification. Ikaros isoforms lacking the DNA-binding domain act in a dominant negative fashion, preventing the generation of the earliest lymphoid progenitors and of mature lymphocytes [74]. SNP array analysis identified the presence of *IKZF1* deletions (typically monoallelic deletions of exons 3–6) in more than 80% of patients with Ph + ALL. Deletions were not present in CML CP cases but were found in 66–75% of CML CP cases transformed to lymphoid (but never to myeloid) CML BP [55, 75]. Downregulation of Ikaros expression causes partial block of B-cell maturation at the pro-B-cell stage in mice [76], and inactivation of Ikaros function blocks the development of B-lymphoid progenitors at the pre-B-cell stage [77]. *IKZF1* haploinsufficiency or the expression of dominant negative Ikaros isoforms may contribute to the pathogenesis of *BCR-ABL1*-positive lymphoid malignancies by inducing arrested B-cell maturation.

The transcription factor CCAAT/enhancer binding protein-α (CEBPα), a master regulator of myeloid differentiation [78], is expressed in normal bone marrow cells and in CML CP samples but not in CML BP [79]. Transplantation of *BCR-ABL1*-expressing CEBPα$^{-/-}$ fetal liver cells fails to induce myeloproliferative disease in mice. Rather, it induces an immature, lethal transplantable erythroleukemia. Transplantation of CEBPα-transduced cells consistently yielded a disease that closely resembles CML CP [80], suggesting that CEBPα downregulation abrogates cell commitment toward a myeloid cell fate. Differentiation arrest in myeloid CML BP is driven by BCR-ABL1/MAPK-induced activity of the poly(rC)-binding protein heterogeneous nuclear ribonucleoprotein E2 (hnRNP E2), which regulates the translation of specific mRNAs [79]. Expression of hnRNP E2 is low or undetectable in CML CP but is high in CML BP CD34+ bone marrow progenitors. Upon interaction with the 5′-untranslated region of *CEBPA* mRNA causes suppression of CEBPα [79]. MicroRNAs (miRNAs), small noncoding RNAs that have been shown to be important regulators of oncogene and tumor-suppressor gene expression in human cancer, can also inhibit the activity of RNA-binding proteins [81]. Indeed, miR-328 binds hnRNP E2, likely through its C-rich clusters in a seed sequence-independent manner, and as a consequence prevents the binding of hnRNP E2 to *CEBPA* mRNA, thus rescuing *CEBPA* mRNA translation and myeloid maturation. Not surprisingly, miR-328 expression is lost in CML BP in a BCR-ABL1 dose- and kinase-dependent manner through the MAPK-hnRNP E2 pathway. Restoration of miR-328 rescued differentiation and impaired the survival of *BCR-ABL1*-positive blast cells, partly by targeting the survival factor PIM [81].

Hybrid dominant negative transcription factors arising from chromosomal translocations such as *NUP98-HOXA9* [82] or *AML1-EVI1* [83] have been implicated in the pathogenesis of CML BP. NUP98-HOXA9 alters the balance between symmetric and asymmetric renewal division,

favoring the former and causing preferential growth of immature precursors, while *AML1-EVI1* has been shown to cause differentiation blockade, in both cases facilitating the transition to CML BP [84]. NUP98-HOXA9 induces expression of the RNA-binding protein Musashi2 (Msi2), which in turn represses differentiation factor Numb, known to be expressed at low levels in CML BP [85]. Msi2, normally highly expressed in HSCs and overexpressed in advanced CML, is associated with poor survival. In a mouse model, it cooperates with BCR-ABL1 to induce an aggressive leukemia [86].

Genomic Instability and DNA Repair

BCR-ABL1 expression has been associated with increased production of endogenous reactive oxygen species (ROS) that result in chronic oxidative DNA damage, double-strand breaks (DSBs) in S and G_2/M cell cycle phases, and mutagenesis [87]. DNA damage surveillance is faulty in CML owing to inhibited ataxia telangiectasia and RAD3-related (ATR) nuclear protein kinase signaling, which attenuates the activation of checkpoint kinase 1 (CHK1) and abrogates the intra-S-phase cell cycle checkpoint [88]. Nonhomologous end-joining and homologous recombination as well as nucleotide excision repair exhibit unfaithful repair of DSBs induced by ROS [87] and γ-irradiation [89] as a consequence of BCR-ABL1 kinase activity [87]. As a result, G/C-to A/T-transitions and G/C-to-T/A transversions in the coding regions of multiple genes (including the kinase domain of *BCR-ABL1*) have been demonstrated in CML cells but not in *BCR-ABL1*-negative cells [87, 90]. It has been shown that lymphoid (but not myeloid) CML BP cells express the B-cell-specific mutator enzyme activation-induced deaminase (AID), which contributes to genetic instability by hypermutation of tumor suppressor and DNA repair genes and to induction of mutations in the kinase domain of *BCR-ABL1* [91]. These results indicate that ROS generated by BCR-ABL1, in addition to aberrant regulation of DNA repair, contribute to a mutator phenotype in CML cells and lead to genomic instability that results in cytogenetic aberrations, point mutations, and consequently TKI resistance [90, 92]. Indeed, *BCR-ABL* has been shown to disrupt proteins involved in DNA DSB repair [93–95] and to cause cell cycle arrest in G_2/M in cells treated with DNA-damaging agents [96].

Chromosomal Abnormalities in CML

Approximately 80% of patients with CML develop additional nonrandom cytogenetic aberrations in Ph + cells, an occurrence known as "clonal evolution," which is a reflection of the genetic instability that characterizes the transition to advanced-phase CML [97]. In some reports, clonal evolution has been reported in advanced-phase CML at higher frequencies than *BCR-ABL1* mutations [98]. The most frequent cytogenetic abnormalities associated with clonal evolution are trisomy 8 (34%), isochromosome 17 (20%), and duplicate Ph chromosome (38%) [90, 99], which have been linked to c-*Myc* overexpression, loss of 17p (which results in *p53* loss), and *BCR-ABL1* overexpression, respectively [61, 100, 101]. Other cytogenetic abnormalities, such as trisomy 21, trisomy 17, and deletion 7, have been identified in less than 10% of cases of clonal evolution [102]. Also, 10–15% of patients with CML present with deletions within the derivative chromosome 9, which may lead to more rapid progression to BP [103]. In patients with 3q26.2 rearrangements (approximately 5%), the disease fails to respond to TKI treatment, exhibits a high rate of transformation to BP, and has a poor outcome [104, 105]. 3q26.2 gene rearrangements cause overexpression of a proto-oncogene, transcription factor EVI1 [106, 107]. Co-occurrence of RAS/receptor tyrosine kinase mutations contributes to leukemic transformation in myeloid malignancies [108]. Clonal evolution may therefore reflect a state of genetic instability that is frequently associated with advanced phases of CML and appears to play a pivotal role in CML progression. In the era of TKI therapy, single chromosomal change that includes trisomy 8, -Y, and an extra copy of Ph confers overall good response to therapy and favorable prognosis, while i(17)(q10), -7/7q (-7/del7q), and 3q26.2 rearrangements or concurrent emergence of more than two additional chromosomal abnormalities is associated with poor survival [109]. Cytogenetic abnormalities have also been detected in Ph-negative metaphases of 2–17% of patients with CML and have been occasionally linked with development of myelodysplasia or acute myeloid leukemia (AML) [110]. The SNP array findings that patients with CP CML harbored a mean 0.47 copy number alterations while those with BP CML harbored a mean 7.8 copy number alterations [55] further support the idea that multiple genomic aberrations accumulate during progression to BP CML.

Inactivation of Tumor-Suppressor Genes

The most frequently mutated tumor suppressor in human cancer is *p53*. In CML, *p53* can be found mutated during progression to BP in 25–30% of patients with myeloid CML BP. In addition to *p53*, exon 2 of the *INK4A/ARF* locus is deleted in 50% of cases of lymphoid CML BP [111], leading to loss of *p16* and *p14/ARF* expression, which regulates the G_1/S checkpoint by inhibiting the G_1-phase cyclin D-Cdk4/Cdk6 and by downregulating p53, respectively [100]. Deletion of the *P19ARF* gene in mice alters the nature of leukemia-initiating cells, rendering common lymphoid progenitors and precursor B-lymphocytes susceptible to transformation by BCR-ABL [112]. Because ARF enhances

p53 levels by interfering with the activity of MDM2, the principal negative regulator of p53, homozygous deletion at the *p16/ARF* locus represents a functional equivalent of *p53* mutation in myeloid CML BP. Clones of CML cells carrying such deletions are likely to be selected during CML progression [100]. Retroviral transduction of *BCR-ABL1* into *ARF*-null murine bone marrow cells rapidly generates polyclonal expansion of self-renewing pre-B cells [113]. Given the impact of p53 in disease progression, it is intuitive to think that alterations in the p53 pathway may also play a role in response to TKI therapy. Imatinib therapy causes p53 activation that is a direct consequence of BCR-ABL1 kinase inhibition [114]. By contrast, p53 inactivation has been shown to impair imatinib activity in vivo, suggesting that a mutated p53 pathway may contribute to imatinib resistance in advanced-phase CML [114].

The *RUNX* family of transcription factors has also been implicated in imatinib response in CML [115]. In mice transplanted with bone marrow cells retrovirally infected with *BCR-ABL1* and subsequently treated with imatinib to select for leukemic cells in which the proviral integration had affected genes modulating imatinib response, clonal outgrowth of cells carrying similar integration sites has been shown. Proviral integration near the *RUNX3* promoter induced expression of RUNX3, and *BCR-ABL1*-positive cell lines with stable or inducible expression of RUNX1 or RUNX3 were protected from apoptosis induced by imatinib treatment [115]. Imatinib therapy was also selected for *RUNX1*-expressing cells in vivo after infection of primary bone marrow cells with both *BCR-ABL1* and *RUNX1* [115], suggesting that *RUNX1* contributes to disease persistence.

Several miRNAs have been shown to act as tumor suppressors in CML and therefore they are subjected to a strong selection pressure. miRNA 203, which maps to 14q42, is frequently lost in lymphoid CML BP. Both *ABL1* and *BCR-ABL1* genes contain miR-203 target sequences. It has been shown that miR-203 is silenced through genetic (loss of one allele) and epigenetic (promoter CpG hypermethylation in the remaining allele) mechanisms, which suggests the existence of enormous selective pressure in CML cells to silence miR-203 in order to gain a proliferative advantage [116]. These data suggest that loss of miR-203 may play a critical role in CML progression. Decreased expression of other miRNAs such as miR-10a [117] and the miR-17-92 cluster [118] has also been associated with a gain in proliferative potential and possible transformation to CML BP. The RNA-binding protein Lin28 is highly expressed in CML BP, causing repression of miRNA let-7 and activation of let-7 targets, including signaling pathways important for CML proliferation [119].

PP2A functions as a tumor suppressor by antagonizing BCR-ABL1 [120]. BCR-ABL1 kinase inhibits PP2A by upregulating SET, a phosphoprotein that inhibits PP2A [120]. In turn, PP2A activates SHP1, which abrogates BCR-ABL1 phosphorylation and targets it for proteasomal degradation [120]. Both SET inhibition and PP2A activation represent potential therapeutic strategies. The PP2A activator fingolimod (FTY720) [121] induces apoptosis and impairs the clonogenic potential of the TKI-resistant 32D-p210(T315I)$^{BCR-ABL1}$ cell line and of primary bone marrow cells from patients with BP CML or Ph + B-ALL [122]. Fingolimod induced molecular remissions in severe combined immunodeficiency (SCID) mice transplanted with myeloid or lymphoid progenitors transformed with p210$^{BCR-ABL1}$ or p190$^{BCR-ABL1}$, respectively [122].

In summary, multiple lines of evidence suggest that the increased survival, proliferation, and differentiation arrest of CML BP cells relies upon the intimate cooperation of BCR-ABL1 with an array of genes deregulated during disease progression. A better understanding of these abnormalities and the generation of more faithful CML animal models will likely facilitate the development of more effective therapies for CML BP.

CML Stem Cells

The existence of LSCs was first demonstrated in AML, when upon transplantation into nonobese diabetic (NOD)–SCID mice, only the CD34 + CD38− population was capable of propagating AML in a new host [123]. These cells encompass <1% of the total number of AML cells. LSCs were then demonstrated in CML [124] and shown to contain two distinct populations of cells: a very small set consisting of highly quiescent diploid cells in the G_0 phase, and a larger one consisting of cells in $G_1/S/G_2/M$ [125]. While solid experimental data support the existence of a subset of leukemic cells capable of giving rise to new leukemic cells, thus promoting the proliferation of the malignant clone, the precise origin of such cells remains unclear. Ph + stem cells isolated from patients with CML treated with imatinib are able to repopulate immunocompromised mice, suggesting that TKIs are unable to eliminate quiescent CML stem cells [126]. Yet, approximately 40% of CML patients in the “Stop Imatinib Trial” (STIM) who achieved a complete molecular response were able to discontinue imatinib and maintain molecular remission [127], indicating either that CML stem cells are eliminated over time by the TKI or that minimal residual disease is eliminated through immune surveillance.

Quiescence and Persistence

One of the main features that sets *BCR-ABL1*-expressing LSCs apart from more committed leukemic progenitors is that LSCs are innately resistant to chemotherapeutic agents, radiation [128], and BCR-ABL1 TKIs [129–131]. Mathematical

models have shown that, when exposed to imatinib or other TKIs, CML cells decline in number in a biphasic pattern. During the initial stages of treatment, TKIs induce brisk and acute clearance of *BCR-ABL1* transcripts, likely a reflection of the elimination of the most differentiated CML cells. This is followed by a second slope of slower decline of *BCR-ABL1* transcripts, reflecting the targeting of more primitive CML progenitors, including CML LSCs, typically resulting in persistent residual disease [132, 133]. The factors underlying resistance of *BCR-ABL1*-positive LSCs to TKI therapy are not yet clearly defined. Factors invoked to explain this phenomenon include the following: (a) enhanced expression by CML stem cells of interleukin-3 (IL-3) and granulocyte colony-stimulating factor, which correlate with the primitive status of LSCs; (b) downregulation of the influx transporter human organic cation transporter-1 (hOCT1) and upregulation of the adenosine triphosphate-binding cassette transporter ABCB1 (MDR-1) and ABCG2, responsible for the influx and efflux of imatinib, respectively [65]; (c) increased expression of *BCR-ABL1* mRNA, protein, and kinase activity, which suggests that TKI-induced killing of CML LSCs requires doses much higher than those required to eliminate more mature *BCR-ABL1*-positive progenitors [134–136]; and (d) increased instability of the *BCR-ABL1* oncogene, which has been linked to increased levels of ROS and oxidative DNA damage, resulting in a higher rate of BCR-ABL1 kinase domain mutations in *BCR-ABL1*-positive LSCs even before exposure to therapy [137, 138]. There is therefore ample evidence that CML stem cells are resistant to the pro-apoptotic effects of TKIs, which may set the stage for CML relapse. However, other possibilities must be taken into account. For instance, in addition to imatinib, CML stem cells have proven highly resistant to the potent TKIs nilotinib and dasatinib [134–136]. In these cells, MAPK, PI3K, and STAT5 remain active despite BCR-ABL1 kinase inhibition [136]. Although CML LSCs express BCR-ABL [139], blockade of BCR-ABL activity by TKIs fails to eradicate CML stem cells [140, 141]. These observations suggest the interesting possibility that primitive quiescent CML stem cells may not depend on BCR-ABL1 kinase activation for survival. This would explain the TKIs' lack of activity against CML stem cells. An even more intriguing possibility is that TKI-induced BCR-ABL1 inhibition in CML stem cells might reverse the LSC phenotype to a "normal HSC" phenotype, thus calling into question the clinical importance of eradicating this subset of cells.

A potential way to eradicate LSCs is to stimulate their entry into the cell cycle [142, 143]. Interferon alpha (IFNα) has been shown to have this effect in quiescent CML stem cells. Upon binding to its receptor, IFNα induces STAT1 and STAT2 phosphorylation, which activates HSCs through the phosphorylation of AKT1 [142] and other factors involved in proliferation and by forming a complex with interferon regulator factor 9 (IRF9), which binds to the interferon-stimulated responsive element (ISRE) in genes whose transcription is regulated by IFNα. The negative regulator IRF2 competes with IRF9 for binding to ISRE, and its inactivation causes constitutive IFNα activity that causes HSCs to exit G_0 and enter an active cell cycle [142] that results in the depletion of the dormant HSC pool [144]. Therefore, while chronic activation of the IFNα pathway causes HSC depletion and compromises HSC function, acute INFα administration causes proliferation of dormant HSCs [142].

Stem Cell Maintenance Pathways

Several signaling pathways involved in embryonic development processes (tissue patterning, cell proliferation, differentiation) have been implicated in stem cell maintenance. These pathways have been shown to be involved in the pathogenesis of human cancer as they confer growth and/or survival advantage. The β-catenin pathway is key for HSC self-renewal in mice. Upon translocation to the nucleus, β-catenin interacts with its transcriptional coactivator lymphoid enhancer factor/T-cell factor (LEF/TCF) to modulate the transcription of genes such as *MYC* and *cyclin D1*. The transition from CP to BP in humans is characterized by a six- to tenfold expansion of GMPs rather than expansion of the HSC pool. Transfection of axin, a specific inhibitor of the β-catenin pathway, abrogates leukemic GMP replating and results in similar levels of β-catenin and LEF/TCF in HSCs in both normal controls and patients with CP or BP CML. Increased levels of β-catenin, LEF/TCF, and *BCR-ABL1* transcripts can be detected in GMPs isolated from patients in BP CML. The latter are endowed with increased self-renewal capabilities and stemness in vitro (as assessed by serial replating assays), compared with normal GMPs [56]. These data indicate the coexistence of two distinct self-renewing cell populations: one mainly consisting of GMPs that express high *BCR-ABL1* transcripts and enhanced nuclear β-catenin, which would be responsible for the transition to BP CML, and a second one involving *BCR-ABL1*-positive HSCs with a quiescent cell cycle, which would be responsible for the expansion and maintenance of the disease in CP. In this context, the role of the *BCR-ABL1* oncogene is not entirely clear, as this oncogene, unlike other leukemogenic fusion oncogenes such as *MLL-ENL* or *MOZ-TIF2*, can transform HSCs but is not sufficient to transform committed myeloid progenitors lacking inherent self-renewal capacity [145]. Additional pathways must therefore be implicated in LSC maintenance in CML.

The hedgehog (Hh) pathway is important during embryonic and postnatal development and in cancer [146]. Mutations in genes encoding proteins involved in the Hh pathway, such as *patched-1* (*PTCH1*) and *smoothened* (*SMO*), have been reported in several malignancies

[146–148]. Hh has been shown to play a role in primitive and adult hematopoiesis and is activated in LSCs [149–151]. Smo is a transmembrane receptor negatively regulated by the Hh receptor patched, which, in turn, is alleviated upon binding of the Hh proteins Shh, Ihh, or Dhh to patched [152]. In a murine model of CML, *BCR-ABL1*-expressing cells exhibited Smo upregulation, which was partially decreased upon treatment with imatinib or nilotinib [150]. Smo loss impairs HSC renewal, attenuates *BCR-ABL1*-induced CML, and depletes CML stem cells, likely through activation of Numb [152]. When $Smo^{-/-}$ cells transduced with *BCR-ABL1* were transplanted into irradiated mice, the number of LSCs was significantly lower than in control mice. Constitutively active Smo stimulates the propagation of CML stem cells and causes disease progression, supporting the important role of the Hh pathway in CML stem cells [152]. Pharmacological inhibition of Hh signaling with cyclopamine, which stabilizes Smo in its inactive form, abrogated the propagation of *BCR-ABL1*-positive cells and prolonged survival in a CML mouse model. These results, as well as recent data demonstrating the acquisition of *SMO* mutations that impair the binding of the Smo protein to Smo small-molecule inhibitors [153], highlight the importance of the Hh pathway in the pathogenesis of human cancer, and support the use of drugs that inhibit Hh signaling to eradicate LSCs in CML.

Blast cells obtained from patients with CML CP express high levels of the promyelocytic leukemia (PML) tumor-suppressor protein, which cannot be detected in more committed progenitors [154]. Genetic deletion of PML in mice or PML downregulation by arsenic trioxide resulted in increased cell cycling and ultimately exhaustion of HSCs that impaired hematopoietic reconstitution in recipient mice. CML leukemia-initiating cells (LICs) were generated by transduction of $p210^{BCR\text{-}ABL1}$ into $Pml^{-/-}$ HSCs. PML is therefore required for LIC mitotic quiescence and maintenance and this is accomplished through mTOR repression. Activation of mTOR with arsenic trioxide hampers HSC and LIC maintenance. Therefore, Hh inhibitors, mTOR activators, and IFNα are potential therapeutic strategies to eradicate LSCs in CML as they compromise LSC propagation, maintenance, and function. However, these may not be the only alternatives to effectively targeting LSCs, as other pathways appear to play a critical role in LSC homeostasis in CML. It has been shown that BCR-ABL1 kinase activates Akt signaling, which abrogates the forkhead O transcription factors (FOXO), resulting in proliferation and inhibition of apoptosis of CML cells [155]. By using a syngeneic transplantation system of immature bone marrow cells retrovirally transduced with *BCR-ABL1*, LICs have been found to be characterized by nuclear localization of FoxO3a and low Akt phosphorylation, both phenomena critically modulated by transforming growth factor-beta (TGF-β). In serial transplantation experiments utilizing LICs derived from $Foxo3a^{+/+}$ and $Foxo3a^{-/-}$ mice, genetic deficiency of Foxo3a remarkably limited the ability of LICs to induce a leukemic phenotype. In keeping with these results, TGF-β inhibitor therapy impaired the colony-forming ability of human $CD34^{+}CD38^{-}Lin^{-}$ CML cells in vitro [155], which suggests that the TGF-β–FOXO pathway has an essential role in the maintenance of CML LICs. Similarly, *ALOX5*, the arachidonate 5-lipoxygenase (5-LO) gene, has been identified as a critical regulator of LSCs in CML [156]. Alox5 deficiency renders BCR-ABL1 unable to induce CML in mice by impairing differentiation, cell division, and survival of LSCs but not normal HSCs. BCR-ABL suppresses Blk (encoding B-lymphoid kinase), which functions as a tumor suppressor in CML stem cells through an upstream regulator, Pax5, and a downstream effector, p27 [157].

Regulation of quiescence in LSC and insensitivity to TKIs is modulated by a pathway of peroxisome proliferator-activated receptor gamma (PPARγ) and its downstream targets STAT5 and HIF2α/CITED2, known to facilitate LSC dormancy [158]. In turn, activation of PPARγ by this antidiabetic glitazone drugs decreased STAT5 expression and reduced the LSC pool, causing stem cells to exit quiescence and eliminating disease when combined with TKIs. Additional pathways and transcriptional regulators implicated in CML stem cell maintenance include BCL-6 [159], MPL/JAK [160, 161], SIRT1 [162], Notch [163], Bmi1 [164], IL2/CD25 signaling [165], and autophagy [166]. Interactions between LSCs and bone marrow microenvironment may also influence the success of CML therapy [167, 168], and approaches targeting LSC-niche interactions have been shown to be effective in preclinical model systems [169, 170]. Additionally, the hypoxic nature of the marrow niche has been proposed to offer LSC maintenance and protection from TKIs [171].

BCR-ABL1 Kinase Domain Mutations and TKI Resistance

CML may fail to respond or may lose its response to TKI therapy through a series of BCR-ABL1-dependent or -independent mechanisms of resistance including TKI compliance and bioavailability, pharmacodynamics, genetic changes, *BCR-ABL1* kinase domain mutations, or BCR-ABL1 overexpression. The most frequent and clinically relevant mechanism of resistance to TKI therapy is the acquisition of mutations within the kinase domain of *BCR-ABL1* (Fig. 4.4). Mutations have been reported at frequencies ranging from 40 to 90% among patients with imatinib-resistant CML [172–177]. Kinases are plastic multimodular structures that oscillate between an active and an inactive conformation. Different TKIs bind different conformations of the BCR-ABL1 kinase. For instance, imatinib and

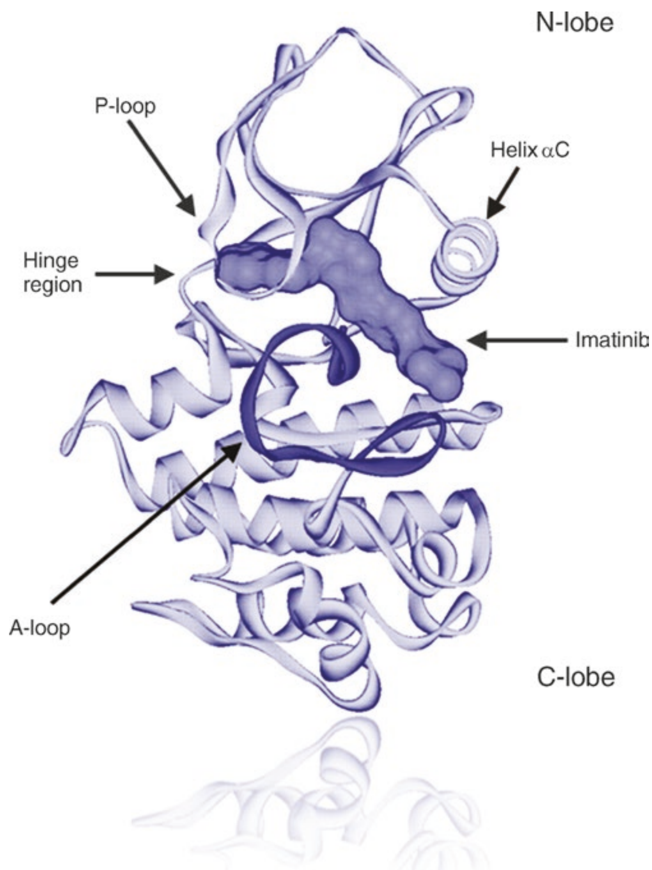

Fig. 4.4 3D structure of the ABL1 kinase domain in complex with imatinib. The ATP-binding site in the ABL1 kinase domain is located between the activation loop (A-loop) and the phosphate-binding loop (P-loop). The A-loop controls the ABL1 catalytic activity by switching between the active and the inactive conformations of the kinase. Imatinib inserts its pyridinyl group underneath the helix αC in the NH2-terminal lobe of ABL1 kinase, displacing ATP and freezing the kinase in its inactive conformation. Mutations mapping at the P-loop, the A-loop, and imatinib contact sites are the most common causes of acquired resistance to imatinib therapy

nilotinib bind the inactive conformation of ABL1 kinase, in which the highly conserved Asp-Phe-Gly (DFG) residues are swung out of the catalytic cleft ("DFG-out") [178, 179]. Imatinib extends deeply into the catalytic domain, and its pyridinyl group locates underneath the αC helix in the NH_2-terminal lobe of ABL1 kinase [178]. On the other hand, X-ray crystallography [180] and NMR spectroscopy [181] have shown that dasatinib binds the active ("DFG-in") conformation of ABL1.

Over 100 different point mutations encoding single-amino acid substitutions within the kinase domain of *BCR-ABL1* have been detected in patients with imatinib-resistant CML [20, 177, 178, 182, 183], and others have been generated in vitro by random mutagenesis of *BCR-ABL1* [182, 184]. Imatinib-resistant mutations tend to cluster at specific regions within ABL1 kinase. One such region, the P-loop region (residues 248–255) of the kinase domain, serves as a docking site for phosphate moieties of ATP [185–187]. While some studies linked P-loop mutations to a poorer clinical outcome [188, 189], others have not confirmed this observation [190]. In fact, not all P-loop mutations have the same transformation potency or sensitivity to different TKIs. Second-generation TKIs such as dasatinib, bosutinib, and, to a lesser extent, nilotinib are active against some P-loop mutations (Table 4.1). Other areas within ABL1 kinase frequently affected by mutations include the activation (A) loop (residues 381–402), whose mutations prevent the kinase from adopting the inactive conformation to which imatinib binds, and the catalytic (C) domain (residues 350–363). Particularly worrisome are those mutations that affect ATP-contact sites within the ATP-binding region (e.g., T315I, F317L, V299L). Selected ATP-binding loop mutations such as Y253F increase intrinsic BCR-ABL kinase activity [191, 192]. The gatekeeper residue Thr315 sits at the periphery of the nucleotide-binding site of ABL1 and forms an H-bond with imatinib and dasatinib [183]. Mutation of Thr315 to isoleucine (T315I) disrupts this H-bond interaction, which, in addition to the steric hindrance imposed by the isoleucine side chain and the stabilization of the kinase in the active conformation, impairs imatinib binding, causes complete insensitivity to this compound as well as to second-generation TKIs, and promotes malignant transformation [6, 174, 179, 193–197]. T315I mutation has been reported in approximately 15% of patients after failure of imatinib therapy [198]. For patients with a gatekeeper T315 mutation, the only TKI approved for clinical use is ponatinib [199]. Ponatinib is a type II inhibitor that avoids T315 by inclusion of a rigid triple-carbon bond. Ponatinib at higher concentrations is capable of inhibiting other BCR-ABL mutations (such as E225V), and these levels are clinically achievable, accounting for higher response rates to ponatinib in CML patients with multiple mutations [200]. The F317L and V299L mutations almost invariably arise during dasatinib therapy but retain sensitivity against nilotinib [201]. Mutations occurring at a subset of residues (Q253, Y253, E255, T315, E459, and F486) are more frequently detected in patients with advanced-phase CML [202].

Despite the wide variety of *BCR-ABL1* point mutations, most mutants are rare, with mutations involving residues Gly250, Tyr253, Glu255, Thr315, Met351, and Phe359 accounting for 60–70% of all mutations [203]. The presence of T315-inclusive compound mutations, i.e., two or more mutations within the same BCR-ABL molecule, confers resistance to all currently available TKIs [204] and has been found in patients in whom ponatinib failed [200, 205]. This is not the case for non-T315I compound mutations, which are variably sensitive to several TKIs. Over 60 different BCR-ABL1 compound mutations have been reported in association with sequential TKI use and resistance [206–208]. Clones with the E225K/T315 compound mutation

Table 4.1 Sensitivity of BCR-ABL1 kinase domain mutations to imatinib and the second-generation tyrosine kinase inhibitors nilotinib, dasatinib, and ponatinib

	$BCR\text{-}ABL_1$ isoform	Imatinib (nM)	Nilotinib (nM)	Dasatinib (nM)	Ponatinib (nM) [199]
	Native	260	13	0.8	0.5
P-loop	$M_{244}V$	2000	38	1.3	2.2
	$G_{250}E$	1350	48	1.8	4.1
	$Q_{252}H$	1325	70	3.4	2.2
	$Y_{253}H$	>6400	450	1.3	6.2
	$Y_{253}F$	3475	125	1.4	2.8
	$E_{255}K$	5200	200	5.6	14
	$E_{255}V$	>6400	430	11	36
	$V_{299}L$	540	NA	18	NT
ATP-binding site	$F_{311}L$	480	23	1.3	NT
	$T_{315}I$	>6400	>2000	>200	11
	$T_{315}A$	971	61	125	1.6

were shown in vitro to produce paracrine factor IL-3, which promotes survival of bystander non-mutated cells through the MEK/ERK and JAK2/STAT5 pathways [209]. Novel allosteric BCR-ABL inhibitors binding in non-ATP pocket sites have entered clinical trials and have been shown in preclinical studies to restore the sensitivity to conventional TKIs of the T315I mutant [210]. Whether such inhibitors can block compound mutations remains to be determined.

It is worth emphasizing that different mutations are endowed with different transforming capabilities that are not tightly related to their kinase activity. In pre-B-cell transformation assays, T315I (which has weaker kinase activity than $p210^{BCR\text{-}ABL1}$) and E255K consistently showed a 10–20% increase in oncogenic potency relative to that of $p210^{BCR\text{-}ABL1}$; whereas the P-loop mutants Y253F and E255V had potencies similar to those of $p210^{BCR\text{-}ABL1}$ and Y253H, T315A, F317L, and M351T were markedly weaker [192]. Relative to unmutated *BCR-ABL1*, Y253F and E255K mutants have higher transformation potency, whereas M351T and H396P mutants are less potent. The kinase activity of E255K, H396P, and T315I did not correlate with transforming potency. Analysis of the phosphotyrosine proteome by mass spectroscopy confirmed the presence of different phosphorylation signatures among the different mutants, confirming that different mutations determine substrate specificity leading to activation of different downstream pathways [191]. Importantly, some patients with CML tend to accumulate more than one BCR-ABL1 mutation, frequently within the same *BCR-ABL1* allele, when they experience sequential TKI therapy failure, and this accumulation of mutations was associated with greater oncogenic potency than each individual mutation [206].

BCR-ABL1 kinase-independent mechanisms of resistance are thought to involve activation of alternative signaling pathways and might involve multiple mechanisms. For example, activation of pSTAT3, STAT5, MAPK, JAK2, LYN, SYK, PI3K, and XPO1/CRM1 has been implicated in kinase-independent resistance to TKIs [68, 211–219]. Other mechanisms of resistance include impaired inhibitor influx or increased drug efflux, such as cation transporter OCT1 for imatinib resistance [220, 221] and MDR1 for nilotinib resistance [222].

Concluding Remarks

The central role of *BCR-ABL1* as the causative agent in the pathogenesis of CML is firmly established. Cells expressing *BCR-ABL1* acquire growth factor independence and exhibit deregulated cell proliferation and increased resistance to apoptosis. These capabilities are acquired and sustained by a complex network of signals that emanate from the constitutive kinase activity of BCR-ABL1. Such signals result initially in unbridled myeloproliferation of

mature myeloid elements; over time CML cells exhibit a marked loss of differentiation and growth arrest at the very early steps of myeloid maturation, which, in the absence of appropriate therapy, results in the transformation to BP. The initial steps of the pathogenesis of CML are directly choreographed by BCR-ABL1. Its activity during transformation, while necessary, is no longer sufficient. The mechanisms that govern the transformation process are not well understood, but research advances in this area have unveiled the previously unknown involvement of a series of transcription factors, miRNAs, and tumor suppressors in this process. Accordingly, blocking the constitutive activation of BCR-ABL1 kinase with TKIs such as imatinib results in high rates of response and a dramatic prolongation of survival among patients with CML CP. However, this strategy is not durably effective in patients with CML BP. It is therefore important to continue unraveling the intimate molecular mechanisms of transformation to better devise therapeutic strategies for patients with advanced-phase CML. In addition, while current TKI therapy for CML CP is highly effective, it does not fully eradicate the leukemic clones in most patients. The persistence of circulating and bone marrow-based CML cells is likely a consequence of the lack of sensitivity of primitive progenitors and CML stem cells to TKIs. A better understanding of the mechanisms that regulate CML stem cell homeostasis would facilitate the development of molecularly curative strategies for patients with CML.

5 Diagnosis and Treatment of Chronic Myeloid Leukemia

Charles A. Schiffer

Introduction

The original recognition of leukemia in the nineteenth century and the story of our progressive understanding of the biology and the development of treatment of chronic myeloid leukemia (CML) have been well reviewed in recent years [1–3]. Today, the diagnosis of CML usually presents few problems. In contrast, planning a therapeutic strategy for a patient who presents in chronic phase and monitoring a patient who starts treatment with a tyrosine kinase inhibitor (TKI) present a number of challenges. The same is true for a patient in chronic phase whose disease proves resistant to initial treatment with a TKI. Even more difficult may be the issue of how best to treat a patient presenting in or progressing to an advanced phase of CML. In this chapter, we review some of the essentials of diagnosis of CML with the main focus on the results of available treatment options and guidance on therapeutic strategy.

Diagnosis

Definition, Diagnostic Criteria, and Differential Diagnosis

CML is a clonal myeloproliferative expansion of transformed primitive hematopoietic progenitor cells involving myeloid, monocytic, erythroid, megakaryocytic, B-lymphoid, and occasionally T-lymphoid lineages [4]. Since 1960 when Nowell and Hungerford [5] described the specific karyotypic abnormality, a G group chromosomal abnormality that came to be known as the Philadelphia (Ph[1] or Ph) chromosome, there has been rapid progress in our understanding of the pathogenesis of the leukemia, providing us with the means to easily diagnose and monitor the disease. Subsequent studies further characterized the Ph to be the result of a balanced translocation between chromosomes 9 and 22 (t(9;22)(q34;q11)) [6]. A series of subsequent studies demonstrated that this resulted in a fusion gene involving the *BCR* (breakpoint cluster region) gene from chromosome 22 and the Abelson cellular oncogene, *ABL* from chromosome 9, which produces a chimeric protein which is responsible for the constitutive proliferation of myeloid cells [9]. Mice transfected with the *BCR-ABL1* fusion gene develop a myeloproliferative disorder resembling human CML or other Ph1 acute leukemias [1, 7–9].

The detection of the BCR-ABL1 fusion gene is the pathognomonic feature of almost all cases of CML. A few conditions demonstrate overlapping clinical features, the most common being a “leukemoid reaction” which occurs usually in response to severe infection. In contrast, however, the presence of splenomegaly and a low leukocyte alkaline phosphatase score (a test which is no longer performed routinely) suggest a diagnosis of CML. The presence of the characteristic Ph chromosome will allow the distinction of CML from disorders such as primary proliferative polycythemia, idiopathic myelofibrosis, and primary thrombocythemia, which can occasionally have a somewhat overlapping clinical presentation. The identification of *BCR-ABL1* in a peripheral blood sample by reverse transcriptase-polymerase chain reaction (RT-PCR) techniques or by fluorescence in situ hybridization (FISH) will give the definitive answer, though approximately 5% of patients with a blood picture resembling CML are negative for the Ph chromosome by cytogenetics [10, 11].

Among such Ph-negative patients, there is a preponderance of males and older patients, with lower leukocyte counts and thrombocytopenia being more typical of this subgroup. Of those patients who lack a Ph chromosome, about half are also *BCR-ABL1* negative; they are sometimes designated as “atypical CML” and their prognosis is poorer than that of patients with *BCR-ABL1*-positive leukemia

[10]. The other half have cryptic *BCR-ABL1* fusion gene on a normal-appearing chromosome 22 and such patients are usually designated Ph-negative, *BCR-ABL1*-positive CML. Their clinical features and response to treatment with TKIs differ little, if at all, from those of patients with a Ph chromosome. Specific mention should also be made of those patients who appear to have primary thrombocythemia but with a Ph chromosome and a *BCR-ABL1* gene. Such patients should be considered to have CML and should be managed as if they had classic CML. It is therefore recommended that all patients with apparent primary thrombocytosis should be tested for the Ph translocation and/or *BCR-ABL1* by RT-PCR.

Evaluation of a Suspected Case of CML

The specifics of the investigation of a newly presenting patient with CML are detailed in Table 5.1. In the presenting history, it is helpful to ask about certain features, such as the presence of night sweats or bone pain, as they may indicate transforming disease. Symptoms suggestive of hyperviscosity such as headaches, confusion, and visual disturbances are important to identify, but occur infrequently even in patients with very elevated WBC. It may be helpful to determine exposure to potential mutagens, especially high levels of ionizing irradiation, although it is very unusual for CML to develop as a "secondary" leukemia. There was a transient increase in the incidence of CML in Japanese survivors in the first decade after the atomic bomb exposure [12–14], but it is not clear that irradiation in the doses used for therapy of other cancers results in CML. Examination should particularly focus on retinal examination and lymph node areas, and include documenting the size of the spleen and liver. It is important to reassure the patient and family that the disease is not inherited, and to establish whether the patient has any siblings and hence potential for allografting.

Table 5.1 Investigations to be performed in suspected cases of CML

• CBC with differential and review of blood film
• Biochemistry screen including uric acid
• Bone marrow aspirate and trephine biopsy for:
Morphology (assess cellularity and degree of fibrosis on biopsy) • Cytogenetics (fluorescent in situ hybridization [FISH] if metaphase cultures fail) • Sample for immunophenotyping (process only if blast crisis is evident morphologically; not necessary if typical chronic phase) • Samples stored for research purposes if appropriate locally or for mailing to research group • RT-PCR if not available from peripheral blood (needed to define breakpoint for future monitoring)
Consider CMV serology and HLA type patient and siblings if allograft is being considered

A complete blood count and film review are critical in establishing the prognostic score (discussed later), and the number of blasts, basophils, and eosinophils should be calculated for this purpose. Immunophenotyping is only relevant to classify blast crisis. The trephine biopsy should be assessed for cellularity and the degree of fibrosis. Complete karyotypic analysis is necessary to assess for the presence of additional cytogenetic abnormalities in the Ph clone since FISH and RT-PCR will not detect abnormalities on chromosomes other than 9 and 22. It should be noted that all of these studies, save the assessment of marrow fibrosis, can be done on peripheral blood, since, because of the presence of circulating immature elements, chromosome analysis can generally be done successfully. Hence, some clinicians forego bone marrow evaluation in patients with typical, early-stage disease.

Clinical Presentation and Phases of Disease

Savage et al. [15] described a series of 430 consecutive cases presenting to one center for consideration of allogeneic transplant and these data are the first description of the presenting features of such a large group of CML patients in the modern era (Table 5.2). Approximately 20% of the patients were diagnosed when a blood sample was taken for other reasons. It is likely a higher fraction of people in developed countries are currently diagnosed "incidentally" given the increased use of "routine" screening blood tests. Some cases were diagnosed during pregnancy, while donating blood, or undergoing routine surgery.

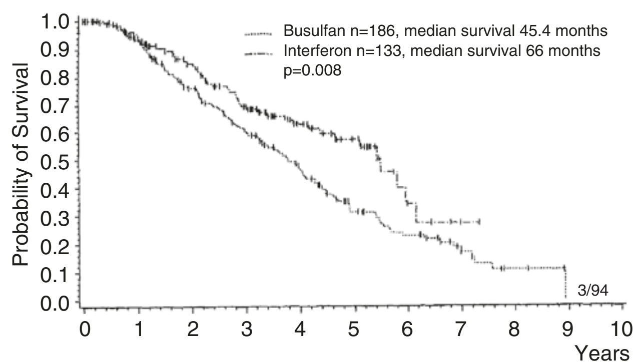
Of those presenting with symptoms, the 10 most commonly recorded are shown in Table 5.2. In retrospect, patients may describe fatigue, weakness, or a sense of fullness in the left upper quadrant with early satiety after meals. Other symptoms including visual disturbance, weakness, arthralgia, cough, malaise, dizziness, nausea/vomiting, ankle edema, priapism, and mental changes occurred in less than 5% of the cases. Thrombocytosis with a count above 1×10^{12}/L was found in 25% of cases, although there did not appear to be any correlation between abnormal bleeding and the level of thrombocytosis. Splenomegaly and purpura were the most common physical signs at presentation, at 75% and 16%, respectively.

Ninety-three percent of the patients presented in chronic phase, i.e., with fewer than 5% blasts in the bone marrow. It is sometimes difficult, particularly if the marrow or blood smear staining is not done well, to confuse younger myeloid elements with true blasts, and it is not unusual to have the appearance of a somewhat higher percentage of blasts at presentation, although it eventually becomes clear that the

Table 5.2 Clinical presentation of 430 patients referred to the Hammersmith Hospital for consideration of transplantation from 1981 [15]

• 80% of the patients were symptomatic at the time of presentation, although most symptoms were mild to moderate in severity	
• 20% of the patients had the diagnosis of CML made incidentally on routine CBC	
• 93% of the patients presented with chronic-phase disease	
• Thrombosis and leukostasis were rare even with very high platelet/white blood cell counts	
Median CBC values (range):	
WBC	174 (5.0–850.0) × 10^9/L
Hemoglobin	10.3 (4.9–16.6) g/dL
Platelets	430 (17–3182) × 10^9/L
• 19% of the patients presented with a WBC >350 × 10^9/L	
• 25% of the patients presented with platelets >1 × 10^{12}/L	
Most common symptoms at presentation	
Fatigue and lethargy	33%
Weight loss	20%
Abdominal mass or fullness	15%
Bone pain	7%
Headache	6%
Bleeding	21%
Splenic discomfort	19%
Sweats	15%
Infection	6%
Dyspnea	~5%
Most common findings on physical examination	
Spleen palpable	75%
1–10 cm	37%
>10 cm	39%
Purpura	16%
Palpable liver	2%

The median age of 34 years was somewhat younger than CML in general because these were patients referred for transplantation



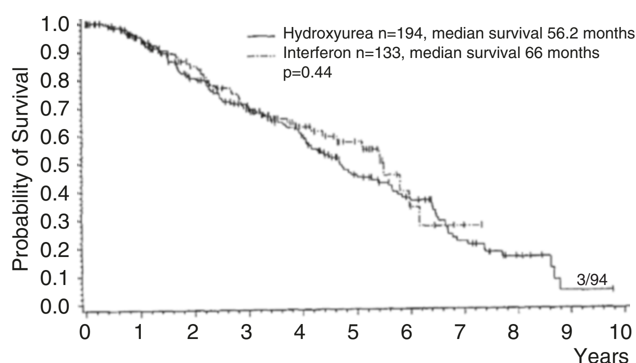


Fig. 5.1 These survival curves demonstrate the inexorable rate of death due to blastic transformation in patients not undergoing allogeneic transplantation in the pre-TKI era. Reprinted with permission [43]

Table 5.3 Criteria used in defining phases of disease in CML

WHO criteria for accelerated phase 2016 [17]
• >10–19% blasts in blood or marrow
Persistent or increasing WBC (>10 × 10^9/L), unresponsive to therapy
• >20% basophils in blood
• Thrombocytopenia (<100 × 10^9/L) unrelated to therapy
• Persistent thrombocytosis (>1000 × 10^9/L) unresponsive to therapy

patient was truly in chronic phase after observing the response to treatment.

Before the introduction of tyrosine kinase inhibitors (TKI), the duration of chronic phase was usually between 3 and 8 years (median 4–5 years in most series), although exceptions occurred, with some patients evolving rapidly to blast crisis, whereas others did not progress for 15 or more years (Fig. 5.1). In the past, the disease inevitably progressed from this "benign" chronic stage to the accelerated phase and ultimately to a fatal blast crisis. The situation is now very different. Patients who respond to treatment with a TKI and achieve a complete cytogenetic response (CCyR) may maintain this response for many years and possibly indefinitely, provided that they continue to take a TKI on a regular basis. Thus, the progression from chronic phase to advanced phase that seemed in the past to be inevitable now appears to be preventable.

Accelerated Phase

The definition of *accelerated phase* is vague, and different criteria have been used in the past by different groups [16]. A recent definition proposed by the World Health Organization [17] is summarized in Table 5.3, with anemia, increasing basophils or eosinophils, thrombocytopenia (or occasionally thrombocytosis), or increasing proportion of blasts being the most common findings. Clinical features suggesting "acceleration" supplement these laboratory findings and commonly include fever, night sweats, weight loss, bone pain, increasing splenomegaly despite therapy, and development of extramedullary disease (chloromas).

Failure to achieve a hematologic response to initial therapy with a TKI, hematological, cytogenetic, or molecular resistance to two sequential TKIs, or the development of two mutations in BCR-ABL1 during TKI therapy, is also a worrisome feature, in the absence of the findings listed above.

Blast Phase

The definition of *blastic transformation* (also referred to as blast phase or blast crisis) is based on the presence of more than 20% blasts in the peripheral blood or bone marrow, or the demonstration of extramedullary infiltration by blast cells. In two-thirds of the cases, the blasts are myeloid with one-third of B-lymphoid lineage. The blasts are often undifferentiated morphologically and immunophenotyping is therefore recommended in all cases. Transformation to lymphoid blast crisis can occur suddenly, sometimes even early in the course of chronic phase, and carries a marginally better prognosis than myeloid transformation. Both are usually fatal despite intensive treatment and have a median survival from diagnosis of blast crisis of only 3–6 months, unless remission can be achieved and followed by allogeneic transplantation.

It can be difficult to distinguish patients presenting initially with Ph-positive acute myeloid leukemia (AML) or acute lymphoblastic leukemia (ALL) from those with blast crisis of CML. For patients with Ph + ALL, the presence of significant splenomegaly is more in keeping with preexisting, undiagnosed CML, whereas the presence of p190$^{BCR\text{-}ABL1}$ suggests de novo ALL while p210$^{BCR\text{-}ABL1}$ might suggest preexisting CML. It is possible, in both children and adults with CML, to develop blast transformation with mixed lineages, i.e., both lymphoid and myeloid surface markers detectable on the same cells [18] or distinct subpopulations of blasts with either lymphoid or myeloid characteristics [19]. T-lymphoid blast transformation is rare, but there are several cases showing both the *BCR-ABL1* fusion gene and T-cell receptor (TCR) gene rearrangements [20].

Cytogenetic and molecular changes are well recognized in 50–80% of the patients during transformation to accelerated or blast phase. So-called minor cytogenetic changes include monosomies of chromosomes 7 and 17, loss of the Y chromosome, and trisomies of chromosomes 17 and 21 [21]. Major cytogenetic changes, which suggest a more aggressive clinical course, include a double-Ph chromosome, trisomy 8, isochromosome i(17q), trisomy 19, and translocations of chromosome 3 with chromosome 21, t(3;21)(q26;q22) [22–24]. Alterations of the p53 gene on the long arm of chromosome 17 by deletion, rearrangement, or mutation, occurring predominantly with myeloid blast crisis, have been identified in up to 30% of CML patients entering the blast phase [25, 26]. Even before clinical manifestations, it is sometimes possible to detect these cytogenetic changes in the bone marrow, extramedullary masses, or splenectomy specimens [27].

Clinical signs of blastic transformation may be due to the rapid increase in blasts in the peripheral blood. The most significant areas compromised are the cerebral and respiratory circulations, resulting in multifocal bleeding, dyspnea, and hypoxemia [28]. Tumors due to the deposition of blast cells, known as chloromas or granulocytic sarcomas, may be visible before the detection of blasts in the peripheral blood. It is important to distinguish such tumors from undifferentiated carcinomas and diffuse large-cell non-Hodgkin's lymphoma, which may require immunohistochemical staining. Commonly, the tumors are detected in lymph nodes, cutaneous tissue, or as lucent bone deposits on X-ray. Meningeal deposition may result in cord compression or a variety of neurologic symptoms [29].

Prognostic Scores

Prognostic models aim to categorize patients into different risk groups at diagnosis. These scores all require examination of the first blood film made on the newly diagnosed patient, and the subsequent loss of this blood film is the most common reason for an incomplete score. Prognostic scores have traditionally been utilized in the context of analyzing large clinical trials and thus they should be applied to the individual patient with some caution. Small variations in the parameters described can make a significant difference to the final score; accurate determination of these blood values is therefore crucial. Older scores were proposed by Tura et al. [30], and subsequently in 1982 by Cervantes and Rozman [31]. More contemporary systems are described in Table 5.4. It should be noted that the outcomes for the Sokal and Hasford scores evaluated patients in the pre-TKI era whereas the EUTOS score included 2060 patients treated with imatinib between 2002 and 2006.

Gratwohl et al. [35] devised a simple scoring system based on five main factors following analysis of 3142 patients who had undergone allogeneic stem cell transplantation for CML between 1989 and 1997. The combined score for these factors (donor/recipient histocompatibility, stage of disease, patient and donor age and sex, and time from diagnosis) in an individual patient predicted the probability of survival after allografting and was helpful in the counseling of patients. Although many of these factors are probably still relevant, it is difficult to use this formula with precision now, given the major improvements in transplant methodology which have decreased transplant-related mortality, as well as possible improved outlook in patients treated predominantly with TKIs.

Table 5.4 Prognostic scores commonly used in CML

Sokal score (*1984*) [32]
• Criteria required at presentation (prior to treatment): 1. Age 2. Spleen size (cm below costal margin measured clinically with a tape) 3. Platelet count prior to any treatment 4. Blast percentage in peripheral blood (preferably 500 cells counted, but at least 200)
• Formula: Exp[0.0116(age—43.4) + 0.0345(spleen—7.51) + 0.188 (platelets/700) 2—0.563) + 0.0887 (% blasts—2.1)] Good prognosis <0.8 Moderate prognosis 0.8–1.2 Poor prognosis >1.2
Hasford (*Euro*) *score* (*1998*) [33]
• Data analyzed on 1573 patients
• Criteria required at presentation (prior to treatment): Same as Sokal score with the addition of: – Eosinophil percentage in peripheral blood (same no. of cells counted) – Basophil percentage in peripheral blood (same no. of cells counted)
• Formula: (0.6666 × age [0 when <50 years; otherwise 1]) +0.0420 × spleen size [cm from costal margin] +1.0956 × platelet count [0 when platelets <1500; otherwise 1] +0.0584 × blasts [%] +0.0413 × eosinophils [%] +0.2039 × basophils [0 when basophils <3%; otherwise 1] multiplied by 1000 Low risk ≤780—median survival 100 months Intermediate risk >780 < 1480—median survival 69 months High risk >1480—median survival 45 months
EUTOS score [34]
• Formula: (7 × basophil [%]) + (4 × spleen [cm]) Low risk <87 (79% of patients) High risk ≥87 (21% 0f patients)

An online calculator for the most commonly used scores is available at http://bloodref.com/myeloid/cml/sokal-hasford

Treatment

The introduction of the tyrosine kinase inhibitors in 1998 fundamentally changed the treatment of CML. Until that time it has been widely accepted that an allogeneic stem cell transplant, if the patient had a suitable donor and if the procedure was successful, could cure CML, whereas other therapies were essentially palliative and would modestly prolong life, if at all. Early studies with imatinib mesylate, the original TKI, showed that it could reduce Ph-negative hematopoiesis in patients shown previously to be resistant to interferon-alpha [36], and subsequent studies demonstrated that it had the capacity to induce durable CCyR in 60% or more of the patients presenting in chronic phase. It is now widely accepted that CML presenting in chronic phase should be treated initially with a TKI. The choice of which TKI to use is still a matter of discussion, as described below. Treatment decisions for patients presenting in advanced phases of CML are more difficult.

Immediate Management of Newly Diagnosed Patients

The immediate management of a newly presenting patient with possible CML involves the initial history taking and investigations described in the previous sections. The next step is to control any immediate life-threatening complications such as leukostasis, hemorrhage, or infection, before appropriate antileukemic chemotherapy. Tumor lysis syndrome is relatively rare in patients in chronic phase, but nonetheless, it is prudent to commence allopurinol 300 mg daily and encourage plentiful oral fluid intake. Once the leukocyte count has been reduced below 30×10^9/L, allopurinol should no longer be required unless the patient has a history of gout or continues to be hyperuricemic. On some occasions it may be necessary to reduce the leukocyte load more urgently, especially if there is evidence of leukostasis causing the clinical manifestations previously described. This may be achieved by the temporary use of large doses of hydroxyurea, on the order of 3–6 g daily, and/or by leukapheresis. Leukapheresis may also be considered as a useful temporizing treatment during pregnancy [37, 38].

Prior to the initiation of antileukemic therapy, it is important to discuss and document the implications for future fertility with the patient and possibly his or her partner. It is possible to arrange cryopreservation of spermatocytes and sometimes oocytes, and this is preferably done in liaison with a center specializing in fertility medicine. Although unusual, if blood products are required, CMV-negative products should be administered until the CMV status is available.

Historically, before the development of TKIs, patients were treated with either hydroxyurea or busulfan, both for initial cytoreductions and for long-term control. Although generally well tolerated, therapy was palliative, and neither drug was able to reduce or eliminate the Ph clone and neither changed the inexorable evolution to blast crisis (Fig. 5.1). Hence, all suitable patients were considered for allogeneic transplantation. Trials with interferon-alpha, alone or in combination, were initiated in the early 1980s. The results with these older therapy will be reviewed briefly before detailed discussion of treatment with TKIs, initially studied in the late 1990s and widely available a few years later.

Hydroxyurea (Hydroxycarbamide)/Busulfan (Myleran)

Hydroxyurea, in doses of 2–3 g/day, may be given for a few days or weeks if a TKI is not immediately available [39, 40]. The dose is decreased as the WBC declines. Since its introduction in 1972 and until 2000, hydroxyurea was the "workhorse" therapy for CML. It is highly effective in controlling the hematological abnormalities of this disorder but does not produce any useful cytogenetic responses, even at

high dose [40]. It has the advantage of relatively few side effects but has to be given continuously. Busulfan was also used by many clinicians and had the potential advantage that it could be given intermittently. A randomized comparison suggested an advantage for hydroxyurea [41].

Interferon-Alpha

Since the first reports of its activity in CML in 1983 [42], interferon-alpha has been widely investigated both as a single agent and in combination [43] (Fig. 5.1). There are no convincing data that there were significant differences between Roferon (Roche) and Intron A (Schering Plough). Both products are available in a pen device similar to those used for delivering insulin and a pegylated version which can be given weekly is now available. The precise mechanism of action is unclear although many possible mechanisms have been proposed [44, 45].

A meta-analysis by the CML Trialists' Collaborative Group of seven randomized trials [46, 47] demonstrated a statistically significant survival advantage of IFN (57% at 5 years) over either hydroxyurea or busulfan (42% at 5 years). The initial adverse effects of IFN administered daily include fevers, chills, malaise, arthralgia, and myalgia, sometimes summarized as "flu-like," whereas chronic toxicities include autoimmune-type phenomena, hypothyroidism, Raynaud's phenomenon, connective tissue disorder, and neuropsychiatric disorders. Patients commonly feel very tired and depressed. Elevations of liver enzymes and triglycerides are common.

Interferon in combination with cytarabine has been evaluated in a number of studies. Guilhot et al. reported data from a multicenter randomized trial comparing IFN+ low-dose cytarabine with IFN alone [48]. They reported a significant increase in the rate of major cytogenetic response (41% vs. 24%) and improved survival (85.7% vs. 79.1% at 3 years) in chronic-phase CML patients treated with the combination. The rate of CCyR was low. The main problem was discontinuation of the combined therapy due to side effects. Other investigators have also demonstrated the efficacy of this regimen [49], but other studies have failed to confirm a survival advantage. Interestingly, although most cytogenetic responses were partial, a small fraction of interferon-treated patients achieved persistent complete cytogenetic responses. This combination served as the control arm in the IRIS study which evaluated the benefit of imatinib as initial treatment in chronic phase [50].

Imatinib Mesylate for CML in Chronic Phase

The tyrosine kinase activity of the *BCR-ABL1* oncogene is required for malignant transformation of hematopoietic cells in CML [9, 51, 52]. Imatinib mesylate is a 2′-phenylaminopyrimidine compound designed to inhibit the binding of phosphate donor ATP to the kinase domain (SH1) of the protein. This activity prevents the downstream phosphorylation of the signal transduction proteins involved in leukemogenesis [51, 53–56]. Imatinib inhibits *BCR-ABL1*, *TEL-ABL*, and *ABL* kinase activity and inhibits growth and viability of cells transformed by any of these *ABL* oncogenes. In addition, it was found to inhibit other tyrosine kinases encoded by *PDGF-R* and *c-KIT* as well as cells expressing the p210 BCR-ABL1 protein tyrosine kinase found in Ph + ALL.

Imatinib was developed by Lydon and Druker [57] in collaboration with Ciba-Geigy (now Novartis) in the early 1990s. The compound entered clinical trials in June 1998 and by the end of 1999 it had become clear that imatinib was active in controlling the hematological and clinical features of CML, with high bioavailability as an oral compound. A phase I study demonstrated that at a dosage level of over 300 mg/day by mouth, the drug was able to restore the leukocyte count to normal in patients with IFN-resistant CML in chronic phase with a few patients achieving Ph negativity [36]. The drug was also active in controlling the blast cell count in patients in myeloid blast and lymphoid transformation, but the majority relapsed within 6 months [58].

A series of large phase II studies in interferon-refractory or -intolerant chronic-phase patients confirmed the remarkable efficacy of 400 mg imatinib daily, with high rates of durable CCyR with excellent overall tolerance, resulting in regulatory approval in this patient population [59], as well as in patients with more advanced disease [60–62]. Subsequently, a phase III prospective randomized trial (the so-called IRIS study) was conducted in 1106 previously untreated patients, comparing interferon and cytarabine as per the previous French regimen [48], with imatinib at a dose of 400 mg daily [50]. Fourteen and one-half percent of the patients receiving interferon and low-dose cytarabine achieved a CCyR as opposed to 76% of the patients in the imatinib arm. These differences were highly significant and in terms of side effect profile, tolerability, and quality-of-life measures and rate of major molecular response (MMR) [63], there again were major and significant differences in favor of imatinib [63]. Other trials [64–67], as well as longer term follow-up of the IRIS patients [68, 69], confirmed the durability of these benefits with an estimated event-free survival at 6 years of 83%, and freedom from progression to accelerated or blast phase of 93% on the IRIS trial (Fig. 5.2). Furthermore, responding patients whose disease had not progressed in their first 3 years were extremely unlikely to relapse at a later time and also unlikely to suffer from late-onset side effects. These results were the first to validate the achievement of CCyR as a surrogate for significant and durable long-term benefit of TKI treatment in newly diagnosed patients. Historical comparisons showed a survival advantage from imatinib treatment compared to interferon-based therapies [70, 71].

International Randomized Study of Interferon versus STI571 (IRIS) 7-year follow-up: sustained survival, low rate of transformation and increased rate of major molecular response (MMR) in patients (pts) with newly diagnosed chronic myeloid leukemia in chronic phase (CML-CP) treated with imatinib (IM). Blood 2008; 112: 76 (Abstract #186))

Imatinib Dose

Investigators at the MD Anderson Cancer Center in Houston reasoned that clinical results might be improved by starting treatment with a higher dose of imatinib and therefore designed a study in which newly diagnosed patients started treatment with imatinib at 800 mg daily [72]. Many patients are unable to tolerate this higher dosage, but comparison with the results of the standard 400 mg daily showed that CCyRs and major molecular responses (MMR), defined as a 3-log reduction in *BCR-ABL1* transcripts on the International Scale (IS—see below), were achieved more rapidly with the higher dose of imatinib. This experience led other investigators to design studies to compare prospectively 400 mg daily with 600 or 800 mg daily [64, 66, 73, 74]. The large German CML IV trial extended these observations showing that a higher fraction of patients treated with the higher dose achieved a 4.5-log reduction with the higher dose [66]. It does, however, appear that whereas response to the higher dose is clearly more rapid, the longer term results show less convincing superiority for the higher dose and no survival benefit has been demonstrated, likely in part because of the effect of potent second-generation TKIs given after initial imatinib treatment. Thus, at this time, there seems no good reason to alter the "standard" 400 mg initial dosage for adults. Parenthetically, pediatricians have opted to adapt imatinib dosage based on the child's body weight or body surface area [75].

Side Effects of Imatinib

Though patients taking imatinib are spared the more unpleasant side effects associated with conventional cytotoxic drugs, imatinib can still cause a variety of unwanted adverse reactions and some are severe enough to necessitate reducing dosage or discontinuing the drug [76–78]. Among the most prominent non-hematologic side effects are nausea, fluid retention, weight gain, diarrhea, bone pains, rashes, and disturbances of liver function. Most of these symptoms occur early in the treatment course, are of low grade, and can resolve over time. Imatinib can also cause significant cytopenias which almost always improves; occasional patients with anemia may benefit from administration of erythropoietin. An international consortium evaluated more than 800 patients in CyCR for greater than 2 years and then followed for a median of ~6 years. Fatigue and muscle cramps were the most prominent longer term side effects. The findings were very reassuring in that there was no increase in the occurrence of cardiovascular events, organ dysfunction, or other cancers. The overall survival of these patients was identical to that of age-matched normal controls [79]. Another long-term evaluation showed that other medical comorbidities did not influence response or CML-related survival [80]. In children, prolonged use of imatinib may cause skeletal growth velocity and comprehensive long-term follow-up studies are desirable, given the likelihood that most patients will be receiving imatinib indefinitely [81].

Monitoring Responses to Treatment with TKIs

The first evidence of response is reduction of the elevated leukocyte count and resolution of splenomegaly, followed by normalization of a more sensitive measure of residual leukemia, namely the number of Ph-positive metaphases in the bone marrow. The most sensitive test for low levels of leukemia is to measure *BCR-ABL1* transcript numbers in the blood or marrow using a real-time quantitative reverse transcriptase-PCR (RT-PCR or RQ-PCR) [82–84]. Analysis of blood gives results equivalent to those derived from bone marrow, but the specimen needs to be processed within 48 h of collection. Fluorescence in situ hybridization (FISH) used to identify a *BCR-ABL1* fusion gene in interphase cells is more sensitive than metaphase cytogenetics but less sensitive than RT-PCR. Peripheral blood FISH, which correlates very well with marrow cytogenetics, may be used if RQ-PCR for *BCR-ABL1* is not available [85]. In the past, the standard approach was to monitor marrow metaphase cytogenetics until a patient achieves CCyR and then to monitor RQ-PCR for *BCR-ABL1* transcripts at regular intervals to quantify the depth of reduction and to recognize incipient relapse. In patients with a clear-cut marked reduction in RT-PCR levels to a level consistent with at least a CCyR, some clinicians no longer do bone marrows for cytogenetic analysis.

Although RQ-PCR to quantify *BCR-ABL1* transcript numbers is now widely available, it must be remembered that

the technique is demanding and can give both false-positive results (if for example the specimen is accidentally contaminated with material from another patient) and false-negative results (if for example the patient's specimen is degraded during collection and processing). The measurement of a control gene, usually *ABL1*, can assess whether the sample is adequate for analysis and results are expressed as the ratio of BCR-ABL1 to levels of the control gene. Initially, the methods by which results are expressed in different laboratories were not standardized, although most laboratories now express results as a log reduction using the International Scale (IS) which uses a correction factor applied to the "raw" results which are unique to individual laboratories and kits, and which provides standardization and comparability of results among different testing laboratories [86–88].

The IS arbitrarily assigns a baseline value of 100% to each patient [86]. A two-log reduction on the IS (i.e., a value of 1%) roughly corresponds to a CCyR while a greater-than-three-log reduction is termed a "major molecular response" (MMR). Both CCyR and MMR have been used as endpoints in clinical trials (see below). Current PCR technologies permit detection of a single CML cell among ~10^5 normal cells with corresponding IS values of 4.5- to 5-log reductions. In contrast, cytogenetics can detect ~1 Ph + cell among 20 normals and FISH ~1/200 normal cells. If transcripts are not detectable, the term "complete molecular response (CMR)" is sometimes used although this result is still consistent with the survival in a patient's body of perhaps 1×10^7 leukemia cells [88, 89], some of which may be resistant to all currently available TKIs. At very low levels of residual leukemia, the use of a DNA-based PCR technique may be more sensitive than one based on cDNA [89]. Lastly, although highly quantitative, there can be variation in QT-PCR values in duplicate specimen analyzed in the same laboratory, and hence, it is recommended that values be repeated before making decisions about changing therapy.

Resistance to Imatinib

A small proportion of patients who start imatinib in chronic phase, but a larger proportion of those who start the drug in advanced phases, do not respond well initially and require treatment with alternative agents. This is defined as primary resistance. Other patients can respond initially, achieving either a hematological response or a cytogenetic response followed by loss of response. This is defined as secondary resistance. The overall incidence of resistance is obviously time dependent but is of the order of 20–30% in patients who start treatment in chronic phase. The risk of developing secondary resistance appears to diminish with time and patients who have been in CCyR for more than 2 years, and who continue to take imatinib, seem to have an exceedingly low risk of relapse. Treatment failure occurs more commonly in patients with more "advanced" chronic phase as assessed by clinical measures such as the Sokal score, an observation consistent with the lower response rates in patients in accelerated phase. Patients with higher scores who do respond well, however, have long-term outcomes similar to other responding patients.

Resistance can also be classified according to whether it is associated with continuing inhibition of kinase activity of the *BCR-ABL1* oncoprotein or reversal of this inhibition. The mechanisms associated with this reversal of inhibition are not well defined, but some patients have cytogenetic evidence of clonal evolution and occasional examples of amplification of the *BCR-ABL1* gene in patients resistant to imatinib have been identified. The best characterized molecular event in patients with imatinib resistance is the acquisition of point mutations in the kinase domain of the *BCR-ABL1* gene, most commonly evaluated by Sanger sequencing, such that a mutant oncoprotein is produced. The prototype is the T315I mutation whereby a threonine at position 315 in the *BCR-ABL1* protein is replaced by an isoleucine which impedes binding of imatinib in the ATP-binding pocket of the enzyme [90–93]. Other mutations in residues that make contact with imatinib in the P-loop of the enzyme can also be associated with clinical resistance. More than 50 different mutations have been identified in patients who have lost their response to imatinib and other TKIs [94], although such mutations are found in at most 50% of such patients, indicating that other as-yet unidentified molecular events are the direct cause of resistance. Testing for mutations in *BCR-ABL1* should be done whenever a change in therapy is contemplated because of resistance to treatment, since occasionally the mutational profile would suggest using a particular TKI [95, 96]. Mutations are more common in advanced stages of CML and multiple mutations, consistent with progressive genetic instability, can sometimes be identified at the time of progression. In contrast, *BCR-ABL1* mutations are rarely found at diagnosis in chronic phase and mutational testing is not advised at this stage.

Another possible mechanism of resistance is related to increased expression of the P-glycoprotein (Pgp) efflux pump affecting the transmembrane transport of imatinib [97, 98]. Conversely, imatinib is transported into cells by the human OCT1 transporter and low levels of OCT1 have also been linked with poor clinical response to imatinib [99]. In practice, acquired resistance is likely to be multifactorial and mechanisms may differ in different patients. One study identified a gene signature suggestive of disease progression which could be found in patients in clinical chronic phase prior to their disease progression although this approach is currently not in use clinically [100].

In vitro measurement of the concentration of imatinib that will inhibit proliferation by 50% (IC50) of an individual

patient's cells has been studied in an attempt to predict the desirable in vivo imatinib concentration [101]. Two studies suggested that low plasma "trough" levels of imatinib, as defined as the lowest level before the next scheduled dose of imatinib, can correlate with a lower probability of achieving a CCyR [102, 103]. Such low trough levels might be an indication for increasing the prescribed dose of imatinib. There was considerable overlap between the levels in good and less robust responders, and neither approach can be recommended for use in individual patients.

Perhaps most importantly, it must be appreciated that a major cause of an inadequate response or loss of initial response to imatinib may be the simple fact that some patients may not take the prescribed dose on a regular basis, for which there may be a variety of reasons, including forgetfulness, desire to lessen side effects, or desire to save money in countries where the patient has to pay for the drug themselves [104, 105]. Moreover, casual questioning of the patient about his or her adherence to the prescribed dosage may not always yield reliable answers. It is imperative to carefully question patients about compliance before switching treatment or increasing dosage.

Evaluation of Response to Imatinib: European LeukemiaNet Recommendations

In order to optimize the treatment benefit from imatinib, molecular and/or cytogenetic responses should be monitored serially so that changes in therapy can be recommended as needed. The European LeukemiaNet has presented the consensus recommendations of a panel of experts who agreed on a series of criteria for CP patients who started imatinib at 400 mg daily to define treatment "failure," "optimal response," and an intermediate "warning" group who require closer monitoring [106]. The most recent iteration of these recommendations, published in 2013 [107], is summarized in Table 5.5 with an updated version currently being assembled.

It must be emphasized that fluctuations in values are common over time and that there is also considerable inherent variability in the tests themselves. Thus, values near these somewhat arbitrary "cutoffs" should be repeated before changes in therapy are considered. These guidelines may also be used to evaluate the effectiveness of treatment with other TKIs, used either as initial or salvage therapy. Similar guidelines have been offered by the National Comprehensive Cancer Network in the USA (http://www.nccn.org). In earlier years, the treatment change usually involved an increase in imatinib dosage to 600 or 800 mg/day; more recently, switches to newer, more potent TKIs are usually recommended. This approach is supported by a randomized phase II trial which demonstrated superior outcomes with the use of dasatinib in this setting when compared with increased doses of imatinib [108].

Perhaps the most debated aspect of the ELN recommendation concerns the "warning" should patients not achieve BCR-ABL1 ≤ 10% at 3 or 6 months. Numerous studies have shown that a > 1-log reduction (i.e., <10%) is associated with an excellent long-term outcome with few long-term treatment failures, assuming continued compliance with the medication [66, 69, 109–113]. The results are poorer in patients who remain >10% at 3 months, although still >80% of these patients are long-term survivors with continued therapy with either imatinib or other TKIs [66]. Although the temptation is to switch therapy rapidly in patients with slower responses, the only trial which evaluated this approach systematically failed to demonstrate benefit from earlier switching from imatinib to nilotinib [114]. In addition, the 10% number is not an absolute dichotomous decision point in that values of 11% and 9%, for example, are within the range of tests of the same sample done in duplicate. Similarly, the implications of 11% vs. 50% (both >10% on the IS) are certainly different. Thus, tests should be repeated and a pattern or trend established, before therapy is switched to another TKI, particularly at the 3- and 6-month time points.

Some recent studies have suggested that the rate at which the transcripts decrease in the first few months after

Table 5.5 Criteria for definition of response based on European LeukemiaNet recommendations [107]

	Failure	Warning	Optimal response
3 months	Non-CHR and/or Ph+ >95%	BCR-ABL1 > 10% and/or Ph + 36–95%	BCR-ABL1 ≤ 10% and/or Ph + ≤35%
6 months	BCR-ABL1 > 10% and/or Ph+ >35%	BCR-ABL1 1–10% and/or Ph + 1–35%	BCR-ABL1 < 1% and/or Ph + 0
12 Months	BCR-ABL1 > 1% and/or Ph+ >0	BCR-ABL1 > 0.1–1%	BCR-ABL1 ≤ 0.1%
18 months	Less than CCyR		MMR (3-log reduction in transcripts)
Any time	Loss of CHR	CCA/Ph– (−7, or 7q–)	BCR-ABL1 ≤ 0.1%
	Loss of CCyR		
	Kinase domain mutation insensitive to Imatinib		
	Confirmed loss of MMR		
	Clonal evolution		

CHR complete hematological response, *CyR* cytogenetic response, *CCyR* complete cytogenetic response, *MMR* major molecular response

TKI therapy is begun, sometimes termed the "velocity of elimination," might be a more sensitive means of distinguishing between good and poor responders. This approach requires better standardization of the transcript levels at the time of diagnosis and is not broadly applicable at this time [111, 115].

Managing the Patient in Whom Imatinib Has Not Been Sufficiently Effective

Changes in therapy after treatment with imatinib can be prompted by the development of intolerable side effects, failure to obtain adequate reduction in BCR-ABL1 transcripts as defined above, or less commonly obvious disease progression. It is critical to assess patient compliance with the imatinib before attributing treatment failure to drug resistance [104]. If a switch in therapy is contemplated, assessment of BCR-ABL1 mutations should be done because occasionally the type of mutation will suggest the use of a specific TKI with better activity against that particular conformational change in the BCR-ABL1 [116–118]. Most often however, either no mutation is detected or the sensitivities to other TKIs are predicted to be similar, and the choice of second TKI is predicated on issues such as convenience of therapy and side effect spectrum.

So-called second-generation TKIs were synthesized and entered the clinic remarkably rapidly after the discovery of imatinib. All of these agents are orally bioavailable, were initially evaluated and approved by regulatory agencies for use in patients with treatment failure or intolerance to imatinib, and were subsequently tested in comparative trials with imatinib as initial therapy. All are administered orally. These agents have never been directly compared with each other in randomized trials, but the overall response rates of dasatinib, bosutinib, and nilotinib are similar in imatinib-relapsed/refractory/intolerant patients. CCyR rates of ~40–50% which, if achieved, are generally sustained for many years, can be anticipated, with the highest response rates, as might be expected, in patients switched for intolerance [119–125]. Response rates are lower with "third-line" TKI treatment although sustained responses can also be achieved with a switch to an alternative TKI. Ponatinib is the most potent of these drugs when used in the more advanced setting but has a very high rate of cardiovascular side effects as described below [126, 127]. Because of the lower response rates with second-line treatment, many clinicians evaluate for possible allogeneic transplant, reserving transplant for patients poorly responsive to the subsequent treatment.

The side effect profile varies considerably among the different TKIs, presumably because all inhibit multiple tyrosine kinase pathways in addition to BCR-ABL1 signaling. All can be associated with usually transient rash, diarrhea, fatigue, headache, elevations of liver transaminases, and pancreatic enzymes, with occasional overt pancreatitis, but each also can produce side effects relatively unique to that agent.

Dasatinib

Dasatinib (Sprycel) is an inhibitor with activity against a range of tyrosine kinases including SRC and SRC family kinases. In vitro studies showed that it was 325 times as potent as imatinib against BCR-ABL1 [128]. It is effective in producing major cytogenetic responses in ~40% of the patients still in chronic phase who develop resistance to imatinib [108, 129]. A randomized study evaluating different doses and schedules of dasatinib identified 100 mg/day as the preferred starting dose, although many patients wind up taking lower doses long term with continued effectiveness [122]. These responses can be sustained, and with follow-up of 7 years, the PFS and OS were ~42% and 65%, respectively, using the 100 mg dose [130].

Dasatinib causes more profound cytopenias than does imatinib, and can be associated with QTc prolongation, and pleural effusions can develop in more than 20% of patients [108, 130]. Effusions are more common in patients with more advanced CML and those with prior cardiac disease. Most are asymptomatic and can resolve spontaneously or with dose reduction, but some require thoracentesis and occasionally a switch to another TKI. Effusions are usually detected within the first few months of dasatinib treatment but can occur after many months or years of treatment and patients should be advised to contact their CML care giver should symptoms of shortness of breath or chest discomfort develop. Pericardial effusions have also been noted and a small number of patients have been described with pulmonary hypertension, clinically indistinguishable from "primary" pulmonary hypertension. These can resolve with dasatinib discontinuation but fatalities have been reported [131, 132]. The mechanism(s) responsible for these fluid retention and vascular changes are not known. Lastly, ~30% of CML patients develop a proliferation of T/NK cells within the first few months of treatment which in some patients can persist for years [133–136]. There is a suggestion that the rates of CyCR and PFS may be higher in such patients, suggesting an immunomodulatory effect [137], but these findings need further confirmation.

Nilotinib

Nilotinib (Tasigna) is a chemically modified form of imatinib with greater potency and selectivity for *BCR-ABL1* than imatinib [138]. A large phase 2 study in 321 patients

resistant to or intolerant of imatinib demonstrated a 45% CyCR rate with PFS of 57% and OS of 78% after 4 years of follow-up using a dose of 400 mg twice daily [139, 140]. Nilotinib should be taken on an empty stomach, at least 2 h apart from meals. More recent trials have suggested that the recommended dose should be 300 mg twice daily [141].

Although nilotinib is well tolerated overall, patients have to be monitored carefully during the first 1–2 months for hepatic transaminase elevations and for clinical or subclinical pancreatitis manifested by elevations of lipase and amylase. These abnormalities are usually transient and subclinical, and most patients can be restarted on nilotinib after the values normalize. There is a "black box" warning on the nilotinib label because of a few cases of sudden death occurring early in the nilotinib trials. Fortunately, this was a very rare event in the thousands of patients treated subsequently, although monitoring of the QTc interval is recommended after nilotinib is started. Lastly, the more recent randomized ENESTnd trial in newly diagnosed patients with CML trials demonstrated a somewhat alarming incidence of >15% of cardiovascular events including myocardial and cerebrovascular ischemia and infarction as well as peripheral arterial occlusive disease [141, 142]. The incidence of these problems in imatinib-treated patients was ~1%. This experience confirmed earlier case reports describing peripheral arterial occlusive disease in nilotinib recipients [143]. The mechanism is not known although nilotinib can precipitate or exacerbate diabetes. These issues need to be considered in individual patients when deciding among different TKIs and patients receiving nilotinib should have other vascular risk factors such as hypertension, hypercholesteremia, smoking cessation, and diabetes monitored and treated as needed. Many clinicians also prescribe prophylaxis with aspirin, although there are no prospective data supporting this approach [144].

Bosutinib

Bosutinib (SKI-606, Bosulif), a 7-alkoxy-3-quinolinecarbonitrile, functions as a dual inhibitor of SRC and ABL kinases, and preclinical studies demonstrated a high antiproliferative activity in human and murine CML cell lines [145, 146]. Bosutinib was recently approved in the USA for the treatment of imatinib-resistant/intolerant patients as well as some patients refractory to either nilotinib or dasatinib, based on a phase 2 trial using a dose of 500 mg/day, which demonstrated a major cytogenetic response rate of 40% and OS of 78% with approximately 4 years of follow-up [119, 123, 124, 147]. Newer studies with bosutinib utilize a dose of 400 mg/day. Diarrhea and transaminase elevations occurring during the first few months of treatment are the most common toxicities, sometimes requiring dose reductions and/or temporary cessation of therapy [148].

Ponatinib

Ponatinib is a potent *BCR-ABL1* developed as a scaffold (unlike the other TKIs) designed to make a hydrogen bond with the T315 mutant oncoprotein [91, 127, 149, 150]. Ponatinib adapts to such steric hindrance by virtue of a long and flexible ethynyl tricarbon linker. X-ray crystallographic analysis of the ponatinib-murine T315I ABL complex revealed that the compound binds to the complex in the inactive conformation, similar to imatinib, and interacts via hydrogen bonds at five distinct amino acid residues. In vitro studies demonstrated potent activity against cell lines resistant to other TKIs and large phase 2 studies were conducted in patients resistant to therapy with nilotinib or dasatinib. The phase 2 PACE trial reported major cytogenetic responses in 51% of the 203 patients with chronic-phase CML resistant or intolerant to dasatinib or nilotinib and in 70% of the 64 patients in chronic phase with T315I mutations. Approximately 90% of responses were sustained at 1 year and the drug was effective across a broad range of *BCR-ABL1* mutations [126].

Ponatinib was approved for use in this patient population as well as for patients in more advanced-stage CML. Short-term toxicities included skin rash, hypertension, and occasional pancreatitis. However, longer term follow-up demonstrated a disturbing incidence of predominantly arterial cardiovascular events including strokes, myocardial infarction, peripheral arterial occlusive disease, and heart failure [144]. At least 27% of study participants experienced such side effects and although cardiovascular events were more common in older patients with predisposing risk factors, some younger patients without apparent vascular issues were also affected [151]. The original studies used a dose of 45 mg/day and more recent studies are in progress evaluating lower doses and/or rapid reduction of dose as soon as responses are detected. The mechanism of the vascular toxicity is not known [144]. The drug was initially withdrawn from the market but is now available for use in highly selected patients and in particular those with the T315I mutation for which there is no other effective therapy [152, 153]. If patients are responding, the lowest effective dose should be used and the author follows some patients in sustained molecular response using 15 mg/day.

Omacetaxine (Homoharringtonine)

Omacetaxine mepesuccinate (Homoharringtonine HHT) is a novel plant cephalotaxine alkaloid originally derived from the *Cephalotaxus fortunei* tree [154–156]. Omacetaxine is approved in the USA for the treatment of chronic-phase CMl resistant to two TKIs, including patients with the T315I mutation. The recommended dose and schedule are 1.25 mg/m^2

subcutaneous injection twice daily for 14 days of a 28-day cycle for the induction phase and 1.25 mg/m^2 subcutaneous injection twice daily for 7 days of a 28-day cycle for maintenance. Rates of complete hematologic, major cytogenetic, and complete cytogenetic response were 77%, 23%, and 16%, respectively [109, 157]. The main side effects include significant cytopenias, infection, diarrheas, fatigue, and fever. Median PFS was ~7 months. Omacetaxine is sometimes used as a bridge to transplantation in patients in more advanced stages, although hydrea and myleran are also used for disease control and palliation in this situation.

Initial Therapy of Chronic Phase with Newer TKIs

Shortly after approval of the second-generation TKIs for imatinib refractory patients, randomized trials were initiated using these drugs as initial treatment in chronic phase. In the Dasision study, previously untreated patients were randomized to receive either 100 mg daily of dasatinib or imatinib, 400 mg daily [110, 158]. In the ENESTnd study, two different doses of nilotinib, 300 mg twice daily and 400 mg twice daily, were compared with imatinib 400 mg daily [141, 142, 159]. The primary endpoints were CCyR and MMR after 12 months of treatment. In both studies, cytogenetic and molecular responses were achieved more rapidly than with imatinib and in both studies the early rate of progression from CP to advanced phase was higher in the imatinib arm than in any of the three test arms. Based on these results, both dasatinib and nilotinib were approved by regulatory agencies as initial treatment in chronic phase.

A trial of similar design (BELA) evaluating bosutinib was also completed, and although overall results were actually very similar to the other trials, bosutinib has not yet been approved as initial therapy [160, 161]. A repeat trial using a dose of 400 mg of bosutinib was recently completed and demonstrated higher rates of CyCR in the bosutinib treated patients.

Lastly, a trial comparing ponatinib and imatinib was stopped before completion when the cardiovascular side effects of ponatinib became apparent [162]. Even in this trial, with only short follow-up, 6% of ponatinib-treated patients experienced severe cardiovascular events (Table 5.6).

These studies have appropriately influenced discussions of the preferable first-line treatment of chronic phase. Cross-study comparisons cannot be done because of some differences in statistical methods, definitions of endpoints, duration of follow-up, and most importantly variability in the details of follow-up and types of treatment after patients went "off study" or switched from their original randomized treatment. All of these trials were sponsored by pharmaceutical companies. A study comparing imatinib and dasatinib done in the USA, and coordinated by the Southwest Oncology Group, was similar in design to Dasision and reported very similar results [113].

The overall results of these studies are very similar and a number of general statements can be made:

- OS was very high with no differences according to initial treatment, although most studies reported slightly higher rates of "CML-related" deaths in the imatinib-treated patients.
- With longer follow-up, 40–50% of patients were no longer receiving their initial treatment. Switches were made because of side effects and occasionally for disease progression (somewhat more commonly in the imatinib groups) and presumably most of these patients received alternative TKIs. Details of secondary treatment are generally not available, but it is important to emphasize that one must consider the totality of initial and subsequent therapy in evaluating overall results. Given the excellent OS and low rates of progression, it is clear that subsequent treatment has a critical role in achieving these outcomes.
- Transformation to AP/BP occurred more frequently with imatinib treatment. Almost all these events occurred within the first 1–2 years and were quite uncommon with longer follow-up, although the overall rate of transformation was low with all treatments. Information about whether transformations developed primarily in patients with "advanced" chronic phase with high-risk features is not available. This is important because many experi-

Table 5.6 Summary of long-term results

	Dasision (*n* = 519) (Minimum of 5 years of follow-up)		ENESTnd (*n* = 846) (Minimum of 5 years of follow-up)			BELA (*n* = 502) (Minimum of 2 years of follow-up)

enced clinicians now utilize second-generation TKIs in preference to imatinib in such patients, based on the results of the randomized trials.

- All studies showed that results were inferior in patients with transcripts >10% at 3 months, independent of treatment arm, although a higher fraction of patients achieved this "milestone" with the second-generation TKIs. There is no information about subsequent approaches to treatment in such patients and the problems of relying on a single IS value to change treatment have been described above.
- The "depth" of molecular response continued to improve over time and all studies noted lower rates of "deep" reductions >4 and 4.5 logs in imatinib-treated patients. There is speculation that this may permit more patients treated with second-generation TKIs to successfully discontinue treatment but there are as yet no data addressing this issue. It should also be noted that all the response rates reported in the table utilized the cumulative incidence statistic and information as to whether these deep responses persisted on repeated testing is not available.

The decision about which TKI is preferable as initial therapy must also consider the unique toxicity profiles of the drugs. Some notable issues include the following:

- There was an appreciable incidence of **cardiovascular events** of approximately 15–20% in nilotinib-treated patients which continues to increase over time, compared to 3–4% in imatinib-treated patients. Rates in the Dasision trial were ~5% vs. 2% in dasatinib- and imatinib-treated patients, respectively. Glucose intolerance and hypercholesteremia were also more common with nilotinib compared to imatinib. Recommendations about concurrent treatment of cardiovascular risk factors and patient selection for treatment with nilotinib have recently been published [163–165], but it is not known if these approaches will be effective in reducing the incidence of cardiovascular side effects.
- **Pleural effusions** developed in ~28% of dasatinib-treated patients compared to 0.1% in the imatinib group. Most such patients could continue dasatinib with temporary discontinuations and dose adjustments. **Pulmonary hypertension** with clinical manifestations was detected in 5% of dasatinib-treated patients.
- Eleven **infectious deaths** were reported in the dasatinib group in the Dasision trial, compared to one in the imatinib group. There is no apparent explanation for this discrepancy.

The debate about the best initial treatment continues [166]. It is apparent from these studies that the second-generation TKIs are more potent than imatinib in that the rate of initial response is faster, and the depth of response may be greater with a likely lower (albeit still very low) rate of initial disease progression, but with equivalent overall survival. Longer term toxicity data with bosutinib are lacking, but it is clear that both nilotinib and dasatinib have important issues unique to each agent, whereas the long-term follow-up data with imatinib are very reassuring [79, 80, 106]. Certainly, preexisting medical problems in individual patients have to be an important consideration. In any event, it is likely that with the increasing availability of generic imatinib, insurers and other payors will be directing, if not mandating, initial treatment with imatinib. Fortunately, the results of these randomized trials provide reassurance that this is a most reasonable approach for the overwhelming majority of newly diagnosed patients. In addition, a large trial of ~1500 patients conducted by the German CML group which evaluated different approaches using imatinib confirmed these excellent long-term outcomes [66].

Stopping Imatinib in Responding Patients: The Concept of "Treatment-Free Remission"

A small number of patients treated with interferon-alpha in the 1990s achieved durable CCyR which has continued for many years after the interferon was stopped [47]. In 2007, Rousselot and colleagues reported details of 12 CML patients in France who received imatinib as primary treatment or after prior treatment with interferon and achieved CMR [167]. These patients had stopped their imatinib for different reasons after 2 or more years in CMR; six had relapsed at the molecular level and six were still in CMR at the time of the report. These observations were extended in the STIM ("Stop Imatinib") study of 100 patients who had undetectable transcripts over a number of years using highly sensitive PCR assays. Approximately 50% of patients had a molecular relapse, almost all within 6 months of treatment cessation [168]. All relapsing patients promptly responded to reintroduction of imatinib which was restarted when MMR was lost (>0.1 on the IS) [169, 170]. Remarkably, only rare recurrences were detected in the remainder of the patients, with the latest update at a median follow-up of 4 years. The relapse rate was lower in patients who were PCR undetectable for >8 years. Other studies have shown similar results [171]. Importantly, discontinuation should only be considered in patients with consistently very low to undetectable transcript levels for at least a few years and many trials, some of which use different durations and depth of "negativity" prior to cessation, are in progress. All trials mandate careful molecular monitoring for the first 12 months with continued intermittent long-term monitoring thereafter, because it is not known if very late relapses will occur. It has been postulated that the long remissions may be due to immunologic control of any residual CML stem cells, but the precise mechanisms are unknown.

Whether such patients can really be regarded as "cured" is debatable but undoubtedly one major target today should be to find strategies that will enable us to increase the proportion of patients who may safely stop treatment [172, 173].

An interesting "withdrawal syndrome" characterized by musculoskeletal and articular discomfort and pain has been described in an appreciable fraction of patients who discontinued TKIs. The symptoms are usually mild and transient and easily managed with nonsteroidal anti-inflammatory agents, although persistence of clinically significant achiness can occur in a few patients, which may or may not improve with restarting TKIs [174, 175].

Imatinib and Other TKIs During Pregnancy

Preclinical studies based on animal data suggested that imatinib and other TKIs could be teratogenic in certain circumstances and women taking imatinib have been routinely advised to take steps to avoid conception. Nonetheless, some women have conceived while taking imatinib and in most cases where the pregnancy went to term the baby appeared to have been normal. However, certain specific developmental abnormalities including hypospadias, exomphalos, and defective skeletal formation have been seen more often than would have been expected in women not taking imatinib [176, 177] and the advice to avoid pregnancy while being treated with the drug must be upheld.

Therefore, counseling a woman already on imatinib who wants to start or to enlarge her family is difficult, and generally clinicians continue to advise against pregnancy. If the patient has achieved a deep response, stopping imatinib to allow the patient to conceive and carry the child without exposure to imatinib is a consideration, but this approach almost certainly puts the patient at increased risk of relapse and possibly disease progression. Interferon-alpha is not known to be teratogenic and has been considered to be an alternative, particularly for women who become pregnant while receiving a TKI. There are few published data evaluating this approach, however. Women who become pregnant while receiving imatinib should contact their physicians immediately. Available evidence suggests that patients who stop imatinib and then relapse respond as well to reintroduction of imatinib as they did originally [170]. Less is known about the possible harmful effect of imatinib on male spermatogenesis and small case series have shown a very low rate of fetal abnormalities in children whose fathers were taking imatinib [178].

Advanced-Phase Disease

In the past, patients who presented in accelerated and blastic phases were treated with a higher starting dose of imatinib of 600 mg daily [61], although the use of dasatinib or nilotinib is now preferred in such patients. In general, advanced-phase patients respond much less well to imatinib than those who start treatment in chronic phase with low rates of CyCR and high rates of relapse should response be achieved. However, patients who satisfy the criteria for "acceleration" are in fact heterogeneous: at one end of the spectrum the term covers patients whose leukemia is only slightly more advanced than late chronic phase while in others the leukemia may be verging on blastic phase. Patients with "early" accelerated phase may obtain long-term responses to imatinib as a single agent, while others usually have much shorter responses [61]. Patients presenting in blastic transformation need a much more aggressive initial strategy. All patients in AP/BP should be evaluated for allogeneic stem cell transplantation while they are receiving their initial TKI treatment.

It can sometimes be difficult to distinguish between patients in lymphoid blast phase at the time of diagnosis, from de novo Ph + acute lymphoblastic leukemia (ALL). Combining a TKI with standard anti-ALL treatment is the best initial approach [179]. Once remission is achieved, maintenance treatment with cytotoxic drugs together with a TKI can then be continued. Neuroprophylaxis is also advisable. For patients presenting in myeloid blast phase, the combined use of a TKI with therapy appropriate to AML may be the best approach. AML-like chemotherapy alone produces few complete remissions [180]. In both circumstances, allogeneic stem cell transplantation should be done in all suitable patients, preferably while the patient is in complete remission. Most centers continue the use of a TKI after engraftment, but no comprehensive studies about the duration of such maintenance TKI are available.

Allogeneic Stem Cell Transplantation

Until the advent of TKIs, allogeneic stem cell transplantation was the recommended initial approach for patients who were relatively young and had suitable donors, with rates of disease-free survival approximating 70%, with very few late relapses [181]. Currently, allogeneic SCT is reserved for those with advanced-stage disease or those in whom treatment with second-generation TKIs was not successful. More details about conditioning regimens and donor selection are presented in other chapters. *BCR-ABL1* transcripts should be monitored serially for the first few years after transplant. It is important to recognize that there can be transient *BCR-ABL1* positivity in the first year posttransplant in patients who are ultimately destined *not* to proceed to overt relapse [181]. Two or more consecutive samples with increasing numbers of *BCR-ABL1* transcripts are required at a minimum to establish a relapse. For patients with confirmed relapse after allogeneic SCT, options for treatment include the withdrawal of immunosuppression, use of a TKI to which the patient has not previously been exposed, and/or donor lymphocyte infusions.

Summary

The therapy of CML has been revolutionized over the last 15 years with the advent of TKI therapy, such that the survival of chronic-phase patients responding to TKI treatment approximates that of age-matched controls. There is now the prospect that some patients might be able to stop TKI therapy and remain in remission and possibly even be cured in the longer term. Over the next decade, research will focus on evaluating how to use the various TKIs in the most cost-effective way to further improve the long-term outcome and quality of life of patients with CML. Stem cell transplantation has a minor, but still important, role in the small number of patients for whom TKIs are not effective or tolerated.

Acknowledgments This section is an extensive update of the chapter from the earlier edition authored by Drs. Stephen O'Brien and John Goldman and is dedicated to the memory of John Goldman who was a pioneer and leader in our understanding of the biology and therapy of CML and a valued friend and colleague.

Etiology and Epidemiology of Chronic Lymphocytic Leukemia

6

Helen E. Speedy, Daniel Catovsky, and Richard S. Houlston

Introduction

Chronic lymphocytic leukemia (CLL) is an indolent malignancy resulting from an accumulation of CD5-positive neoplastic B-cells, characterized by a low rate of proliferation. CLL accounts for approximately 30% of all newly diagnosed leukemia cases each year and is the most common form of adult leukemia in Western countries [1]. Although still an incurable malignancy, recent studies have identified over 30 common genetic variants that are associated with the risk of developing CLL. Deciphering the mechanisms by which these variants influence disease risk represents the next challenge in studies of CLL susceptibility and will be key in advancing our understanding of its biological basis.

Descriptive Epidemiology

CLL is primarily a disease of later life with a median age of diagnosis in European populations of around 70 [1]. Two key features of the disease have hampered the acquisition of descriptive data on CLL. Firstly, CLL is often encountered as a chance (and often late) diagnosis and this in turn can be merely a consequence of healthcare provision rather than any true difference in disease incidence between countries. Secondly, many epidemiological studies have failed to distinguish B-cell disease including prolymphocytic leukemia and possibly lymphocytic lymphomas as part of CLL. Even accepting these caveats it is apparent that the CLL incidence rates are nearly twice as high in men as in women and that rates vary considerably throughout the world.

CLL occurrence is highest in Europe and European populations elsewhere in the world, with low rates in South and East Asia and sub-Saharan Africa (Table 6.1). The lowest recorded rates of CLL come from Japan. The observed

Table 6.1 World incidence rates of chronic lymphocytic leukemia

Race/ethnicity	Male	Female
All races	6.3	3.3

30-fold variation in national rates has led many researchers to investigate a genetic basis for CLL risk. This notion is reinforced by the observation that the incidence of CLL remains low in Asians, even in those born in the United States, suggesting that genetic susceptibility rather than environmental or lifestyle factors are the greater determinant of risk [2, 3].

Environmental-Lifestyle Risk Factors

Although several environmental risk factors for acute myeloid leukemia are well recognized, such as exposure to benzene [4], smoking [5], and ionizing radiation [6], information regarding the role of chemical exposures in the development of CLL is very limited and no robust associations have so far been documented. In fact, there does not seem to be a clear association between CLL risk and any of the exposures that commonly cause other types of cancer.

Links with agricultural occupations or agricultural chemicals probably provide the strongest leads to date for environmental risk factors [7, 8]. These associations have been observed in several studies of different designs and in different geographical locations, but very few have evaluated specific agricultural agents. Excesses of CLL noted in studies of the rubber [9] and petroleum [10, 11] industries have raised the possibility of links with benzene and other solvents, but such associations remain essentially unvalidated. Other occupations that have been considered as potential risk sources for CLL include mining [12], or those with exposure to asbestos [13] and certain chemicals [14], but again no conclusive etiologic links exist.

Ionizing radiation has been implicated as a cause of most forms of leukemia for several decades, but a number of studies of highly exposed populations have not indicated an association with CLL. The justification for concluding that the risk of CLL is increased by exposure to ionizing radiation has been challenged owing to considerations such as the low background incidence rate of CLL in some studies on which the presumption is based, and the anticipated long latency between initiation and death from CLL [15]. However, a follow-up study specifically taking into account these and other confounding factors did not find a consistent association between radiation and CLL [16].

Immune Dysfunction as a Risk Factor

Intuitively, links between genetics and immune dysfunction as a possible basis for CLL are highly attractive. One study reported that infection is a constant risk in CLL that is associated with shortened survival [17]. It seems apparent that CLL tumor cells utilize immunosuppressive mechanisms to evade immune recognition. Although CLL cells express tumor antigens that can be presented by major histocompatibility complex class I and class II molecules, an effective immune response is not elicited against the tumor cells [18, 19]. However, there is no compelling evidence linking infection by human T-cell lymphotropic virus, human immunodeficiency virus, or immunosuppression following organ transplantation with CLL [20].

A variety of prior medical conditions have been reported to confer an increased risk of CLL including scarlet fever, bronchitis, and rheumatoid arthritis [21]. However, no consistent association has yet emerged and these assertions must be considered as unreliable.

Familial Clustering of CLL

Over the last seven decades more than 100 families have been reported in the literature in which clustering of CLL has been documented. While not exclusively a consequence of genetic predisposition, familial aggregation provides strong evidence for inherited genetic factors playing a role in disease development. In a number of the families reported, CLL co-segregates with other B-cell lymphoproliferative disorders (LPD), such as Hodgkin's lymphoma (HL), suggesting that part of the familial predisposition could be mediated through pleiotropic mechanisms [22–24].

Eight epidemiological case-control and cohort studies have systematically enumerated the risk of relatives of CLL patients developing CLL or other LPDs [21, 22, 25–29]. The largest and most comprehensive of these was based on an analysis of 9717 CLL cases and 38,159 controls ascertained through the Swedish Cancer Registry [27]. This study firmly underscored the notion that CLL is characterized by a high familial relative risk (RR); the RR of CLL in first-degree relatives of cases was increased 8.5-fold. Furthermore, the risk of other non-Hodgkin lymphoma (NHL) in these relatives was increased 1.9-fold. Evaluating NHL subtypes revealed a striking excess of indolent B-cell NHL, specifically lymphoplasmacytic lymphoma/Waldenström macroglobulinemia and hairy cell leukemia [27]. These findings substantiate a relationship between the risk of CLL and other LPDs which has anecdotally previously been noted in case reports of single families and that may reflect the pleiotropic effects of an inherited predisposition.

In familial CLL, the proportion of affected females is higher when compared to sporadic CLL. Females might therefore have more predisposition genes or their genes might be more penetrant than those of males. The relatives of affected females probably share the same predisposition genes, which increase their genetic liability, accounting for the higher proportion of familial cases among females compared to males.

The phenotype of earlier age of onset and increased risk of second tumors is a classical feature of many familial cancers. An early survey of 28 CLL families suggested that familial cases present around 10 years earlier than sporadic cases, implying a more aggressive clonal expansion [30]; however, more recent studies provide little support for such an assertion [31]. Anticipation, the phenomenon of intensified clinical severity and earlier age of onset with each successive generation, has been reported for CLL, with mean declines between parents and offspring being as many as 22 years [32–34]. However, findings were based on data from families ascertained for genetic studies, which are enriched for younger cases, thereby introducing bias through censoring or cohort effects. In a study using Swedish registry data where corrections were made for possible sources of bias there was little evidence to support anticipation in CLL [35].

Models of Inherited Genetic Susceptibility

The observation of large families segregating CLL in an apparent Mendelian fashion provided a strong rationale for searching for moderate–high-risk gene mutations. To date, five linkage scans of CLL families have been performed [36–40]; however none has provided robust evidence for the existence of a single major locus conferring susceptibility to the disease. The premise of these studies is that in a proportion of families with CLL, chromosomal regions that harbor mutations conferring a substantive disease risk will segregate with the affected family members.

The failure of linkage analysis to identify a high-impact CLL risk locus led to a reappraisal of the inheritance pattern in CLL and an increased interest in a polygenic model of disease susceptibility (Fig. 6.1).

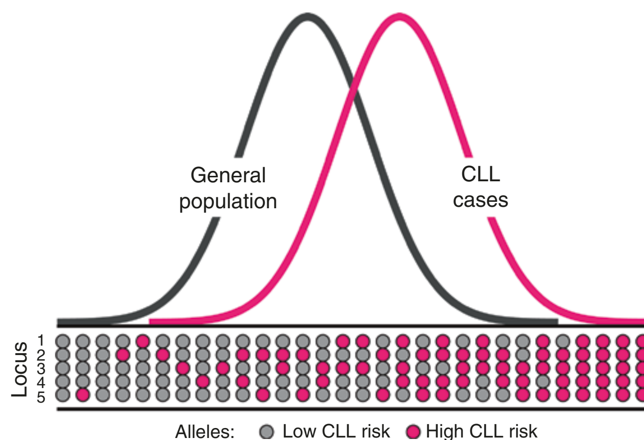

Fig. 6.1 The polygenic model of disease susceptibility. The distribution of alleles at CLL risk loci in both cases and controls follows a normal distribution. However in cases there is a shift toward an increased number of high-risk alleles. For clarity, only five risk loci are illustrated

This model, which is based on disease risk being a function of the inheritance of multiple low-risk variants, is amenable to interrogation by a genome-wide association study (GWAS) design. This approach has proved particularly successful in determining genetic risk factors for CLL and is discussed in detail below.

Common Genetic Susceptibility to CLL

The search for low-risk alleles for CLL has centered on association studies, where the frequencies of common variants (usually single-nucleotide polymorphisms, SNPs) are compared between cases and controls. Initial efforts were small-scale studies that employed a candidate gene-based approach. No susceptibility alleles have been unequivocally identified by this method which is hampered by the inherent statistical uncertainty that results from studying just a few hundred cases and controls and has only limited power to reliably identify genetic determinants conferring modest but potentially important risks [41]. Furthermore, without a clear understanding of the biology of predisposition the definition of suitable genes for the disease is inherently problematic making an unbiased approach to loci selection highly desirable.

The publication of International HapMap Consortium catalog of common human genetic variation [42] and the subsequent widespread manufacture of high-density SNP genotyping arrays revolutionized the case-control association study design. The GWAS approach assesses disease association in an unbiased manner, by comparing the frequencies of thousands of SNPs, surveyed across the genome, in a large number of cases and controls. In the past 8 years, GWAS have identified 35 independent variants at 31 genetic loci that are significantly associated with CLL risk (Table 6.2, [43–51]).

The effect size of the individual variants identified by GWAS is modest, with relative risks in the order of 1.16–1.87 per allele (Table 6.2). However, it is worth noting that the common occurrence of the risk alleles (>5% frequency) means that their cumulative burden in the population and contribution to disease incidence is high. Moreover, the burden increases with increasing numbers of variant alleles and for the 2% of the population who carry 13 or more risk alleles; the risk of CLL is increased approximately eightfold. Grouping cases and controls according to the number of risk alleles carried illustrates that the effect of these loci fits the polygenic model of inheritance (Fig. 6.1), with the number of risk alleles following a normal distribution in both cases and controls, but with a shift toward a higher number of risk alleles in cases [45].

Latest estimates suggest that common variation can explain up to 57% of the familial risk of CLL. To date, the

variants identified by GWAS account for approximately 16.5% of the familial risk [43]. Therefore it seems likely that new larger studies or meta-analysis of existing datasets will provide the power to identify further common genetic variants that contribute to CLL risk. Furthermore, it is possible that some of the "missing heritability" may be explained by low-frequency variants (<1%) of intermediate effect size. The advent of next-generation sequencing, which allows high-throughput examination of whole-exome and whole-genome DNA sequences, should extend our capabilities to examine the impact of these germline variants on CLL risk.

Using Genetic Associations to Understand CLL Biology

With more than 30 regions of the genome that play a role in CLL susceptibility now identified, a somewhat clearer picture of the key biological processes involved in CLL development is beginning to emerge. Network-based approaches have revealed that perturbation of apoptosis-related pathways is an important factor in CLL with SNPs close to *BCL2L11*, *BMF*, *BCL2*, *PMAIP1*, and *BAK1* (part of the intrinsic BCL2-regulated apoptosis pathway) as well as *FAS* and *CASP8* (part of the extrinsic death receptor-led pathway)

being robustly associated with CLL risk (Fig. 6.2). It is noteworthy that BH3 mimetics such as Venetoclax [52] inhibit the pro-survival BCL2 proteins, facilitating apoptosis of CLL cells, thus illustrating how GWAS discoveries could prove useful in identifying future CLL treatment targets.

GWAS findings also implicate dysfunctional lymphocyte proliferation and immune response in CLL susceptibility. *IRF4* is a strong candidate for involvement in CLL risk a priori, being a key regulator of lymphocyte development and proliferation. Moreover, *IRF4* expression is involved in the development of CLL [53] and multiple myeloma [54]. Through interaction with transcription factors including PU.1, IRF4 controls the termination of pre-B-cell receptor signaling and promotes the differentiation of pro-B-cells to small B-cells. Furthermore, via BLIMP1 and BCL6, IRF4 controls the transition of memory B-cells, thought to be a precursor cell type for CLL, to plasma cells [55–57]. A model of disease etiology based on the causal variant impairing transition of memory B-cells through reduced IRF4 expression is supported by the association of the risk allele with lower *IRF4* mRNA levels in Epstein–Barr virus (EBV)-transformed lymphocytes [47].

Variation in *IRF8* also represents a strong candidate for the association with CLL risk through its regulation of the α (alpha)- and β (beta)-interferon response. Moreover, *IRF8* is involved in B-cell lineage specification, with IRF8 deficiency skewing development of progenitor cells toward myeloid lineages at the expense of B-cells [58]. Additionally, IRF8 is implicated in immunoglobulin rearrangement and the selection of high-affinity B-cell receptor clones in the germinal center [59, 60]. It has also been shown to negatively regulate the differentiation of plasmablasts, antagonizing the actions of IRF4 [59, 61], and is a mediator of the extrinsic apoptosis pathway [62, 63].

SP140 is the lymphoid-restricted homolog of *SP100* expressed in all mature B-cells and plasma cell lines, as well as some T-cells [64, 65]. SP100 is a major mediator of EBV-encoded nuclear antigen leader protein co-activation, which is important for establishment of latent viral infections and B-cell immortalization [66]. *SP140* expression has also been

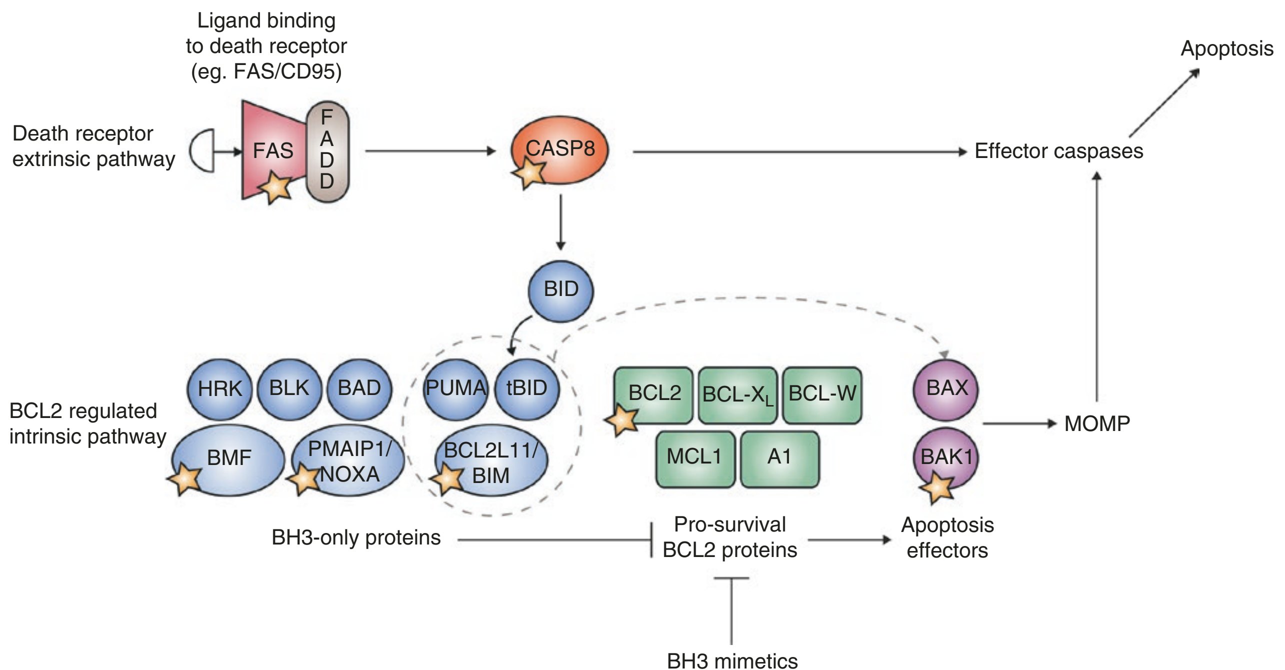

Fig. 6.2 Variation in components of the intrinsic and extrinsic apoptosis pathways is implicated in CLL predisposition. Apoptosis in humans can occur via the intrinsic or extrinsic pathway. In the intrinsic pathway, apoptotic stimuli activate the pro-apoptotic BH3-only proteins which can sequester the pro-survival B-cell CLL/lymphoma 2 (BCL2) family members, thus enabling activation of pro-apoptotic effectors BCL2-associated X protein (BAX) and BCL2-antagonist/killer 1 (BAK1). Some BH3-only proteins (surrounded by dotted line) may also directly activate BAX and BAK1, while therapeutic BH3 mimetics function by inhibiting BCL2 proteins. The pro-apoptosis effectors facilitate mitochondrial outer membrane permeabilization (MOMP), which leads to a cascade of effector caspases that culminates in cell death. The extrinsic apoptosis pathway is activated by binding of a death receptor ligand to its receptor. One such receptor is FAS (also known as CD95). Ligand-receptor engagement leads to CASP8 (caspase 8) activation via the FAS-associated death domain (FADD). Active CASP8 links to the intrinsic pathway by converting the BH3-only protein, BH3 interacting domain death agonist (BID) to truncated BID (tBID), and also feeds into the effector caspases which catalyze cellular destruction. GWAS have identified SNPs near to *BMF*, *PMAIP1*, *BCL2L11*, *BCL2*, *BAK1*, *FAS*, and *CASP8* that are associated with CLL risk, demonstrating that dysfunctional apoptosis is likely to play an important role in disease susceptibility

implicated in host response to immunodeficiency virus type 1 [67]. Another CLL susceptibility locus resides close to *OAS3* and *OAS1*. The *OAS* genes encode enzymes that produce 2′–5′-linked oligoadenylates, which in turn activate the RNaseL system to limit viral replication following infection [68]. It is therefore possible that CLL risk is increased by alterations in the immune response to viral challenge.

LEF1, encoding lymphocyte enhancer factor-1, is a member of the LEF-1/TCF family of transcription factors which acts via the Wnt signaling pathway. LEF1 is vital for the proliferation and survival of B-cells and T-cells and overexpressed in CLL compared to normal mature B-cell subsets [69, 70]. *EOMES* (eomesodermin) plays a role in CD8+ T-cell differentiation [71] and the relative levels of CD8+ T-cells expressing high levels of *EOMES* are critical in maintaining the antiviral T-cell response to chronic infection [72]. SNPs at the *EOMES* locus have also been associated with Hodgkin's lymphoma [73], as well as two autoimmune disorders: multiple sclerosis [74] and rheumatoid arthritis [75].

Mechanisms of Effect of CLL Risk Variants

Although the proximity of CLL risk variants to biologically plausible genes implicates these genes in the etiology of CLL, it remains to be elucidated exactly how the change of a single-nucleotide of DNA sequence can modulate an individual's susceptibility to CLL. Only one of the published SNPs is a missense variant. SNP rs757978 results in the substitution of threonine for isoleucine at amino acid 260 in *FARP2* (FERM, RhoGEF, and Pleckstrin Domain Protein 2) and is predicted to be deleterious by the SIFT algorithm [76].

The majority of published CLL GWAS SNPs reside within noncoding regions of the genome and it is likely that they exert their effects on CLL risk through *cis*-regulation of nearby genes. Indeed, correlations between SNP genotype and mRNA levels have been shown for a number of the risk SNPs including rs872071 and *IRF4*; rs13397985 and *SP140*; rs210134 and *BAK1;* rs10936599 and *TERC*; as well as rs10735079 and *OAS1/2/3* [77–79].

The mechanisms by which these SNPs modulate gene expression might involve mediation of chromatin accessibility, differential transcription factor binding, and/or formation of looping chromatin interactions. Such effects have recently been described for SNPs associated with type 2 diabetes [80], prostate cancer [81], and neuroblastoma [82] although perhaps the archetypal model for a noncoding variant mediating a long-range regulatory effect is demonstrated by previous work on the 8q24.21 interval in colorectal cancer. In this instance the associated SNP, rs6983267, resides 335 kb upstream of *MYC*; however the risk locus is characterized by enhancer-related histone modifications and can form chromatin loop to the *MYC* promoter and the risk variant is shown to increase binding of the transcription factor TCF4 [83–85]. Given that 8q24.21 also harbors a risk variant for CLL, which resides some 565 kb upstream of *MYC* [45], it is appealing to predict a similar mode of action. This is especially relevant because MYC and IRF4 form an auto-regulatory loop during B-cell activation [54].

Monoclonal B-cell Lymphocytosis as a Precursor Condition

The recognition that common variants influence the risk of CLL raises the possibility that, while clinically diagnosed CLL may be uncommon in the population, susceptibility may be far more common. Intriguingly this assertion is supported by the observation that CLL-phenotype B-cells (CD5+, CD23+, CD20low, sIgMlow) of monoclonal B-cell lymphocytosis (MBL) are detectable in ~3% of adults in the general population [86] and that they are essentially indistinguishable from CLL B-cells in terms of chromosomal abnormalities and *IGHV* mutation status.

The recent report that MBL develops into CLL at a rate of 1.1% per year provides direct evidence that MBL is a precursor lesion for CLL [87]. These data coupled with the observation that approximately 10% of relatives of familial CLL patients have MBL support the assertion that MBL is a surrogate marker for genetic predisposition. In an evaluation of 10 CLL risk variants in 419 MBL cases and 1753 controls, six of the risk SNPs were also significantly associated with MBL, thus providing further evidence for MBL being a precursor condition to CLL [88].

Links Between Germline Variants and the Tumor

A small number of GWAS SNPs have been associated with clinical features of CLL. For example, the *IRF8* variant rs305061 was associated with IGHV mutational status, with the risk allele correlating with poor prognosis unmutated CLL [45]. In a separate study of 840 CLL cases, carriers of the risk allele of the *IRF4* 3′UTR variant rs872071 had a significantly shorter treatment-free survival time than non-carriers [89].

Recent next-generation sequencing efforts of tumor DNA from CLL patients [90–92] have identified recurrent somatic mutations in two genes (*POT1* and *IRF4)* which also harbor common germline predisposition variants. As studies of the tumor DNA are extended, it will be of interest to note whether further overlap with germline risk factors is identified or to determine whether germline factors might predispose to particular somatic changes.

Conclusions and Reflections

Our knowledge of the role of germline genetic factors in CLL predisposition is rapidly progressing. It is now well established that the disease is characterized by having amongst the highest familial risks of any malignancy. Moreover, the observation that MBL represents a progenitor lesion offers considerable opportunities for understanding the key events in the development of CLL.

Using the GWAS approach, over 30 susceptibility loci for CLL have been identified. Further investigation of these regions to identify the causal genetic variants is likely to yield mechanistic insights into the biological basis of CLL. Building on our current understanding that impaired apoptotic processes and a dysfunctional immune response are important in disease predisposition could also help identify potential therapeutic targets.

Despite the success of GWAS, a substantial proportion of the familial risk of CLL remains unexplained. In part this may be accounted for by the presence of low-frequency variants of moderate effect size, too rare to be captured by GWAS but with lower effect sizes than would be expected in Mendelian disease. To this end, utilization of whole-exome and whole-genome sequencing strategies could help to identify additional genes involved in CLL predisposition and further advance our knowledge of this complex disease.

Morphology and Immunophenotype of Chronic Lymphocytic Leukemia

7

Mir Basharath Alikhan and Girish Venkataraman

Introduction

Chronic lymphocytic leukemia (CLL) is a low-grade, mature B-cell lymphoproliferative disorder (LPD) characterized by proliferation of small lymphocytes in the bone marrow and peripheral blood, often with extramedullary involvement in lymphoid tissues, such as lymph nodes and spleen [1]. The most common mature B-cell lymphoma, particularly in Western countries, CLL was first clinically described in 1845 and morphologically characterized by Minot and Isaacs in 1924 [2, 3]. Since these initial descriptions, the diagnosis of CLL is now often made by a combination of characteristic morphologic and immunophenotypic features. While the diagnosis of CLL is often straightforward based on these criteria, distinction from other mature B-cell lymphomas or reactive conditions may sometimes be challenging. Monoclonal B-cell lymphocytosis is a related entity now thought to represent the precursor to overt CLL, and consists of "low-count" and "high-count" variants; the two have significant clinical and prognostic differences [4]. Recent advances in the molecular genetics of CLL necessitate further ancillary studies to ensure timely and adequate treatment, including targeted therapies, for patients requiring intervention. Although CLL is best characterized as an indolent neoplasm, progression to an aggressive lymphoma, most often either large-cell transformation or less commonly Hodgkin lymphoma transformation, occurs in 1–12% of patients [5–7]. Determination of *IGHV* mutation status, detection of certain chromosome aberrations, and positivity for immunohistochemical markers (such as CD38 and ZAP-70) can help to prognosticate patients and guide therapy.

Definitions

CLL is a neoplasm of mature B-cells that primarily affects the bone marrow and peripheral blood, and often shows involvement of extramedullary tissues such as lymph node and spleen. According to the World Health Organization (WHO) classification criteria based on the 2008 International Workshop on Chronic Lymphocytic leukemia (IWCLL), the diagnosis of CLL can only be made in the presence of an absolute B-cell monocytosis of ≥5000 B-lymphocytes/μL in the peripheral blood for at least 3 months [1, 8]. Although most cases of CLL show a characteristic immunophenotype (B-cells with CD5 and CD23 co-expression), these features are not always present and thus not strictly required for the diagnosis [9].

The term "small lymphocytic lymphoma (SLL)" is given to neoplasms which lack a significant leukemic component and show a predominant extramedullary disease distribution, often in lymph nodes and spleen. Patients present with lymphadenopathy in the absence of any cytopenias or significant lymphocytosis. In these cases, the degree of lymphocytosis does not meet the criteria of CLL (e.g., absolute B-lymphocytosis is <5000 B-cells/μL).

On the other hand, patients with a smaller population of circulating monoclonal B-cells that do not meet the criteria for CLL and are asymptomatic (i.e., without lymphadenopathy, cytopenias, or autoimmune disease) are classified as having monoclonal B-cell lymphocytosis (MBL) [4, 10] (see Table 7.1 for timeline of important studies in MBL). This is a heterogeneous entity wherein otherwise healthy patients are found to have small populations of clonal B-cells in the peripheral blood. The term "lymphocytosis" does not refer to overall absolute lymphocytosis, but only to the monoclonal B-cells. Indeed, patients with MBL may have normal white cell peripheral blood counts. These populations of clonal B-cells are essentially absent in healthy individuals.

MBL is subclassified into three immunophenotypic categories and two clinical subtypes. With regard to the immunophenotypic subtypes of MBL, the vast majority have a typical

Table 7.1 Timeline summary of major MBL-related studies leading up to the WHO 2016 revision

Author (year)	Comment
Marti G (2005) [10]	Publication of consensus guidelines of MBL: definition of absolute B-cell count (ABCC) <5000/μL in the absence of signs and symptoms of lymphoproliferative disorder or autoimmune disease
Swerdlow (2008) [11]; Hallek M (2008) [8]	Adoption of 2005 consensus guidelines by WHO and International Workshop on CLL
Rawstron AC (2008) [12]	Identification that cases with ABCC <1900/μL had a very low rate of progression to CLL
Rawstron AC (2010) [13]	Meta-analysis noting bimodal distribution of clonal B-cells within MBL with one peak between 0.1 and 10 B-cells/μL and another at >500/μL
Gibson (2011) [14] & Ghia (2011) [15]	Recognition of "nodal counterpart" of MBL
Vardia A (2013) [16]	Closer immunogenetic relationship of HC-MBL to Rai stage 0 CLL based on similar somatic hypermutation and BCR stereotypy
Swerdlow (2016) [17]	WHO 2016 revision emphasizing the need for closer follow-up of HC-MBL cases; disallows ability to diagnose CLL with ABCC <5000/μL with cytopenias in the absence of clinical signs or symptoms

CLL-type immunoprofile, with expression of B-cell marker CD19, co-expression of CD5 and CD23, and dim expression of CD20 and surface light and heavy chain [18]. Other, less common subtypes include the non-CLL phenotype, without expression of CD5, and atypical CLL phenotype, with co-expression of CD5 but with strong expression of CD20 and/or negative or low expression of CD23. Mantle cell lymphoma (MCL) should be excluded in those with atypical CLL phenotype while those with the non-CLL profile may be related to marginal zone or lymphoplasmacytic lymphomas [19].

More clinically important is the distinction between high-count MBL (HC-MBL) and low-count MBL (LC-MBL), based on the concentration of circulating clonal B-cells. The cutoff most widely applied to distinguish the two subtypes is 500 clonal B-cells/μL. LC-MBL is generally detected in asymptomatic patients without lymphocytosis, often as an incidental finding or in the setting of population-based studies, using high-sensitivity flow cytometry techniques. Employing eight-color flow cytometry analysis in population studies showed that CLL-like clonal B-cells are present in up to 12% of the general population, more often in the elderly [20]. In contrast, patients with HC-MBL present with lymphocytosis and are recognized in a clinical setting.

The biologic relationship between HC-MBL and CLL is significant, as 1–4% of patients with HC-MBL per year go on to develop overt CLL, highlighting the importance of lifelong follow-up of lymphocytosis [12, 21] as well as the notion that HC-MBL is an obligate precursor of CLL. LC-MBL, conversely, does not require follow-up as the risk of progression is quite low and is not considered a pre-leukemic condition [16].

Another line of evidence that supports the relationship between HC-MBL and CLL is the analysis of immunoglobulin gene repertoires. LC-MBL often shows rearrangement of the *IGHV4-59/61* gene which is rarely observed in CLL. In contrast, HC-MBL shows a repertoire more similar to CLL, such as expression of *IGHV3-23* and *IGHV4-34* [16]. Additionally, mutational analysis using massive parallel deep sequencing found similar acquired genetic mutations between HC-MBL and CLL (such as *NOTCH* and *Wnt*) [22] and was unable to distinguish between HC-MBL and Rai stage 0 CLL. Factors related to progression from HC-MBL to CLL remain largely elusive, with some suggesting that noncoding mRNAs, particularly microRNAs such as miR-155, have a role to play [23].

Finally, it is important to note that although most MBL are CLL-like with regard to immunophenotype, non-CLL forms exist. In these cases, the diagnostic considerations include mantle cell lymphoma (in CD5+, CD23− cases; atypical CLL-like) or marginal zone lymphoma (in CD5− cases; non-CLL) [24]. Appropriate ancillary studies should be carried out to exclude these entities.

Epidemiology and Clinical Aspects

CLL is the most common adult mature B-cell leukemia in the Western world, where it accounts for 30% of all leukemias in this population. The incidence increases in the elderly and the median age at diagnosis is about 70 years [25]. Similarly, the incidence of MBL also increases with advanced age, paralleling CLL. Familial cases of CLL have also been described [26]. It is estimated that in 2016, the about 19,000 new cases of CLL will be diagnosed in the United States and about 5000 patients will die of the disease [25]. SLL accounts for about 7% of all non-Hodgkin lymphomas and also tends to occur in elderly males.

Due to more accurate and sensitive diagnostic techniques, the vast majority of CLL patients (up to 70%) are asymptomatic at presentation [27, 28], and the disease is often detected as an incidental finding on routine complete blood counts, which, in most cases, will show preserved hematopoietic cell lineages. Symptomatic patients may show cytopenias, which is most often due to infiltration of the bone marrow by leukemic cells. Autoimmune cytopenias are fairly frequently described in CLL and may affect all three cell lines. Anemia may also be attributed to immune-mediated destruction of red blood cells or red cell precursors (pure red cell aplasia). Although multiple mechanisms are postulated, one line of evidence suggests that CLL B-cells may act as antigen-processing cells which take up red cell antigens, and induce a secondary T-cell activation which in

turn leads to activation of normal B-cells resulting in red cell antibody production and consequent destruction of red cells [29]. Hypogammaglobulinemia may also be present at the time of diagnosis in up to half of cases.

Extramedullary disease in CLL/SLL comes to clinical attention most often as lymphadenopathy and, less commonly, splenomegaly. Not uncommonly, it is diagnosed on lymphadenectomy specimens excised for other tumors, such as carcinomas [30]. Lymphocytic infiltrates can be found in a variety of other anatomic sites, such as gastrointestinal tract, kidney, liver [31], and skin. However, with the exception of possibly the latter two sites, these often do not manifest clinically and are detected as part of routine workup. Cutaneous involvement by CLL can present at localized disease or generalized erythematous papules, plaques, nodules, or tumors [32]. Rare sites of involvement include Waldeyer's ring, thyroid, lung, gallbladder, prostate, central nervous system, leptomeninges, serosal surfaces, and other sites [33–38].

Cell of Origin and Pathogenesis

The understanding of CLL leukemogenesis has undergone considerable modifications in the past few years. Most now agree that CLL derives from an antigen-experienced B-cell that can be of two general subtypes: either with somatic mutations in the variable genes of the immunoglobulin heavy-chain gene (*IGHV*), termed "mutated CLL" which are derived from CD5+/CD27+ post-germinal center B-cells, or with germline configuration (or low-level somatic hypermutation) of the gene, referred to as unmutated CLL which in turn are derived from CD5+/CD27− mature B-cells.

At a molecular level, unmutated CLL is defined as having at least 98% sequence homology to the germline [39]. Mutated CLL characterizes the majority of cases. In both subtypes, initial inducing mutations in the B-cell provide a growth advantage [40]. Unmutated CLL cells express surface immunoglobulin receptors with relatively more intact/functional BCR signaling pathway that can be activated by multiple antigens such as auto-antigens and carbohydrate components of microbes. Repetitive stimulation of the induced B-cells by these antigens results in clonal proliferation and leukemia. In contrast, CLL cells with mutated *IGHV* genes do not have the polyreactivity seen in unmutated CLL cells, and their ability to proliferate is relatively diminished compared to the latter. In some cases, anergy develops due to excessive B-cell receptor stimulation, leading to compromise of antigen binding and subsequent apoptosis.

However, changes in the B-cell receptor signaling pathway promote expansion of the leukemic clone and development of CLL. In particular, CLL cells overexpress Toll-like receptor 9 (TLR9), an innate immune receptor that responds to bacterial unmethylated cytosine guanine dinucleotide (CpG) oligodeoxynucleotides (ODNs) [41]. When stimulated, TLR9, through coregulation with MYD88, induces the NF-κB pathway, resulting in apoptosis. Some have suggested that this pathway may be exploited through TLR9 stimulators, such as CpG ODNs [42]. Zeta-associated protein 70 (ZAP70, see below) is often seen in unmutated CLL. In such cases, activation of TLR9 leads to ZAP70-dependent activation of spleen tyrosine kinase (Syk). This results in the degradation of proapoptotic protein Bim, leading to survival of the CLL clone. Additionally, activation of Syk leads to downstream production of autoreactive IgM, which binds the B-cell receptor complex and, in an autocrine manner, causes a continual positive feedback loop [43]. This model may explain why unmutated status of CLL has a poor prognosis compared to the mutated type, as the former is subject to constant antigenic stimulation and production of leukemic subclones [44] as well as increased tumor cell survival. Interestingly, up to 30% of unmutated CLL show similar B-cell receptors, suggesting that a unique set of antigens is responsible for clonal expansion. One may speculate that stimulation at the pre-CLL stage by antigens such as an environmental agent, i.e., a virus or commensal bacteria, or specific autoantigen is responsible for leukemic proliferation [45–47].

Additional lines of evidence that supports the derivation of CLL cells from activated B-cells as opposed to naïve B-cells as was previously thought include similar gene expression profiling data to memory B-cells, presence of mRNA for various cytokines, and expression of memory cell markers such as CD27, regardless of mutational status [48, 49]. The activated B-cell may arise from the marginal zone of follicles or from germinal centers. Those arising from germinal centers require T-cell activation and mutation of *IGHV* genes. In contrast, CLL cells from the marginal zones may or may not require T-cell activation, and only a subset show mutation of *IGHV* genes.

Although the putative normal counterpart of the CLL cell is thought to be an antigen-experienced memory B-cell as outlined above, some studies have shown that the earliest genetic changes leading to CLL can be found in hematopoietic stem cell (HSC). In particular, HSCs from patient will CLL were successfully engrafted into immunodeficient mice and resulted in clonal B-cell lymphoproliferations [50]. The data suggest that these HSCs are primed towards the B-cell lineage and subsequent clonal proliferation.

Morphology of CLL/SLL

Peripheral Blood

Involvement of peripheral blood is required in the diagnosis of CLL and is often the initial mode of diagnosis. As mentioned above, there is absolute lymphocytosis with monoclonal B-cells exceeding a concentration of 5000/μL. The

overall white cell count may be normal or elevated. Patients may be anemic, which is most often attributed to leukemic infiltration of the bone marrow, although autoimmune erythrocyte destruction is also common at the time of diagnosis.

The circulating leukemic cells of CLL are often monotonous, small- to medium-sized lymphocytes with fairly round and even nuclear membranes, scant agranular, basophilic cytoplasm, inconspicuous nucleoli, and exaggerated clumping of nuclear chromatin. This latter feature is often characterized as a "cracked mud," "chocolate chip cookie," or "soccer ball" appearance of the nuclei on well-stained smears (Fig. 7.1). The cytoplasm may contain vacuoles or crystals and can occasionally be more abundant. Cytoplasmic inclusions containing immunoglobulin have also been described [51]. Smudge cells (Fig. 7.1) are often observed due to the tendency of leukemic cells to be easily disrupted during smear preparation. This is an important clue to the diagnosis of CLL as this feature is lacking or rare in most other B-cell leukemias when analyzing well-prepared smears. The addition of albumin to the peripheral blood can prevent the disruption of leukemic cells and the presence of smudge cells on the smear [52].

Cells with more abundant cytoplasm and a prominent single nucleolus are termed *prolymphocytes* and often constitute less than 10% of the total leukemic cells (Fig. 7.1). If they predominate, the diagnosis of B-cell prolymphocytic leukemia (B-PLL) should be considered, which is defined as a mature B-cell leukemia with greater than 55% prolymphocytes. A patient diagnosed with typical CLL who is found to have rising numbers of prolymphocytes on follow-up smears may represent transformation to a higher grade leukemia. Other patients may present with large numbers of prolym-

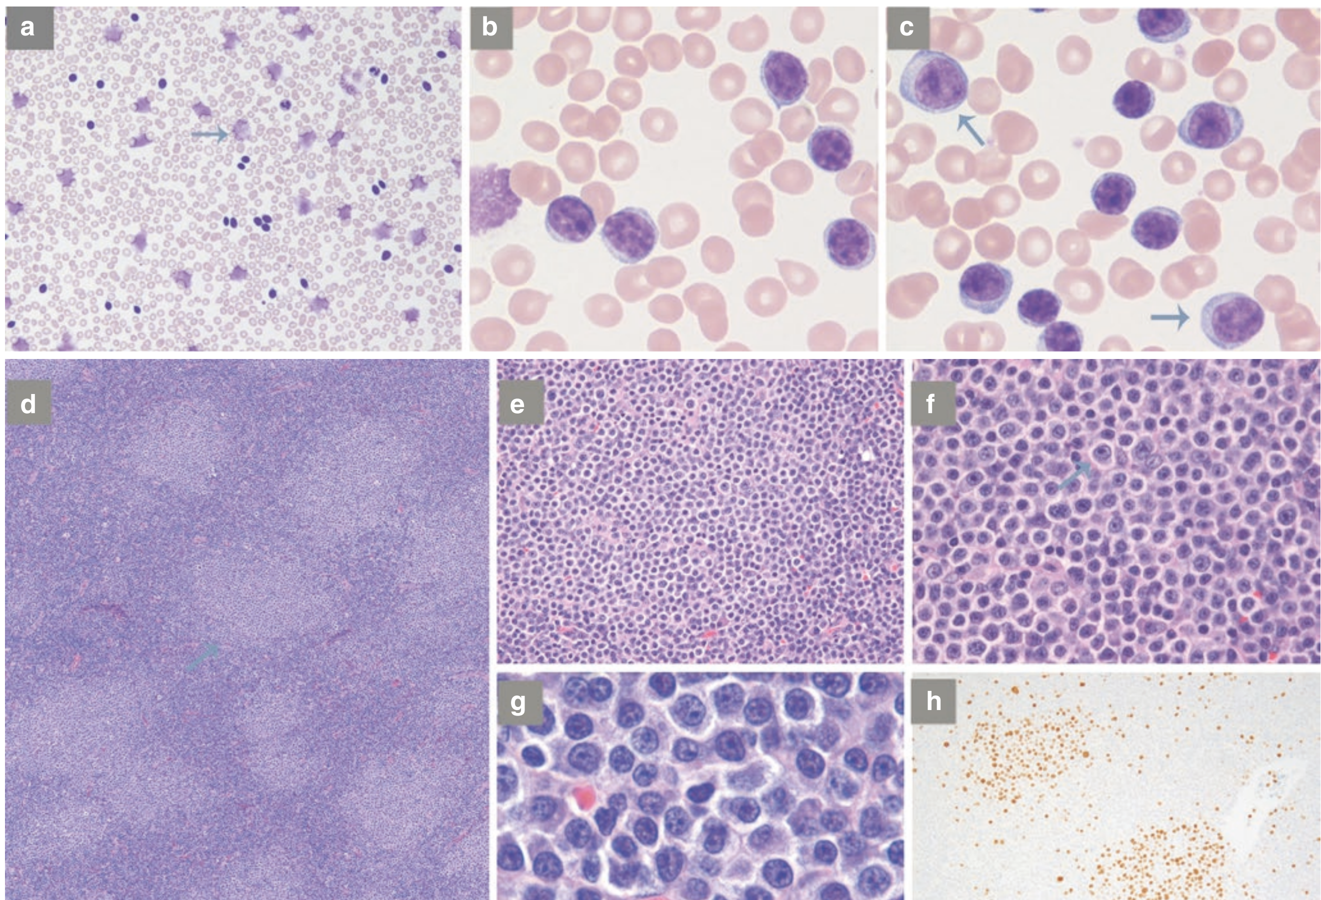

Fig. 7.1 CLL morphology in peripheral blood and lymph nodes: (**a**) Peripheral blood with absolute lymphocytosis and numerous smudge cells (*arrow*) which are sheared CLL cells with fragile cytoplasmic membranes. This smudging can be prevented by incubating the cells with bovine albumin before preparing the smear. (**b**) High power of CLL cells in peripheral blood demonstrated small CLL cells with typical "cracked-mud" chromatin and inconspicuous nucleoli. (**c**) CLL with trisomy 12 demonstrating increased number of larger cells with prominent nucleoli consistent with prolymphocytes. (**d**) Low-power histology of CLL with diffuse sheets of small lymphoid cells and associated nodular clusters of pale areas called "growth centers/proliferation centers." CLL is probably unique in being the only lymphoma exhibiting such proliferation. (**e, f**) High-power views of a growth center with scattered prolymphocytes and paraimmunoblasts that are larger cells with prominent nucleoli (H&E stain). (**g**) High-power view of CLL cells in lymph node demonstrating clumped nuclear chromatin and inconspicuous nucleoli. (**h**) Growth centers with proliferating cells (Ki-67 immunostain)

phocytes in the blood that remain stable throughout the disease course. A recent study found that increased circulating prolymphocytes at presentation with distinct immunohistochemical and genetic variation from classic CLL was an independent adverse prognostic factor with frequent progressive disease to Richter transformation and shorter overall survival [53].

Slight differences in the classic morphology may be observed. The nuclear contours can sometimes be irregular and mildly indented and/or the lymphoid cells are larger. In cases of typical CLL, these account for less than 2% of the leukemic cells. When they are more abundant, the diagnosis of *atypical* CLL should be considered (see below). In such cases, cytogenetic analysis should be performed as specific findings have been linked with atypical morphology, particularly trisomy 12, which can present with slightly higher numbers of prolymphocytes or CLL cells with atypical morphology (Fig. 7.1) [39, 54–56].

Plasmacytoid differentiation can also be observed in atypical CLL and has morphologic overlap with lymphoplasmacytic lymphoma. Patients may present with an IgM paraprotein, but levels often do not exceed 3 g/dL. The morphologic features often lead to diagnostic difficulty, but the presence of prolymphocytes/paraimmunoblasts, proliferation centers, and typical CLL/SLL immunophenotype aids in the diagnosis of CLL/SLL over lymphoplasmacytic lymphoma in such cases [57]. Some have suggested a possible association with del(7)(q32) [58].

Uncommonly, Reed-Sternberg-like cells can be observed in otherwise typical cases of CLL/SLL, characterized by the presence of rare or occasionally large, pleomorphic cells. Only if a distinct region of the biopsy has typical Hodgkin inflammatory background can the diagnosis of transformation to Hodgkin lymphoma be rendered [59]; sparse presence of R-S-like cells in otherwise extensive small lymphocytic proliferation is not diagnostic of transformation. Epstein-Barr virus is often detected in these cases.

A recent study suggests that increased circulating monocyte-derived cells promote CLL survival through cell-cell interactions and secreted factors and thus worse patient outcomes. Indeed, increased monocytes were found to be an adverse prognostic factor leading to decreased time to first therapy and overall survival [60].

In all cases of atypical CLL, cytogenetic analysis should be performed, as studies have consistently shown adverse prognosis, more severe cytopenias, worse lymphocytosis at presentation, and more rapid disease progression [61]. Such cases can also show immunohistochemical differences from classic CLL and the results can overlap with other B-cell lymphoproliferative disorders such as mantle cell lymphoma, lymphoplasmacytic lymphoma, and marginal zone lymphoma [62].

Bone Marrow

Although the bone marrow is invariably involved in virtually all cases of CLL, bone marrow biopsy examination is not required to render the diagnosis. However, the biopsy may be helpful in assessing the degree of involvement and aid in correlation with peripheral blood cell counts in cases presenting with cytopenias. Leukemic cells in the marrow aspirate are morphologically similar to those in the peripheral blood (Fig. 7.2) and often comprise greater than 30% of all nucleated cells. However, the percentage of CLL cells may differ, due to the multifocal nature of the disease in the marrow. In view of this, examination of an adequate bone marrow trephine biopsy (greater than 10 mm in length, but preferably up to 20 mm, taken from the posterior iliac crest) provides more useful information with regard to the extent of involvement [63]. Additionally, the histologic pattern of involvement can aid in the diagnosis of CLL and help exclude other lymphomas in the differential.

Various patterns of CLL infiltration may be observed, and multiple patterns can be observed within the same bone marrow biopsy. The most common architectural pattern seen is multifocal, interstitial nodular involvement (Fig. 7.2). Importantly, the nodules are non-paratrabecular, in contrast to bone marrow infiltrates of follicular lymphoma, which characteristically show paratrabecular localization. On low-power examination of the biopsy, the nodular interstitial infiltrates are readily identifiable due to their darker appearance compared to the surrounding hematopoietic marrow. On higher magnification, the cells are small with round nuclei, inconspicuous nucleoli, and a clumped chromatin pattern. The edges of the nodules may show diffusion of the leukemic cells into the marrow interstitium. Proliferation centers that harbor prolymphocytoid cells are common in lymph nodes involved by CLL/SLL, but not usually observed in the marrow. The presence of germinal centers (interfollicular pattern) is quite rare; their presence should prompt exclusion of other lymphomas [64].

Other common patterns include a more diffuse interstitial infiltrate wherein the leukemic cells are in close association with and interspersed between the normal hematopoietic marrow elements with effacement of the overall marrow architecture. These areas are more difficult to identify on low-power examination than the nodular infiltrates. However, they often impart a slightly darker appearance than the surrounding normal marrow elements. Less commonly, solid growth of leukemic cells replacing the marrow elements can be seen. In such cases, peripheral cytopenias are expected, which can predict a more aggressive disease and worse overall outcome. Some studies have demonstrated that a solid growth pattern is linked with expression of the 70-kDa zeta-associated protein (ZAP-70) and unmutated status of *IGHV*, which is thought to confer a worse prognosis [65, 66].

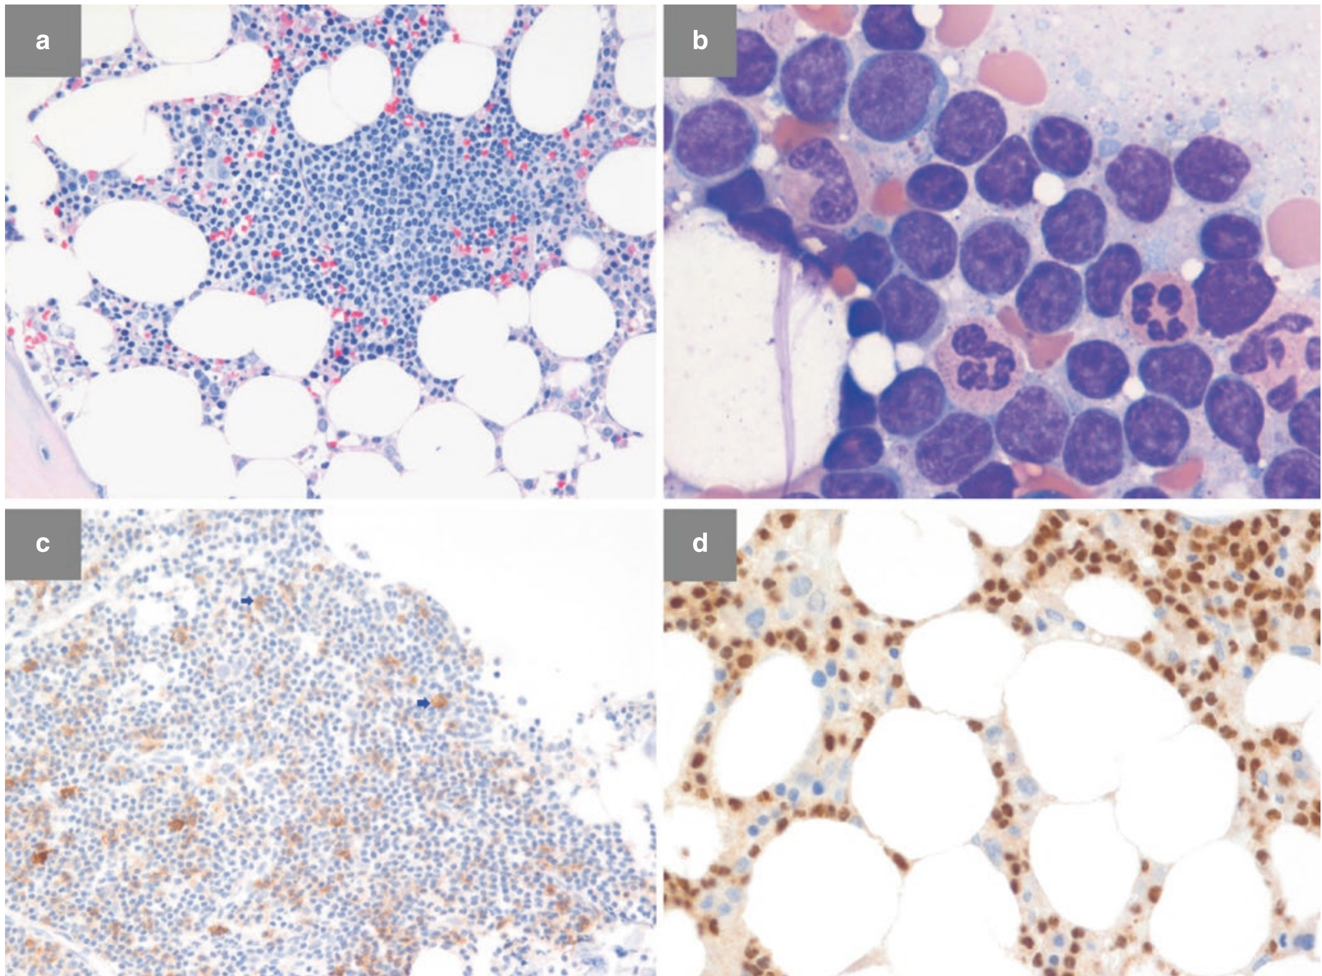

Fig. 7.2 Bone marrow in CLL: (**a**) Nodular infiltrate of small lymphoid cells of CLL involving the interstitial areas of the marrow. (**b**) High-power view of CLL cells in the marrow aspirate. (**c**) CD20 immunostain in a CLL with very dim expression in a subset of the B-cells (*arrow*). CD20 may also be downregulated after rituximab-containing regimens such as fludarabine, cyclophosphamide, and rituximab (FCR). In such cases, Pax5 may be more helpful. (**d**) Pax5 immunostain highlights prominent interstitial infiltrate of CLL cells

Marrow involvement can be detected in most MBL cases and with three different patterns described (focal interstial, nodular and diffuse interstitial) in one study examining 26 MBL cases (CLL-like, atypical CLL-like, and non-MBL types). In this study focal interstitial pattern was the most common pattern observed in most CLL-like and atypical CLL-like MBL. Uncommonly, the bone marrow may be the first detected site of involvement by transformed CLL, showing enlarged, atypical lymphoid cells that differ from the usual small cells of classic CLL [67].

Marrow biopsy is often performed to assess the underlying cause of cytopenias which may be secondary to diffuse involvement of the marrow by leukemic cells or autoimmune destruction of one or more cell lineages. The presence of erythroid hyperplasia in an anemic patient may suggest peripheral red cell destruction due to autoimmune disease, which is not an uncommon presentation in CLL patients [68]. Anemia without a marrow response can indicate the rare instance of pure red cell aplasia [69]. In turn, red cell aplasia can result as a result of direct immune destruction by activated B-cells or evolve as a result of secondary T-large granular lymphocyte expansion in the context of CLL.

Another advantage of assessing the bone marrow biopsy is the ability to perform immunohistochemical stains, particularly when fresh cells are not available for flow cytometric analysis. The immunophenotype by immunohistochemistry would be similar to results of flow cytometry (see below). However, some important caveats when assessing immunohistochemistry results include careful evaluation of CD20 staining. As in flow cytometry, CD20 expression can be dimmer than the surrounding normal B-cells (Fig. 7.2). In patients that have undergone anti-CD20 immunotherapy, CD20 expression can be lost and hence may not be reliable in picking up the CLL population. In these cases, staining with PAX5 (Fig. 7.2) can be helpful to determine B-cell lineage.

Lymph Node

The predominant pattern of lymph node involvement by CLL/SLL is diffuse effacement of the nodal architecture. The lymph node follicles and sinuses are often obliterated, and the neoplastic cells can extend into the surrounding adipose tissue. The predominant neoplastic cell is small to medium sized with clumped chromatin, inconspicuous nucleoli, and scant cytoplasm (Fig. 7.1), imparting a dark appearance to most of the affected lymph node. The nucleus is most often round, but can have some irregularity or cleaving which may cause diagnostic confusion with follicular lymphoma or mantle cell lymphoma.

Characteristically, proliferation centers (so-called pseudofollicles) are present throughout the node as part of the diffuse architectural effacement and are characterized by paler staining areas compared to the darker zones of the remainder of the neoplasm (Fig. 7.1). The lighter staining is due to involvement of the proliferation centers by larger lymphoid cells: prolymphocytes and paraimmunoblasts (see below and Fig. 7.1). Prolymphocytes in the lymph node are medium-sized cells with more abundant cytoplasm and a more prominent nucleolus compared to the predominant CLL cells. Paraimmunoblasts are larger, with a wider rim of cytoplasm, dispersed chromatin, and a distinct central eosinophilic nucleolus.

The more abundant cytoplasm of these cells causes separation between the tumor nuclei and imparts the lighter appearance. The contrast can be better appreciated at low-power light microscopy if the light is dimmed. Proliferation centers can also be assessed using a marker of DNA synthesis, such as Ki-67, which would be high in the proliferation centers and virtually negative in the remainder of the lymphoma (Fig. 7.1). If such areas dominate the lymph node histology, concern for high-grade transformation to a large-cell lymphoma should be considered.

Proliferation centers can mimic germinal centers of a normal follicle. However, the absence of a distinct mantle zone and apoptotic debris can be histologic clues of a proliferation center rather than a germinal center. Additionally, immunohistochemical study would show that the cells of proliferation centers are CD10−, Bcl6−, and Bcl2+, in contrast to normal germinal centers [70]. Rarely proliferation centers may also express cyclin D1 but there is no underlying *IgH/CCND1* translocation in these cases [71].

Variant patterns of lymph node involvement are less common and include an interfollicular architecture where the neoplastic cells surround remnant reactive lymph node follicles [72]. A perifollicular pattern is also described. These may lead to diagnostic confusion with follicular lymphoma, marginal zone lymphoma, or mantle cell lymphoma. Helpful features in the diagnosis of CLL/SLL include presence of proliferation centers, absence of cyclin D1 immunostaining, and characteristic immunoprofile (see below). As mentioned above, Reed-Sternberg-like cells can be observed in cases of CLL/SLL. If rare or occasional, they are not considered to represent transformation to Hodgkin lymphoma (HL). However, if more abundant and present with the typical milieu seen in HL, the concern for transformation is much higher.

Spleen

Splenic involvement by CLL is almost always present as part of the generalized disease. However, the degree of involvement is variable. Spleens are almost always enlarged, sometimes to massive weights, but the capsule is usually not compromised [73]. On gross examination, there is a miliary pattern of involvement, with 0.2–1.5 cm micronodules present throughout the cut surface. Histologically, the white pulp is replaced and expanded by proliferation of the small leukemic cells of CLL, similar to the predominant cells seen in the lymph nodes. In contrast to the lymph node morphology, proliferation centers with prolymphocytes and paraimmunoblasts are not usually observed. The tumor often infiltrates into the red pulp cords and sinuses and will extend along the periarteriolar lymphoid sheaths and splenic trabeculae [74, 75].

Other Organs

Although the liver is commonly involved in CLL, clinically apparent hepatic dysfunction is not common [76]. The leukemic cells often infiltrate the portal tracts and less commonly the sinuses can also be involved. The neoplasm can be mistaken for inflammatory infiltrates of hepatitis, for example. However, the monotonous nature of the lymphoid cells and characteristic immunophenotype can help to distinguish the two entities.

Cutaneous involvement can present in a variety for different clinical forms, including plaques, nodules, or tumors. Histologically, the dermis shows leukemic infiltrates that tend to be localized around vascular and adnexal structures [32].

The gastrointestinal tract, central nervous system, and other organs can also be involved, albeit rarely, and are often seen only on autopsy specimens as “case reports” in the literature [77–79].

Immunophenotype of CLL

Immunophenotyping of CLL is one of the most essential aspects of diagnosis and prognosis of the disease, allowing for differentiation between reactive conditions and other lymphoproliferative disorders as well as assessment of adverse prognostic markers. The most useful, rapid, and efficient method of immunophenotyping is multicolor

flow cytometry, which allows for multiparameter testing with multiple antibodies, and facilitates determination of the strength of antigen expression. Most tissues can be submitted for flow cytometry, the easiest being peripheral blood, but also bone marrow aspirates and freshly procured solid tissues such as lymph nodes, following disaggregation. Immunophenotyping on solid, fixed tissues with immunohistochemistry can also be useful in cases when fresh tissue or peripheral blood is not available for analysis.

In the typical form of CLL, neoplastic cells show moderate expression of CD19 and the nuclear B-cell transcription factor PAX5, supporting a B-lymphocytes lineage [80]. Other B-cell antigens are characteristically downregulated (Fig. 7.3) and show weak/dim expression, such as CD20, CD79a/b, and surface immunoglobulin (Fig. 7.3), which is usually IgD with or without IgM. Expression of other immunoglobulin heavy chains (IgG or IgA) is uncommon. This low expression of CD20 and Ig is quite unique to CLL and is an important differentiating clue between this and other B-cell lymphoproliferative disorders [8, 28]. Mechanistically, the low sIg levels in CLL are thought to result from altered glycosylation and folding of the CD79a and μ chains although the BCR signaling remains intact [81].

Another important marker is the co-expression of CD5, a T-cell antigen (Fig. 7.3). Compared to the background T-cells, CD5 expression is slightly weaker. CD5+ B-cells can be found normally in the mantle zones of secondary follicles. Additionally, regenerating naïve B-cell can also express CD5 [82]. The co-expression of CD5 can also be observed in mantle cell lymphoma. However, MCL does not show the weak expression of most B-cell markers as does CLL, and often does not express CD23. Immunohistochemistry for cyclin D1 is present in most cases of MCL, in contrast to typical cases of CLL.

CD23 is a low-affinity receptor for IgE and an adhesion molecule that is expressed by naïve B-cells. It is normally

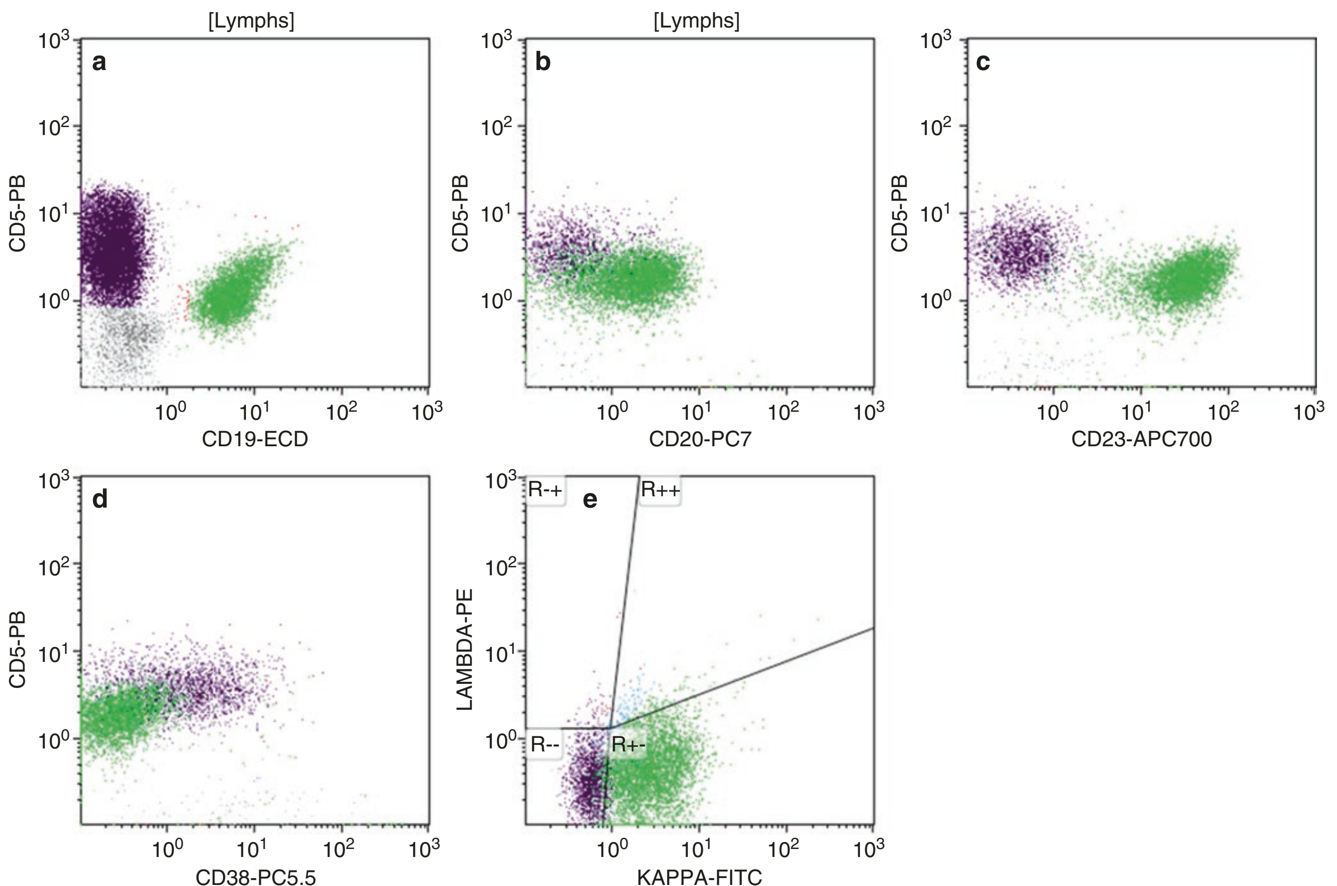

Fig. 7.3 Flow cytometry of CLL: (**a**) The CLL cells are marked *green* and express CD19 (**b**) The CD5 + CLL cells express dim-negative CD20 with slightly dimmer CD5 compared to the T-cells (*violet*). (**c**) There is co-expression of CD23, but the CLL cells are negative for CD38 (**d**) and express dim surface-restricted kappa immunoglobulin light chain (expression level is barely more than the background light chain-negative T-cells) (**e**)

lost after the germinal center reaction in the process of memory B-cell formation. Some have suggested that CD23 correlates with proliferative activity in CLL [83]. Most cases of CLL show expression of CD23 (Fig. 7.3), in contrast to other B-cell neoplasms, such as mantle cell lymphoma. FMC7, an epitope on the CD20 molecule that is expressed by most MCL, is often negative in CLL, although up to 15% of cases can be positive for this marker [84, 85], especially in cases with bright CD20 and Ig positivity.

Bcl-2 is overexpressed in CLL and is related to resistance of apoptosis in the tumor cells, conferring a survival advantage [86]. The mechanism of overexpression in follicular lymphoma is related to the recurrent translocation t(14;18). This is not the case with CLL; rather, hypomethylation of DNA is felt to be the mechanism driving Bcl-2 overexpression [87]. With the advent of selective inhibitors of Bcl-2, the overexpression of the molecule on CLL cells is now more clinically relevant [88, 89].

CD11c, a marker often seen in hairy cell leukemia and B-cell prolymphocytic leukemia, can be observed in CLL. However, the intensity of positivity in cases of CLL, when evaluated by flow cytometry, is usually less than what is observed in hairy cell leukemia (dim negative in most cases), providing a clue to differentiate the two neoplasms using this marker [90].

Among CLL prognostic markers, CD38 and ZAP-70 are the most studied and prognostically important. CD38 is a membrane protein that functions as an adenosine diphosphate ribosyl cyclase. Downstream, this enzymatically controls intracellular calcium levels and is a marker for cell activation [91]. Analysis by flow cytometry would yield three patterns of CD38 positivity: uniformly negative (Fig. 7.3), uniformly positive, and a bimodal pattern with only a subset of the CLL population showing expression [92]. The latter two patterns are associated with unmutated *IGHV* in most cases, which is implicated in poor prognosis. Although a cutoff of 20% positive cells in the tumor has been proposed by some authors, the presence of smaller CD38+ subpopulations (e.g., <10%) may be significant to predict unmutated *IGHV* status. A subset of cases, up to 30% in some studies, shows discordant results with *IGHV* mutation status. In this regard, CD38 positivity is thought to be an independent prognostic factor in CLL [93, 94].

ZAP-70 is not normally expressed in B-cells, but is a tyrosine kinase involved in T-cell receptor signal transduction [95]. The expression of ZAP-70 facilitates the recruitment of Syk to the BCR complex resulting in additional increased BCR signaling. Compared to CD38 expression, ZAP-70 shows more concordance with unmutated *IGHV* status, with up to 97% of ZAP-70-positive cases showing unmutated *IGHV* [95, 96]. Protein expression can be tested by either flow cytometry or immunohistochemistry. In flow cytometry analysis, ZAP-70 in CLL is considered positive when over 20% of tumor cells show expression [97]. In conjunction with CD38 and mutational analysis, three prognostic subgroups can be determined: those with concordant results (ZAP-70+, CD38+, unmutated *IGHV*) have the worst prognosis, while patients without ZAP-70 or CD38 expression and mutated *IGHV* have better prognosis. Those with discordant results have a prognosis intermediate between the two [98, 99]. It is now known that CD38, CD44, CD49d, and matrix metalloproteinase-9 (MMP-9) expressed on ZAP-70+ CLL cells form a macromolecular complex which promotes cross talk between BCR signaling and CD44 further affecting CLL cell migration and homing [100].

A small subset of CLL cases can exhibit variant immunophenotypes and are sometimes termed "atypical" CLL. Some cases can show bright CD20 or sIg expression, and have been correlated with the presence of trisomy 12 [101, 102]. As mentioned above, about 15% of cases can be positive for FMC7. Lack of CD5 co-expression has also been reported, and thought to confer a worse prognosis than CD5+ cases [103].

On the other hand, the classic immunophenotype of CLL can be seen in other lymphomas, including MCL and MZL [104, 105]. Thus, the typical findings on flow cytometry and/or immunohistochemistry are not entirely sensitive nor specific. Indeed CD5 positivity has been described in all other non-CLL small B-cell lymphomas [106]. This highlights the importance of morphologic correlation when evaluating all cases of B-cell lymphoproliferations.

Some of the more recent immunohistochemical markers of CLL include CD200 and lymphoid enhancer binding factor 1 (LEF1). CD200 is a glycoprotein belonging to the immunoglobulin superfamily. It is expressed in most cases of CLL in contrast to MCL, giving it diagnostic utility in cases where the immunophenotyping results may be overlapping between the two entities [107]. Some have suggested a prognostic utility as well, with cases showing strong expression of CD200 having a better overall survival and longer time to treatment [108]. LEF1, on the other hand, is a transcription factor related to the Wnt pathway that helps to regulate genes associated with cell death and survival [109]. LEF1 expression was also found in CD19+/CD5+ B-cells in patients with monoclonal B-cell lymphocytosis, suggesting that this pathway may play an early role in the leukemogenesis of CLL. Most cases of CLL show expression of LEF1 in contrast to MCL [110, 111]. Recent studies also show that strong expression of LEF1 is an adverse prognostic factor [112].

In addition to these diagnostic and prognostic markers, CD2 and CD13 have both been aberrantly described to be expressed in cases of familial CLL [113]. Given the immune derangements consequent to CLL, expansions of certain unusual T-cell populations have been noted in CLL including CD4 + CD8+ populations in line with evidence indicating expansions of these population in elderly patients and CLL-like MBL [114, 115].

Transformation in CLL

The development of an aggressive lymphoma either synchronously or subsequent to a diagnosis of chronic lymphocytic leukemia (CLL) is called "Richter transformation" (RT) and is the accepted definition in the 2008 (and 2016 revision) WHO classification of hematopoietic tumors [11, 17, 116]. Two distinct pathologic variants are described, namely diffuse large B-cell lymphoma (DLBCL) variant (90% of all RT) and the less common Hodgkin lymphoma (HL) variant (10% of all RT) [117]. The former occurs ~2 years after a CLL diagnosis (including in treated and untreated patients) while the latter occurs at a median of 6 years subsequent to a diagnosis of CLL mostly in treated patients [118, 119].

Diffuse Large B-Cell Lymphoma-Richter Transformation (DLBCL-RT)

General Considerations

CLL patients with significant lymphadenopathy, certain genetic polymorphism, and somatic *NOTCH1* carry an increased risk of transformation [7, 120–123]. While the diagnosis of DLBCL-RT is fairly straightforward in most instances, there are three situations in which a diagnosis of DLBCL-RT should not be rendered: (1) Cases of CLL with numerous expansive and at times confluent growth centers: While such "accelerated" cases exhibit more aggressive clinical course with a median overall survival intermediate between typical CLL and DLBCL-RT, the current upcoming revisions note that these cases should not be termed as DLBCL-RT [124]. (2) The occurrence of EBV+ aggressive lymphomas after T-cell-depleting therapies for CLL including alemtuzumab, and as such these malignancies are considered to be secondary to iatrogenic immunosuppression and do not warrant a diagnosis of DLBCL-RT [125]. However, clonally identical B-cells have been reported to be detected in the both the CLL component prior to therapy and the post-alemtuzumab B-cell lymphoproliferation [126]. (3) Lastly, identification of small CD5+ B-cell clones in staging marrows of patients with extramedullary DLBCL without prior/concurrent history of CLL is likely unrelated biologically to the DLBCL and such cases are best considered as de novo DLBCLs.

Histopathology

DLBCL-RT occurs typically as a nodal disease but may also involve extranodal tissues including peripheral blood and bone marrow (Fig. 7.4). Involved lymph nodes show partial or total effacement of the nodal architecture by a DLBCL component with variable amounts of associated CLL component, which is spatially separate or intimately admixed with the DLBCL component. Cytologically, the DLBCL exhibits immunoblastic cytomorphology (with prominent eosinophilic nucleoli and moderate amount of cytoplasm, Fig. 7.4) but cases with centroblastic morphology and in rare instances plasmablastic/plasmacytic morphology has also been described [127–129]. A small proportion of cases may be positive for EBV with coexistent herpes simplex infection, which may be apparent as areas of extensive necrosis with typical Cowdry Type A inclusions. Prior fludarabine exposure increases the risk of HSV infection. Immunophenotypically, the DLBCL-RT exhibits non-GCB phenotype (CD10-, BC6-, MUM1/IRF4+) phenotype in 62–100% of cases based on the Hans classifier with variable expression of CD5 (32–77%) and CD23 (14–80%) [7, 130] (Fig. 7.4). Expression of Mum-1/IRF4 is in keeping with the phenotype of activated B-cell (ABC)/IRF-4- DLBCLs which have worse outcome compared to cases of de novo DLBCLs (Fig. 7.4). Specifically among DLBCL-RTs, there is overrepresentation of non-germinal center B-cell phenotype compared to de novo DLBCLs where the frequency is much lower [131–133].

Given the prognostic relevance of ZAP-70 and p53 in CLL, there has been interest in relevance of these two proteins in the DLBCL-RT. One recent study including 34 DLBCL-RTs noted that ZAP-70 expression by immunohistochemistry in DLBCL-RT (Fig. 7.4) was less frequent (13% of all DLBCLs tested) compared to the CLL component (66%) [130]. However, ZAP-70 status did not have any prognostic value. However, a significant proportion of DLBCL-RT in this study expressed p53 [130]. This observation is in congruence with reported genomic studies corroborating overrepresentation of *TP53* mutations in CLL and their corresponding DLBCL-RT tissues compared to CLLs that have not transformed to DLBCL with reported *TP53* disruption and *CDKN2A* as a main mechanism of transformation in CLL [134]. This study further identified a second major subgroup characterized by the presence of trisomy 12 comprising a third of the cases in the series indicating the existence of distinct pathways of transformation to DLBCL in CLL.

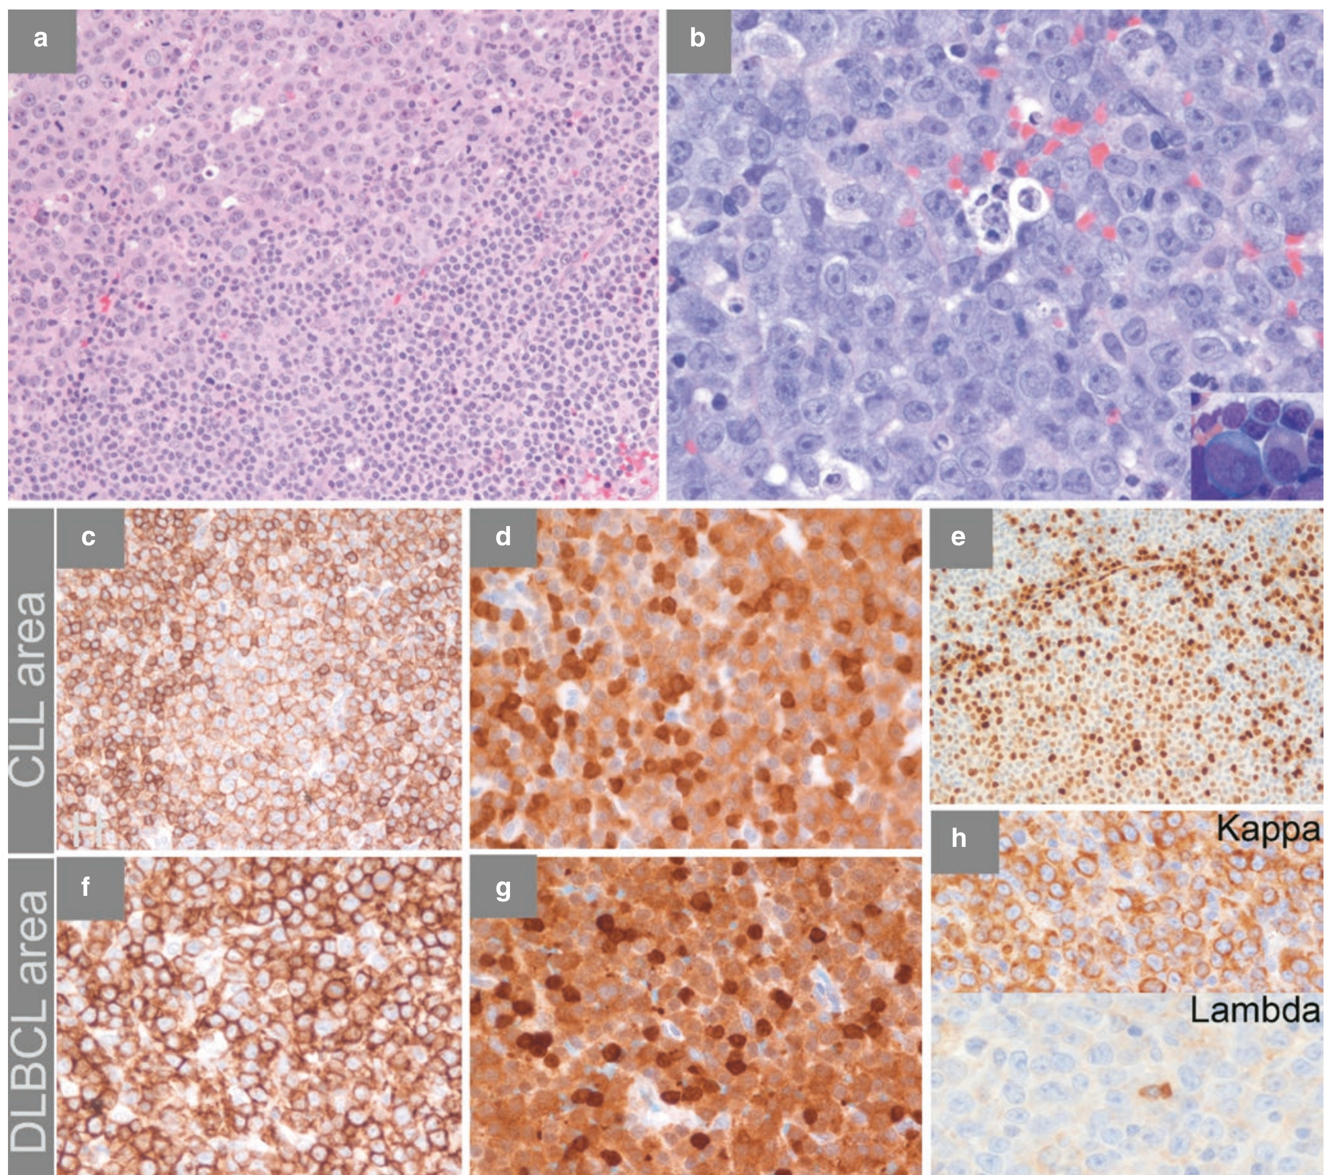

Fig. 7.4 Diffuse large B-cell lymphoma-Richter transformation (**a**). Bone marrow with spatially distinct large cell (*top left*) and CLL component (*bottom right*). (**b**) Large cell area at high power with prominent immunoblastic cytomorphology (inset shows large cells on marrow aspirate smears). (**c**, **f**) demonstrate CD5 immunostain in the CLL (proliferation centers) and DLBCL areas. Both components in this case are CD5 positive and ZAP-70 positive (**d**, **g**) In both stains, background T-cells express bright CD5 and ZAP-70. (**e**) Mum-1/IRF4+ staining within growth centers (*lower half of figure*) with an associated plasmacytic component at the periphery (*upper half of figure*). (**h**) The large-cell component shows restricted kappa light chain by immunohistochemistry (*top panel*)

Clonality Studies and Differential Diagnostic Considerations

Despite the frequently differing immunophenotype of DLBCL-RT in comparison with the prior CLL, clonality studies of IG genes and *IGHV* segment usage indicate that both components are frequently clonally related in up to 80% of cases [123, 130]. Also, with respect to *IGHV* status and cell of origin status, de novo DLBCLs differ from DLBCL-RT in frequently carrying mutated *IGHV* genes as opposed to DLBCL-RT which harbor unmutated *IGHV* genes. Another important differential in this setting is de novo CD5+ DLBCL since CD5 expression is otherwise unusual for de novo DLBCLs. However, CD5+ DLBCLs, despite being clinically/immunophenotypically similar (advanced age and stage at presentation, non-GC phenotype) to DLBCL-RT, in contrast carry mutated *IGHV* (up to 80% of cases) and are frequently CD23 negative as opposed to CD5+ transformation of B-CLL which is unmutated in most instances [135–137].

Clonally unrelated DLBCL-RT were noted to harbor less frequent *TP53* mutations, less frequent B-cell receptor stereotypy,

and longer outcome compared to clonally related cases, nearly 47% of which harbored *TP53* aberrations [123]. This study noted MYC aberrations in up to 26% of DLBCL-RT cases. It is unclear as yet if MYC IHC positivity/aberrations in DLBCL-RT are independently prognostic or are only reflective of an aggressive *TP53* mutation-driven biology. There is some evidence that it is implicated in transformation [123, 138, 139]. One recent study noted that *MYC* aberrations are frequently acquired during the course of the disease and when present as part of a complex karyotype were associated with the development of RT and adverse outcome in contrast to cases harboring *MYC* aberrations as a part of a non-complex karyotype which responded well to standard risk-adapted therapy [140].

Classical Hodgkin Lymphoma-Richter Transformation (CHL-RT)

This variant of CLL transformation is 10–20 times less common than DLBCL-RT and occurs in less than 1% of CLL patients [118, 141–143]. In one of the first studies from Mayo Clinic looking at the incidence of CHL-RT in CLL patients within a prospective and a nested cohort (including only the subset with newly diagnosed CLL within the study period 1995–2011), the 10-year risk of CHL was 0.5% [118]. Compared to de novo CHL patients, CHL-RT patients in this study exhibited shorter overall survival and frequently presented at higher IPS stage and furthermore patients receiving any CLL therapy prior to the CHL transformation did worse compared to those who did not. Although 67% of cases in this series developed EBV+ CHL-RT, it was not possible to draw conclusions on outcome stratified by EBV status due to confounding prior nucleoside analog therapy in most patients within the EBV+ subset.

Two different histologic patterns of CHL have been described in the context of CHL-RT [59, 144, 145]. “Type I” pattern referred to the occurrence of isolated Hodgkin/Reed-Sternberg (HRS) cells scattered in a background of CLL lacking the typical polymorphous cellular milieu of CHL (viz. fibrosis, eosinophils, and neutrophils). “Type II” denoted cases with HRS cells scattered within typical CHL microenvironmental milieu (Fig. 7.5). These lesions may demonstrate synchronous composite histology with CLL and

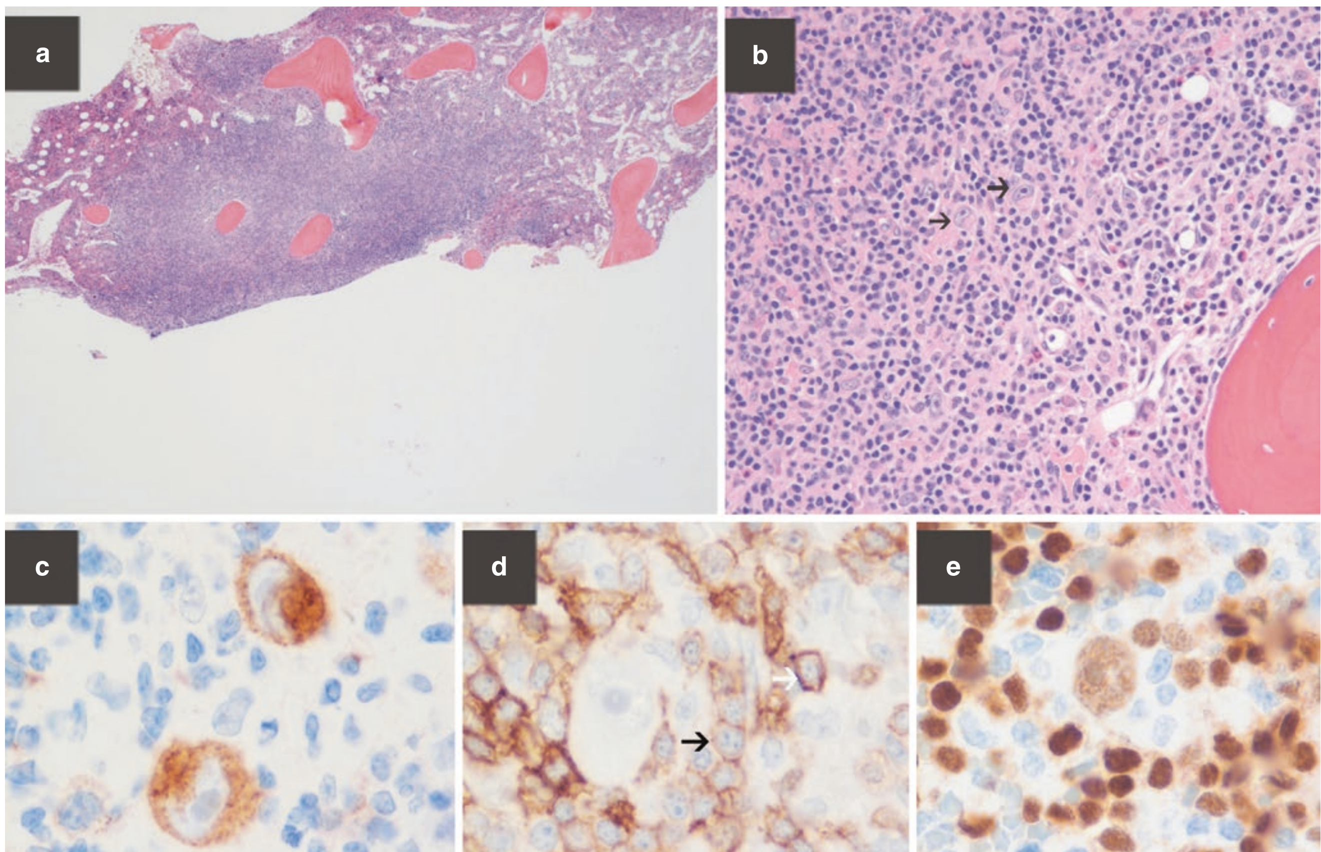

Fig. 7.5 Hodgkin lymphoma-Richter transformation in a CLL patient with two prior treatments including fludarabine, cyclophosphamide, and ofatumumab as well as acalabrutinib (irreversible Btk inhibitor) with progressive lymphadenopathy in whom bone marrow biopsy was performed for cytopenias. (**a**) Low-power view of marrow core biopsy showing nodular interstitial lymphohistiocytic aggregates which at high power (**b**) shows scattered HRS cells (*arrows*) amidst a polymorphous cellular milieu comprising lymphocytes, histiocytes, and few eosinophils. (**c**) The HRS cells express CD30 and are rimmed by CD5+ T-cells. (**d**) The CD5 immunostain shows T-cells with bright CD5 (*white arrow*) and CD5-dim lymphoid cells corresponding to CLL cells (*black arrow*) better highlighted on Pax5 immunostain (**e**)

Hodgkin components (either in the same node or different sites) or as metachronous development of CHL subsequent to CLL diagnosis. Progression from type I to type II histology may occur in some instances.

Immunophenotypically, the HRS cells exhibit a similar phenotype as seen in de novo classical Hodgkin lymphoma (CD30+, CD15+/variable, CD45-, weak Pax-5) (Fig. 7.5) with variable downregulation of other B-cell markers (CD20, CD79a, Oct-2, Bob.1) [117]. Most cases are usually positive for EBV (71%) in the HRS cells by in situ hybridization or EBV-LMP1 immunohistochemistry [141, 146]. While earlier biologic studies informed us regarding the occurrence of some clonally related and other clonally unrelated cases with inverse association of EBV and clonal relatedness, these were mostly single reports and small case series where results were not generalizable [59, 144, 145, 147]. In one of the largest series of such cases published recently including 26 type I Hodgkin-like lesions, the authors examined the EBV status, clonal relatedness (of both CLL and CHL components), and ZAP-70 status [146]. In this study, the authors noted that the CHL component was clonally related in about 40% of cases and interestingly all CLL negative for ZAP-70 were clonally related to the paired CHL component. This is in contrast to DLBCL-RT wherein all or most cases of DLBCL-RT are clonally related to the CLL component regardless of *IGHV* status. Only age > 70 years was predictive of adverse outcome in this study. While it was controversial from earlier studies whether type I lesions should be considered transformation, the study by Chen noted that cases with type I histology had an overall survival similar to cases with type II histology.

Minimal Residual Disease Testing in CLL by Flow Cytometry

With the progress made with combinations of chemotherapy and immunotherapy in CLL, there is growing recognition of association of MRD-negative status and other outcome measures. Several studies have demonstrated the utility of MRD-based flow cytometric testing in a variety of clinical settings including first-line, salvage/high-risk, and post-allogeneic transplant settings and it is thought that it may perhaps be useful even as a clinical trial endpoint with novel immunotherapy agents [148].

While earlier studies examined MRD status using two-, three-, or four-color tubes including CD19, CD5, and Kappa/lambda [149–152], the first major approach to standardized combinations was proposed by the European Research initiative in CLL (ERIC) which examined 728 paired blood and marrow samples and demonstrated that there was a high concordance between blood and marrow although marrow FC was required for definitive assessment of MRD-negative status 3 months after alemtuzumab therapy. There was concordance of the FC-based MRD status and real-time quantitative allele-specific oligonucleotide (RQ-ASO) immunoglobulin heavy-chain gene (IgH) polymerase chain reaction (PCR) [153]. This study identified specific useful four-color FC combinations including CD19/CD5 with CD20/CD38, CD81/CD22, and CD79b/CD43 as the most useful combination for detecting MRD at the 0.01% level. These observations were then extended in a follow-up study demonstrating equivalence of a harmonized six-color panel with the previously proposed four-color panel in detecting residual CLL at the 0.01% level utilizing the same marker combinations including CD20, CD22, CD38, CD43, CD79b, and CD81 [154]. This latter study utilized a threshold of at least 50 events to define a CLL population with the need for CD3 for determining the limit of detection. Very recently, a combination of markers proposed by ERIC were tested in an eight-color panel with the ability to detect MRD at 0.007% level [155].

Differential Diagnosis

In the assessment of a patient with B-cell lymphocytosis, the differential diagnosis can be broad and range from benign, reactive conditions to a number of B-cell lymphomas. An important and useful first step in differentiating between these conditions is a systematic assessment of lymphocyte morphology. Generally, uniformly small-to-medium cells in the peripheral blood is suggestive of CLL, while variability in cell size and shape is more indicative of a reactive condition or another lymphoma. Clinical history is also important, as lymphocytosis in a young patient is more likely to represent an infectious process, such as a viral illness, rather than lymphoma. Polyclonal B-cell lymphocytosis, a rare condition more common in young female smokers and associated with HLA DR7 [156], may also enter the differential. It is characterized by a persistent B-cell lymphocytosis of mostly small, round lymphocytes with only mild morphologic variability, closely resembling CLL. Often, flow cytometry and/or clonality studies may be necessary to exclude lymphoma.

Distinction between CLL and other mature B-cell neoplasms can be more difficult especially when the morphology of CLL is atypical. In the early 1990s, a flow cytometric scoring system was proposed by Matutes and coworkers which examined the expression levels of CD5, CD22, CD23, FMC7, and surface immunoglobulin. CLL with a typical expression pattern (CD5+, CD23+, FMC7-, dim sIg, and dim CD22) were assigned a score of 5 [157]. However, in these cases, particular attention to morphologic features, along with correlation with immunophenotype, can aid in arriving at the correct diagnosis.

Mantle cell lymphoma, particularly the small-cell variant, is possibly the most important differential diagnosis, due to some similar morphologic and immunophenotypic features with CLL, despite its significantly poorer prognosis. Leukemic presentation can occur in MCL [158] and the cells can resemble CLL, namely medium-sized cells with scant cytoplasm. However, the nuclei in MCL are often cleaved and the chromatin usually is more dispersed. In tissue sections, proliferation centers that are characteristic of CLL are notably absent in MCL. Additionally, prolymphocytes are not found in cases of MCL. Although both lymphomas share expression of CD5, in contrast with CLL, MCL shows strong expression of CD20 and CD79b. A key differentiating factor is the expression of cyclin D1 in MCL, which is correlated with the presence of t(11;14)(q13;q32). In cases where cyclin D1 is absent, SOX11 is present in most cases [159]. Absence of SOX11 was found to confer better survival and a more indolent form of MCL [160].

Uncommonly, CLL can exhibit plasmacytoid features, morphologically resembling lymphoplasmacytic lymphoma (LPL). The latter contains a mixture of plasma cells, plasmacytoid cells, and small lymphocytes. The peripheral blood may also exhibit red cell agglutination, indicative of the presence of antibodies on the red cell surface (Fig. 7.6). The bone marrow may show diffuse infiltration (Fig. 7.6). Mast cells are typically increased in LPL. Proliferation centers are absent and CD5 is generally not expressed although CD10 can rarely be expressed in LPL. Expression of CD20, surface immunoglobulin, and CD79a is usually higher than in CLL. Testing for serum IgM paraprotein and presence of concurrent *MYD88* L265P mutation (which is now known to be present in almost all LPL) allows confirmation of LPL [161].

CLL with increased prolymphocytes or in prolymphocytic transformation can resemble B-cell prolymphocytic lymphoma (B-PLL). However, as defined by the WHO, the diagnosis of B-PLL requires that the neoplastic cells comprise 55% or more of the peripheral white blood cells (Fig. 7.6). Although lymph node involvement is uncommon in B-PLL, if present, proliferation centers are not observed. CD20 expression in B-PLL is typically bright, in contrast to most cases of CLL.

The distinction between follicular lymphoma and CLL is often straightforward. Although at times the pseudofollicles of CLL can resemble the true neoplastic follicles of follicular lymphoma and the neoplastic cells can appear slightly cleaved, attention to all architectural and morphologic features, along with immunophenotypic profiles, would aid in the diagnosis. When evaluating bone marrow samples, follicular lymphoma typically occupies the paratrabecular spaces, rather than interstitial or diffuse involvement that is characteristic of CLL.

Splenic marginal zone lymphoma presents with peripheral blood and spleen involvement without significant lymphadenopathy. The neoplastic cells characteristically have polar villi (Fig. 7.6) with a chromatin pattern quite similar to CLL cells. The bone marrow shows intra-sinusoidal infiltrates (Fig. 7.6), which are very unusual in CLL. Immunophenotypically, there is strong expression of FMC7 and B-cell markers, in contrast to CLL cells. CD5 can be expressed in some cases of splenic marginal zone lymphomas, and some suggest that cases with this immunophenotype present with higher levels of lymphocytosis. However, there was no difference in overall outcome in CD5+ lymphomas as compared to CD5-negative cases [162].

Differentiation of hairy cell leukemia (HCL) from CLL is usually not very challenging. HCL often presents in the peripheral blood, spleen, and bone marrow, without significant peripheral lymph node involvement. The classic cytomorphology of HCL cells is medium-sized lymphoid cells with circumferential hairlike cytoplasmic projections (Fig. 7.6). The nuclear membrane is often oval or indented and the chromatin is slightly more dispersed than the clumpy chromatin pattern seen in CLL cells. Examination of the bone marrow often shows diffuse involvement and a “fried-egg” appearance of the neoplastic cells (Fig. 7.6). Immunophenotypically, HCL cells have strong expression of sIg and B-cell antigens, such as CD20. More specific hairy cell markers such as CD103, CD25, and CD123 are often present. Immunohistochemical stains for annexin A1, tartrate-resistant acid phosphatase (TRAP) (Fig. 7.6), and DBA.44 on tissue sections can also be helpful. CD5 is often negative.

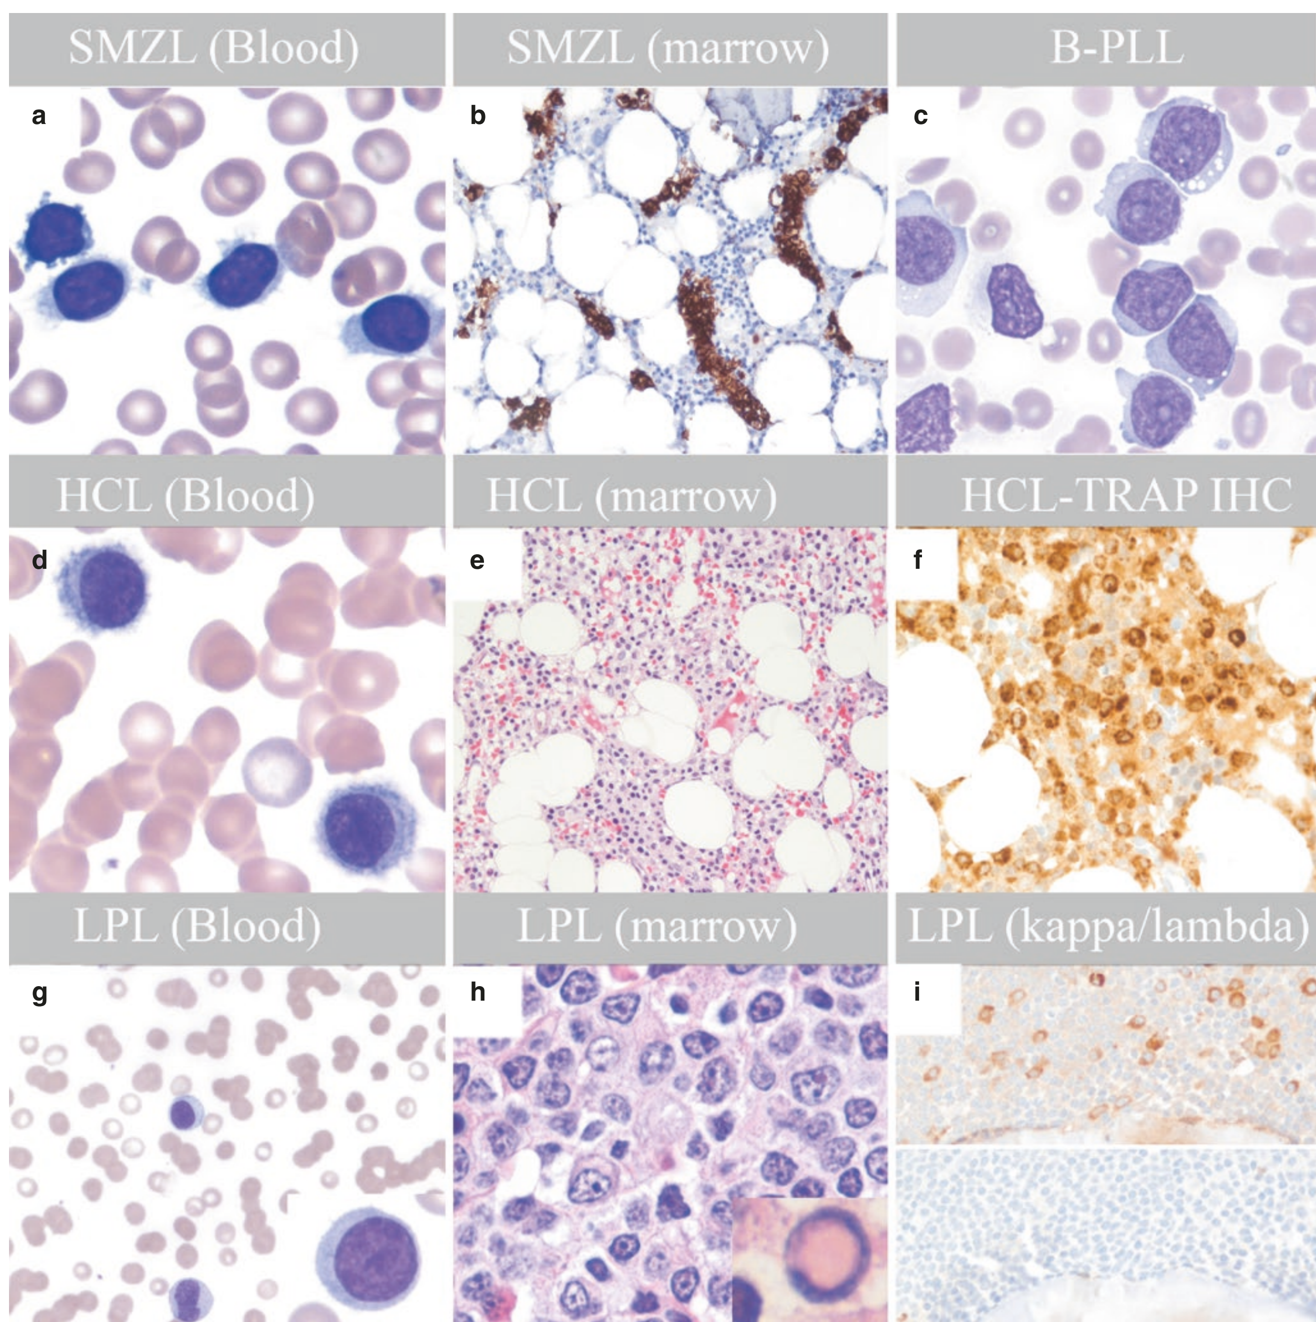

Fig. 7.6 Differential diagnostic considerations. (**a**) Splenic marginal zone lymphoma (SMZL) involving peripheral blood with polar villous projections (**b**) SMZL in marrow characteristically shows intra-sinusoidal infiltration pattern of lymphoma cells more frequently which is a useful diagnostic feature (CD20 immunoperoxidase stain). There is often heterogeneity of cell size in such cases but typical clumped nuclear chromatin and smudge cells as seen in CLL are not present. (**c**) B-Prolymphocytic leukemia (B-PLL) containing uniform population of large cells with distinct nucleoli and moderate amount of cytoplasm. With growing understanding, very few of such cases represent CLL in prolymphocytic transformation. (**d**) Hairy cell leukemia (HCL) involving peripheral blood with typical hairy cytomorphology. (**e**) HCL involving bone marrow core biopsy with typical fried-egg appearance (**f**) Tartrate-resistant acid phosphatase (TRAP) immunohistochemistry strongly positive in HCL. (**g**) Lymphoplasmacytic lymphoma involving peripheral blood with marked red cell agglutination (*inset:* typical cell with morphology intermediate between lymphocytes and plasma cells). (**h**) Core biopsy of LPL showing extensive infiltration by LPL cells (*inset:* Dutcher body, defined as intranuclear inclusions of cytoplasmic immunoglobulin) (**i**) Kappa light-chain restriction with LPL cells demonstrated via IHC on core biopsy. Although the morphologic distinction is easy in most instances, HCL, SMZL, and B-PLL may variably express CD5 and CD23 in a significant proportion of cases and may pose diagnostic confusion from a flow cytometric perspective

Conclusion

As our understanding of the pathogenesis of CLL grows, "bench-side" discoveries are increasingly finding their way to the "bedside," with more examples of targeted therapy and precise prognostication discovered each year. The molecular genetic profile of each tumor can aid clinicians in providing the appropriate therapy, a delicate balance between effective medicine against the tumor and minimizing any toxic side effects. Despite these advances, the diagnosis of CLL is still dependent on analysis using the classic, ageless light microscope and evaluation of characteristic morphologic and architectural features. With the additional help of flow cytometry and immunohistochemistry, CLL can be differentiated from its mimics and a precise diagnosis can be rendered by the pathologist. Only after this point do molecular tests have meaning and a context can be drawn that links the basic science discoveries in CLL to the practical treatment and care of the patients we serve.

8 The Genomic and Epigenomic Landscape of Chronic Lymphocytic Leukemia

Jonathan C. Strefford, Renata Walewska, and David G. Oscier

Introduction

Since the previous edition of this book, our understanding of the cytogenetics and genomics of chronic lymphocytic leukemia has taken a quantum leap forward, principally the result of seminal technological advances (Fig. 8.1). In the 1970s, the development of polyclonal B-cell mitogens culminated with the discovery of the first cytogenetic abnormality in CLL, trisomy 12, in 1980, shortly followed by the interstitial deletion of 13q14 [1, 2]. With the advent of more effective mitogens, most recently CpG oligonucleotides combined with interleukin 2 [3, 4], the majority of cases of CLL yield metaphase preparation and clonal abnormalities are identifiable in approximately 80% [5]. In contrast to many other mature B-cell tumors, recurrent reciprocal translocations are uncommon in CLL, whereas copy number changes, particularly deletion events such as those affecting 11q, 13q, and 17p, and trisomy of chromosome 12 occur frequently.

In the 1980s, fluorescent *in situ* hybridization (FISH) approaches overcame the need for dividing cells, thereby permitting the analysis of interphase nuclei. The seminal study by Döhner and colleagues established the relative prognostic significance of a panel of recurrent copy number changes, based on the presence of 17p, 11q, and 13q deletions, and trisomy 12, with 13q deletions (as a sole abnormality) and 17p deletion being the markers of best and worst prognosis, respectively [6]. Similar data can now be obtained using either multiplex ligation-dependent probe amplification (MLPA) or quantitative PCR [7–10], although these approaches are rarely used in the clinical setting.

The development of comparative genomic hybridization (CGH) initially with a chromosome template [11], but later with an array-based template [12], allowed the entire genome to be screened for copy number alterations (CNAs) in a single experiment. Currently, copy number changes and loss of heterozygosity (LOH) events can be detected using arrays with more than two million unique genomic features, enabling the identification of genomic alterations of 10–100Kb in size. These studies have identified novel recurrent regions of copy number changes and permitted the gene content of more established lesions to be accurately delineated.

While early molecular studies, employing traditional approaches, identified important mutated cancer genes in CLL, such as *TP53* and *ATM* genes occurring in approximately 80% of patients with *TP53* loss and 40% of patients with *ATM* loss, respectively [13, 14], it was the development of high-throughput massively parallel sequencing that permitted the analysis of the entire CLL genome [15]. Whole-genome (WGS) and -exome (WES) sequencing of more than 1000 CLL patients has led to the discovery of novel mutated cancer genes, positioned within key biological pathways, and has allowed the aforementioned "Döhner" prognostic model to be nuanced with both gene mutation and immunogenetic data [16]. Furthermore, these experiments can be performed with much greater resolution, allowing clinically relevant low-level subclonal mutations to be identified and providing insights into the nature and extent of intraclonal heterogeneity [17, 18]. Indeed, single cells can be isolated using modern flow cytometry or microfluidic approaches and analyzed using next-generation sequencing (NGS) techniques, providing even greater resolution of the clonal architecture of human neoplasms. Methodological advances are also contributing to a greater understanding of the methylome

and chromatin landscape in CLL and their relationship to the putative cells of origin of *IGHV*-mutated and unmutated CLL [19–22]. While a complete annotation of the CLL genome and epigenome is in sight, ongoing analysis of the CLL proteome, transcriptome including microRNA expression, and functional consequences of specific genomic and epigenetic abnormalities are beginning to unravel the drivers for clonal selection while also providing prognostic data and identifying therapeutic targets.

In the remainder of this chapter we provide an overview of the genomic landscape, and discuss the commonest genomic abnormalities found in both CLL (Tables 8.1 and 8.2) and Richter's transformation, epigenetic abnormalities, genetic predisposition to CLL, and finally the clinical importance of genomic abnormalities in the management of patients with CLL.

Chromosomal Abnormalities

Deletion of Chromosomal Band, 13q14

Deletion of 13q14.3 is the commonest cytogenetic abnormality in CLL, seen in 50–60% of patients (Table 8.1). Recent WGS data demonstrates the result of interstitial deletions in approximately 60% of patients and translocations involving numerous, sometimes recurring, partner chromosomes (e.g., chromosomes 1, 2, and 14) in the remainder [48]. Approximately 10% of 13q deletions are the result of a complex chain of genomic lesions targeting several chromosomes, characteristic of chromoplexy [49]. 13q14 deletions may be heterozygous (in 70% of cases) or homozygous, where the latter can be the result of copy number-neutral LOH in rare cases [23].

The size of the 13q14 deletion is highly heterogenous in both size and gene content, but a minimally deleted region which includes exons from *DLEU2*, a long noncoding RNA, *DLEU1*, and miRNA 15a/16-1 cluster has been reported [50]. The importance of these genes is demonstrated most

strikingly by a transgenic mouse model, in which either the minimally deleted region encompassing both *DLEU2* and miR 15a/16-1 or miR 15a/16-1 alone was deleted [51]. In both models a clonal B-cell population proliferated in approximately 30% of mice. In the majority of cases the histology and immunophenotype of these B-cell expansions resembled human CD5-positive monoclonal B-cell lymphocytosis (MBL), CLL, or small lymphocytic lymphoma (SLL). A minority of mice developed clonal CD5-negative lymphomas. Bi-allelic deletions and deletions of both *DLEU2* and miR 15a/16-1 were associated with more aggressive disease [51]. In this model, the miRNA cluster regulates the expression of a series of cell cycle genes including *CCND1, CCND2, CCNE1, CDK4*, and *CDK6* which, in turn, regulate transition from G0 to G1 to S phase [51].

Several other studies have shown a correlation between downregulation of miR 15a/16b and upregulation of BCL2 expression [52, 53]. The consequences of loss of DLEU2 and other genes outside the minimally deleted region which nevertheless are deleted in most cases with 13q14 loss are areas of intensive research, where it is clear that 13q deletion size has significant biological and clinical consequences [23, 54, 55].

Genomic Lesions Targeting 11q23

Structural abnormalities of the long arm of chromosome 11 are frequent in CLL, occurring in approximately 20% of patients (Table 8.1). The incidence is higher in advanced- than in early-stage disease and patients frequently have widespread bulky lymphadenopathy. Cytogenetic studies show that most cases with an 11q abnormality have a deletion involving 11q23. Deletions vary in size usually occurring within the 11q21–q25 region. Balanced translocations in this region are rare [54].

The great majority of 11q deletions in CLL result in loss of the ataxia telangiectasia-mutated (*ATM*) gene and approximately 40% of patients with *ATM* loss carry a mutation of the remaining allele (Table 8.2) [55, 56]. Approximately 12% of patients have an *ATM* mutation without an accompanying 11q deletion [57]. In patients with bi-allelic *ATM* abnormalities, the mutation may either precede or follow the deletion of the other allele [40]

As only 40% of 11q deleted cases carry an inactivating mutation of *ATM*, and in vitro studies of the function of the double-stranded DNA repair pathway appear to be preserved in patients with an 11q deletion without an *ATM* mutation, it has been postulated that other genes on 11q may impact disease pathogenesis [40]. The postulated role of other genes on 11q has not been supported by the analysis of genes within the well-defined MDR on 11q, where studies have shown reduced expression of these genes, but have not identified deleterious mutations [57]. However, genomic profiling approaches have shown that 11q deletions are heterogeneous in both size and location, and it has been proposed that other genes involved in DNA damage response, such as Mre11 and *H2AFX*, deleted in 50% and 18% of

cases with an 11q deletion, respectively, might also contribute to leukemogenesis [58].

Another gene on 11q of potential importance is *BIRC3*, a negative regulator of NF-κB signaling. *BIRC3* deletions occur in approx. 80% of cases with 11q loss, where they are always concomitant with *ATM* deletion [56, 57]. Mutation occurs in approx. 2% of cases, where they associate with constitutive noncanonical NF-κB activation in fludarabine-refractory CLL patients with these mutations [40]. However, *ATM* and *BIRC3* lesions often coexist in the same patient, and it is an *ATM* mutation that is most associated with poor outcome in del(11q) CLL [57]. 11q deletions can also include the microRNA (miR) cluster that included miR-34b and miR-34c. These miRs interact with p53, with reduced expression and hypermethylation of miR-34b/c locus occurring preferentially in non-11q deleted cases [58].

Deletion and Mutations of the Tumor-Suppressor Gene, *TP53*

Structural abnormalities of chromosome 17p, including deletions, translocations (usually unbalanced), and isochromosome 17q, are detectable cytogenetically in less than 5% of patients with early-stage CLL rising to over 30% in patients with advanced chemo-refractory disease (Table 8.1). In routine practice it is usual to screen for 17p loss using a FISH probe encompassing the *TP53* gene. Factors that can influence interphase FISH results such as the choice of probe, number of cells counted, scoring of all lymphocytes or just clonal B cells, and choice of cutoff are of particular importance for TP53 screening in view of the clinical significance of *TP53* loss. 80–90% of cases with *TP53* loss have a mutation of the remaining allele (Table 8.2). 3–5% of patients acquire a *TP53* mutation without loss of the other allele [59–62]. Bi-allelic *TP53* mutation also occurs in rare cases, due to either a second unique mutation or the presence of 17p copy number-neutral loss of heterozygosity [59].

Using traditional molecular screening approaches, *TP53* mutations can be identified in approximately 9% of untreated CLL cases, with loss of the second allele seen in the majority of mutated cases (Table 8.2). Differences in the incidence of *TP53* loss and/or mutation among series reflect differences in patient populations and methods for screening for *TP53* mutations. The majority of *TP53* mutations are missense and located within the DNA-binding domain of p53 encoded by exons 5–8. Approximately 20% of mutations occur within 6 “hot spots.” The *TP53* mutation profile is similar in both previously untreated and treated patients suggesting that chemotherapy selects preexisting small p53 mutated clones [59]. The presence of a *TP53* mutation, thought to be an event preceding clonal evolution [60], is a strong independent marker of adverse survival and a powerful predictor of poor response to chemo-immunotherapy, and therefore has direct implications on treatment decisions [61]. Low-level subclonal mutations, beyond the resolution of Sanger sequencing (down to 0.3% of the cancer cells), reside in approximately 9% of untreated CLL, mutations that expand to become more clonal in sequential samples from patients that ultimately relapse [61, 62]. Patients with these subclonal *TP53* mutations show the same clinical phenotype and poor survival [61] as patients with clonal mutations and carry a higher risk of mutation selection by therapy. Identifying *TP53* defects early in their evolution may enable improved clinical management of high-risk CLL. It is important to mention a rare subset of early-stage CLL patients with mutated *IGHV* genes and *TP53* abnormalities do exhibit a more stable disease course [63].

Functional studies in which double-stranded DNA breaks are induced in leukemic cells in vitro and the expression of p53 and its downstream targets such as p21 and miR34a are measured are also able to detect TP53 abnormalities in CLL [63]. More recent studies suggest that primary abnormalities of p21 and miR34a expression in patients with no detectable TP53 abnormality may also cause p53 dysfunction and can be associated with poor clinical outcome [30, 32]. *TP53* abnormalities are frequently associated with complex genomic abnormalities and a poor outcome as discussed below.

Trisomy 12

Trisomy 12 is the most frequent numerical chromosome abnormality in CLL occurring in approximately 10% of patients (Table 8.1). It is usually the primary cytogenetic abnormality detectable at diagnosis; acquisition of trisomy 12 during the course of disease is extremely rare. There is a strong but as-yet unexplained association between trisomy 12 and both atypical lymphocyte morphology and an atypical immunophenotype [64]. The role of trisomy 12 in the pathogenesis of CLL remains unclear. Structural abnormalities of chromosome 12 may result in a partial trisomy 12 with duplication of the region between q13 and q22. This region includes the MDM2 gene which is overexpressed in patients with trisomy 12 [65]. Trisomy 12 may occur as the sole cytogenetic abnormality in CLL but is frequently accompanied by additional trisomies, particularly of chromosomes 19 and 18 [66], deletion of 13q14, or immunoglobulin gene translocations, as discussed below.

Other Copy Number Aberrations

In addition to chromosomal rearrangements, a number of rare, but recurrent, copy number changes are present in the genome of CLL patients (Table 8.1). Interstitial deletions of 14q are rare and deletion break points are clustered and may juxtapose the immunoglobulin enhancer to an as-yet unidentified gene. Deletions of 6q can be detected in approximately

5% of patients with CLL, but multiple minimally deleted regions have been identified or candidate gene has been proposed. The clinical significance of 6q loss is uncertain but has been associated with atypical lymphocyte morphology-extensive lymphadenopathy but not chemoresistance. Overrepresentation of chromosome 2p has been consistently reported as a genomic abnormality in CLL in studies using CGH and SNP arrays. Overall occurrence has been reported in 5% of early-stage CLL patients, rising to 28% in stage B and C disease. Conventional cytogenetics shows a variety of mechanisms resulting in duplication. However, 2p duplication rarely occurs in isolation and is often associated with adverse genetic abnormalities: del(11q) and del(17p) and unmutated *IGHV* genes. The duplicated region most commonly reported includes the oncogenes *REL* and *MYCN*. Expression of NMYC has been shown to be elevated in the presence of a 2p24 duplication suggesting that this gene may be of significance in disease progression. Other regions targeted by recurrent copy number changes at a low incidence include duplications of 8q24, and deletions of 15q15.1 (4% of cases) and 3p21 (3% of cases), with *c-MYC*, *MGA*, and *SETD2* as candidate genes, respectively [30, 32].

Structural Chromosomal Rearrangements

Translocations involving the immunoglobulin gene loci are rare in CLL (<5%) and result in juxtaposition of a number of recurring partner genes to the transcriptional control of the immunoglobulin locus. The most common partner genes are *BCL2* (18q22) and *BCL3* (19q13) and more rarely *BCL11A* (2p15), *CCND3* (6p21), *CMYC* (8q24), and *CCND1* (11q13). The t(14;19)(q32;q13) is usually associated with trisomy 12 and most patients have atypical lymphocyte morphology, an atypical immunophenotype, and unmutated IGHV genes. The clinical course is usually progressive and the response to standard chemotherapy is poor. The t(11;14) translocation has been described as a rare secondary aberration in patients relapsing after therapy [64]. The clinical importance of the t(14;18) is uncertain, and it occurs as a primary or secondary event, commonly concomitant trisomy 12. The t(2;14)(p16;q32) is extremely rare and is associated with atypical morphology, immunophenotype, and bulky disease [67]. Translocations involving *CMYC* and a variety of partners including the immunoglobulin gene loci are associated with increased prolymphocytes, complex cytogenetic abnormalities, and a poor prognosis.

Patterns and Mechanisms of Genomic Complexity

Growing evidence suggests that the presence of genomic complexity [5, 65], defined by the presence of increased numbers of chromosomal lesions, can predict short overall survival [5, 65], independent of the presence of 17p deletions [66]. Indeed, interest has recently refocused on the presence of karyotypic complexity, defined by chromosomal banding analysis, as it represents a powerful independent predictor of poor response to the kinase inhibitor, ibrutinib [68].

As genomic complexity is often observed in patients with *ATM* and *TP53* gene lesion [69], it may be that these defects allow telomeres to shorten below the length at which apoptosis or senescence is normally triggered, thus leading to further telomere attrition and accumulation of short telomeres [70, 71], enabling uncapped telomeres to fuse, resulting in genomic instability. While DNA damage can be accumulated over time, high levels of DNA damage can also be acquired rapidly. One example is chromothripsis, a catastrophic process involving genome shattering that occurs during a single mitotic cycle resulting in a pattern of oscillating DNA copy number changes along a single chromosome, or a few chromosomes [67]. The frequency of chromothripsis is approximately 3–5% of human cancers, was first identified in a CLL patient [30, 67], and is the result of a partitioned chromosome(s) in a micronucleus that becomes damaged and is reintegrated into the daughter nuclei [72, 73]. Chromothripsis occurs preferentially in patients with unmutated *IGHV* genes and high-risk genomic aberrations [30], such as mutations in *TP53*, suggesting that a defective DNA damage response is critical to the process of chromothripsis, or the tolerance of the genomic damage [74]. While patients with chromothripsis exhibit both inferior OS and PFS, it is unclear if this is independent of the aforementioned poor-risk genomic lesions [30]. The acquisition of multiple single-nucleotide variants can also occur in a single mitotic explosion, termed kataegis [75], and has also been observed in the genome of CLL patients. This process drives cytosine-specific mutagenesis, often in regions flanking sites of genomic rearrangement, and can result in up to several thousand base-pair substitutions occurring rapidly [76].

In CLL, the biological and clinical importance of telomere structure has been well studied. Telomeres cap the ends of chromosomes, playing a crucial role in the maintenance of genomic integrity. Telomere length is a critical determining factor of telomere function, with critically eroded telomeres being subjected to aberrant DNA repair leading to telomere fusion and genomic instability. The presence of shortened telomere length (TL) is associated with poor clinical survival when assessed by a variety of techniques, as with terminal restriction fragment analysis, FISH-based approaches, and quantitative PCR, with a strong association between short TL and unmutated *IGHV* status [77–81]. The application of STELA (single telomere length analysis) to detect very short telomeres showed that shortening TL in CLL patients can result in loss of their end capping function and make them subject to telomere fusion [82]. Clinically, the acute telomere attrition can precede disease progression, providing further evidence that TL in asymptomatic disease may have powerful predictive value [83].

The Mutational Landscape of CLL

NGS technology has permitted the interrogation of the entire cancer genome for sequence changes at base-pair resolution. WGS and WES data has been collected on more than a thousand CLL patients [17, 18, 33, 34, 36, 38, 42, 84, 85]. However, papers from Landau et al. [17] and Puente et al. [38] published in 2015 provide the most comprehensive and current depiction of the mutational landscape of CLL. Based on the six possible base substitutions and information on the bases immediately 3′ and 5′ to the mutated base, 30 distinct mutational signatures have been identified across all cancer types [76]. Five different signatures have been recognized in CLL. Two (signatures 1 and 5) show a correlation between the number of mutations and increasing age, while two (signatures 2 and 13) have been attributed to activation of AID/POBEC cytidine deaminases. Signature 9 is confined to B-cell tumors that have undergone somatic hypermutation of variable region immunoglobulin genes and is attributed to DNA polymerase η-mediated repair of AID-induced lesions [76, 86]. Understanding underlying mutational mechanisms has clear clinical utility. Modifying the age-related mutational signatures may delay cancer initiation. Furthermore, the recognition of key signatures in asymptomatic patients may facilitate early diagnosis or quantify genotoxic exposure levels.

CLL cases have a median of 0.6–0.87 mutations per megabase (Mb) of genomic DNA which is low compared to solid tumors. Landau et al. and Puente et al. identified an average of 15.3 and 26.9 somatic mutations per patient, respectively [18, 38]. There is a level of discordance between the recurrently mutated genes identified by these two studies. These discrepancies probably reflect the relatively small cohort size and therefore consequent statistical power to identify rare mutated cancer genes, but may also be attributable to the different cohort composition, sequencing platforms, and bioinformatics pipelines used. For example, 22 recurrently mutated genes were implicated in both studies (including *BIRC3*, *CHD2*, *XPO1*, and *EGR2*), while genes only identified by a single study include *SETD2*, *ARID1A*, *NFKBIE* [38], *KRAS*, and *SAMHD1* [17]. While these two studies and indeed a plethora of others have failed to identify a unifying mutation in all patients, and it is unlikely that such a mutation exists at the genomic level, four genes are recurrently mutated at relatively high frequencies across multiple studies. In addition to the aforementioned genes, *TP53* and *ATM*, the other prevalent mutated genes are *NOTCH1* and *SF3B1* (Fig. 8.2). In addition, a glut of additional mutated genes occur at a frequency of approx. 5%, and lead to the dysfunction of eight key cellular processes: (1) cell cycle regulation, (2) DNA damage response, (3) apoptosis, (4) NOTCH1 signaling, (5) RNA metabolism, (6) NF-kB signaling, (7) chromatin remodeling, and (8) BCR signaling (54) (Tables 8.2 and 8.3, Fig. 8.3). These mutations can be present in the entire cancer cell population (clonal) or found in only a small "subclonal" population of cells. Deep sequencing approaches can detect low-level subclonal mutations present in as little as 0.3% of cancer cells [61] beyond the resolution of standard Sanger sequencing [89].

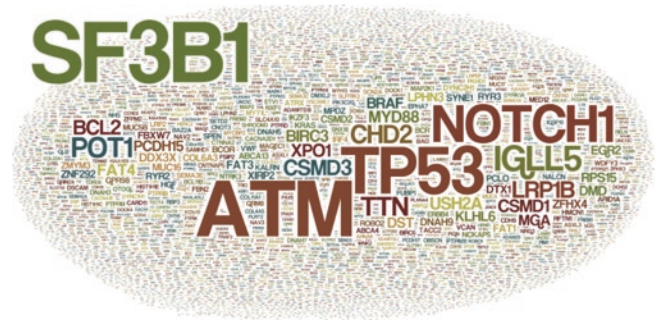

Fig. 8.2 Recurrently mutated cancer genes identified in CLL. This word cloud represents the presence and prevalence of gene mutations in CLL, where the font size represents the mutational frequency of a given gene. The mutation data was obtained from the Sanger Institute Catalogue of Somatic Mutations in Cancer web site, http://cancer.sanger.ac.uk/cosmic [87], with permission

Mutations of *NOTCH1* and Associated Proteins

In CLL, the importance of Notch signaling is well established where activation confers apoptosis resistance and cell survival in CLL cells [90] and Notch1-signaling inhibitors, such as γ-secretase inhibitors, accelerate B-CLL cell apoptosis by proteasome inhibition and endoplasmic reticulum stress enhancement [91]. The role that gene mutations play in activating Notch signaling and mutations was first described in a small cohort of 43 patients, where 2 patients (4.6%) harbored a heterozygous 2 bp frame-shift deletion (ΔCT7544–7545, P2515Rfs*4) within the PEST domain of *NOTCH1* [35]. The Spanish CLL Genome Consortium confirmed these early observations and demonstrated that this variant creates a premature stop codon, the removal of the PEST sequence from C-terminal protein domain that ultimately results in the accumulation of an active Notch1 isoform in tumor cells [42]. Subsequent studies show that mutations across exon 34 of *NOTCH1* [33, 34, 36, 42], and even within the 3′ UTR of the gene, where noncoding mutations create aberrant splicing events, result in the loss of the *NOTCH1* PEST domain, and consequent constitutive Notch1 activation [38]. *NOTCH1* mutations associate with unmutated *IGHV* CLL, expression of CD38 and ZAP-70, the presence of trisomy 12, short telomeres, and increased prevalence of prolymphocytes [81, 92, 93]. Mutation frequency varies enormously based on the stage of the disease analyzed, ranging from 3% in MBL and 6–10% at CLL diagnosis to >20%

[a]Frequency in those patients with large 13q deletions which include the *RB1* locus. Defined as "type II" deletions [55]

of patients with alkylating agent or purine analogue-refractory disease [33, 94]. An additional 3% of CLL patients harbor the noncoding 3′UTR mutation [38, 62, 95]. Patients with a mutant *NOTCH1* have inferior survival compared to wild-type patients, compared to 11q deleted patients [16, 92]. The mutational frequency of *NOTCH1* is higher in CLL lymph nodes than in matched peripheral CLL B-cells (24%) and the Notch pathway is frequently activated in lymph node cases independently of *NOTCH1* mutational status, suggesting the existence of other initiating mechanisms, such as ligand activation [96]. Functionally, microenvironmental interactions appear to be required for Notch activation in mutated cases, where these interactions foster conditions that may favor drug resistance [97], but may be overcome with the use of γ-secretase inhibitors, particularly in combination with fludarabine [98]. Mutations in other Notch signaling

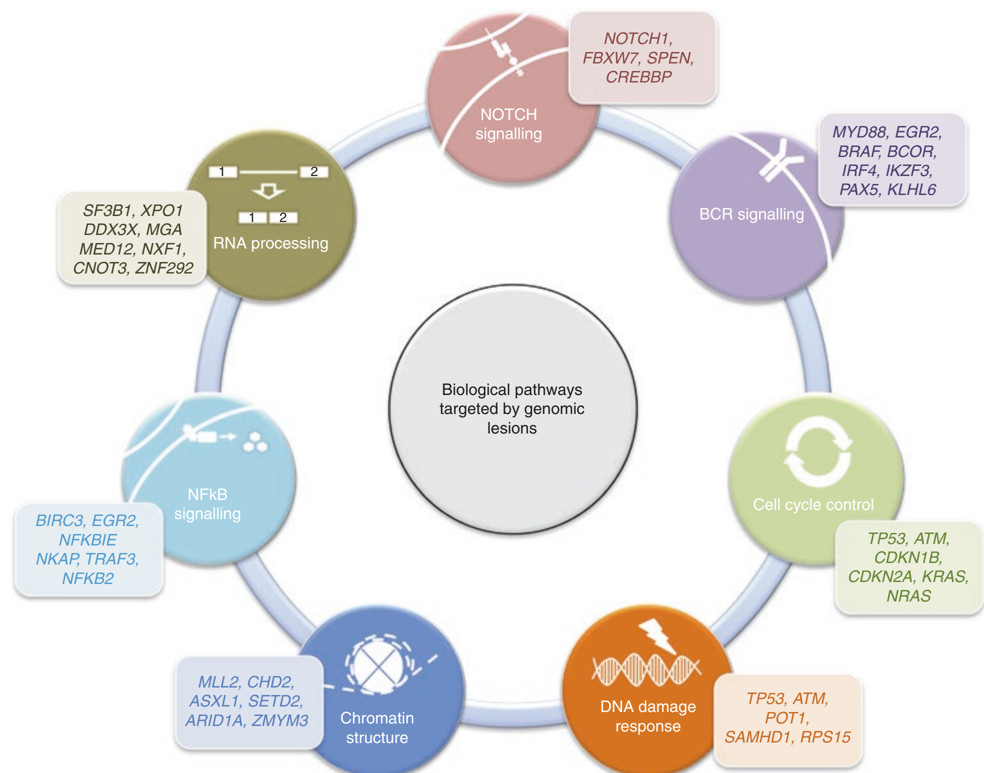

Fig. 8.3 The biological pathways deregulated in CLL by somatic gene mutations. The key biologically relevant genes recurrently mutated in CLL, and the pathways and processes to which they contribute. Genes with functional diversity are represented in the pathway to which they most significantly contribute

proteins have been identified in CLL. For example, *FBXW7*, which targets activated *NOTCH1* for degradation, is mutated in ~2.5% of patients and may provide another mechanism for activated Notch signaling [99].

SF3B1 Mutations and RNA Processing

SF3B1, an important component of the RNA splicing machinery that achieves successful transcription and guarantees the functional diversity of protein species using alternative splicing, is recurrently mutated in CLL but not in other chronic B-cell lymphoproliferative neoplasms [34, 36, 85]. 5–17% of CLL patients harbor *SF3B1* mutations where they are associated with advanced clinical stage, 11q23 deletions, presence of stereotyped IGHV usage (subset #2), and fludarabine-refractory disease in cases with no *TP53* abnormality. Furthermore, they predict reduced TFTT and OS independent of other prognostic variables [34, 36, 85, 99–101].

Using targeted and global experimental approaches, early studies showed that *SF3B1* mutations result in aberrant splicing [34, 36] that is driven by the use of a different branch point sequence in mutant *SF3B1* patients [102]. Initial studies identified a highly expressed truncated *FOXP1* transcript, *FOXP1w* in *SF3B1*-mutated CLL, that lacks two putative PEST domain sequences involved in protein degradation [34]. A subsequent RNA-Seq study implicated an aberrant spliced *ATM* transcript [103] and it is now evident that *SF3B1* mutations may impact DNA damage response [104]. Aberrant splicing of genes involved in B-cell differentiation, Hippo signaling, and NF-κB activation has also been implicated in *SF3B1*-mutated CLL [103]. The identification of mutations within the spliceosome complexes raises the possibility that CLL tumor cells may be sensitive to spliceosome inhibitors. Indeed, *SF3B1* mutations confer sensitivity to the splicing modulator sudemycin, promoting an anti-tumor effect with the BTK inhibitor, ibrutinib [105], and the SF3B1 inhibitor spliceostatin A induces cell death in CLL cells through Mcl-1 downregulation, most markedly in combination with Bcl-2/Bcl-XL antagonists [106].

Another gene involved in RNA processing has also been implicated in CLL pathogenesis, *XPO1*, which encodes the nuclear exporter, Exportin-1, responsible for controlling the directional movement of 100 s proteins and RNA species from the nucleus to the cytoplasm. 4.6% of *IGHV*-unmutated CLL cases harbor somatic mutations in *XPO1* [42], and cause increased Exportin-1 levels in tumor cells, and consequent externalization of key TSP, compromising a cell's ability to respond to DNA damage [107]. Inhibitors of XPO1 may restore apoptotic pathways and chemosensitivity in CLL cells by facilitating nuclear export of key proteins [107, 108].

Other Mutations

Other recurrently mutated genes have emerged, and are continuing to emerge, from high-throughput sequencing projects, albeit at low frequencies (Tables 8.2 and 8.3) [18, 36, 42].

As previously noted, these genes often act within key biological pathways (Fig. 8.3) [18, 34, 36]. Some of the most established are outlined below:

1. **NFKB Signaling**. Recurrently mutated genes have been identified in both the canonical and noncanonical NFκB signaling pathways, where they can result in activation signaling [37, 56, 109, 110]. In addition to aforementioned involvement of the *BIRC3* gene, up to 10% of CLL cases have mutations targeting *NFKBIE*, which encodes NFκB inhibitor epsilon (IKBE). Cellular studies show reduced IKBE expression in mutant cases, decreased IKBE-p65 interactions and increased nuclear p65 levels, and constitutive NFκB activity [110].
2. **B-cell Receptor Signaling.** *MYD88*, a crucial adaptor of the Toll-like receptor (TLR) complex, is mutated in approx. 5% of CLL cases, occurring exclusively in patients with mutated *IGHV* genes. Upon TLR ligand binding, a homodimer of MYD88 is recruited to the receptor, forms a complex with IRAK4, activates IRAK1 and 2, and ultimately leads to TRAF6 activation, phosphorylation of IκBα, and activation of NF-κB [111]. In CLL, the L265P mutation provides constitutive activation of NF-κB activity, by imposing MYD88-IRAK signaling even when ligand receptor binding is absent [42]. However, the clinical impact of MYD88 mutations remains controversial, as conclusive evidence demonstrating independent prognostic significance is lacking [112, 113]. The transcription factor, *EGR2*, is activated by B-cell stimulation and also mutated in 8% of advanced-stage CLL. *BRAF* mutations have a postulated role in fludarabine sensitivity and are associated with reduced time to first treatment [37, 38, 114].
3. **Cell cycle, Apoptosis, DNA Damage.** In addition to the well-studied involvement of the *TP53* and *ATM* loci, other genes with a role in these processes have been recently implicated. *RPS15,* which encodes a component of the 40S ribosomal subunit, is mutated in 20% of CLL patients relapsing post-chemo-immunotherapy [39]. *RPS15* mutations are early clonal events, associated with reduced survival, the functional consequences of which are defective p53 stability and increased degradation [39]. Mutations in the nuclease *SAMHD1* are reported in 3% of patients at diagnosis and are enriched in therapy-refractory patients [43]. Preliminary data suggests that mutations may promote tumorigenesis by deregulation of DNA repair [43]. *POT1*, a component of the shelterin complex, plays a critical role in the protection of telomeres. At diagnosis, mutations occur in approx. 3% of patients [84, 115] rising to 8.1% in patients receiving chlorambucil-based therapy, where they are associated with a shorter survival [46]. In *POT1*-mutated cell lines, chromosomes become fragile, with numerous telomeric and structural aberrations implicating these mutations in promoting genomic instability [84]; this association is not supported by the study of primary CLL tumors [115].
4. **Chromatin Modifiers.** *CHD2*, a chromatin modifier, is mutated in 5.3% of patients, principally in *IGHV*-mutated tumors. Mutations are principally truncating or target functional domains and functional experiments demonstrate alteration of the nuclear distribution of *CHD2* and protein association with actively transcribed genes in mutated patients [116]. Histone methyltransferases (HMTs) are essential epigenetic regulators of chromatin modification and recurrent mutations targeting such genes have only recently been documented in CLL [38]. *SETD2*, the histone methyltransferase non-redundantly responsible for the trimethylation of lysine 36 on histone 3 (H3K36me3), is mutated in up to 4% of patients, and likely to be an early loss-of-function event associated with aggressive disease [32].
5. **Noncoding mutations.** In addition to the aforementioned *NOTCH1* 3′UTR mutations, a second recurrent noncoding mutation has been reported, resulting in deregulation of *PAX5*. In CLL, mutations located within a telomeric enhancer element, 330Kb from the *PAX5* locus, result in reduced *PAX5* expression, and were the only recurrent mutation in a subset of IGHV-unmutated CLL patients, suggesting that these mutations may contribute to disease pathophysiology [38].

Clonal Evolution

Historically, we often consider genomic heterogeneity to exist between patients (inter-tumor), in part explaining the biological and clinical variability that exists between individuals with the same disease. However, it is evident that considerable "intra-tumoral" heterogeneity also exists, such that a tumor can contain many genetically and biologically unique subclonal populations of cancer cells. This cellular plasticity is a prerequisite for Darwinian selection that ultimately selects cellular populations with favorable biological traits, driven by the pressure of therapy and even the tumor microenvironment. In CLL, researchers working with FISH and SNP arrays have long observed the acquisition of genomic aberrations during disease course, with the suggestion that the diagnostic and relapse disease can be genetically distinct [117–120]. However, it has been the application of NGS to temporally and even anatomically discrete cancer specimens from the same CLL patient that has conclusively revealed the composition of clonal expansion [121]. Clonal evolution can occur quickly, or over a more protracted period of time, and follows two simple evolutionary models [122]. Firstly, tumor evolution can develop in a linear fashion, with the maintenance of a founder clone with successive acquisition of new mutations. Secondly, competition between different cancer subclones can persist, resulting in a more

complex branching anatomy. In the context of a branching evolution, convergence can occur, where independent mutations in the same genes can be acquired in different subclones [123].

Landau and coauthors [18] showed that passenger events accumulate before the acquisition of recurrent driver mutations (e.g., del(13q), tri12, and *MYD88* mutations) with subsequent malignant initiation. During CLL progression, later subclonal driver mutations target cancer genes like *ATM*, *TP53*, and *RAS* and undergo clonal expansion. The authors also showed an elevated prevalence of clonal evolution in treated patients, and linked the presence of subclones to adverse survival [18]. Subsequent studies demonstrated genomic heterogeneity between different anatomical compartments with mutations expanding in the lymph node and repopulating the peripheral blood compartment at relapse following positive selection by therapy [122, 124, 125]. Rose-Zerilli et al. reported a CLL patient whom at diagnosis presented with mutated immunoglobulin genes, but who developed a fatal *IGHV*-unmutated CLL clone years later, not evident at diagnosis with traditional molecular approaches, but detectable with modern NGS approaches. These observations have important clinical implications and support a model in which low-level subclonal mutations present in early-stage disease can anticipate the evolutionary course of the disease [17].

Epigenetic Abnormalities

There is increasing evidence that epigenetic abnormalities are both frequent and important in the initiation and progression of human malignancies, including CLL. Epigenetic mechanisms that are deregulated in cancer include changes to higher order chromatin structure, such as histone modifications, and DNA methylation, both of which are crucial layers of epigenetic programming that regulates gene transcription and genome stability, and contribute to normal B-cell development. DNA methylation, which occurs predominantly at the cytosine residue of CpG dinucleotides, is the most well-studied epigenetic mechanism in CLL [19, 20, 126, 127]. Candidate gene approaches identified differential methylation at promoters and CpG islands of genes including *DAPK1*, TCL1, *ZAP70*, *HoxA4, TWIST2*, as well as CLL-associated microRNAs and long intervening noncoding RNAs [128, 129]. Although DNA methylation and gene expression are frequently poorly correlated, a strong association was noted between the methylation status of *ZAP70*. The methylation status of a single ZAP70 CpG site was subsequently shown to have prognostic significance [130, 131].

New insights have emerged from global methylation profiling of normal B-cell subsets and large CLL cohorts, using both methylation arrays and whole-genome bisulfite sequencing [19, 20, 126, 132]. Normal B-cell maturation from naive to memory B-cells is accompanied by prominent hypomethylation, especially of enhancer and promoter regions and gene bodies together with hypermethylation in regions of transcriptional elongation [20, 132]. The methylation profile of CLL closely recapitulates that seen in normal B cells, such that IGHV-mutated and unmutated CLL maintain the epigenetic signature of memory B-cells (MBC) and naive B-cells (NBC), respectively. Interestingly, both studies identified a third epigenetic CLL subgroup with an intermediate methylation signature enriched for M-CLL with fewer somatic IGHV mutations [126]. These three CLL epitypes exhibit different clinico-biological features, with the MBC-like CLL cases exhibiting a more indolent clinical course. As a result of these studies, an assay has been developed to assess the methylation status of 5 CpG dinucleotides that can identify these three prognostically relevant groups in a simple manner [127].

Despite the similarity of CLL methylation signatures to their likely cells of origin, aberrant methylation is also observed, for example in the binding sites for key transcription factor families [20]. The mechanisms underlying aberrant methylation and its importance in the pathogenesis of CLL are under investigation. Although initial observations showed that global DNA methylation tends to remain temporally stable in sequential tumor samples [133], more recent studies have identified intra-tumor epigenetic heterogeneity. This is associated with subclonal genomic heterogeneity and an adverse outcome [19, 126].

Genetic Predisposition to CLL

Epidemiological surveys have shown that CLL has one of the highest familial risks of any cancer, with an 8.5-fold increased risk among first-degree relatives for developing CLL and a 1.9-fold risk for other B-cell chronic lymphoproliferative disorders, especially lymphoplasmacytic lymphoma and hairy cell leukemia [134, 135]. Genome-wide association studies undertaken in over 5000 patients with CLL and 12,000 controls have identified over 30 loci associated with increased susceptibility to CLL [136–140]. The susceptibility to CLL associated with each variant single-nucleotide polymorphism (SNP) is low, but increases if multiple risk variants are co-inherited. Most SNPs map to noncoding regions of the genome, frequently close to or within genes involved in apoptosis, B-cell differentiation, or telomere function suggesting that they may act by influencing the expression of these genes. This mechanism was recently confirmed at the susceptibility locus located at 15q15.1. A SNP (rs539846) within this locus maps to a super-enhancer in intron 3 of the B-cell lymphoma 2 modifying factor gene (*BMF*), a pro-apoptotic BH3 protein which binds to, and neutralizes, the anti-apoptotic protein BCL2. The rs539846 risk allele modifies a transcription binding site

for the transcription factor RELA, reducing BMF expression and potentially attenuating the apoptotic response [141].

Although the somatically acquired genomic mutations associated with sporadic CLL have rarely been implicated in genetic susceptibility to CLL, inactivating germline mutations in shelterin genes, especially POT1, critical for telomere function, have recently been discovered in CLL patients with strong family histories of CLL, consistent with the GWAS data. The authors estimated that 11% of familial CLL may be ascribed to mutations in this class of genes [142].

The Molecular Pathogenesis of Richter's Syndrome

Richter's syndrome (RS) denotes the histological diagnosis of either diffuse large B-cell lymphoma (DLBCL) or more rarely Hodgkin's lymphoma in a patient known to have CLL. In most cases the lymphoma is clonally related to the CLL but clonally unrelated lymphomas are also well documented. Preliminary investigations into the molecular mechanism of transformation to clonally related DLBCL have been performed [143, 144], but considerably less is currently known about the transformation process of other clonally related lymphoma subtypes or in patients who transform to clonally unrelated DLBCL.

In clonally related transformed DLBCL, the BCR is likely to play an important role in the transformation process, as clonally related DLBCL cases show remarkable bias in BCR usage, with enrichment of stereotyped "subset 8" cases (Fig. 8.4). This suggests that a restricted panel of antigenic epitopes are important in the transformation process. Deletions and/or mutations of the TP53 genes are the most prevalent genetic lesions found in clonally related DLBCL, identified in approx. 60% of cases [143]. The chemo-refractory phenotype that predominates in this disease is likely to be determined by loss of *TP53* function, and the resultant loss of cell cycle control that mediates resistance to chemotherapeutic agents. Approximately 40% of cases with clonally related DLBCL transformation show evidence of *MYC* aberrations, often acquired at transformation [143, 144]. In 30% of cases, *MYC* is targeted by structural rearrangements, including juxtaposition of *MYC* to the *IGHV* locus, genomic gain of 8q24, or activating point mutations [143]. Mutually exclusive to *MYC* abnormalities are activating mutations within the PEST domain of *NOTCH1* occurring in approximately 30% of cases, resulting in constitutively activated Notch signaling. While rare in diagnostic CLL cohorts, *CDKN2A* deletions can be identified in 30% of DLBCL transformed patients, and are likely to emerge in the tumor clone at transformation [143, 144].

Risk factors for the acquisition of a clonally related DLCBL principally focus on CLL cases with "subset 8" IGHV usage [145], who have a very high risk of transformation, approximately 80% at 10 years, and those that harbor a *NOTCH1* mutation; *NOTCH1*-mutated CLL cases have a cumulative probability of Richter transformation of 45% (compared to 4% for wild-type *NOTCH1* cases) [146]. Post-transformation, patients lacking TP53 lesions display more

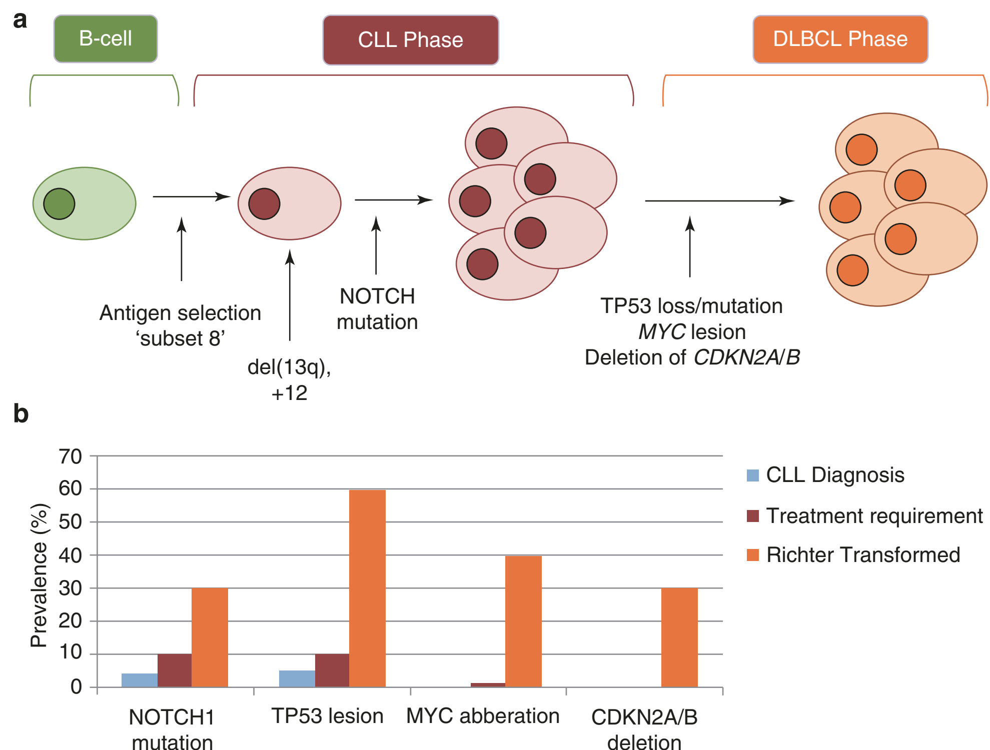

Fig. 8.4 The molecular pathogenesis of Richter's syndrome. (**a**) shows the accumulation of genomic lesions through the process of CLL development, progression, and transformation. (**b**) shows the prevalence of key genomic aberrations through the process of CLL development, progression, and transformation that are causally implicated in Richter transformation

favorable outcome than TP53-deleted or -mutated cases [147]. The changing therapeutic landscape for CLL will likely mold the epidemiology of transformation, as the non-genotoxic nature of modern treatment modalities will exert a different selective pressure on the tumor clone. Given the high prevalence of *TP53* lesions in transformed DLBCL, the prediction is that fewer *TP53*-driven transformation events will occur. However, it will be important to study transformation mechanisms in the context of new therapies, as clonal selection will sculpture the molecular mechanisms of transformation. Using targeted therapeutics against the molecular pathways that are disrupted in transformed CLL may show promise in the management of these tumors, such as the BCR, gamma secretase, bromodomain and cyclin-dependent kinase inhibitors, and novel compounds gaining traction for the management of aggressive lymphoma, such as immune checkpoint and XPO1 inhibitors.

Genomic Abnormalities in Clinical Practice

Genomic abnormalities are one of an increasing number of biomarkers that have clinical relevance in the management of patients with CLL. Although the diagnosis of CLL is based on immunophenotypic and morphological criteria, genomic abnormalities have both prognostic value in calculating the natural history of CLL patients and predictive value in determining the response to therapy. Furthermore, genomic screening can identify mechanisms of drug resistance and finally genomic abnormalities may act as therapeutic targets. Table 8.4 lists examples of the genomic abnormalities reported to have adverse prognostic significance in CLL in either large patient cohorts or clinical trials.

Predicting Natural History

Over 80% of CLL patients are asymptomatic at diagnosis and have a low tumor burden. Precisely identifying those likely to progress has the potential to inform patients and their families, and influence the need for and timing of follow-up and the timing and selection of optimal treatment. Following the recognition that individual copy number abnormalities, genomic mutations, and genomic complexity could influence both time to first treatment (TTFT) and overall survival when measured at or close to diagnosis, a variety of models have been developed which encompass the most frequent genomic abnormalities alone or in combination with other biomarkers.

A large study by Davide Rossi and colleagues has proposed a prognostic algorithm for overall survival through the integration of gene mutations and chromosomal abnormalities [16]. The authors analyzed CLL patients for FISH abnormalities and sequence mutations and offered four

Time to first treatment (TTFT), progression-free (PFS) and overall survival

risk classifications: (1) high-risk patients with either *TP53* defects and/or *BIRC3* disruption; (2) intermediate-risk, harboring *NOTCH1* and/or *SF3B1* mutations and/or del(11q); (3) low-risk, harboring trisomy 12 or a normal profile; and perhaps most importantly (4) a very-low-risk group with del(13q) only, whose survival did not differ from that of a matched general population. This model added significantly to the "Döhner" model [157], due to the coexistence of poor-risk gene mutations in low-risk groups defined purely based on FISH and retained prognostic significance over time regardless of clonal evolution. However subsequent similar large studies which also used TTFT as an endpoint have failed to completely replicate these findings, highlighting the difficulty of developing models that are sufficiently precise for routine use and the need for even larger, well-designed prospective studies [99, 112].

A recently introduced international prognostic index (CLL-IPI) performed multivariate analysis of 27 clinical and biological factors including 13q, 11q, 6q, and 17p loss; trisomy 12; and mutations of *TP53*, *SF3B1*, and *NOTCH1* on a large cohort of patients predominantly entered into first-line chemotherapy or chemo-immunotherapy trials. Five prognostic factors were identified: *TP53* status, *IGHV* mutational status, serum B2 microglobulin, clinical stage, and age, from which a prognostic index was derived identifying four risk groups with different overall survivals [158]. The CLL-IPI has subsequently been shown to predict TTFT in early-stage CLL [159].

Predicting Outcome Following Treatment

TP53 abnormalities. As outlined earlier in this chapter, copy number abnormalities such as del(11q) and deletion of *SETD2* and genomic mutations of *SF3B2, NOTCH1, BIRC3, SAMHD1*, *RPS15*, and *EGR2* appear to influence the outcome of patients receiving chemotherapy or chemo-immunotherapy. However the effect is either modest or has not been evaluated in multivariate analyses of large clinical trials. As a consequence the only genomic abnormalities that determine the choice of therapy in routine clinical practice are deletion and/or mutation of *TP53*, and current guidelines recommend screening for TP53 abnormalities prior to first-line and relapse therapy. Their presence is unequivocally linked to a dismal response to standard chemo-immunotherapy and is an indication for novel agents such as signaling inhibitors or pro-apoptotic BH3 mimetics acting through TP53-independant mechanisms. Conversely the absence of del(17p) or del(11q) in patients with mutated *IGHV* genes identifies patients with long overall survival following standard chemo-immunotherapy for fit patients (FCR) [160].

Although evidence for the predictive value of *TP53* abnormalities is overwhelming, the outcome of patients with these abnormalities is not uniform and is influenced by coexisting genomic abnormalities, immunogenetic status, and treatment type. As previously mentioned, it is well recognized that a small subset of early-stage patients with TP53 abnormalities may pursue a stable clinical course [161]. A more recent study of 69 patients with >10% TP53 loss using WES and SNP arrays to detect genomic mutations and CNAs, respectively, showed that the poorest outcomes were associated with bi-allelic TP53 abnormalities; clonal TP53 mutations; deletions of 3p, 4p, or 8p; and genomic complexity. Conversely cases that remained untreated for 5 years were enriched for mutated IGHV genes, subclonal or no TP53 mutations, and fewer CNAs [59]. Similarly, Guieze et al. noted that the poorest outcome of patients who received salvage therapy, having failed to respond to or relapsing after chemo-immunotherapy, had mutations of *TP53, ATM*, and *SF3B1* [162].

The impact of *TP53* abnormalities on treatments that act through *TP53*-independent mechanisms is mixed. *TP53* status does not influence the outcome of patients receiving an allogeneic stem cell transplant whereas the efficacy of ibrutinib in patients with a *TP53* abnormality is much greater than chemo-immunotherapy but inferior to *TP53* wild-type cases. This implies that *TP53* abnormalities may have an indirect effect on facilitating ibrutinib resistance possibly related to increased genomic instability.

NOTCH1 mutations. An interesting observation that emerged from genomic analysis of the German Study Group CLL8 trial was that the outcome of patients in the chemo-immunotherapy arm (FCR) was superior to those in the chemotherapy arm (FC) apart from those with *NOTCH1* mutations [153]. A similar phenomenon was observed in a trial of chlorambucil with or without the anti-CD20 antibody, ofatumumab, suggesting that NOTCH1 mutations may be a predictive factor for reduced benefit from chemotherapy and anti-CD20 antibody combinations [163].

Identifying Resistance Mechanisms

TP53 abnormalities account for primary or acquired resistance to chemotherapy-containing regimens in at least 50% of cases, reflecting the importance of an intact DNA damage response pathway for the activity of these agents. Unsurprisingly acquired resistance is encountered in a variety of hematological malignancies treated with signaling inhibitors or BH3 mimetics, and in CLL the mechanisms of resistance to ibrutinib have been partially elucidated. Whole exomic sequencing of tumor samples from six patients who relapsed during ibrutinib therapy identified a cysteine-to-serine mutation (C451S) in Bruton's tyrosine kinase (BTK). This reduced the binding affinity of ibrutinib for BTK, resulting in only transient, rather than the usual irreversible,

inhibition of *BTK*. In addition three distinct gain-of-function mutations in *PLCG2*, the kinase immediately downstream of BTK, were found in two patients [164, 165]. A subsequent study used whole exomic and deep sequencing in serial samples from five patients who relapsed after an initial partial response to ibrutinib. At relapse, one patient had a *BTK* C4815 mutation and one had multiple *PLCG2* mutations. The remaining three cases showed expansion of a preexisting clone harboring del(8p) with additional driver mutations. Deletion of 8p resulted in halpoinsufficiency of the TRAIL receptor and the authors provided functional data to suggest that this may be a resistance mechanism [166].

A key question is whether *BTK* and *PLCG2* mutations can also be detected either prior to BTK administration or during BTK therapy before clinical relapse and therefore act as a predictive marker. Although computational analysis indicates that very small *BTK* mutant clones are present pretreatment, these have not been identified in deep sequencing studies [166, 167].

Summary

Since the previous edition of this book, our understanding of the CLL genome has been transformed by modern technology. New driver mutations have been discovered and it can be safely predicted that all clonal and subclonal genomic abnormalities that impact the survival and proliferation of tumor cells in at least 1% of CLL cases will be identified. It can also be anticipated that single platforms that robustly and affordably identify all common drivers will become available. Furthermore, mechanisms underlying genomic instability and phenotypic consequences of both single and multiple genomic abnormalities and their interaction with environmental factors are becoming increasingly understood.

These advances coincide with a revolution in treatment of CLL brought about by the introduction of novel small molecules and immune therapies which are highly effective, frequently easier to administer, and better tolerated than previous chemotherapy regimens. Importantly, the treatments that target key signaling and apoptosis pathways retain activity in cases that acquire the common genomic abnormalities including those affecting DNA repair.

Given the trend towards precision medicine, it is pertinent to ask what impact genomic advances might have in an era of increasingly effective therapies. It is probable that the genomic basis of familial CLL will be sufficiently understood to justify screening of high-risk individuals. The presence of key genomic lesions may have utility for the differential diagnosis of mature B-cell malignancies in general. It is also highly likely that screening for genomic abnormalities will contribute further to the recognition of early-stage patients at risk of disease progression who might benefit from early therapy prior to clonal evolution and expansion. It remains to be seen whether combinations of highly active agents targeting different pathways will be curative regardless of the genomic landscape, but should resistant clones emerge, then next-generation sequencing will be instrumental in determining resistance mechanisms and the choice of alternative therapies.

Acknowledgments Jonathan Strefford, Renata Walewska, and David Oscier wrote the chapter. This work was funded by Bloodwise (11052, 12036), Cancer Research UK (C34999/A18087, ECMC C24563/A15581), and the Kay Kendall Leukaemia Fund (873).

9 Treatment of Chronic Lymphocytic Leukemia and Related Disorders

Deepa Jeyakumar and Susan O'Brien

Burden of CLL

According to 2016 SEER data, there will be 18,960 new cases of CLL diagnosed and more than 100,000 people with CLL living in the USA [1]. The median age at diagnosis for chronic lymphocytic leukemia was 71 years and age-adjusted incidence rate was 4.6 per 100,000 men and women per year.

Diagnosis of CLL

The diagnosis requires peripheral blood clonal B lymphocytosis of ≥5 × 10^9/L persisting for at least 3 months [2]. The clonality of the cells needs to be confirmed by flow cytometry-based immunophenotyping demonstrating aberrant expression of the T-cell antigen CD5 along with B-cell antigens CD19, CD20, and CD23, and also by restriction of light-chain expression to either kappa or lambda (Table 9.1). The percentage of prolymphocytes in the peripheral blood may be up to 55%. Any excess of prolymphocytes will favor the diagnosis of B-cell prolymphocytic leukemia (B-PLL). Demonstration of cytopenias along with marrow infiltration by typical CLL cells is adequate for the diagnosis of CLL irrespective of the degree of lymphocytosis.

Small lymphocytic lymphoma (SLL) is a disease restricted to lymph nodes and lymphocytosis of <5 × 10^9/L.

"Monoclonal B lymphocytosis" (MBL) is a disease comprised of clonal B-cell lymphocytosis <5 × 10^9/L in the absence of lymph node involvement, disease-related symptoms, and cytopenias. The prevalence of MBL can be 4–5% [3, 4] among the general population over the age of 40 years. In a prospective study [3], 15% of subjects with MBL and lymphocytosis developed CLL after a median follow-up of 6.7 years. The absolute lymphocyte count correlated with progression to CLL.

Table 9.1 Criteria for diagnosis of CLL

	Working groups: NCIWG/IWCLL [2]
Parameter	
Diagnosis	
Lymphocytes (×10^9/L)	>5; ≥1 B-cell marker (CD19, CD20, CD23) + CD5
Atypical cells (%) (e.g. prolymphocytes)	<55
Duration of lymphocytosis	At least 3 months

NCIWG National Cancer Institute Working Group; *IWCLL* International Workshop on CLL

Table 9.2 Immunophenotypic analysis in chronic B-cell disorders

Disease	Sig	CD5	CD23	FMC7	CD22	CD79b
CLL	Weak	++	++	−/+	Weak/−	Weak/−
B-PLL	Strong	−/+	−	++	+	++
HCL	Strong	−	−	++	++	+
SL VL	Strong	−/+	−/+	++	++	++
FL	Strong	−/+	−/+	++	++	++
MCL	Strong	++	−/+	++	++	++

CLL chronic lymphocytic leukemia, *B-PLL* B-cell prolymphocytic leukemia

Modified from Matutes E, Owusu-Ankomah K, Morilla R, et al. The immunological profile of B-cell disorders and proposal of a scoring system for the diagnosis of CLL. Leukemia. 1994;8:1640–5

The differential diagnosis of CLL includes several other B-cell disorders. Flow cytometric analysis is critical for differentiating between CLL and other B-cell disorders (Table 9.2). A flow cytometry-based scoring system has been useful in situations where the diagnosis is not straightforward [5].

Clinical Features

At diagnosis, most patients are older than 70 years, with more than 95% over 45 years. The diagnosis of CLL is often incidental; routine blood counts may reveal an elevated absolute

lymphocyte count (ALC). In symptomatic patients, fatigue and infections may be presenting features; B symptoms are rare. A smaller percentage of patients may present with autoimmune hemolytic anemia (AIHA) or autoimmune thrombocytopenia (AIT). Physical examination may reveal cervical, axillary, and/or inguinal lymphadenopathy. Splenomegaly is not uncommon. The majority of patients with CLL will develop hypogammaglobulinemia in their disease course [6, 7]; impaired cellular immunity is evidenced by lack of response to skin testing with tuberculin, candida, and other antigens. These immune defects predispose patients to recurrent infections [8].

Staging

The well-described staging systems for CLL include those of Rai [9] and Binet [10] staging (Table 9.3). The original Rai staging defined five stages from 0 to 4; this has been modified [11] to three stages by defining Rai stage 0 as low-risk group, stage 1 and 2 together designated as an intermediate-risk group, and joining stage 3 and 4 to form a high-risk group with a median survival of >12.5, 7, and 1.5 years for each risk group, respectively. Similarly in Binet stages A, B, and C median survivals are >10, 6, and 2 years, respectively [10]. Both these clinical staging systems are based on physical examination and routine blood counts and do not require radiological imaging. The value of computed tomography (CT) in early-stage CLL is not established.

Workup at Diagnosis

A physical examination that includes examination of the lymph nodes, routine blood counts, and peripheral blood flow cytometry to establish clonal B-cell lymphocytosis is sufficient to establish the diagnosis of CLL. Though the type of bone marrow infiltration (diffuse vs. nondiffuse) may carry prognostic information, the need for a bone marrow aspiration and biopsy can be replaced by new prognostic markers. FISH is required prior to any line of therapy given that therapy in patients with CLL with del(17p) may differ from first-line therapy for patients with CLL without del(17p).

Prognostic Factors

Clinical Prognostic Factors

In a randomized trial of chlorambucil versus observation in Binet stage A patients [12, 13], a subgroup of patients (designated "A") with hemoglobin ≥12 g/dL, lymphocyte count $<30 \times 10^9$/L, and fewer than 80% lymphocytes in the bone marrow aspirate was identified and had an overall survival (OS) comparable to an age-matched French population. Similarly, a lymphocyte doubling time of >12 months, Rai stage 0 disease, nondiffuse bone marrow pattern, hemoglobin ≥13 g/dL, and absolute lymphocyte count $<30 \times 10^9$/L define a group of "smoldering CLL" with an excellent prognosis [14]. Age and response to treatment are also prognostic factors [15]. Women fare better than men and this is independent of stage and age.

Laboratory Parameters

Several serum factors have been identified as prognostic indicators in early-stage CLL. Among patients with early-stage CLL (Binet stage A, Rai stage 0–2) considered to have "smoldering disease" (blood hemoglobin greater than 13.0 g/dL, a low absolute lymphocyte count (<30,000/μL), a lymphocyte doubling time greater than 12 months, and a nondiffuse pattern of lymphoid bone marrow infiltration [14]), serum thymidine kinase (TK) level >7.0 U/L identifies a group with significantly shorter progression-free survival (PFS) compared to those with lower TK levels [16]. Elevated serum β2-microglobulin level is also an adverse prognostic feature [17]. Serum soluble CD23 segregates Binet stage B disease into more or less aggressive forms [18]. High serum LDH levels indicate a poor prognosis [19]. These parameters appear to be surrogate markers of disease burden or cellular turnover.

Table 9.3 Staging of CLL

Rai stage [9]	Modified Rai stage [11]	Description	Binet stage [10]	Description	Median survival
0	Low risk	Lymphocytosis	A	Two or fewer lymphoid bearing areas	>10 Years
1	Intermediate risk	Lymphocytosis and lymphadenopathy	B	Three or more lymphoid bearing areas	5–7 Years
2	Intermediate risk	Lymphocytosis and splenomegaly with/without lymphadenopathy			
3	High risk	Lymphocytosis and anemia (hemoglobin <11 g/dL)	C	Anemia (hemoglobin <10 g/dL) or thrombocytopenia (platelets 100×10^6/dL)	2–3 Years
4	High risk	Lymphocytosis and thrombocytopenia (platelets $<100 \times 10^6$/dL)			

A series of new prognostic markers have been identified. Testing for these is not needed for the diagnosis of CLL but may help clinicians to have an informed discussion with patients regarding prognosis. As most patients with CLL are diagnosed with early-stage disease, these data aid in predicting the likelihood of disease progression. Also, some (although not all) of the prognostic markers are correlated with response to therapy.

Genetic Studies

Using conventional chromosome banding techniques, cytogenetic abnormalities can be detected in 40–50% of cases of CLL [20]. This technique is hampered by the low mitotic activity of CLL cells; B-cell mitogens may be used to enhance this activity. In addition, metaphases obtained for karyotyping after mitogen stimulation may arise from normal T cells in the sample [21].

Fluorescence in situ hybridization (FISH) using genomic DNA probes has greatly enhanced the ability to detect molecular abnormalities in malignant cells. This technique can detect aberrations in interphase cells. FISH has demonstrated that molecular abnormalities occur in up to 80% of cases of CLL [22].

13q deletion is the most common genetic aberration found in CLL by FISH (55%) followed by 11q deletion (18%), 12q trisomy (16%), and 17p deletion (7%) [22]. Prior to the use of FISH, trisomy 12 was the most frequently detected chromosomal abnormality in CLL by conventional cytogenetic methods. Structural abnormalities of 13q were often missed by Giemsa banding, presumably because of the small size of the deletion. The prognosis of CLL varies with the chromosomal abnormality. When divided into five prognostic categories, 17p deletion, 11q deletion, 12q trisomy, normal karyotype, and 13q deletion (as sole abnormality), the survival times were 32, 79, 114, 111, and 133 months [22], respectively. Patients with 17p or 11q deletion [23] had more advanced disease with frequent splenomegaly, mediastinal and abdominal lymphadenopathy, as well as more extensive peripheral lymphadenopathy. As part of clonal evolution, patients with CLL can acquire additional mutations. Therefore, at the time of relapse, it is advisable to repeat FISH prior to selection of therapy.

The search for tumor-suppressor genes in the commonly deleted region of 13q14 led to the discovery that two microRNA genes, mir-15a and mir-16, are located in this region [24] and in majority of patients with CLL (approximately 68%) these microRNAs are deleted or downregulated. These two microRNAs are inversely linked to the expression of the antiapoptotic Bcl-2 protein at a posttranslational level [25]. Thus loss of these two microRNAs can be linked to apoptosis resistance in CLL cells through upregulation of Bcl-2. Additional targets of mir-15 and -16 include proteins related to cell cycle progression [26]. The 11q22-q23 deletion is associated with loss of the ataxia telangiectasia mutated (ATM) [27], a gene that is responsible for repair of DNA double-stranded breaks (DNA DSB), activation of cell cycle check points, and inducing of apoptosis in response to DNA DSB. ATM also functions directly in the repair of chromosomal DNA DSBs by maintaining DNA ends in repair complexes generated during VDJ gene rearrangement in the lymphocyte receptor assembly [28]. This explains the occurrence of lymphoid malignancies in patients with ataxia telangiectasia as chromosomal instability in the lymphoid population arises at a time when lymphoid cell receptor diversity is established. The residual ATM allele is mutated in 36% of CLLs with an 11q deletion [29]. Deletion of 17p13 in CLL always includes loss of tumor suppressor TP53 [30]. Deletion of the TP53 gene is associated with poor overall survival (OS) and chemoresistance [30, 31]. In CLL cases with monoallelic loss of TP53, the other allele is mutated in the vast majority [32]. TP53 mutation even in the absence of 17p13 abnormality is associated with poor OS in CLL [33]. The frequency of TP53 mutations is higher among patients with relapsed/refractory disease.

Somatic Hypermutation of Immunoglobulin Heavy-Chain Variable Gene

Recombination of variable (V), diversity (D), and joining (J) genes and insertion of nontemplated nucleotides at the V–D and D–J junction occur in the pregerminal phase of B-cell development. In addition to the diversity brought about by such VDJ recombination, somatic hypermutations are introduced in the V(D)J rearrangement in normal B cells in the germinal center to increase the B-cell repertoire. Assessment for somatic hypermutation in the immunoglobulin heavy-chain variable gene (IgV_H) defines two "subsets" of CLL. Approximately 50% of CLL cases have somatic hypermutation of the IgV_H gene and thus appear to arise from post-germinal B cells while the subset of CLL lacking IgV_H gene hypermutation appears to arise from naive B cells [34]. The mutation status of CLL cells appears fixed and mutational status is not gained or lost during the course of disease. The prognosis of patients with unmutated IgV_H gene is worse than that of patients with IgV_H mutations; the unmutated population is more likely to have advanced-stage and progressive disease [34, 35], as well as markedly shorter PFS and OS after chemoimmunotherapy. The prognostic value of mutation status may be changing in the era of targeted inhibitors.

Stereotyped B-Cell Receptors

Study of VDJ rearrangement of immunoglobulin gene in CLL indicates that certain gene segments are overrepresented across different patients, indicating a stereotyped use

of these gene segments (an event occurring more frequently than by chance). A higher proportion of unmutated CLL cases carry stereotyped VDJ rearrangements resulting in similar complementarity-determining regions (CDRs) [34]. More than 20% of CLL cases can carry stereotyped BCRs which suggests exposure to similar antigens which are related to the pathogenesis [36–40]. Use of stereotyped IgV_H genes also affects prognosis. The use of IgV_H 3–21 gene is associated with an aggressive clinical course independent of the IgV_H mutation status [41].

ZAP-70 and CD38 Expression

An attempt was made to identify surrogate markers for IgV_H mutation status. A gene expression analysis identified ZAP-70, a tyrosine kinase protein normally expressed in T and NK cells, to be differentially expressed between mutated and unmutated CLL cases [42]. Immunophenotypic analysis of CLL cases with known mutation status identified higher CD38 expression in cases with unmutated IgV_H [35]. Thus CLL cell expression of ZAP-70 [43–46] and CD38 [35] tends to correlate with unmutated IgV_H and predict poor prognosis. However, their correlation with unmutated IgV_H is not absolute [47, 48], and CD38 and IgV_H mutation status can be independent prognostic factors. Moreover, unlike IgV_H mutation status, CD38 expression can change with time.

Factors That Identify Patients More Likely to Need Treatment

The CLL Research Consortium evaluated the relative value of ZAP-70, CD38 expression, and IgV_H mutation status for predicting time to treatment in patients with newly diagnosed CLL [49]. Based on the analysis of these three parameters, patients can be divided into three risk groups: low, ZAP-70 negative and IgV_H mutated; intermediate, ZAP-70 negative and IgV_H unmutated; and high, ZAP-70 positive irrespective of mutation status. Though ZAP-70 expression can predict for need for treatment, there are concerns about standardization of the procedure to detect ZAP-70 including whether flow cytometry or immunohistochemistry should be used and appropriate gating methods to detect ZAP-70 by flow cytometry. Information about CD38 expression did not appear to add any further prognostic information.

Combining FISH and IgV_H mutation status, the group in Ulm divided patients with early-stage CLL into three risk groups [50]: high risk, del (17p13) irrespective of IgV_H mutation status; intermediate risk, del (11q22) and/or unmutated IgV_H; and low risk, IgV_H mutated in the absence of del (17p13) or del (11q22).

Factors That Impact Response to Therapy

Deletion 17p13 and TP53 mutations are associated with resistance to treatment with nucleoside analogs or alkylating agents and their combinations. IgV_H mutation status does not predict for response, but responses (to chemoimmunotherapy) in patients with IgV_H mutations last longer [51, 52]. Ibrutinib does have activity in CLL with del(17p) [53].

Factors That Impact Overall Survival

Based on clinical and laboratory characteristics of 1674 patients with previously untreated CLL presenting to MDACC, Wierda et al. [54] developed a nomogram comprised of easily available parameters that include age, β2-microglobulin, absolute lymphocyte count, sex, Rai stage, and number of involved lymph node groups. This nomogram predicts for survival probability at 5 and 10 years.

Indications for Treatment

Outside the auspices of a clinical trial, patients with asymptomatic early-stage CLL (Rai stage = 0, Binet stage = A) should be observed until there is evidence of disease progression [2]. Patients with advanced disease (modified Rai stage intermediate or high or Binet B and C) may benefit from therapy. In addition to advanced stage, evidence of active disease should be present to initiate therapy. Such indicators of active disease include (1) marrow failure indicated by cytopenia, (2) splenomegaly (>6 cm below the costal margin or symptomatic splenomegaly), (3) massive (>10 cm) or symptomatic lymphadenopathy, (4) lymphocyte doubling time of <6 months, (5) autoimmune hemolytic anemia or thrombocytopenia poorly responsive to corticosteroids, and (6) a minimum of one disease-related symptom: (a) unintentional weight loss of ≥10% within the previous 6 months, (b) significant fatigue, (c) fevers for ≥2 weeks without any evidence of infection, and (d) night sweats for more than 1 month.

Treatment of CLL

Use of single alkylating agents such as chlorambucil for frontline therapy of CLL is now of historical interest though such an approach may have a role in the treatment of elderly patients with CLL and/or patients with significant comorbidities. See Table 9.4 for commonly used regimens in CLL. Purine analogs have shown single-agent activity and combinations built around the use of purine analogs have become the standard of care for patients with CLL.

Table 9.4 Commonly used chemoimmunotherapy regimens in CLL

Regimen	Schedule	ORR/CR	MRD negative	Remission duration
Fludarabine + rituximab [63]	F 25 mg/m² day 1–5	90/47	N/A	70% at 2 years
	R 375 mg/m² day 1 for 6 cycles followed by R 375 mg/m² weekly × 4			
Fludarabine + cyclophosphamide + rituximab (FCR) [65, 66]	**F** 25 mg/m² days 1–3	95/70	78% of CRs	68% at 5 years
	C 250 mg/m² days 1–3			
	R 500 mg/m² day 1			
	For 6 cycles			
Pentostatin + cyclophosphamide + rituximab (PCR) [69]	**P** 2 mg/m² day 1	91/41	73% of CRs	48% at 26 months
	C 600 mg/m² day 1			
	R 375 mg/m² day 1			
	For 6 cycles			
Bendamustine + rituximab (BR) [71]	**B** 70 mg/m² day 1–2	88/23	29.2% of CRs in bone marrow; 57.8% in peripheral blood only	
	R 375 mg/m² day 1			
	For 6 cycles			

Fludarabine

Fludarabine is the most extensively tested nucleoside analog in CLL. Cellular pharmacology suggests that intracellular accumulation of fludarabine triphosphate is dependent on both drug concentration and duration of exposure [55]. Thus a low-dose repeated dosing schedule was adopted for treatment of CLL.

Pentostatin or Deoxycoformycin

Deoxycoformycin is an inhibitor of adenosine deaminase (ADA), and based on lymphopenias observed in patients with ADA deficiency, pentostatin has been tested as single agent in CLL, both in frontline and salvage settings, yielding modest activity [56, 57]. Pentostatin is perceived to be less myelosuppressive than fludarabine and that led to it being investigated as part of chemoimmunotherapy regimens that will be discussed later.

Bendamustine

Bendamustine is a potent alkylating agent with a low rate of cross-resistance with other alkylating agents. In a phase III randomized, open-label trial comparing bendamustine to chlorambucil in previously untreated patients with CLL, the ORR (68% vs. 31%), CR rate (31% vs. 2%), and PFS (median, 21.8 months vs. 8.0 months) were better in the bendamustine-treated patients [58].

Combination of Purine Analogs with Other Chemotherapeutic Agents

Alkylating agents have been tested in combination with purine analogs. The rationale for such combinations is based on the fact that alkylating agents induce base excision, nucleotide excision, and mismatch repair. This involves removal of damaged nucleotides followed by resynthesis. Exposure to alkylating agents results in more CLL cells requiring DNA resynthesis. At this resynthesis step purine analogs are incorporated in DNA strand repair patch, stop elongation of DNA strands, and induce apoptosis [59].

Fludarabine/Pentostatin and Cyclophosphamide

In a cohort of 128 patients with CLL that included untreated and previously treated (including fludarabine refractory) patients, the combination of fludarabine (30 mg/m² intravenously daily for 3 days) and cyclophosphamide (FC) showed an ORR of ≥80% [60]. The cyclophosphamide dose was decreased from 500 mg/m²/day for 3 days to 300 mg/m²/day for 3 days because of myelosuppression in the early part of the study. The response to FC was higher compared to historical responses to single-agent fludarabine among patients undergoing salvage therapy, with a 38% response rate among patients refractory to fludarabine. While the CR rate (35%) was comparable to fludarabine alone among previously untreated patients, minimal residual disease elimination at the end of therapy was achieved at a higher rate compared to fludarabine alone. The German CLL Study Group (GCLLSG) reported similar activity with FC [61]. Myelosuppression leading to infections was the most common side effect of therapy in both studies.

Chemoimmunotherapy

Fludarabine and Rituximab

The combination of fludarabine and rituximab has been shown to have a synergistic effect against lymphoma cell lines [62]. This led to clinical investigations involving this

combination. CALBG 9712 study compared concomitant fludarabine and rituximab with sequential regimen of fludarabine followed by rituximab in patients with previously untreated CLL [63]. The ORR and CR rate was higher in the concomitant arm. A retrospective comparison of 104 patients treated with fludarabine and rituximab on CALB 9712 with 171 patients treated with fludarabine alone in CALBG 9011 study indicated better OS and PFS in patients enrolled on CALBG 9712 [64].

Fludarabine, Cyclophosphamide, and Rituximab

Based on single-agent activity of rituximab in other studies and its synergism with fludarabine, the group at MD Anderson Cancer Center pioneered the combination of rituximab with the most effective chemotherapy combination of fludarabine and cyclophosphamide (FCR) [65]. In their initial report, they noted an ORR of 95% (CR = 70%, nodular PR = 10%, PR = 15%) with the combination regimen of fludarabine, cyclophosphamide, and rituximab (FCR). The CR rate with this regimen was significantly higher than that reported with FC. Moreover, 78% of the patients achieving CR also achieved MRD-negative status as assessed by flow cytometry [defined as CD5- and CD19-coexpressing cells of less than 1%, with normalization of the kappa:lambda ratio (<3:1 in patients with monotypic kappa and >1:3 in patients with monotypic lambda)]. Cytopenias precluded completion of the planned six cycles of treatment in 13% of patients. Neutropenia (≥ grade 3) was encountered in 52% of courses administered to all patients, but only 2.6% of these courses were associated with serious infectious episodes.

Long-term follow-up (median follow-up 6 years) results of this chemoimmunotherapy regimen administered to 300 patients showed a 6-year overall survival of 77% and progression-free survival of 51% with a median time to progression of 80 months [66].

Though all response parameters are superior with the FCR regimen compared to historical data with the FC regimen, a demonstrated survival benefit in a randomized comparison was lacking. The German CLL Study Group performed a multicenter randomized phase III trial [67] involving 817 patients; they reported a better overall survival in patients with previously untreated CLL with the FCR regimen compared to the FC regimen [84.1% in the FCR arm versus 79.0% in the FC arm ($p = 0.01$)]. This improvement in survival was seen in patients with Binet stage A and B CLL. Though cytopenias were more common in the FCR arm, no increased serious infectious episodes were seen (compared to the rate with FC). A multivariate analysis confirmed the beneficial effect of FCR regimen on OS and PFS.

In patients with previously treated CLL, the MD Anderson group reported that the FCR regimen produced a 73% ORR and 25% CR rate [68].

Pentostatin, Cyclophosphamide, and Rituximab

Clinical activity of the combination of pentostatin and cyclophosphamide also encouraged the chemoimmunotherapy regimen of pentostatin, cyclophosphamide, and rituximab (PCR) (see discussion to come). In an initial report of 64 patients, the ORR was 91% and the CR rate was 41% with 23% of patients in CR achieving a MRD-negative status (≤1% positive $CD5^+/CD19^+$ cells) [69]. A total of five patients required transfusions; grade 3/4 cytopenias were encountered in 14.5% of cycles with grade 3/4 infectious complication in only 2% of the cycles.

The initial expectation with the PCR regimen was that the infectious complications would be less than those seen with FCR regimen. However, a randomized community-based trial in previously untreated or minimally pretreated patients comparing the PCR regimen to FCR reported a better CR rate with FCR with a comparable overall response rate, as well as a comparable rate of cytopenias and infectious complications [70].

Bendamustine Rituximab

In a phase II trial of the GCLLSG, bendamustine was combined with rituximab in previously untreated patients with chronic lymphocytic leukemia [71]. The overall response rate was 88% with complete response rate of 23% and partial response rate of 64.9%. At a median follow-up of 27 months, median event-free survival was 33.9 months. The rate of grade 3 or 4 severe infection was 7.7%. Response to therapy was associated with cytogenetics. While 90% of patients with del(11q) and 94.7% of patients with trisomy 12 responded, only 37.5% of patients with del(17p) responded.

The CLL 10 study of the GCLLSG was a phase III, open-label, randomized study comparing bendamustine and rituximab (BR) to FCR [72]. At a median follow-up of 37.1 months, the median progression-free survival was 41.7 months with bendamustine and rituxan and 55.2 months with FCR. However, severe neutropenia and infection were more frequent in the FCR group. The incidence of infectious complications in the FCR group was more pronounced in patients older than 65 years. However, there was a benefit seen in patients with CLL with del(11q) with FCR over bendamustine and rituximab. Of note, patients with del(17p) were not included in this study. Therefore, FCR remains a standard of care in fit patients. However, bendamustine and rituximab are associated with less infectious complications.

Antibodies

CD20 Antibodies

Rituximab, ofatumumab, and obinutuzumab are three anti-CD20 antibodies approved for the treatment of CLL. Ublituximab is being developed as a novel anti-CD20 antibody. CD20 is an antigen expressed on the surface of CLL cells (dim expression by flow cytometry) and is tightly bound to the cell surface. The mechanisms of action of anti-CD20 antibodies against CLL cells include antibody-dependent cellular cytotoxicity [73] (ADCC) and complement-mediated cytotoxicity [74]. In addition, exposure of CLL cells to anti-CD20 antibody has been shown to reduce levels of antiapoptotic proteins including XIAP and Mcl-1 and to induce caspase activation and PARP cleavage [75].

Rituximab

Rituximab is a chimeric monoclonal antibody approved for the treatment of low-grade B-cell lymphomas. The pivotal trial in patients with relapsed low-grade B-cell lymphomas using 375 mg/m^2 weekly for 4 weeks showed responses in 48% of patients, but the response rate among patients with SLL (tissue equivalent of CLL) was 12% [76]. This was attributed to the fact that expression of CD20 was low on SLL/CLL cells compared to cells of follicular lymphomas. O'Brien et al. [77] conducted a dose escalation study of rituximab (375 mg/m^2 dose 1 and dose 2–4 at an escalated rituximab dose). For each patient, the dose of rituximab was kept constant and escalation range was 500–2250 mg/m^2. The ORR among patients with CLL was 36%, all responses being PR.

While Fcgamma RIIA [78] and RIIIA [79] gene polymorphism has been linked to responses to rituximab in patients with non-Hodgkin's lymphoma, no such association has been convincingly established in CLL [80].

Ofatumumab

Ofatumumab is a CD20 monoclonal antibody that binds to a unique epitope that is distinct from the epitope recognized by rituximab. Ofatumumab produces more complement-dependent cytotoxicity (CDC) than is seen with rituximab. As a single agent in patients with relapsed/refractory CLL, the overall response rate was 45% with a median PFS of 5 months [81]. Based on these results, ofatumumab was approved for patients with CLL refractory to fludarabine and alemtuzumab. Ofatumumab has been combined with chlorambucil as first-line therapy (Complement-1) trial [82]. The chlorambucil and ofatumumab combination significantly improved ORR compared to that seen with chlorambucil monotherapy (82% vs. 69%, $p < 0.001$). The combination also improved PFS (median 22.4 months vs. 13.1 months, $p < 0.001$). While ofatumumab is generally well tolerated, the most common side effects are infusion reactions and neutropenia. Based on these results, chlorambucil and ofatumumab were approved for first-line treatment of patients with CLL for whom fludarabine-based therapy is considered inappropriate.

Obinutuzumab

Obinutuzumab is a CD20 monoclonal antibody with a glycoengineered Fc portion leading to enhanced antibody-dependent cellular cytotoxicity (ADCC), increased direct cell death, and lower complement-dependent cytotoxicity (CDC) compared to that seen with rituximab [83]. The CLL11 trial randomized 781 previously untreated patients with CLL with comorbidities to receive chlorambucil monotherapy, chlorambucil with rituxan, or chlorambucil with obinutuzumab. The combination of chlorambucil and obinutuzumab produced an improved PFS compared with that seen with chlorambucil alone (26.7 vs. 11.1 months, $p < 0.001$) [84]. The combination of chlorambucil and obinutuzumab also showed an improved PFS when compared with the PFS noted with the chlorambucil and rituximab combination (median 26.7 vs. 16.3 months, $p < 0.001$). Chlorambucil and obinutuzumab produced a higher ORR as compared to that seen with chlorambucil and rituximab (78.4% vs. 65.1%, $p < 0.001$). These results led to FDA approval of the combination of chlorambucil and obinutuzumab for patients with previously untreated CLL not suitable for more aggressive chemoimmunotherapy. In a recent update, chlorambucil and obinutuzumab showed an improved PFS compared with chlorambucil and rituximab (29.2 months vs. 15.4 months, $p < 0.001$) [85]. However, no overall survival difference was noted between the two antibody arms.

Ublituximab

Ublituximab (TG-1101) is a chimeric IgG1 monoclonal antibody that targets a unique epitope on CD20. In a phase I trial, ublituximab demonstrated a 67% ORR in patients with relapsed/refractory CLL [86]. The combination of ublituximab and ibrutinib is being investigated. In an initial report of 20 patients with high-risk CLL, the overall response rate was 95% [87]. Final results of this trial are yet not reported.

CD52 Antibody

Alemtuzumab, originally known as Campath 1G, is a human immunoglobulin G1 (IgG1) anti-CD52 monoclonal antibody (MAb) that binds to nearly all B- and T-cell lymphomas and

leukemias. Early phase II study with an administration schedule of a 30-mg 2-h intravenous (IV) infusion thrice weekly for a maximum period of 12 weeks produced an ORR of 42% [88]. Most disease elimination was seen in blood, bone marrow, and spleen while lymph node response was less. Keating et al. [89] reported on an international study involving 93 patients with fludarabine-refractory CLL using alemtuzumab 30 mg IV three times a week for 12 weeks. In the first week, the initial dose was 3 mg, which was increased to 10 mg, and then to 30 mg as soon as infusion-related reactions were tolerated. Infection prophylaxis with trimethoprim/sulfamethoxazole and famciclovir was mandatory. The intent-to-treat analysis showed an ORR of 33% (CR = 2%, PR = 31%). Though there was reduction in lymphadenopathy and other organomegalies, response in lymph nodes >2 cm was modest. In this pivotal trial, 25 patients had grade 3/4 infectious complications. Viral reactivation (cytomegalovirus = seven patients and herpes simplex virus = six patients) was seen in 13 patients. Infectious complications were more frequent in nonresponders to alemtuzumab than in responders.

Alemtuzumab is no longer available commercially but can be provided through the company through a distribution program.

Targeting Antiapoptotic Proteins

Antiapoptotic members of the Bcl-2 family of proteins can render CLL cells resistant to chemotherapeutic agents; increased expression of Bcl-2 family members is frequently seen in primary CLL cells [90]. Drugs targeting antiapoptotic members of the Bcl-2 family of proteins can induce apoptosis in CLL cells [91] and have synergistic/additive effect with chemotherapeutic agents.

In addition to antisense oligonucleotides, small-molecule inhibitors of Bcl-2 family members have been developed. These agents mimic the BH3 domain of pro-apoptotic Bcl-2 family proteins and work by releasing BH3 only pro-apoptotic members (BAX and BAK) from sequestration by the antiapoptotic members.

Venetoclax

Antiapoptotic proteins such as BCL-2 are expressed at high levels which make the cells resistance to senescence and death. Venetoclax is an oral BCL-2 inhibitor. In the phase I trial, 56 patients with relapsed chronic lymphocytic leukemia were treated in the dose-escalation cohort [92]. Clinical tumor lysis was diagnosed in three patients in that cohort with one death. Adjustments were made in the dose-escalation schema, increased tumor lysis prophylaxis was employed, and initial hospitalization was required, and the subsequent 60 patients tolerated the drug well. There was a 79% overall response rate with 20% complete responses. The 15-month progression-free survival was 69% in the 400 mg cohort. Other side effects were mild diarrhea (52%), upper respiratory tract infection (48%), nausea (47%), and grade 3 or 4 neutropenia (41%). In a phase II trial, 107 patients with relapsed or refractory CLL with 17p deletion were treated with venetoclax [93]. At a median follow-up of 12 months, the overall response rate was 85%. Most common grade 3–4 adverse events were neutropenia (40%), infection (20%), anemia (18%), and thrombocytopenia (15%). Serious adverse events included pyrexia, autoimmune hemolytic anemia (7%), pneumonia (6%), and febrile neutropenia (5%). These results led to the recent FDA approval of venetoclax in relapsed or refractory patients with CLL and del 17p.

Inhibitors of the B-Cell Receptor

B-cell receptor activation is known to play a crucial role in the pathogenesis of CLL. There are many potential targets for inhibition of the B-cell receptor pathway. Kinases for which targeting agents are commercially available include BTK and PI3K [94].

"Redistribution Lymphocytosis"

As a class effect, all inhibitors of the B-cell receptor appear to cause "redistribution lymphocytosis." During the first few weeks of therapy, these agents can cause transient lymphocytosis due to redistribution of CLL cells from the tissue to peripheral blood [95]. Normally, CLL cells circulate in the peripheral blood where they are attracted to tissue stromal cells by a chemokine gradient. The CXCR4-CXCL12 axis is the predominant one for marrow homing. Inhibition of these homing mechanisms by ibrutinib, a BTK inhibitor, leads to the exit of tissue cells into the blood, resulting in an increased lymphocytosis. Lymphocytosis occurs concomitantly with reduction in lymph node size [95]. The transient lymphocytosis should not be confused with disease progression and should not lead to discontinuation of the drug (Fig. 9.1).

Since this class of drugs is known to cause lymphocytosis, many patients do not meet response criteria defined in the 2008 International Workshop on Chronic lymphocytic leukemia (IWCLL) guidelines [2] despite clear and substantial clinical benefit. Thus, the IWCLL guidelines have been adjusted to define an initial response category called partial response with lymphocytosis (PRL), thus ensuring that patients with a partial response who have persistent lymphocytosis are considered responders [96].

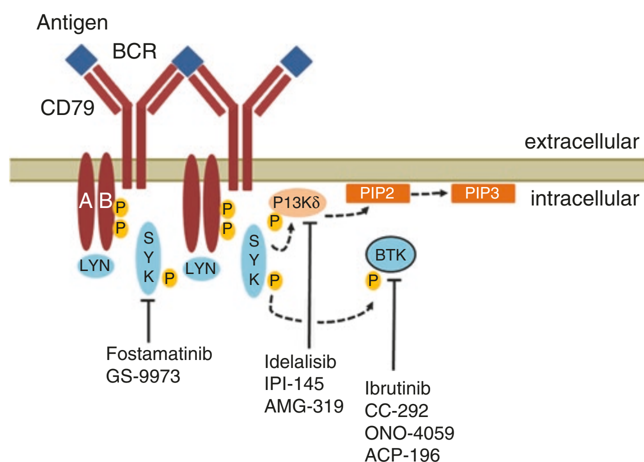

Fig. 9.1 BCR signaling and downstream pathways. The BCR consists of transmembrane receptors. Upon binding of antigen, BCR signaling induces LYN- and SYK-dependent phosphorylation of tyrosine motifs including PI3Kδ and BTK. Several small molecular inhibitors to this kinases are in development (adapted from Wiestner 2014 [94])

Bruton's Tyrosine Kinase (BTK)

BTK is a cytoplasmic tyrosine kinase which is essential to BCR signaling and couples BCR-induced calcium release to activation of the NK-κB pathway and cellular proliferation. X-linked agammaglobulinemia (or Bruton's agammaglobulinemia), which typically presents during childhood, is characterized by an absence of mature B cells and immunoglobulins and leads to recurrent bacterial infections. Loss-of-function mutations in BTK block B-cell maturation at the pre-B-cell stage [97].

Ibrutinib

Ibrutinib is the first BTK inhibitor studied in clinical trials; it inactivates BTK through the formation of an irreversible covalent bond with Cys-481 in the ATP-binding domain [98]. Ibrutinib is also known to inhibit other kinases including ITK (interleukin-2-inducible T-cell kinase), TEC, BMX, and EGFR, which may explain some of the toxicities seen with this agent. Ibrutinib is currently FDA approved for use as initial therapy as well as for the treatment of relapsed disease.

Byrd et al. reported the outcomes of 101 patients with relapsed/refractory CLL, who received ibrutinib [99, 100]. The median age was 64 years old (range, 37–82). Thirty-four percent of the patients had del(17p) and 78% had unmutated IGVH. The median number of prior regimens was four. The overall response rate was 90% with 7% with complete remission (CR). The estimated progression-free survival at 30 months in this heavily pretreated group was 69%. The median PFS in patients with del(17p) and del(11q) was 28 months and 38.7 months, respectively. While this median PFS is a significant improvement over prior experience with chemotherapy regimens in this high-risk group, there is clearly a shorter PFS in patients with del(17p). The most common toxicity was diarrhea which occurred in 55% of patients and was predominately grade 1–2. Notable toxicities >grade 3 included bleeding (8%) and atrial fibrillation (6%).

Ibrutinib was compared to ofatumumab in previously treated patients with CLL in a randomized trial, with results demonstrating improved progression-free and overall survival in the ibrutinib arm [101]. At 12 months, the overall survival was 90% in the ibrutinib arm versus 81% in the ofatumumab arm. The overall response rate was higher with ibrutinib at 43% versus 4% with ofatumumab.

Patients with CLL and a 17p deletion typically have aggressive disease and respond poorly to chemotherapy regimens [102]. A recent report described the outcome of 144 patients with CLL and a 17p deletion who had failed at least one therapy and received ibrutinib 420 mg daily until disease progression [53]. The median number of prior therapies was two with a range of 1 to 7 prior therapies. At a median follow-up of 13 months, the median PFS had not been reached. At 12 months, 79% were alive and progression free and 88% of the responders were progression free. Progressive disease was reported in 13% of patients; 7% of patients developed Richter's transformation and seven of those cases occurred within the first 24 weeks of therapy. The most frequent adverse events were diarrhea in 36% (grades 3–4 in 2%), fatigue in 30% (grades 3–4 in 1%), cough in 24% (grades 3–4 in 1%), and arthralgias in 22% (1% with grades 3–4). Another report described 51 patients with CLL and deletion 17p who were treated with ibrutinib [103]. At 24 weeks, 80% of patients had an objective response: 40% had a PR, 40% had a PRL, and the remaining 20% had stable disease. The adverse effects were similar to those seen in previous reports.

The frontline trial leading to approval of ibrutinib as initial therapy randomized 269 patients who were 65 years or older to receive either ibrutinib or chlorambucil [104]. With a median follow-up of 18.4 months, the median progression-free survival was not reached with ibrutinib versus 18.9 months with chlorambucil. The 24-month overall survival with ibrutinib was 98% versus 85% with chlorambucil.

Toxicity

The incidence of bleeding with ibrutinib was found to be increased. In the phase I/II studies, bruising was seen in 17% of patients: 2% had intracranial hemorrhage [105]. Subsequent trials with ibrutinib have excluded patients on warfarin therapy. In the phase III trial of ibrutinib versus ofatumumab, the bleeding rates were 44% with ibrutinib and

12% with ofatumumab but the rates of serious bleeding were low at 1% versus 2%, respectively [101]. An earlier analysis of the bleeding events with ibrutinib was attributed to effects on the collagen and von Willebrand-dependent platelet functions [106]. However, a more recent analysis attributes the bleeding to inhibition of collagen-dependent platelet aggregation by ibrutinib [107].

The incidence of atrial fibrillation is also increased with ibrutinib. In the phase III trial of ibrutinib versus ofatumumab, ten patients on the ibrutinib arm developed atrial fibrillation versus only one patient on the ofatumumab arm. This led to discontinuation of ibrutinib in one patient [101].

Finally, as with other BCR inhibitors, ibrutinib does cause lymphocytosis. This generally resolves after 6–9 months with continued treatment. Approximately 20% of patients have prolonged lymphocytosis (greater than 12 months) with ibrutinib therapy. Development of lymphocytosis does not appear to be detrimental to long-term clinical outcomes [108].

Ibrutinib Resistance

The outcome of heavily pretreated patients who fail ibrutinib is poor. A previous report described outcomes in 33 patients (26%) (of 127 patients) enrolled on clinical trials of ibrutinib at MD Anderson who discontinued the drug [109]. The majority of these patients had high-risk features including 94% with unmutated IgVH, 58% with 17p deletion by FISH, and 54% with complex karyotype. The reason for discontinuation of ibrutinib included disease transformation in 7%, progressive disease in 7%, and adverse events in 11%; 3% of patients underwent stem cell transplantation. Seventy-six percent of patients died after discontinuing ibrutinib, with a median overall survival after discontinuation of only 3 months. These patients who discontinued ibrutinib had aggressive disease and were heavily pretreated. Recent analysis of outcomes of patients with ibrutinib therapy demonstrated that this does not hold true for patients who receive ibrutinib earlier in their disease course [110]. Patients who were treatment naïve in the Resonate-2 trial and patients that had several lines of prior therapy prior to ibrutinib were compared. The median overall survival in patients post-ibrutinib therapy who had ibrutinib as either first- or second-line therapy was not reached. The median overall survival in patients who had ibrutinib as third-line (or beyond) therapy was only 7–9 months. Therefore, patients who receive ibrutinib in first or second line of therapy were less likely to progress and also experienced better post-ibrutinib survival.

Mutations in the BTK-binding site of ibrutinib have been described in patients who developed resistance while on ibrutinib therapy [111]. Mutations in the cysteine-to-serine in BTK at position 481 (C481S) were seen in five patients. The C481S mutation elicits BTK-independent activation after B-cell receptor activation [112]. Two patients had mutations in PLCγ2 (a downstream kinase from BTK), one at position 665 (R665W) and the other at L845F, leading to gain-of-function mutations that led to potential autonomous B-cell receptor activity. Proximal kinases of SYK and LYN would be critical for activation of mutant PLCG2 and targeting LYN and SYK may combat molecular resistance in cell line models as well as in primary CLL cells from ibrutinib-resistant patients. There has also been a report of clonal evolution leading to ibrutinib resistance. One patient acquired a new clonal mutation in SF3B1(K666 T) and two patients had clonal deletion in chromosome 8p [113]. Other proposed mechanisms for resistance to ibrutinib as well as the other BCR antagonists are reviewed elsewhere [114].

Clinical data are limited on how to proceed after a patient has disease progression on ibrutinib. These patients may be considered for stem cell transplantation, if they are eligible candidates for this intervention [115]. This group may benefit from development of other novel therapies. Because the current second-generation BTK inhibitors bind to the same binding site as ibrutinib, using them in this setting would likely not be productive. A phase I study of the dual-PI3K inhibitor IPI-145 included some patients previously treated with ibrutinib [116]. There was one PR and five patients had stable disease. For further details, refer to the section on IPI-145.

Based on ex vivo data supporting the use of selinexor in the setting of acquired resistance to ibrutinib, as well as in vitro synergy with ibrutinib in chronic lymphocytic leukemia [117], a clinical trial is investigating the combination of selinexor and ibrutinib in relapsed/refractory CLL [118].

Preliminary results from a phase II study of venetoclax in patients with CLL relapsed after ibrutinib or idelalisib are encouraging [119]. In this heavily pretreated group (median of 5 prior regimens) of 54 patients, 41 patients had had prior ibrutinib and 13 patients had prior idelalisib. In the group which had been pretreated with ibrutinib, 13% CR, 48% PR, and 13% SD at 24 weeks were seen. In the group who had been pretreated with idelalisib, the response rate was 50% PR and 25% SD at 24 weeks. At 36 weeks, the overall response rate was 61% in the ibrutinib-pretreated group and 50% in the idelalisib-pretreated group. The drug was well tolerated but serious adverse events were seen, 7% pneumonia and 7% neutropenia.

Second-Generation BTK Inhibitors

Other BTK inhibitors in earlier clinical development include GS-4059 (ONO-4059) [120, 121], acalabrutinib [122, 123], and BGB-3111 [124]. These inhibitors all covalently bind to Cys481 leading to irreversible inhibition. These second-generation inhibitors may have more selective binding to BTK and fewer off-target effects, such as diarrhea, bleeding, and atrial fibrillation.

GS-4059 (ONO-4059)

GS-4059 is a potent and selective BTK inhibitor with an IC50 in the sub-nmol/L range. In a phase I study, the oral inhibitor was given as monotherapy to patients with relapsed/refractory CLL [119]. Of the 16 patients evaluable, 38% of patients had a 17p deletion and 19% of patients had an 11q deletion. Twelve of 16 patients had an unmutated IgVH gene. Eight of 16 patients had a TP53 mutation. The median number of prior therapies was 3. This inhibitor was well tolerated; grade 3 toxicities included febrile neutropenia, as well as one grade 4 neutropenia. The best overall response was 70% as per IWCLL criteria. Two patients had a PR and five patients had a PRL, two had stable disease, and one progressed with Richter's transformation. The results in 60 patients with relapsed hematologic malignancies treated with GS-4059 were recently published [120]. Of 25 patients with relapsed CLL, 24 responded to and 21 patients remained on therapy. One patient had grade 3 bleeding but no diarrhea, cardiac events, or arthralgias were reported. There is an ongoing clinical trial evaluating GS-4057 in various combinations of other agents. There are five different arms comparing GS-4057 with idelalisib, GS-4057 with entospletinib, GS-4057 with idelalisib and obinutuzumab, GS-4057 with entospletinib and obinutuzumab, and just single agent GS-4057 [125]. There is an upcoming clinical trial comparing the combination of GS-4057 and idelalisib with or without obinutuzumab in patients with relapsed/refractory CLL [126].

ACP-196 (Acalabrutinib)

ACP-196 is a second-generation BTK inhibitor which binds covalently to Cys481 with improved selectivity and in vivo target coverage [121]. ACP-196 was able to inhibit 94% of BTK target occupancy after 7 days of dosing in patients with CLL. The results of a phase I–II multicenter study of ACP-196 in patients with relapsed CLL were recently published [122]. Sixty-one patients with relapsed CLL had received a median of three prior regimens and 31% had deletion 17p. No dose-limited toxicities were seen. At a median follow-up of 14.3 months, the overall response rate was 95%, including 85% with partial response and 10% with PRL. The remainder (5%) had stable disease. The response rate in the patients with deletion 17p was 100%. There is an ongoing registration trial randomizing patients with relapsed CLL and deletion 17p or 11q to ibrutinib or acalabrutinib [127]. The FDA registration phase III study for potential frontline approval randomizes patients to one of the three arms, acalabrutinib, acalabrutinib and obinutuzumab, or chlorambucil and obinutuzumab [126].

BGB-3111

BGB-3111 is another oral BTK inhibitor. Ibrutinib antagonizes rituximab-induced antigen-dependent cell-mediated cytotoxicity (ADCC) by inhibiting ITK kinase activity [128]. In murine models BGB-3111 resulted in a tenfold weaker inhibition of rituximab-induced ADCC and was threefold more potent than ibrutinib in target organs [129]. The results of a phase I study of BGB-3111 in patients with B-cell lymphoid malignancies were recently reported [130]. Of 25 patients enrolled, 8 patients had CLL. There were other patients including mantle cell lymphoma, Waldenstrom's, DLBCL, follicular lymphoma, marginal zone lymphoma, and hairy cell leukemia. There were no serious adverse events leading to drug discontinuation or adverse-related disease reported. Of 21 adverse events grade 3 or greater, only 3 were felt to potentially be related to the drug which were neutropenia. There were no grade 3 or 4 bleeding events or cases of atrial fibrillation. Of the CLL patients, two had stable disease and six had partial response. The results of 45 patients with CLL treated with BGB-3111 were recently presented [131]. The drug was well tolerated with 69% of patients without any AE greater than grade 1 within the first 12 weeks of therapy. The most frequent AEs were petechiae/bruising, upper respiratory infection, diarrhea, fatigue, and cough. Three serious adverse events were reported which possibly could have been related to the drug which were grade 2 cardiac failure, grade 2 pleural effusion, and grade 3 purpura. At a median follow-up of 7.5 months, the response rate was 90% with PR in 79% of patients and PR-L in 10%, and stable disease in 7%. These results are encouraging and further studies are planned.

PI3K Inhibitor

The PI3K pathway is a key component of survival in a variety of cancers including CLL. There are three classes of PI3K isoforms. Class I isoforms are made up of two subsets: 1A, which includes p110α, p110β, and p110δ bound by regulatory domains, and 1B, which is composed of p110-γ coupled with p101 [132]. The p110δ is abundantly expressed in CLL as the delta isoform is the most important isoform in hematologic cells. Idelalisib is the first PI3K inhibitor in combination with rituximab approved by the FDA in patients with relapsed CLL. PI3K inhibitors in clinical development include duvelisib, and TGR-1202.

Idelalisib

Idelalisib is a selective oral reversible inhibitor of the p110δ isoform of PI3Kδ. In the phase I study of idelalisib, 72% of patients had an objective response with a median

progression-free survival of 16 months [133]. Overall, the patients on this trial had less functional reserve than the patients on ibrutinib trials, with decreased renal function, therapy-induced myelosuppression, or major coexisting illness. Furthermore, at the optimal doses, progression-free survival was 32 months. Median overall survival was not reached, with a 36-month overall survival of 75%. The most common >grade 3 adverse events were pneumonia in 20%, neutropenic fever in 11%, and diarrhea in 6% of patients. At the second interim analysis, the phase III randomized clinical trial of idelalisib with rituximab versus placebo with rituximab reported that the addition of idelalisib led to an overall response rate of 77% versus 15% with rituximab plus placebo [133]. Furthermore, in the idelalisib and rituximab arm, there was a 12-month progression-free survival of 66% [134, 135]. Serious adverse events occurred in 40% of patients in the idelalisib arm. The most common adverse events were pneumonia, pyrexia, and febrile neutropenia. Grade 3 or higher transaminitis occurred in 5% of patients in the idelalisib arm with onset at 8–16 weeks. The study drug was withheld and four of six patients were successfully rechallenged. Furthermore, in the idelalisib arm, gastrointestinal and skin toxicities led to discontinuation of the drug in six patients. Because PI3kδ influences clonal expansion and differentiation of suppressor T cells, diarrhea and colitis may be an expected autoimmune toxicity. A phase II trial evaluated the combination of idelalisib and rituximab in previously untreated patients with CLL/SLL who were 65 years or older [136]. This combination produced a high ORR of 97%. However, the adverse side effect profile was higher in this previously untreated cohort compared to that seen in relapsed/refractory patients treated with idelalisib The incidence of transaminitis was 67% with 23% of patients having grade 3 or higher toxicity. Diarrhea or colitis was reported in 64% of patients; 42% was grade 3 or higher. On the colonoscopic biopsies, T-cell infiltration was present in the patients with colitis. The authors noted that T-cell levels are typically normal in previously untreated patients with CLL but are quite low in patients with relapsed/refractory disease. This is one possible reason for the increased toxicity noted in the previously untreated group compared with the relapsed/refractory group.

These findings were confirmed in another phase II trial evaluating idelalisib in the frontline setting [137]. This trial enrolled 24 patients with newly diagnosed CLL who were treated with 2 months of idelalisib followed by 6 months of the combination of idelalisib and ofatumumab. Hepatotoxicity was reported in 79% of patients with 54% being grade 3 or higher. The median time to development of transaminitis was 28 days which was prior to the administration of ofatumumab. The transaminitis did resolve with holding the drug and, in some cases, addition of immunosuppressants. This study showed that the toxicity was increased in the younger frontline patients, presumably because they have better functioning immune systems. Clinical trials with idelalisib in the frontline setting have been discontinued because of a higher rate of infections and death than was seen in the control arm.

IPI-145 (Duvelisib)

IPI-145 is another inhibitor of PI3K. It inhibits both the p110δ and the p110γ isoforms. Duvelisib antagonizes BCR cross-linking activated pro-survival signals in primary CLL cells [138] and causes direct killing of primary CLL cells in a dose-dependent fashion while it spares normal B cells. Furthermore, based on ex vivo models, duvelisib could possibly overcome ibrutinib resistance resulting from the BTK C481S mutation [116].

In a phase I/II study of monotherapy with IPI-145, 54 patients with relapsed/refractory CLL were enrolled [139]. The patients were heavily pretreated with 82% having received more than three prior lines of therapy. The median time from prior therapy was 3.5 months. Cytogenetics were poor risk with 49% having TP53 mutations or a 17p deletion and 89% having an unmutated IgVH. The expansion cohort enrolled patients at either 25 or 75 mg twice daily. The best overall response rate was 55% in 49 evaluable patients including 1 CR and 26 partial responses (PR). There were 21 patients with stable disease (in this study PRL was counted as stable disease) and 1 patient with progressive disease. The overall response rate was independent of dose or the presence of TP53/17p deletion. There was early resolution in the lymphocytosis. Overall, the drug was well tolerated with transient cytopenias, with 31% neutropenia, 11% thrombocytopenia, 15% febrile neutropenia, and 11% pneumonia. Treatment was discontinued in 31% of patients due to adverse events, and in another 24% of patients because of disease progression. DUO is a phase III study in relapsed/refractory CLL randomizing 300 patients to either duvelisib 25 mg twice daily or ofatumumab for up to 18 cycles [140].

In the phase I study a cohort of patients with CLL resistant to ibrutinib were treated with duvelisib [116]. This included six patients with relapsed/refractory CLL and six patients with aggressive B-cell NHL (aNHL, including two with DBLCL and four with Richter's transformation). Two patients received duvelisib at 25 mg twice daily and ten patients received duvelisib at 75 mg twice daily. All patients had received more than three prior therapies. The median time from prior therapy to duvelisib was 0.3 months and 67% of patients received it within 2 weeks of ibrutinib. The patients with CLL had received a median of four cycles of duvelisib. The best response in patients with relapsed/refractory CLL

was one PR; five patients had stable disease. Of these six patients, two patients remained on the drug for 8 and 9 months and four patients discontinued the drug due to disease progression or physician decision.

TGR-1202

TGR-1202 is a second-generation PI3Kδ inhibitor. In a phase I study, patients with relapsed/refractory hematologic malignancies were administered monotherapy with TGR-1202 orally once daily following a 3 + 3 dose escalation design [141]. Preliminary results from this phase I study were notable for PR in four of the six patients with CLL treated at doses above 800 mg daily. The nodal reduction occurred rapidly and was accompanied by lymphocytosis. Subsequent reporting revealed that of nine evaluable patients with CLL, eight (89%) achieved a PR in the nodes with a median nodal reduction of 71%, of whom five achieved a PR [142]. Notably, in comparison to other PI3kδ inhibitors, there were no cases of hepatotoxicity or colitis observed. Rates of infection and pneumonia were low at 12% and 6%, respectively, with no cases of febrile neutropenia.

Based on the encouraging phase I data, the combination of TGR-1202 and ublituximab (a glycoengineered anti-CD20 mAb) was studied in a phase I trial following a 3 + 3 dose escalation design [143]. Ublituximab was administered weekly for the first two cycles and then on day 1 of cycle numbers 4, 6, 9, and 12 while TGR-1202 was administered daily. There were 12 patients with CLL included in the trial. Reported toxicities were 44% day 1 infusion reactions, 41% neutropenia, 34% diarrhea, and 28% nausea; no grade 3 or 4 toxicities were seen. There were no cases of hepatotoxicity. In the ten patients with CLL, there was a median progression-free survival of 8 months. Enrollment continues in the higher dose cohort.

The combination of ublituximab with TGR-1202 and ibrutinib has also been administered to patients with B-cell malignancies [144]. Ublituximab was dosed at 900 mg weekly for the first two cycles and then on day 1 of cycles 4, 6, 9, and 12. TGR-1202 was dose escalated at 400, 600, 800, and 1200 mg while the ibrutinib dose was held stable at 420 mg for patients with CLL and 560 mg for patients with NHL. There were three patients with CLL and SLL included. Of the adverse events, 20% of patients experienced day 1 infusion reactions with no grade 3 or 4 reactions noted, while 20% of patients experienced neutropenia which was grade 3 or 4, and 30% experienced diarrhea, constipation, or fatigue with no grade 3 or 4 events. The overall response rate was 86% with two of three patients with CLL/SLL responding. Based on these findings, phase II studies are planned.

Adoptive Cellular Therapy

New cellular therapies including CAR-T cells are being developed for patients with B-cell malignancies including patients with CLL [145]. CAR-T cells can be associated with adverse events including neurotoxicity and cytokine release syndrome. Experience with managing the toxicities of these therapies is critical for safe delivery of these therapies.

Targeting Minimal Residual Disease in CLL

In patients achieving complete remission after therapy for CLL, those who achieve MRD-negative CR tend to have responses that last longer and also have better OS. Four-color flow cytometry or allele-specific oligonucleotide PCR (ASO-PCR) with a sensitivity of detecting 1 CLL cell in 10,000 leukocytes is recommended for use in clinical trials reporting on MRD eradication.

Disease-Related Complications of CLL

Immune-Mediated Cytopenias in CLL

Autoimmune hemolytic anemia (AIHA), autoimmune thrombocytopenia (AIT), and pure red cell aplasia (PRCA) develop in some patients with CLL. The incidence of AIHA is 4–11% [6, 146, 147] and that of AIT 2–3%. PRCA is least common. Fludarabine has been associated with AIT and AIHA [148]. Prednisone is the usual treatment for AIHA and AIT, with a high likelihood of response initially. However, more than 60% of patients relapse when treatment is stopped. Intravenous immunoglobulin produces response in 40% of patients, but these responses tend to be transient. Cyclosporine A is another option for treatment of immune-mediated cytopenias and can produce responses even in patients with steroid refractory immune cytopenias [149]. Rituximab, alemtuzumab, and the combination of rituximab, cyclophosphamide, and dexamethasone [150–152] have also been used to treat autoimmune complications of CLL.

Hypogammaglobulinemia

Hypogammaglobulinemia is a frequent complication of CLL. Because of the high cost of therapy and its limited activity in preventing serious infections, monthly intravenous gammaglobulin replacement therapy is usually limited to hypogammaglobulinemic patients who experience repeated sino-pulmonary bacterial infections.

Transformations

Richter's Syndrome

The term Richter's syndrome (RS) refers to the development of large-cell lymphoma (LCL) during the course of CLL. RS is usually associated with worsening systemic symptoms including B symptoms, elevated LDH, rapid tumor growth, and/or extranodal involvement. Diagnosis requires tissue biopsy. PET scanning helps in identifying sites to direct tissue biopsy. Gene rearrangement studies and isotype analysis suggest that the CLL and LCL cells frequently share identical clonal origins. The LCL is usually resistant to therapy, and the median survival of patients who develop RS is approximately 6–9 months [153, 154]. If the gene rearrangement studies do not show the identical clonal origin, then the LCL should be treated as independent of the history of CLL and the prognosis can be excellent [155]. The presence of NOTCH mutations increases the risk of transformation. The presence of NOTCH mutation was associated with a risk of development of DLBCL in 30% of patients at 10 years [156].

Prolymphocytic Transformation

The NCIWG criteria allow a diagnosis of CLL to be made in the presence of ≤55% prolymphocytes. The presence of prolymphocytes >55% indicates prolymphocytic transformation.

Prolymphocytic Leukemia

Prolymphocytic leukemia (PLL) is characterized by splenomegaly, a high number of circulating prolymphocytes, minimal lymphadenopathy, and a median survival of less than 3 years. Prolymphocytes are larger and less homogenous than CLL cells, and have abundant clear cytoplasm, clumped chromatin, and a prominent nucleolus. Prolymphocytes can be of either B- or T-cell type. B-PLL cells usually do not express CD5 but stain strongly for surface immunoglobulin and FMC-7. TP53 mutations and 11q23 or 13q14 deletions are common in B-PLL [157–159]. Approximately 20% of cases of PLL are of T-cell phenotype. Over 70% of T-PLL shows overexpression of the oncoprotein TCL-1 [160, 161].

Splenectomy and lymphoma-like regimens have been used to treat PLL without much success. In a study at MDACC, a 38% ORR (18% CR) was seen with a 5-day schedule of fludarabine administered every 4 weeks. Dearden et al. reported an ORR of 48% with pentostatin (2′ deoxycoformycin) [162]. Alemtuzumab (Campath-1H) also has shown promising activity in T- and B-PLL [163–165] with an ORR of 51%, CR rates of up to 39.5%, and median survival of 7.5 months. In a study from Royal Marsden Hospital, alemtuzumab (Campath-1H) was administered intravenously three times weekly to patients with previously treated T-PLL until maximal response [166]. The ORR was 76% with 60% CR. However, responses with alemtuzumab are short-lasting and disease progression is the norm. Ibrutinib and idelalisib may have a role in this disease.

Conclusion

Based on the advances made in our understanding of the biology of CLL, there are now many avenues for investigation for novel therapies. Given that these newer therapies are generally better tolerated than chemoimmunotherapy, many more patients are eligible for therapy than in the past. This will hopefully lead to a prolongation in remissions in these patients while maintaining a good quality of life.

Hairy Cell Leukemia

10

Sonia Ali and Alan Saven

Introduction

The WHO categorizes hairy cell leukemia (HCL) as a mature B-cell neoplasm. HCL is characterized by lymphocytes with prominent cytoplasmic projections (hairy cells) infiltrating the bone marrow and spleen, leading to pancytopenia, bone marrow fibrosis, and splenic enlargement. Hairy cells have a unique immunophenotypic profile—CD11c+, CD20+, CD25+, and CD103+—that confirms its diagnosis. The course of HCL is usually chronic, but can often be progressive, and most patients require treatment at some point. The purine nucleoside analogues, pentostatin and cladribine, are highly active, but cladribine is the preferred first-line choice due to its efficacy, brief treatment duration, and favorable toxicity profile. Other therapeutic options include rituximab, interferon-alpha, vemurafenib, and splenectomy. With current therapy, an overall survival of 87% at 12 years has been reported.

History

HCL was originally recognized in the 1920s but was not identified as a unique entity with distinct pathological and clinical characteristics until 1958 when Bouroncle and colleagues characterized it as *leukemic reticuloendotheliosis* [1] and described the first 26 cases. In their landmark article, the authors provided a comprehensive description of the clinical course, pathology, and limited treatment at the time with alkylating agents and splenectomy. The term "hairy cell leukemia" was first coined by Schreck and Donnelly in 1966 when they noted hairlike cytoplasmic projections on phase-contrast microscopy [2]. The last 50 years, and especially the last two decades, have been spent defining HCL as a B-cell neoplasm [3, 4] and have heralded dramatic therapeutic advances with the purine nucleoside analogues.

Epidemiology and Etiology

HCL is uncommon and accounts for 2–3% of all adult leukemias in the USA [5]. According to the Surveillance Epidemiology and End Results (SEER) database, 2856 cases were diagnosed between 1978 and 2004 [6]. There is a 4:1 male predominance and the median age at presentation is 50 years [5]. New data suggest a bimodal incidence pattern, with an early peak around age 40 years and a later peak at 80 years [6]. The disease is more common in Caucasians, with an increased incidence in Ashkenazi Jewish men.

No well-defined etiology for HCL has been reported. Case reports have suggested an association with farming, woodworking, and exposure to organic solvents [7]. A recent hospital-based case-control study in France noted significant associations between HCL and organochlorine insecticides, and phenoxyacetic and triazine herbicides, though the numbers in the study were small [8]. Infectious etiologies such as EBV and HTLV-1 have also been postulated as causes [9, 10]. Familial cases of HCL have been rarely reported. Makower et al. described two cases of familial HCL. In one case, a 50-year-old man developed HCL and a year later his mother was diagnosed with the same entity. In the other family, an aunt of a patient with HCL was diagnosed with Hodgkin's disease. Interestingly, in both families, the younger generation developed the hematologic malignancy at an earlier age. This phenomenon, known as anticipation, has been noted in other malignancies [11]. Cases of familial HCL have also identified HLA haplotypes specific to each family. Each family's HLA haplotype was unique and there has been no identification of a common HLA haplotype among unrelated cases of HCL [11, 12].

Pathogenesis

Ontogeny

With the advances in molecular techniques, the ontogeny of HCL is becoming clearer. The hairy cell phenotype is that of a late B-cell precursor, likely an activated memory B cell, with aberrant gene expression [13]. The post-germinal center origin is supported by the presence of Bcl-6 mutations and somatic point mutations in the immunoglobulin variable region of the heavy chain [14, 15]. Furthermore, hairy cells express several pan B-cell markers including CD19, CD20, and CD37, but are devoid of the early markers of B-cell development, including CD21 and CD 24 [16]. Hairy cells express the plasma cell antigen-1 (PCA-1) but lack expression of PC-1 which appears later in B-cell ontogeny. This observation suggests that hairy cells do not differentiate into terminal B cells, i.e., plasma cells [3]. DNA microarray analysis illustrates a homogeneous phenotype distinct from other B-cell malignancies. When compared to normal B cells, hairy cells share many genes with memory B cells involved in proliferation and apoptosis [4].

Adhesion/Homing

Hairy cells are highly adherent and can spontaneously bind to several matrices, including fibronectin, vitronectin, and hyaluronan [17, 18]. This binding is facilitated by specific adhesive proteins on hairy cells, including the integrins α4β 1, α5β1, and αvβ3 [18]. Hairy cells characteristically disseminate into the red pulp of the spleen and hepatic sinusoids and portal tracts, but spare lymph nodes [19]. Not only do hairy cells infiltrate many different types of tissues, but they also modify the tissues they infiltrate. Thus, they cause bone marrow fibrosis and form vascular lakes (pseudosinuses) in the spleen [20]. This modification is inherent to the tissue matrix and is enhanced by hairy cell interactions [18]. For example, fibronectin is important in the development of bone marrow fibrosis and it is thought that hairy cells themselves are intricately involved in its production and assembly [17]. Recently, gene analysis has provided more insights into hairy cell adhesion and targeting. For instance, the lack of hairy cell lymph node infiltration can be explained by downregulation of CCR7, a chemokine receptor that allows B cells to enter lymph nodes. Also, hairy cells remain confined to blood-related compartments due to upregulation of genes that prevent their extravasation [4].

Cytogenetics

No karyotypic abnormality is pathognomonic for HCL. Clonal karyotypic abnormalities are variable and range from 20 to 67% of patients [21]. Unlike most other B-cell malignancies, HCL lack balanced chromosomal translocations which occur with immunoglobulin gene rearrangements that are switched off in memory B cells [13]. Instead, chromosomal gains, deletions, and inversions have been identified. In one study, 40% of karyotypic abnormalities involved chromosome 5, with aberrations in band 5q13 being most common [21]. Other chromosomal abnormalities include deletion of 14q and losses of the long arm of chromosome 7 [22, 23]. Evaluation by FISH has revealed that p53 deletions, a marker found in aggressive disease, occur in HCL. The clinical significance of this finding in an indolent disease is currently under investigation [24].

Diagnosis

Histopathologic and morphologic evaluation of the bone marrow is key to establishing the diagnosis of HCL [25]. Classical cytochemical stainings such as tartrate-resistant acid phosphatase (TRAP) have generally been supplanted by modern diagnostic techniques of flow cytometry and immunohistochemical (IHC) staining.

Cytology

Hairy cells are uniform and monotonous in their appearance [25]. A typical hairy cell is slightly larger than a mature lymphocyte with a distinct nucleus that is usually ovoid, but can also be slightly indented [25]. Unlike other B-cell malignancies, the chromatin is uniformly granular without clumping [26]. Morphologically, hairy cells display features suggestive of a metabolically active cell [27]. They have variable amounts of blue-gray cytoplasm and abundant mitochondria and ribosomes. Hairy cells exhibit thin cytoplasmic "hair-like" projections often appearing as serrated borders (Fig. 10.1). Phase-contrast microscopic studies of live cells show that the surface of these cells is in a constant state of change, reflecting ongoing cytoskeletal and signaling activity [13, 28].

Rarely, ribosomal lamellar complexes, or broad-shaped inclusions, can be seen in the cytoplasm on electron microscopy. These organelles are thought to originate from the endoplasmic reticulum and are characterized by alternating layers of ribosome-like granules and fibrous lamellae [29, 30]. Present in half of the cases, the ultrastructural inclusions are not unique to HCL and have been noted in other lymphoid malignancies [30]. They are of unclear clinical significance [31].

Hairy cell cytoplasm stains strongly for TRAP [32]. Isoenzyme 5 acid phosphatase present in hairy cell cytoplasm resists decoloration with tartrate [33]. Most other lymphoid cells, monocytes, and myeloid cells stain variably for

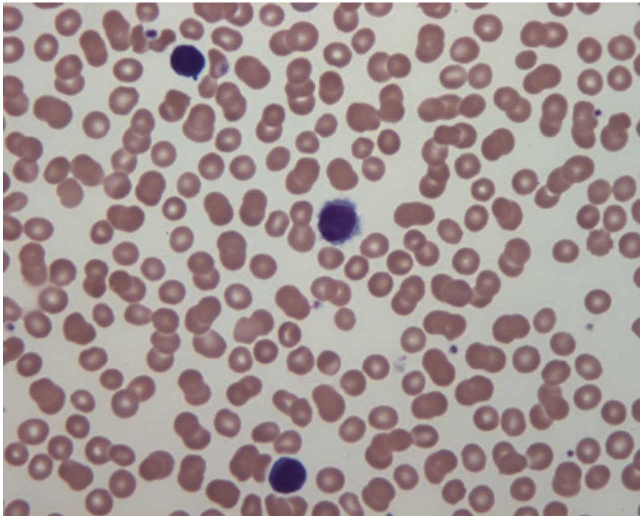

Fig. 10.1 Peripheral blood smear from a patient with HCL. The hairy cell is slightly larger than a mature lymphocyte with ovoid nuclei. Hairy cells characteristically have abundant, *gray-blue* cytoplasm with thin "hairlike" projections (×1000) (corresponds to figure pb 1000×)

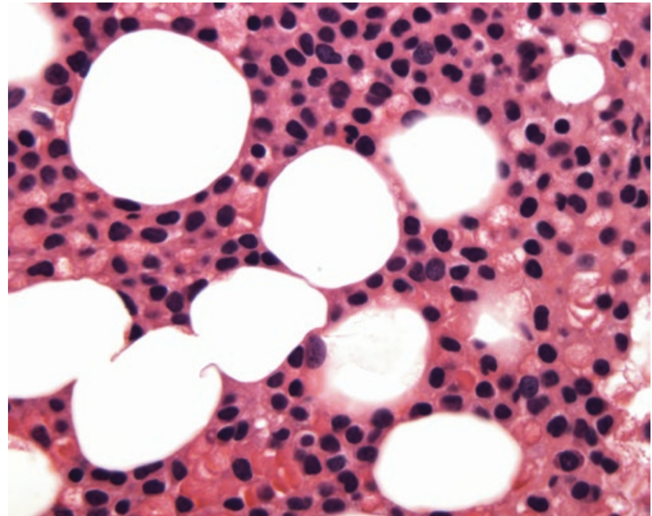

Fig. 10.2 Hairy cell leukemia in the bone marrow, characterized by well-spaced lymphocytes with a "fried-egg" appearance due to the distinct round-to-oval nuclei, which are centrally placed within a pale-staining cytoplasmic domain (×1000) (corresponds to figure bm 1000×)

acid phosphatase activity in the absence of tartrate [16]. TRAP staining is labor intensive and difficult to perform in paraffin-embedded tissues and it is rarely used in the era of immunophenotyping.

Histopathology

Blood and Bone Marrow

Abnormalities in the hemogram are classically seen at presentation in HCL patients [26]. Pancytopenia is common and reported in 80% of patients. Leukopenia is frequently noted [5]. Circulating monocytes are usually absent from the peripheral blood. Despite findings of marrow fibrosis, leukoerythroblastosis is not seen. Circulating hairy cells are variable and oftentimes very difficult to identify [26].

Bone marrow involvement is seen in nearly all patients with HCL [34]. It is often difficult or impossible to obtain an aspirate [25]. The biopsy can show a hypercellular picture. Hairy cells demonstrate patchy or diffuse infiltration of the marrow. A closer examination of the infiltrate reveals a distinctive wide-spaced separation of cells with a surrounding halo, often referred to as a "fried-egg" appearance (Fig. 10.2) [34]. This loose packing of cells results from hairy cells adhering to the reticulin–fibronectin network. Few fibroblasts are seen and trichrome staining does not show deposition of mature collagen [26]. The residual hematopoietic tissues exhibit nonspecific changes [34]. Other collection of cells including small lymphocytes, plasma cells, and mast cells is often identified. Not uncommonly, HCL produces a hypocellular marrow which can be difficult to distinguish from aplastic anemia. Immunostains with CD20 may be helpful (see Fig. 10.3) [35].

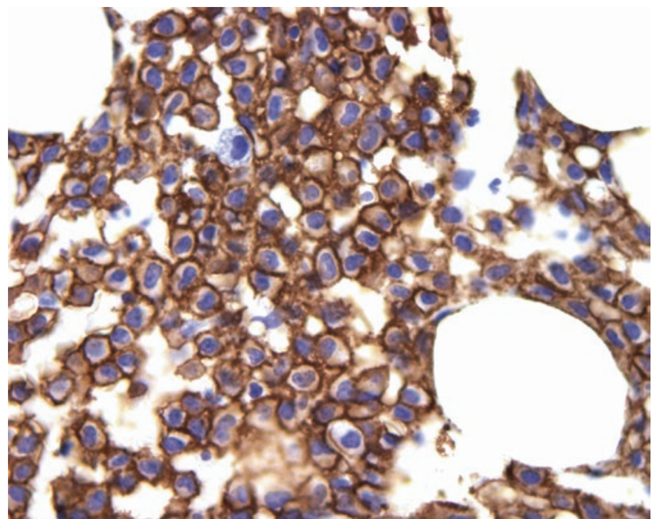

Fig. 10.3 Immunoperoxidase staining with anti-CD20 (B-cell marker), demonstrating strong membrane positivity (×1000). This stain is very useful in evaluating MRD in bone marrow specimens (corresponds to figure bm cd20 1000×)

Spleen and Liver

Splenic sequestration of hematopoietic elements is a characteristic feature of HCL [36]. HCL mostly affects the red pulp. On microscopy, there is a heavy infiltration of monotonous

cells in the expanded red pulp, sometimes making the individual cords and sinuses indistinguishable. The white pulp atrophies overtime [36]. Hairy cells replace endothelial cells that line the splenic sinusoids and merge to form congested splenic lakes, often appearing as hemangiomas [20]. Remodeling is thought to occur when hairy cells directly network with endothelial cells via integrin receptors and the vitronectin matrix of the basement membrane [13]. Such splenic findings are striking and can sometimes be seen in the bone marrow.

Similarly in the liver, hairy cells infiltrate the hepatic sinuses and portal tracts but spare the parenchyma. They also form characteristic lesions but appear more as angiomas than pseudosinuses since they lack circumferential ring fibers [20].

Genetic Features

With the use of whole-exome sequencing, Tacci et al. recently detected the BRAF V600E mutation in an entire cohort of 48 HCL patients. The absence of this variant in 195 patients with other peripheral B-cell lymphomas or leukemias established it as a key genetic lesion in HCL [37]. The oncogenicity of this mutation results from constitutive activation of the RAF-MEK-ERK mitogen-activated protein kinase pathway. Subsequent studies have confirmed the presence of the BRAF V600E mutation in HCL, with two exceptions [38, 39]; the molecular variants HCL-variant [38] and HCL with IGHV4–34 immunoglobulin rearrangement [39] lack this mutation. Thus, while distinct in the indolent lymphoproliferative disorders, the BRAF V600E mutation has yet to be incorporated into the diagnostic criteria for HCL.

Downstream of BRAF is MEK1, a dual-specificity kinase encoded by MAP 2 K1 (mitogen-activated protein kinase kinase 1). Mutations of the MAP 2 K1 gene have recently been identified in classical, variant, and IGHV-34-expressing HCL patients and appear to be mutually exclusive of the BRAF V600E mutation [40]. Aside from isolated reports [41, 42], MAP 2 K1 mutations in other hematologic malignancies have not been reported. This seemingly unique mutation makes it an attractive target for therapeutic manipulation and warrants further investigation.

Immunophenotyping: Flow Cytometry

Hairy cells can be identified by multicolor flow cytometry to a high degree of certainty even when they compose less than 1% of circulating lymphocytes [43, 44]. They display a mature B-cell phenotype and express pan B-cell markers including CD19, CD20, CD22, and CD 79A [16]. One or more heavy chains and a single light chain are displayed on the cell surface [45, 46]. Frequently, hairy cells demonstrate the presence of surface IgG, specifically the IgG3 isotype, and do not undergo normal B-cell differentiation with class switching [47]. Three markers of importance in the characterization of HCL include CD11c (common in myelomonocytic cells), CD25 (the IL-2 receptor), and CD103 (the alpha subunit of the alpha-beta integrin in intraepithelial T cells) [48–50]. Though these markers are not limited to HCL and can be seen in other lymphoproliferative disorders, such as splenic marginal zone lymphoma (SMZL), their co-expression is unique. For instance, CD11c is distinguished from other disorders by its nearly 30-fold higher intensity of expression in HCL [47, 49]. Moreover, CD103 has the greatest sensitivity and specificity for HCL [26, 51]. Researchers have evaluated the predictive value of the composite phenotype of these antigens. A scoring system was developed by the Royal Marsden Group using the markers: CD11c, CD25, CD103, and HC2 (HCL-associated antigen involved in cell differentiation). Ninety-eight percent of the evaluated cases of HCL had a score of 3 or 4 [52]. Also of note, primarily due to its potential therapeutic implications, is CD52, a marker that has recently been identified in both variant and classical HCL [53].

Further distinctions between variant and classical HCL can be made via flow cytometry. CD123, which is the alpha chain of the IL-3 receptor, is positive in the majority of classical HCL and dim or negative in variant HCL [54–56]. Additionally, CD25 has been shown to be commonly absent in HCL variant [56].

Immunophenotyping: Immunostains

Monoclonal antibodies with specificity for HCL are useful diagnostic tools. They can be performed easily in peripheral blood and paraffin-embedded tissues, and are thus valuable in the evaluation of minimal residual disease (MRD) in treated patients [16]. In addition to the routine B-cell markers like CD20 and PAX5, specific markers for HCL include TRAP, DBA.44, and cyclin D1 [27, 57, 58]. DBA.44 recognizes an unknown fixation-resistant B-cell antigen that is expressed in mantle zone lymphocytes, reactive immunoblasts, and monocytoid B cells [57]. It reacts strongly with HCL (Fig. 10.4) [59]. Although DBA.44 is expressed in other low-grade B-cell lymphoproliferative disorders, a recent study suggests that the combination of DBA.44/TRAP staining has a 97% specificity for HCL [60]. Moreover, CD20 immunostaining is a useful marker in quantifying disease, as it often highlights HCL infiltrates not detected on routine hematoxylin and eosin staining [61].

Annexin A1 (ANXA1) has been identified as a gene that is upregulated in HCL. One study evaluated samples of 500 B-cell tumors for the anti-ANXA-1 monoclonal antibody and found the assay to be both highly sensitive and specific

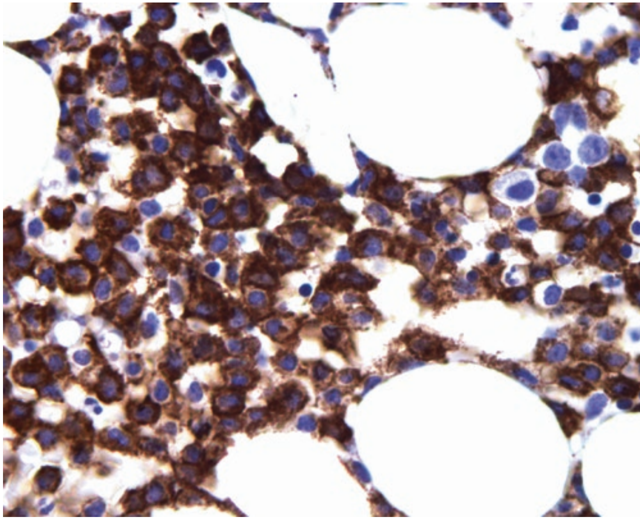

Fig. 10.4 Immunoperoxidase staining with DBA.44. in bone marrow of HCL patient. DBA.44 reacts strongly with HCL. A combination of DBA.44/TRAP staining has a 97% specificity for HCL (corresponds to figure dba-44 1000×)

for HCL (100%) [62]. This precision was not reproduced in a subsequent study, in which only 74% of HCL cases stained positive for ANXA1. Interestingly, none of the HCL variant or BRAF V600E-mutated HCL cases stained for ANXA1 [56].

Clinical Features

General

The onset of HCL may be insidious and its course chronic. It is characterized by pancytopenia and in particular monocytopenia, splenomegaly, and impaired immunity without significant lymphadenopathy [36]. This unique clinical presentation reflects the leukemic infiltration of hairy cells in the bone marrow, spleen, and liver.

In the original description of HCL, fatigue and weakness were the most common symptoms on initial presentation [1]. Also, frequently noted are symptoms of an opportunistic infection and abdominal fullness from splenomegaly. Some patients are incidentally found on physical examination or laboratory workup [5].

On physical examination, splenomegaly is the most prominent finding seen in 80–90% of patients. Spleen size may be variable, but sometimes can be massive [34]. Older studies have suggested that massive splenomegaly, along with patient age and hemoglobin concentration, is associated with a worse prognosis [63]. When present, hepatomegaly usually accompanies splenomegaly, and is seen in 50% of patients [5]. Palpable peripheral lymphadenopathy, unlike other chronic lymphoproliferative disorders, is not common [64]. Internal adenopathy is recognized in one-third of patients with HCL and is thought to be related to disease duration and may correlate with overall survival [64, 65].

Infectious Complications

Infections are a common complication in HCL and a cause of death throughout its course [36, 45]. Among multiple case series, the incidence of serious infections has ranged from 20 to 47%, which includes pneumonia and septicemia [36, 66, 67]. Pyogenic organisms consist of *Pseudomonas aeruginosa*, *Escherichia coli*, and *Enterococcus* species [68]. A higher frequency of intracellular organisms such as *Legionella pneumophila* and *Mycobacterium kansasii* has also been noted and thought to arise from defects in monocytes and decreased dendritic cells [45, 69]. Multiple studies have chronicled neutropenia and monocytopenia as contributing causes of the immunodeficiency in HCL [5]. A study of 73 long-term patients found that baseline lymphopenia may be a prognostic factor of increased risk of infectious complications [67].

Secondary Malignancies

Patients with HCL are at increased risk of secondary malignancies [70–72]. Secondary cancers have been attributed to decreased T-cell function from treatment as well as immunologic aberrations from the underlying disease itself [70, 73, 74]. In their 20-year experience with HCL, Wing et al. noted that 22% of their 117 patients developed second malignancies. Cancer risk peaked at 2 years after the diagnosis of HCL and then steadily declined [73]. The authors in this study conclude that HCL patients may be prone to secondary malignancies from the HCL tumor burden rather than genetic predisposition or the immunosuppressive effects of treatment.

Long-term data suggest that secondary cancers are only moderately increased with exposure to purine nucleoside analogues. In their extended follow-up of HCL patients treated with cladribine at Scripps Clinic, Goodman et al. noted 58 second malignancies in 379 treated patients [75]. A subsequent study at the same institution evaluated 83 patients ≤40 years with HCL treated with cladribine; though the excess frequency of developing a second primary malignancy was 1.60 (95% confidence interval, 0.80–2.89), it was not statistically significant [76]. In a retrospective analysis of 487 patients with HCL treated with purine nucleoside analogs, Cornet et al. reported an increased incidence of second malignancies, especially hematological malignancies (standardized incidence ratio 1.86, CI 1.34–2.51 for all malignancies; 5.32, CI 2.90–8.92 for hematological malignancies) [74]. The National Cancer

Institute (NCI) quantified second cancer incidence and cause-specific mortality among 3104 survivors of HCL between 1973 and 2002. They found that the rate of second cancers was 32% compared to the expected 23% in the general population [70].

Other

Extremely rare manifestations of HCL include cutaneous, bone, serosal, and meningeal involvement [77]. Hypocholesterolemia and elevated liver function tests are disease-related findings in HCL [78, 79]. Polyclonal and monoclonal gammopathies have also been noted in 3–20% of patients and can be associated with plasma cell disorders, lymphoma, or autoimmune processes. Autoimmune-associated disorders include polyarthritis nodosa and leukocytoclastic vasculitis [78, 80].

Differential Diagnosis

HCL must be distinguished from other chronic lymphoproliferative disorders that present with splenomegaly and cytopenias, such as hairy cell leukemia variant (HCL variant), splenic lymphoma with villous lymphocytes, and prolymphocytic leukemia. This distinction is critical since these different disorders have unique management approaches and respond quite differently to treatment with interferon-alpha and purine nucleoside analogues.

The differential diagnosis is based on morphologic and phenotypic criteria (Table 10.1).

Hairy Cell Leukemia Variant

HCL variant is a very rare B-cell lymphoproliferative disorder with features distinct from HCL. Patients with HCL variant

Table 10.1 HCL differential diagnosis

Lymphoid malignancy	Clinical characteristics (age/sex)	Morphology	Peripheral blood count	Immunophenotype	Genetics	Spleen	Survival
HCL	Median age: 50 years	Cytoplasm: Irregular	Neutropenia and lymphopenia	CD11c:+++	BRAF V600E mutation ++/–	Red pulp	87% at 12 years

+ present, – absent
HCL hairy cell leukemia, *SMZL* splenic marginal zone lymphoma, *CLL* chronic lymphocytic leukemia

are often diagnosed in their seventh or eighth decades and unlike HCL lack a strong male predominance. They typically present with splenomegaly and high leukocyte counts. Though cytopenias may be noted, neither monocytopenia nor neutropenia is a feature of HCL variant [81, 82]. The bone marrow and splenic histologies are similar to those of HCL [81]. Morphologically, cells of HCL variant are intermediate between HCL and B-cell prolymphocytic leukemia [83]. The cells lack monotony and are more varied in appearance. The nucleus is well circumscribed with a prominent nucleolus similar to that of prolymphocytes, while the cytoplasm is more basophilic [81]. Akin to the morphology, the diagnostic profile for HCL variant can be quite distinct. TRAP staining is variable and often negative. Considering the three markers that are characteristically expressed in HCL, CD11c is strongly positive, CD103 is positive in 60% of cases, and CD25 is negative [83, 84].

Examination of the immunoglobulin heavy-chain (IGH) rearrangements and somatic hypermutation patterns has noted significant differences between HCL and HCL variant. In fact, the mutation status of HCL variant mirrored splenic marginal zone lymphoma (SMZL) more than HCL. Specifically, IGHV4–34 was overrepresented in patients with HCL variant and SMZL [85]. Exploration of IGHV4–34 overexpression has established it as a distinct and separate entity from HVL variant, predicting an even worse prognosis [86, 87].

With an aggressive clinical course and refractoriness to traditional therapy, the median survival of patients with HCL variant is 9 years [84]. In addition, approximately 5–10% of patients have transformation to a large-cell process, characterized by significant leukocytosis, B symptoms, and an overall poor prognosis [88]. Moreover, a Japanese variant of HCL has also been described with large granular lymphocytosis [89].

Splenic Marginal Zone Lymphoma

SMZL is a chronic B-cell lymphoproliferative disorder characterized by splenomegaly and lymphocytosis with more polar villous projections. These cells are smaller than hairy cells and have more condensed chromatin [90]. When the hairy cell scoring system is applied to SMZL, the score is usually low [52]. CD103 is rarely positive in SMZL, and in most studies, CD25 and CD11c were positive in 25–47% of cases [91]. The immunologic profile of SMZL is very similar to that of HCL variant and can present a diagnostic challenge. Histologically, SMZL can be distinguished from HCL and HCL variant by splenic expansion of the white pulp and appearance of nodularity in the bone marrow [26].

SMZL usually has a more indolent clinical course with reported 5-year overall survivals of 80% [90].

B-Cell Prolymphocytic Leukemia

B-cell prolymphocytic leukemia is frequently noted in elderly males with prominent splenomegaly without significant lymphadenopathy [92]. The presenting WBC is elevated and often greater than 100×10^9/L with predominant prolymphocytes [93]. Like SMZL, B-cell prolymphocytic leukemia shares many similarities with HCL variant. B-prolymphocytes are larger lymphocytes with a condensed chromatin and a prominent central nucleolus. Immunophenotypically, they are CD25, CD103, and CD11c negative. Overall, they have a poor prognosis and their median survival is 3 years [94].

Treatment

General

Though HCL is an indolent disease, most patients ultimately require treatment [66]. Generally, patients are treated for worsening cytopenias (hemoglobin <10 g/dL, platelet count $<100 \times 10^9$/L, or absolute neutrophil count $<1.0 \times 10^9$/L), infectious complications, and symptomatic splenomegaly. Other less common reasons include bulky lymphadenopathy, progressive visceral or bony disease, or significant autoimmune processes.

Purine Nucleoside Analogues

For many years, splenectomy and interferon-alpha were the standard therapeutic approaches to HCL. The purine nucleoside analogues, cladribine [2-chlorodeoxyadenosine (2-CdA)] and pentostatin (2′-deoxycoformycin), came into clinical use in the mid-1980s and are considered to be the cornerstone of HCL therapy. The discovery that adenosine deaminase (ADA) deficiency produced lymphopenia in children with combined immunodeficiency syndrome led to the development of purine nucleoside analogues [95]. ADA is the major pathway for deoxypurine nucleoside degradation. Resistance to or inhibition of ADA can lead to a buildup of intracellular purine nucleotides which are very toxic to lymphocytes [96–98]. Cladribine (substrate analogue) and pentostatin (direct inhibitor) were developed to oppose the action of ADA.

Cladribine (2-CdA)

Cladribine is commonly chosen as the initial therapy because of its brief treatment administration and high, durable response rates. As a purine nucleoside analogue, it is resistant

to ADA. Cladribine accumulates in lymphoid cells because they have high levels of deoxycytidine kinase [98]. This enzyme phosphorylates cladribine, creating a deoxynucleotide which is then incorporated into DNA, thereby inducing DNA strand breaks and inhibiting repair. Cladribine's potency in indolent lymphomas is a function of its cytotoxicity to both dividing and nondividing lymphocytes [99].

Cladribine was first reported to be effective for HCL in 1990. Under the leadership of Ernest Beutler, investigators at Scripps Clinic first reported on 12 HCL patients treated with a single 7-day course of cladribine at 0.1 mg/kg/day by continuous intravenous infusion. Of those 12 patients, 11 achieved a complete response and the responses were maintained for 16 months [100].

The largest single-institution series was at Scripps Clinic and evaluated 349 previously treated and untreated HCL patients [71]. After a median follow-up of 52 months, 91% of patients achieved a complete response and 7% a partial response. Ninety patients (26%) had relapsed at a median of 29 months. The median survival rate at 48 months was 96%. Rosenberg et al. subsequently reported on 83 patients aged 40 years or less [76]. After a median follow-up of 251 months, 88% of patients achieved a complete response and 12% a partial response. Forty-five (54%) of patients who achieved a response ultimately relapsed at a median of 54 months. Median overall survival for all patients following the first cladribine course was 231 months. The authors hypothesized that the variation in survival data may be attributable to the intrinsic biologic differences between young and old HCL patients.

In the 25-year interval since the introduction of cladribine, many studies have acquired long-term patient data (Table 10.2). Among the assessable patients with HCL treated with cladribine as a single 7-day continuous infusion, complete responses have ranged between 76 and 100%. The majority of these patients have enjoyed long-term remissions with relapse rates of 14% at 24 months and 36% at 9.7 years [101, 102]. In one of the longest follow-up studies, 85% of the patients were alive at 20.9 years [76].

Standard cladribine dosing is a 7-day continuous infusion at a dose of 0.1 mg/kg/day. Alternative treatment schemes have been developed in the hopes of ameliorating prolonged myelosuppression and obviating the need for a pump. Alternative schedules have included a 5-day 2-h infusion at a dose of 0.14 mg/kg/day, weekly 2-h intravenous infusion, subcutaneous administration, and oral administration. Several studies have shown that the 2-h 5-day infusion is equally efficacious with a similar toxicity profile [111]. Robak et al. conducted a prospective study of 132 patients, comparing cladribine administered in a weekly versus daily schedule. Patients were randomized to receive either cladribine 0.12 mg/kg as a 2-h intravenous infusion daily for 5 days or 0.12 mg/kg in a 2-h intravenous infusion once a week for 6 weeks. Results of the trial showed similar complete remission rates, progression-free survival, and overall survival between the two groups. Despite prior reports showing improvement in infectious complications with the weekly dosing, there was no significant difference in grade 3 or 4 infections [112]. Similar results were noted in a Swiss study that compared subcutaneous daily 2-CdA with weekly treatment [113]. Though treatments with these alternative schedules appear promising, they lack the support of long-term follow-up, and the 7-day continuous infusion and 2-h 5-day infusion of cladribine are both considered standard.

Neutropenic fever is the principal acute toxicity of cladribine therapy in HCL, occurring in 42% of treated patients [71]. Infectious complications include bacterial and opportunistic infections. Immunosuppressive effects of

aafter a second course of cladribine in some patients

cladribine can persist for extended periods with decreases in CD4+ lymphocytes [103]. Herpes zoster is the most frequently reported late infection [75]. Granulocyte colony-stimulating factor (G-CSF) was evaluated in patients treated with cladribine therapy. Although G-CSF ameliorated neutropenia, it did not improve rates of neutropenic fever or hospital admissions for antibiotics and is thus not routinely recommended [114].

Pentostatin (2′-Deoxycoformycin)

Pentostatin is a natural product that is derived from *Streptomyces antibioticus*. Unlike cladribine, it irreversibly inhibits ADA and leads to the accumulation of cytotoxic metabolites. Pentostatin was first described to be an effective agent against HCL in the mid-1980s [115].

One of the largest studies evaluating its efficacy randomized 313 patients to pentostatin or interferon-alpha-2a for 6–12 months. This study used a crossover design where patients in the interferon arm could cross over to pentostatin upon progression. In the initial results, 76% of pentostatin patients achieved a complete remission compared to only 11% treated with interferon-alpha. In patients who crossed over from initial interferon to pentostatin, the complete response rate was 66% [63]. This study underscores the benefits of pentostatin both in treated and untreated patients. Flinn et al. reported on the long-term data from this trial with a median follow-up duration of 9.3 years. The relapse rate was 18% and included both patients initially treated with pentostatin and those who crossed over from the interferon arm. The estimated 5- and 10-year relapse-free survival rates were 85% and 67%, respectively. The 5-year survival was 81%. Acknowledging that this was a crossover design, the survival outcomes were similar between the two groups [116]. The findings in this study have mirrored other long-term follow-up trials with pentostatin (Table 10.3).

Currently, pentostatin is given every 2 weeks usually at a dose of 4 mg/m^2 for 3–6 months until maximum response is achieved. Previous experience with high-dose pentostatin (twice the standard dose) was associated with serious infectious complications [118]. With this interrupted dosing schedule, febrile neutropenia is significantly reduced, especially in comparison to cladribine [63, 71]. Other common side effects of pentostatin include nausea, vomiting, photosensitivity, and keratoconjunctivitis [119].

Cladribine and pentostatin have amassed significant long-term data with many years of follow-up. Else et al. reported on outcomes of 233 patients with a median follow-up of 16 years. In this retrospective review, treatment with single cycle of cladribine or multiple cycles of pentostatin showed equal efficacy: complete remissions (76% vs. 82%) and overall survival (100% vs. 95%) [101]. Lopez et al. described a median treatment-free interval of 95 months with first-line pentostatin and 144 months with first-line cladribine; the difference was not statistically different (p = 0.476) [107]. Despite similar effectiveness, a single course of cladribine is generally considered the preferred first-line treatment because of its brief treatment duration and paucity of adverse effects.

Other Treatments

Splenectomy

Historically, splenectomy was the first effective therapy for HCL. Splenectomy did not affect bone marrow infiltration, but did remove a major site of hairy cell proliferation and alleviated the symptoms of hypersplenism [120]. Most studies noted 60–80% improvement of blood counts with rapid improvements in thrombocytopenia [121, 122]. These responses were not consistent. The degree of splenomegaly was not predictive of hematological improvement or duration of response [123] and most patients ultimately relapsed. The median time to failure with splenectomy was variable, ranging from 5.4 to 56.5 months [124]. No randomized trial has shown a survival benefit with splenectomy [121, 125]. The present indications for splenectomy are active and uncontrolled infection, the resolution of which can be rapid and reflects the improvement of peripheral blood counts. Splenectomy is used in the rare event of a splenic rupture and is beneficial in patients with splenomegaly and severe

Table 10.3 Long-term follow-up studies with pentostatin

thrombocytopenia who are bleeding. Splenectomy can also be considered in the refractory setting as well as in the second trimester of pregnancy [121, 126].

Interferon

Interferon-alpha is an active agent in HCL and had a significant impact on treatment prior to purine nucleoside analogues. The exact mechanism of action is unknown, but it is thought that interferon-alpha acts as a cytostatic agent in HCL, inducing hairy cell differentiation and making these cells less responsive to growth stimuli [127].

In 1984, Quesada and colleagues first reported the successful use of partially purified alpha human interferon in seven patients with HCL. All seven had normalization of their blood counts with the responses maintained for 6–10 months [128]. Two recombinant interferon-alpha drugs were subsequently developed and approved by the FDA: interferon-alpha-2a and interferon-alpha-2b. Differing by only an amino acid, the recombinant forms showed equal efficacy [129].

Quesada's landmark trial has paved the way to many national and international trials. Treatment with interferon-alpha results mostly in partial remissions ranging from 69 to 87%. Few complete responses are noted and the duration of response is 18–25 months [129–131]. Long-term studies have reported improved survivals of 85–90% at 5 years [132, 133]. Interferon-alpha has activity even in previously treated patients and response rates are robust in patients with splenomegaly [131, 134]. The standard treatment for interferon-alpha-2b is 2×10^6 U/m^2 subcutaneously three times per week for 6–12 months and for interferon-alpha-2a is 3×10^6 U/m^2 three times per week for 12 months. The most common side effects of interferon-alpha are a flu-like syndrome consisting of fever, myalgias, and malaise. Rarely, central and peripheral nervous system complaints have been documented [128, 129].

Although interferon-alpha is an active agent in HCL, it does not induce the same complete responses seen with purine nucleoside analogues and thus is no longer utilized as initial therapy. Treatment with interferon-alpha should be reserved for patients with active infection who cannot receive a purine nucleoside analogue because of its associated immunosuppression.

Evaluation and Follow-Up of Treatment

Patients with HCL should be followed closely for months after treatment to evaluate for cytopenias, possible infectious complications, and ultimately treatment responses [113]. Recovery of blood counts may take weeks to several months following treatment with purine nucleoside analogues. In one study, the median recovery time to normalization of peripheral blood counts after the first cladribine course was 49 days (range 9–379 days) [71]. In addition to evaluating bone marrows for treatment response, translational studies have shown that soluble serum IL-2 secreted by hairy cells correlates closely with disease course and can be used as a noninvasive parameter for disease response [135]. Resolution of hepatosplenomegaly, adenopathy, cytopenias, and eradication of hairy cells from the peripheral blood and bone marrow by non-immunologic studies currently constitutes a complete response [136].

Despite robust responses to treatment with purine nucleoside analogues, long-term studies continue to show late relapses [76, 101]. With this in mind, researchers turned their attention to evaluating minimal residual disease (MRD) in posttreatment bone marrows, in the hopes of more completely eradicating hairy cell infiltrates. MRD can be identified by several techniques: immunohistochemistry using CD20, DBA.44, and CD45RO immunostains; immunophenotyping by flow cytometry; or polymerase chain reaction (PCR) [137–139]. Immunohistochemistry was initially thought to be more sensitive for detecting MRD [43]; however, upon direct comparison, PCR was found to be the most sensitive and specific test [138]. With increased diagnostic sensitivity, these studies have identified residual disease in 10–50% of patients previously thought to be in a complete remission [137, 140] (Table 10.4). This MRD usually represents <1% of the total cell population [137, 141].

Using a strategy of initial cladribine therapy followed by rituximab, researchers have shown that they can successfully eradicate MRD [144, 145]; however, it is not clear if this preemptive treatment strategy translates into improved clinical outcomes. Studies evaluating this question have shown mixed results. Sigal et al. reported on 19 patients who were

Table 10.4 Evaluation of minimal residual disease (MRD)

Study	Method of evaluation	Treatment	Patient (no.)	MRD (%)
Ellison et al. [137]	IHC with anti-CD20 and DBA.44	Cladribine	154	50
Hakimian et al. [140]	IHC with anti-CD20, anti-MB2, anti-UCHL-1	Cladribine	34	21
Wheaton et al. [141]	IHC with anti-CD20 DBA.44, anti-CD45RO	Cladribine	39	13
Matutes et al. [142]	IHC with anti-CD11c, anti-CD25, anti-CD103, and anti-HC2	Pentostatin	31	43
Filleul et al. [143]	PCR, IGH genes	Cladribine	10	100

in complete hematologic remission following initial treatment with cladribine with a median follow-up of 16 years [146]. Using flow cytometry and immunohistochemical staining (CD20, DBA.44, TRAP, and annexin positive), these investigators were able to determine that 47% of patients had no MRD. They also found that in patients with MRD or even gross bone marrow involvement, normal blood counts are possible. The study concluded that HCL is potentially curable and that patients with MRD can have long periods of complete remission [146]. More recently, Lopez et al. reported on a group of 82 patients initially treated with purine analogs and found a shorter treatment-free interval in patients with MRD compared to those without MRD (97 months vs. not reached, $p < 0.049$) [107]. Long-term follow-up with greater number of patients will be needed to fully appreciate the clinical significance of MRD.

Treatment for Relapsed and Resistant Disease

Purine nucleoside analogues elicit noteworthy responses in HCL. Despite this, there are a minority of patients who are refractory to treatment, and their prognosis is inferior. Researchers in Italy investigated biologic parameters in patients who did not respond to cladribine therapy. They found that the unmutated status of IGH variable region paralleled treatment failure and rapid progression of disease. Moreover, they identified defects in TP53 gene as a possible mechanism for resistance. These authors suggested that in such patients, a rituximab-based regimen may be more appropriate [147].

In addition to patients who are resistant to purine nucleoside therapy, long-term follow-up studies suggest that 20–40% of patients who initially had a response will eventually relapse. These patients have several options for therapy when treatment is indicated.

Re-treatment with Purine Nucleoside Analogue

Multiple studies have shown good efficacy when patients are re-treated with purine nucleosides. In the Scripps Clinic series, 62% of patients treated with a second course of cladribine on first relapse achieved a complete remission [71]. Similarly, in the Northwestern experience 83% of relapsed patients responded to a second cycle of cladribine therapy [106]. Even though cladribine and pentostatin have similar chemical structures, there is little clinical cross-resistance between the two drugs [148]. Else et al. showed that relapsed patients had a high rate of remission when treated with the other purine nucleoside analogue. On multivariate analysis, a shorter median duration of first remission was the only variable associated with a failure to attain a complete response [101]. Other studies have noted responses with purine nucleosides in the third- and fourth-line setting, but responses decline with each successive course [149]. No randomized trial exists to determine the optimal duration before re-treatment. Balancing efficacy with immunosuppressive effects of therapy, most experts recommend a 1-year interval before reconsidering purine nucleoside therapy [113].

Immunoconjugates and Targeted Therapies

Rituximab

Because hairy cells express CD20 brightly, rituximab, a chimeric monoclonal antibody against CD20, has become an important agent in salvage therapy. Hagberg first described rituximab as an effective therapy in a patient relapsing from HCL in 1999 [150]. Since then, multiple studies with rituximab have been conducted. Use of single-agent rituximab in the relapsed setting have shown response rates ranging from 25 to 80%, with complete response rates as high at 53% [151, 152]. Given these robust response rates, attention then turned to combination regimens with purine nucleoside analogs. Else and colleagues recently updated their results from a series of 26 patients treated with rituximab and either pentostatin ($n = 15$) or cladribine ($n = 11$) following purine analog treatment failure. Rituximab was administered at a dose of 375 mg/m^2 for 4–8 intravenous infusions (median 6.5). Twenty patients received rituximab concurrently and the remainder received sequential therapy. The overall response rate was 96%, and the complete response rate was 88%. At a median follow-up of 78 months, relapse-free survival following combination therapy was markedly improved compared to the RFS of the same patients following their prior first-line treatment (hazard ratio: 0.10; 95% CI: 0.03–0.32; log-rank $p < 0.0001$). Relapse-free survival at 10 years was 87% (95% CI: 75–100%) following combination therapy, versus 12% (95% CI: 0–24%) following the patient's same first-line treatment [153]. The authors did note certain discrepancies: some patients may have had a heavier baseline disease burden at the time of initial therapy compared to relapse, and 8 of the 26 patients received purine analog in combination therapy that they had not been previously exposed to. Though additional studies of rituximab combination therapy with purine analogs have also shown high response rates for classical [154–156] and variant HCL [157], true randomized trials are lacking.

BRAF Inhibitors

Building on the Italian group's discovery of the BRAF V600E mutation in a very high percentage of classical HCL patients, studies exploring the role of BRAF inhibitors have

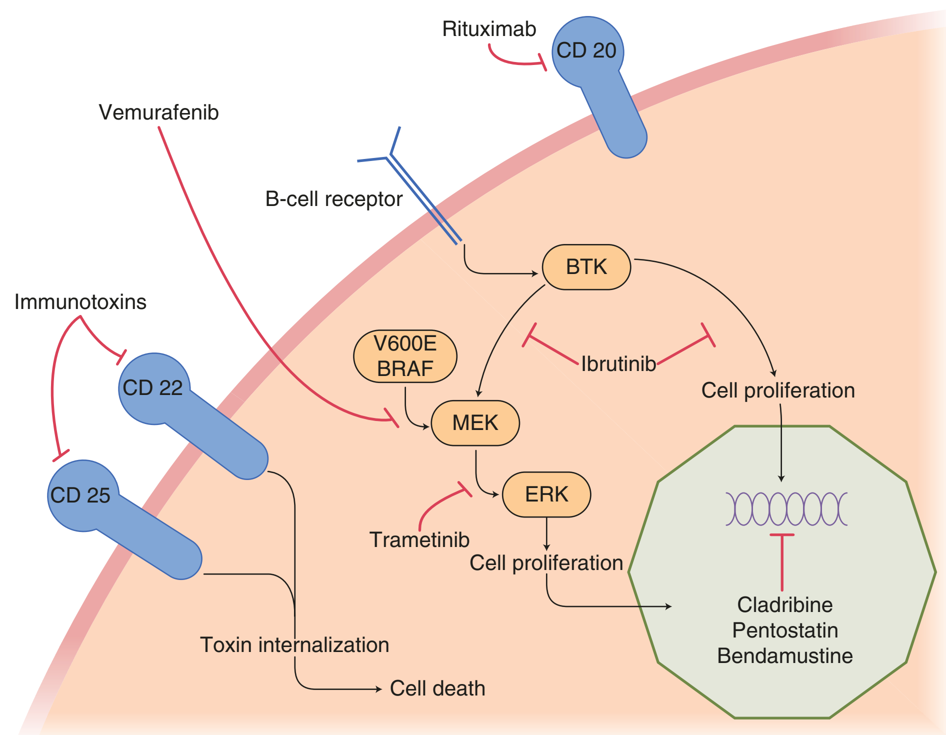

Fig. 10.5 Hairy Cell leukemia therapeutic pathways. *MEK* indicates mitogen-activated protein kinase, *ERK* extracellular signal-regulated kinase, *BTK* Bruton's tyrosine kinase

yielded encouraging results. Early case reports revealed rapid responses, including complete responses, in multiply treated relapsed and refractory classical HCL patients treated with the oral BRAF inhibitor, vemurafenib [158–161] (Fig. 10.5). More recently, results from two phase 2, single-group, multicenter studies of vemurafenib at a dose of 960 mg twice daily were published [162]. The studies were conducted in Italy and the United States. In the Italian study, treatment was administered for a minimum of 8 weeks and, if patients did not have a complete response, for a maximum of 16 weeks. At a median follow-up of 23 months, relapse-free survival was 19 months among patients with a CR. In the US study, patients received treatment on a continuous schedule for 12 weeks; however, patients with residual disease were allowed to receive vemurafenib for up to 12 additional weeks. Median treatment duration was 18 weeks and resulted in an overall survival rate of 91% after a median follow-up of 12 weeks. Therapy was generally well tolerated; drug-related adverse events were mostly grade 1 or 2. Toxicities included rash, arthralgias, and arthritis, among others. However, despite the high response rates, MRD was noted in all patients with complete responses at the end of treatment. In both trials, re-treatment with vemurafenib at relapse elicited some responses.

In the Italian study, bone marrow specimens from 13 of 26 patients were evaluated for phosphorylated ERK and PAX5 double immunostaining. Residual hairy cells expressing ERK were seen in 6 of the 13 patients. All 6 of these patients had a partial response to vemurafenib. Conversely, two patients with complete responses did not express phosphorylated ERK. Post hoc analysis revealed a prolonged median progression-free survival for patients with phosphorylated ERK compared to those lacking this (8 months vs. 13 months, respectively). In addition, residual disease (assessed by the Hairy Cell Index) was greater in patients with persistent phosphorylated ERK than those without measurable ERK. These investigators proposed that circumvention of BRAF inhibition may be explained by alternative mechanisms for reactivating MEK and ERK. The persistence of HCL cells and potential identification of resistance mechanisms indicate the need for additional therapy to improve response rates. One potential method may be to combine a BRAF inhibitor with another drug that targets the pathway, like an MEK inhibitor, as has been done in melanoma patients [163].

MEK Inhibition

The activity of the MEK inhibitor, trametinib, was recently supported by both in vivo and in vitro studies [164]. Pettirossi et al. isolated HCL cells from 26 patients and exposed them in vitro to active BRAF inhibitors (vemurafenib or dabrafenib) or trametinib. The in vitro results were subsequently validated in vivo in the phase 2 study of refractory and relapsed HCL patients treated with oral vemurafenib as detailed above. Vemurafenib, dabrafenib, and trametinib incubation resulted in dose-dependent MEK and ERK

dephosphorylation as well as considerable loss of the hairy morphology. Moreover, the ERK dephosphorylation and apoptosis appeared to be potentiated by the combination of BRAF and MEK blockade with dabrafenib and trametinib. These findings highlight feasible approaches for new treatment options and warrant investigation.

Recombinant Immunotoxins (CD22, CD25)

Recombinant immunotoxins are antibody-toxin chimeric proteins. By engineering the antibody moiety to target antigens expressed preferentially in HCL cells, the toxin moiety is able to exert lethal effects selectively. Recombinant immunotoxin research in HCL has focused on CD25 and CD22.

Kreitman et al. have extensively reported on the efficacy of BL22, a recombinant immunotoxin comprised of a pseudomonas exotoxin fused to a single-chain variable fragment of anti-CD22 [165–168]. Initial results revealed complete remissions in patients with HCL resistant to purine analog therapy [165]. Phase 2 testing of 36 patients with relapsed and refractory HCL, including three patients with variant HCL, was completed [167]. In this study, the complete response rate was 25% after one cycle. Twenty patients were then re-treated, and 47% achieved a complete response. Interestingly, response rates were higher in non-splenectomized patients without massive splenomegaly. Two patients experienced reversible grade 3 hemolytic uremic syndrome, which did not require plasmapheresis. Subsequently, moxetumomab pasudotox, a new recombinant immunotoxin with a 14-fold increased binding affinity for CD22, was developed. Phase 1 testing results are encouraging; the overall response rate was 86% and complete remissions were seen in 46% (13 patients). At 26 months, the median disease-free survival had not been reached. No dose-limiting toxicities were observed [169].

LMB-2 is a recombinant immunotoxin formed from the fusion of a CD25 antibody to the PE38 toxin. Phase 1 testing of this agent in 35 patients with chemotherapy-refractory CD25-expressing hematologic malignancies revealed measurable responses [170]. The most dramatic activity was seen in the HCL cohort. In this group of four patients, one had a complete response, two had partial responses, and the remaining patient had stable disease. Dose-limiting toxicities included reversible cardiomyopathy and transaminitis.

Alemtuzumab

Though it has not been extensively studied, there have been case reports suggesting the activity of alemtuzumab, a humanized monoclonal antibody against CD52, in HCL [171, 172]. Sasaki et al. treated a patient with variant HCL with splenic irradiation followed by alemtuzumab [171]. Splenomegaly resolved, and leukemic cells were eliminated from the peripheral blood by day 12. These reports warrant further investigation into the role of CD52 targeting in the treatment of HCL.

Bendamustine

Bendamustine is a chemotherapeutic agent with features of both alkylators and purine analogs. Following its initial report [173], bendamustine was further studied in relapsed and refractory HCL patients [174]. The results were encouraging; the overall response rate was 100%. At a dose of 90 mg/m^2 on days 1 and 2, for 6 cycles at 4-week intervals, 67% achieved CR, 100% of which were without MRD. At a median follow-up of 31 months, all complete responders with absent MRD remained in CR. Phase 2 trials are currently under way [175].

Ibrutinib

Ibrutinib, a selective and irreversible inhibitor of Bruton's tyrosine kinase (BTK), has activity in multiple low-grade lymphoproliferative disorders including chronic lymphocytic leukemia, mantle cell lymphoma, and Waldenstrom's macroglobulinemia. Recently, Sivina et al. reported their findings showing that BTK protein is expressed in HCL cells, and ibrutinib significantly inhibited HCL cell proliferation, cycling, and survival [176]. Preliminary safety and efficacy data was recently presented [177], and a phase 2 clinical trial is currently under way [178].

Conclusion

Since its initial description more than 50 years ago, the natural history of HCL has been dramatically altered. In the era of Bouroncle, treatment options were few, including splenectomy, and the median survival was only 4 years. Now with purine nucleoside therapies, many patients enjoy long-term remissions frequently surpassing 10 years with good quality of life. The final chapter in this remarkable tale, however, has not been written. Despite excellent responses to the purine nucleoside analogues, cladribine and pentostatin, a small minority of patients will not respond and a proportion who do will eventually relapse. Though these patients respond upon re-treatment, the responses are less rigorous and there is a concern that further therapy will cause long-term immunosuppression. Moreover, disease-free survival curves have failed to show a plateau after 10 years [149]. A few long-term studies, however, have suggested that some patients may be cured. Focusing attention on identifying refractory

patients with HCL through biologic parameters and employing treatment strategies with targeted agents, monoclonal antibodies, and recombinant immunotoxins are currently under investigation. Introduction of BRAF targeting agents represents a major therapeutic advance and addition to the therapeutic armamentarium for patients with refractory or relapsed disease. More research is still needed in understanding the fundamental biology of this disease. Filling in the gaps in our knowledge of the pathophysiology will aid in the development of better treatments with the prospect of more patients enjoying long-term disease-free survival and perhaps even a curative strategy. Also, delving into the biology of HCL will provide insights and potential treatment directions for more common indolent lymphoproliferative diseases.

Acute Leukemias

History of Acute Leukemia

11

Emil J Freireich

Introduction

In 1953, the United States Public Health Service opened the 500-bed clinical center on the Bethesda campus of the National Institutes of Health. James Holland, who had trained at the Francis Delafield Hospital of the Columbia University School of Medicine, was among the first clinicians to join the faculty of the National Cancer Institute's clinical center and he began to utilize these agents for the treatment of children with acute leukemia. In 1954, Charles Gordon Zubrod was recruited to the clinical center to become the head of the medicine branch in the Cancer Institute and he recruited Emil Frei III, who was his chief resident, to come with him to the Cancer Institute. Early in 1955, Emil J. Freireich joined the Cancer Institute with a background in hematology.

Dr. Holland left the Cancer Institute in 1954 to move to Buffalo, the Roswell Park Memorial Institute, and when Freireich arrived in Bethesda there were three patients in the hospital with acute lymphoblastic leukemia. What the new group decided to do was to utilize the newly described technique of the prospective randomized controlled clinical trial which was so successful in developing the antimalarial drugs during the war, and secondly, to test the hypothesis that combination chemotherapy would provide synergistic effects—this had been demonstrated in the treatment of infectious diseases, particularly tuberculosis. In reviewing what was published up to that date on the chemotherapy of acute leukemia, these young investigators discovered that the agents that were described to induce temporary remissions when used singularly [1–8] did not significantly affect the natural history of acute leukemia [9]. They initiated a collaborative study between the group at the Cancer Institute in Bethesda and Dr. Holland and his group at Roswell Park in Buffalo. The goal of the first study was to evaluate the effectiveness of a combination of 6-mercaptopurine and methotrexate. They first reviewed the world's literature on the normal values for blood and bone marrow, physical findings, and symptoms, and published objective criteria for defining complete remission, partial remission, and hematological improvement which were to be used in this cooperative group study [10].

Secondly, a detailed research protocol was constructed and agreed to by the investigators at both institutions, and they devised data collecting flow sheets which mandated the measurement of bone marrow, blood, physical findings, and symptoms at regular intervals. This first study was a landmark study in that it established the feasibility of doing formal clinical trials, and it provided objective quantitative information of the frequency and duration of response and survival for a group of 63 consecutive patients [11].

Because the results of the combination study looked promising, the second protocol, Protocol 2, systematically compared the combination to each of the two drugs used as single agents followed, on failure, by a crossover to the other agent. These studies were designed based on mouse leukemia studies conducted by Lloyd Law and Abe Golden which suggested not only the concept of combination chemotherapy, but also the possibility that there was collateral sensitivity, i.e., the disease resistant to one agent would have enhanced sensitivity to the other. Protocol 2 had three arms—the combination of methotrexate and 6-mercaptopurine which was given at 60% of their maximum tolerated dose that was worked out in mouse toxicology studies because these two drugs were both myelosuppressive agents; and 60% of each combined to a maximum tolerated dose for the two drugs, which was compared with the full therapeutic dose of methotrexate, followed by 6-mercaptopurine upon failure; and the third arm was 6-mercaptopurine followed by methotrexate upon failure. While this study was being prepared, the results of Protocol 1 were publicized through scientific meetings and a number of institutions, specifically ten institutions, elected to join in the study; so Protocol 2 was

able to accrue a much larger sample size in a reasonable period of time. The results of that study were positive in the sense that the combination of the two agents was more effective—in terms of frequency and duration of response, and survival—than the two agents used in either sequence, but no collateral sensitivity was demonstrated [12].

It was clear that one strategy for the control of acute leukemia was to discover new agents with unique mechanisms of action. In the first such study undertaken by the National Cancer Institute group—the study of 6-azauracil which was shown by Arnold Welch in experimental animals to have a high degree of activity—the results of the Phase 2 study revealed some hematological improvements in the patients, suggesting that this was a potential drug for using in newly diagnosed patients [13]. But, before that was undertaken, they recognized that they had little information on patients who had been extensively treated previously with the three active drugs. So, they undertook the first prospective randomized controlled trial in cancer research comparing 6-azauracil to a placebo in these terminal advanced refractory leukemia and found that there was no significant difference between those treated with placebo or the active drug [14]. This was an important study because it demonstrated the importance of concurrent controls and quantitative assessment of response—because the disease was not inevitably progressive and quantitative information to build new hypotheses was essential.

For Protocol 3 [15], they hypothesized that the patients would be in better physical and clinical condition in remission, and therefore, they would have a better opportunity to assess the activity of new agent. The clinical trial was designed to expose all children to the most active remission-inducing drug which, at that time, was hydrocortisone, resulting in approximately 60% of the children achieving complete clinical and hematological remission. The children were then randomized to receive either placebo or 6-mercaptopurine, which was known to be active in inducing complete clinical and hematological remission in approximately 30% of the patients with active leukemia. The study was designed in an innovative way using a sequential design, so that when the probability that one was better than the other was greater than 95% the study stopped automatically. The results of this study were impressive because it first demonstrated a substantial prolongation of remission with 6-mercaptopurine, and it established that corticosteroid-induced remissions had a median remission of only 8 weeks and all patients had recurrence at approximately 10 months. In contrast, the patients who received mercaptopurine, all patients, not just 30%, had significant prolongation of remission and approximately 10–15% of the patients remained in remission for more than a year, which was an unheard of result with any prior therapy. Moreover, those who received placebo and were subsequently treated with 6-mercaptopurine and methotrexate had overall survival which was comparable to the patients who received 6MP during remission, indicating that their survival was not significantly compromised. The results of this study demonstrated, for the first time, the principle of adjuvant chemotherapy, i.e., chemotherapy given to patients free of clinical disease was substantially more effective than the same therapy given to patients with active disease. That was the major outcome of this study, even though that was not the initial plan.

The next major development was the discovery of the vinca alkaloids by Irving Johnson working at Eli Lilly Laboratories. In an effort to develop new antidiabetic drugs, Eli Lilly screened many natural products and the extract from the periwinkle plant contained alkaloids that had little effect on glucose metabolism, but did cause substantial myelosuppression in mice. Dr. Johnson had the impressive thought that this drug might be active in leukemia. To that end, Eli Lilly, at great expense, extracted this alkaloid from very large quantities of the periwinkle plant and initiated clinical trials in Children's Hospital in Boston and with the group at the National Cancer Institute. The Phase 2 trial with this drug gave dramatic responses. Over 50% of the children with far advanced disease refractory to the three known agents developed rapid, complete clinical and hematological remissions [16]. Like steroids, these remissions were short, approximately 8 weeks on average, but the results were impressive and the limiting dose toxicity for this drug was not myelosuppression, but central nervous system and peripheral nervous system toxicity. The group had learned that one could add the full therapeutic dose of adrenocortical steroids, which is not myelosuppressive, to the myelosuppressive drugs methotrexate or 6-mercaptopurine, and in both instances, frequency of complete response to the combination was higher than that predicted from the results of each individual drug used in previously untreated patients. This led the NCI group to consider the possibility of combining all four known active agents into a single therapy because they recognized that vincristine and prednisone did not have additive toxicity, nor were they myelosuppressive. They knew the maximum tolerated dose of the combination mercaptopurine methotrexate, so they created the first multi-agent four-drug chemotherapy regimen, and even more importantly created the first eponym for this combination (VAMP): vincristine, amethopterin, mercaptopurine, and prednisone. The results of the VAMP study were impressive—over 90% of the children entered remission rapidly and with minimal side effects. Since they had recognized the importance of adjuvant chemotherapy from Protocol 3, the NCI investigators used early intensification of the remission induced by VAMP and gave three induction courses to the children in remission. What they observed was that the duration of remission was as long as that achieved with adjuvant 6-mercaptopurine. Then they introduced the concept of continuous intermittent re-induction therapy specifically; they gave the same four agents for induction, consolidation, and continued intermittent therapy at monthly intervals for 1 year (POMP). By 1964, with over 3 years of follow-up, they reported

that one-third of the patients were still alive and disease free, and they suggested that these patients were "cured" of their childhood lymphoblastic leukemia—a prediction which has proven to be correct [17–19].

Treatment of childhood ALL progressively improved over the next 40 years with the addition of new agents, such as asparaginase. The recognition of the importance of meningeal leukemia and the role of prophylaxis for central nervous system involvement is such that at present at least 80–90% of such patients are literally cured of their disease with chemotherapy alone [20].

When the activity of 6-mercaptopurine, methotrexate, and prednisone was described, it was early recognized that the cytological details of the morphology of these leukemia cells were suddenly extremely important. Those leukemia patients who had a lymphoid phenotype responded dramatically, whereas those who had myeloid characteristics had the same natural history as in the untreated state and were found to be quite resistant to chemotherapy [21]. The other prognostic factor that was identified was that the optimal responses occurred in patients under 10, and in patients over 20, the frequency of response and survival was significantly lower.

In addition, they recognized the importance of the degree of leukocytosis as an important prognostic factor.

VAMP was primarily active in children with acute lymphoblastic leukemia. The investigators attempted the same four-drug combination (POMP) therapy in children with myeloid phenotype and in young adults. Although the effects were much less dramatic and quantitatively less effective, they nonetheless reported that approximately 25% of adults in this case (median age well below median age of approximately 40) could achieve complete hematological remission, and with intermittent maintenance, these remissions could last for approximately 1 year. These data were assembled and submitted to the journal, *Blood*, for publication. The manuscript was rejected and Dr. Dameshek, founder of the journal and the editor-in-chief, was inclined to write editorials on the progress in hematology and he wrote an editorial in 1965 which said, "However, not only was this method unscientific, but the initial toxic reaction may be lethal, particularly in adults. Furthermore, it has not yet been clearly shown that this treatment program offers a significant advantage over more conservative approaches. In general, however, they may be thought to represent 'gropings' which engender little enthusiasm for long-term advantages" [22].

The situation for adults in 1965 was still poor—prednisone and 6MP gave 10% responses, and POMP reported to give 25% responses; these were largely ignored by the medical community as being too toxic for adult patients. The breakthrough occurred with the description of the activity of arabinosyl cytosine in 1963 [23].

In 1968, Ellison and Holland described the induction of remission in adults with acute myeloblastic leukemia [24]. Based on the animal experiments which were conducted by Skipper and Schabel at Southern Research Institute [25], it was demonstrated that Ara-C was schedule dependent.

M.D. Anderson reported that a group of patients in 1967 were treated by continuous infusion over 120 h or 5 days [26]. The Southwest Oncology Group conducted a dose schedule study which demonstrated that single injection of Ara-C as high as 3 g/m^2 did not cause myelosuppression, but infusion of 48 h or longer had dose-responsive myelosuppression [27]. The Southwest Oncology Group then compared 48- and 120-h infusions which showed higher frequency and longer duration of response with 120-h infusions [28].

In 1964, an Italian group discovered the natural product, daunorubicin, an anthracycline, antibiotic [29]. And in 1969, adriamycin, another anthracycline antibiotic, was discovered [30]. Both of these drugs had substantial single-agent activity in patients refractory to Ara-C. What followed was a series of studies combining the anthracycline antibiotics with Ara-C in its best schedule. Many of these combinations were studied in cooperative groups, but the one that proved to be best tolerated and most effective for the highest number of patients was the famous 3 and 7 regimen—3 days of daunorubicin and 7 days of continuous infusion of arabinosyl cytosine [31].

The academic hematology community received these reports with skepticism. As late as 1974, one of the giants of hematology, William Crosby, published "chemotherapy should be used only sparing in related cases of leukemia, since the treatment may be killing more patients than proponents of aggressive therapy realize" [32].

In 1976, the editors of the Archives of Internal Medicine published a series of papers in rebuttal of Crosby's comments supporting the use of chemotherapy for adults with AML [33–35].

In 1981, it was clear that the natural history of AML had changed substantially at least for a fraction of these patients [36]. For the first time, completed 5-year survival was observed in approximately 15% of the patients diagnosed with AML before 1976. Shortly thereafter, a major review of the treatment of acute leukemia in many centers and in the cooperative groups was conducted and it was clear that these results from a single institution were confirmed not only in many institutions but also in multi-institution studies. And an analysis of long-term survival was published in 1983 [37].

With the advent of techniques to study the human chromosomes, including banding to identify the individual chromosomes, many investigators reported that acute leukemia patients had a number of abnormalities in the chromosomes which were apparently random. However, in 1979 Trujillo recognized the first nonrandom chromosome abnormality—the translocation between chromosomes 8 and 21 [38]. Over the following years, many nonrandom chromosome abnormalities were identified which allowed a systematic classification of acute leukemia into groups [39]. Favorable was the

inversion 16, the translocation 8:21, and the translocation 15:17, which constituted approximately 20% of all the acute myeloid leukemias. For these diseases, chemotherapy provided long-term (3 years or longer) survival for the majority of the patients. About one-third of the patients had complex cytogenetic and these were clearly unfavorable, where long-term survival occurred rarely. Then the remaining 50% were intermediate: mostly diploid patients who had an intermediate outcome of approximately 20% long-term survival. The most dramatically distinctive group of AML patients was the group which had the translocation between chromosomes 15 and 17 which created a neo-gene (the RARA/PML gene) which was susceptible to remission induction by all-trans-retinoic acid. With the addition of arsenic trioxide it became possible for this small subset of AML patients (approximately 6–10%) to enter complete remission with long-term survival and without any cytotoxic chemotherapy [40]. The discovery of the cytogenetic classifications of patients formed the basis for the new molecular oncology so that now specific genetic traits are used not only for diagnosis and choice of therapy, but also for the detection of residual disease and for guiding the courses of therapy [41].

Another important advance was the development of myeloablative allogeneic stem cell transplantations [42, 43]. This was shown to result in long-term survival for a significant fraction of patients with acute leukemia. This therapy has become a significant therapy, particularly for patients in remission. The transplant techniques have also improved rapidly with the use of peripheral blood stem cells, reduced intensity conditioning and improved tissue typing, matched unrelated donor pools, and improved control of complications such as infection and graft-versus-host diseases [44].

Conclusion

Considering the transformation of AML from a universally fatal untreatable disease in the mid-1960s to one with a significant portion of cured patients and a very high proportion of patients who respond to therapy in a half century, this rapid progress suggests strongly that knowledge about the biology and therapy of acute leukemia will increase at an accelerating pace and hopefully lead to control of this disease in the near future. Recent authoritative reviews of progress in acute leukemia treatment have appeared [45, 46].

The Etiology of Acute Leukemia

12

J.N. Nichol, M. Kinal, and W.H. Miller Jr.

Introduction

Leukemia is a clonal disorder of deranged and disordered hematopoiesis that results from the acquisition of mutations in hematopoietic progenitors that confer a proliferative and/or survival advantage, and impair hematopoietic differentiation. In the case of acute myeloid leukemia (AML), these progenitors are from the myeloid lineage and for acute lymphocytic leukemia (ALL), these progenitors are from the lymphoid lineage (Fig. 12.1). Specifics concerning the clinical features and treatment of acute leukemia can be found elsewhere in this textbook. This chapter focuses on the molecular pathogenesis of acute leukemia.

Over a decade ago, Kelly and Gilliland [1] proposed a two-hit model for the development of AML, which is also applicable to the development of acute lymphoblastic leukemia ALL, whereby they hypothesize that these diseases emerge as a consequence of an association between at least two broad classes of mutations (Fig. 12.2). Class I, or activating, mutations typically result in the aberrant activation of signal transduction pathways and provide a proliferative and/or survival advantage to hematopoietic progenitors. Class II mutations arrest differentiation because of loss-of-function (LOF) mutations in key transcription factors or cofactors that are important for normal hematopoietic differentiation.

Cumulative evidence from different murine models of leukemia provides support for the necessity of cooperative transforming events for leukemogenesis. Induced mutations in these models result in increased self-renewal capacity and reduced differentiation, but are not sufficient to induce malignant transformation, and acute leukemia was not observed in mice until the mutations were combined with a dose of the chemical mutagenic agent, *N*-ethyl-*N*-nitrourea (ENU) [2–4].

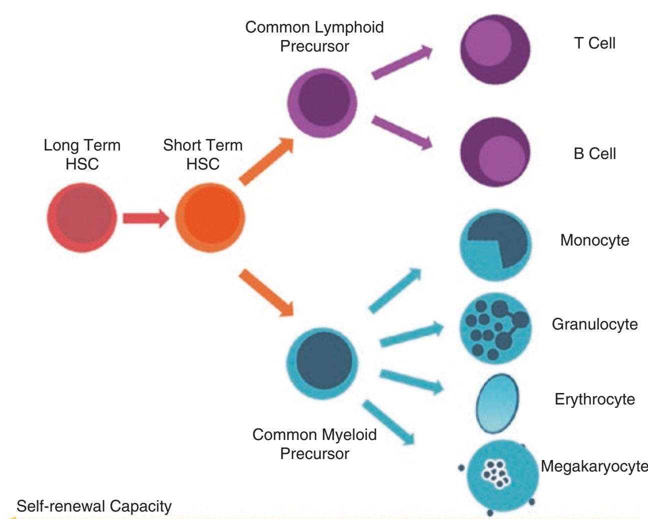

Fig. 12.1 *The hierarchy of hematopoietic development*. Long-term stem cells (HSCs) develop into different precursor cells, whose self-renewal capacity and developmental potential become progressively more restricted

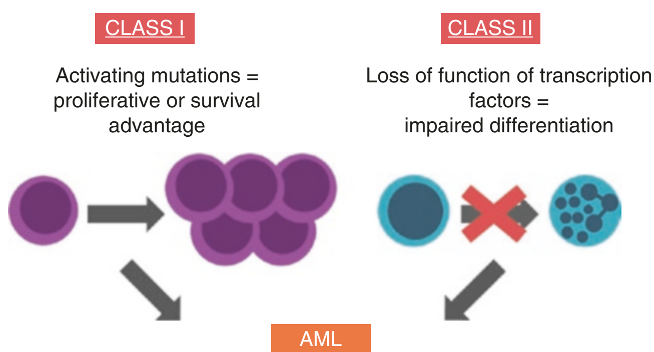

Fig. 12.2 *The two-hit model of acute leukemogenesis*. This model hypothesizes that AML and ALL are the consequence of a combination of at least two broad classes of mutations. Class I mutations involve an activating lesion in signaling pathways and confer a proliferative and/or survival advantage to hematopoietic cells. Class II mutations lead to an arrest of lymphoid or myeloid differentiation as a result of loss of function of transcription factors or cofactors that are important for normal hematopoietic differentiation

A study of monozygotic twins who both developed ETV6/RUNX1-positive ALL [5] with identical chromosome breakpoints, but with different timelines, provides further support for the requirement of secondary genetic insults. Additionally, common leukemia- and lymphoma-associated genetic rearrangements are found in the peripheral blood of individuals with no history of either disease [6] and there are rare familial leukemia syndromes, involving germline *CEBPA* [7] and *RUNX1* mutations [8], where affected individuals exhibit an enhanced, but not guaranteed, risk of developing leukemia.

Over the past decade, technological advances have revolutionized our ability to interrogate cancer genomes, culminating in whole-genome sequencing (WGS), which provides genome-wide coverage at a single base-pair resolution. The information provided by these more sophisticated methods reveals that class I and II mutations are only one part of a more intricate framework. To date, the tumor genome has been sequenced in hundreds of cases of acute leukemia [9–14], and the latest numbers suggest that each AML genome contains hundreds of mutations, including anywhere between 5 and 23 coding mutations [14]. Most of these mutations are “background,” or passenger mutations that were acquired during normal aging of hematopoietic stem cells, but some novel “driver” mutations have been discovered through WGS analysis [11]. Many of these mutations do not fit into either Class I or Class II, suggesting that the “two-hit model” is perhaps oversimplified [9]. Moreover, there is evidence that the sequence and timing of the aberrations during development may be important, suggesting that the cellular milieu in which the transcripts are expressed is relevant. This has been reported, for example, in acute promyelocytic leukemia (APL). The PML/RARA fusion protein in APL may occur at any point in the development of the myeloid cell, but is associated only with leukemia if the translocation occurs at an early stage, while expression of the fusion in late myeloid cells has little effect [15].

Based on the discoveries made by next-generation sequencing, we can now expand the initial two categories of genes relevant for leukemic pathogenesis into nine [9] (Fig. 12.3). In this review, we discuss in detail some of these nine categories and, in particular, we highlight the recent advances in the understanding of acute leukemia in the WGS era.

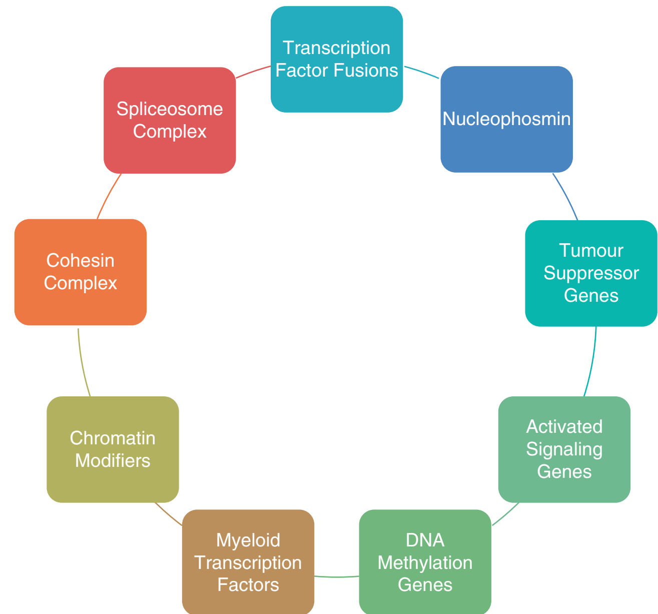

Fig. 12.3 *Functional categories of gene mutations in acute leukemia*. Genes found to be mutated via whole-genome sequencing of patient samples can be organized into nine categories based on related biological function

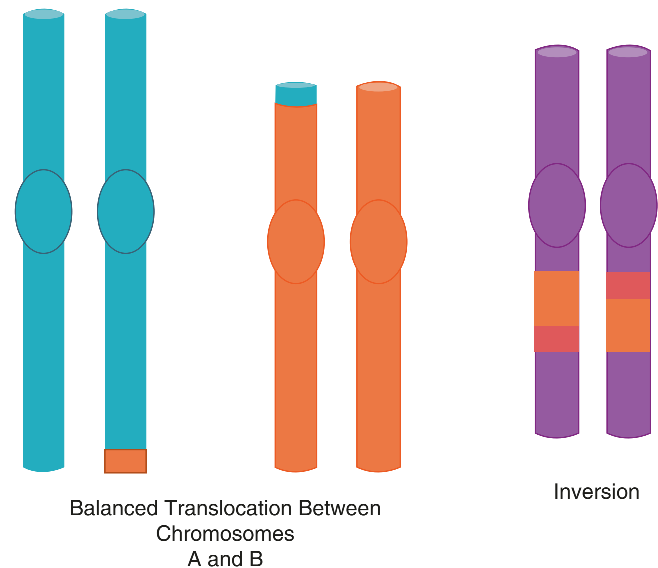

Fig. 12.4 *Structural chromosomal abnormalities*. A translocation arises when an exchange of chromosomal material takes place between two different chromosomes. If the translocation is balanced, the pieces of the chromosomes are rearranged but there is no loss or gain of genetic material (*left*). An inversion occurs when a segment of the chromosome is excised, rotated 180 degrees, and then reinserted into the same chromosome (*right*)

Transcription Factor Fusions

There is a long-established relationship between structural genomic aberrations, especially chromosome translocations and inversions, and acute leukemia. Specific cytogenetic abnormalities are often uniquely associated with clinically distinct subsets of the disease. Identifying the DNA sequences surrounding the chromosomal breakpoints has had an enormous impact on our understanding of leukemogenesis, carcinogenesis in general, and normal cellular functions of the protein products of the involved genes.

A chromosome translocation is a structural abnormality resulting from the exchange of pieces between two nonhomologous chromosomes. Reciprocal translocations are those in which there is no obvious overall loss of chromosomal material, and they probably result from a failure to properly repair DNA double-strand breaks (Fig. 12.4).

Several recurrent reciprocal translocations are frequently found in acute leukemia. Specific translocations are often consistently associated with specific subtypes of leukemia, providing strong support that they represent causal events during leukemogenesis in developing hematopoietic cells. For example, the t(15;17) is found only in patients with APL and not other forms of leukemia, while the t(1;19) is found only in the leukemic cells of patients with B-cell precursor acute lymphoblastic leukemia (ALL). However, there are exceptions to this phenomenon. For instance, the t(4;11) translocation occurs in patients with both AML and ALL. Chromosomal inversions are also seen in acute leukemia. An inversion occurs when a single chromosome undergoes breakage and rearrangement within itself (Fig. 12.4).

Identifying the genes disrupted by breakpoints in translocations and inversions provided the first mechanistic insights into understanding why chromosome abnormalities can be leukemogenic.

X/RARA

Acute promyelocytic leukemia (APL) is a subtype of acute myelogenous leukemia, representing 5–8% of AML cases in adults. At the genetic level, APL is characterized by a specific chromosomal rearrangement between the retinoic acid receptor alpha (*RARA*) on chromosome 17, and a number of partners. The majority of patients (98%) present with the 15;17 translocation, t(15;17), which results in a fusion of *RARA* with the promyelocytic leukemia (*PML*) gene on chromosome 15 [16, 17]. In normal cells, the retinoic acid receptors (RARs) heterodimerize with the retinoid X receptors (RXRs) to form a transcriptional complex. In the absence of ligand, all-trans retinoic acid (RA), a vitamin A derivative, the heterodimers are found bound, along with inhibitory co-repressor molecules, to the retinoic acid response elements (RAREs) of target genes. Treatment with ligand causes a release of the co-repressors and a concurrent recruitment of co-activators, leading to initiation of transcription of genes important for stimulating myeloid differentiation and regulating the cell cycle.

In APL cells, the prevailing view is that the leukemic effects of the resulting chimeric protein, X/RARA, are due to its function as a dominant negative inhibitor of normal retinoid receptor function. The chimera locates to promoters normally regulated by RARA, aberrantly recruits co-repressor proteins, and thereby inhibits the RARA-mediated gene expression. Therapeutic doses of RA can circumvent the differentiation block [18].

To date, eight different chromosomal translocation partners have been identified in patients with APL [19–26] (Fig. 12.5), and, as mentioned above, all involve the *RARA* gene on chromosome 17q21. The N-terminal fractions contributed by the fusion partners donate additional dimerization domains. These acquired dimerization domains, together with the DNA-binding domain of RARA, are required for the oncogenic effect of the fusion proteins and promote formation of chimeric receptor homodimers and provide additional co-repressor binding domains. The resulting X/RARA fusion proteins have been shown to recruit the HDAC, NCOR1 and NCOR2 (NCoR) complex, DNMT1, DNMT3A, repressive histone methyl-transferases, and polycomb group proteins.

However, disruption of the normal RARA signaling pathway does not solely account for the pathogenesis of APL. As mentioned previously, the differentiation block mediated by the X/RARAs is necessary, but not sufficient to cause APL. This suggests that a second transformative event is required for full neoplastic development. Mutations in oncogenes such as *FLT3* can cooperate with the fusions to provide the second hit necessary to generate leukemia. The presence of these second mutations might also explain why APL cannot be cured by differentiation therapy with ATRA alone, but is highly curable by combinations of ATRA and cytotoxic chemotherapy. Additionally, some translocations generate the reciprocal *RARA/X* fusion genes which can result in the co-expression of their transcripts in leukemic blasts [27–29]. Important roles in oncogenesis are now being identified for the co-expressed RARA/X reciprocal fusion proteins [27, 28, 30, 31]. Additionally, the partner proteins in APL have important growth-regulatory roles in normal myeloid cells. It may

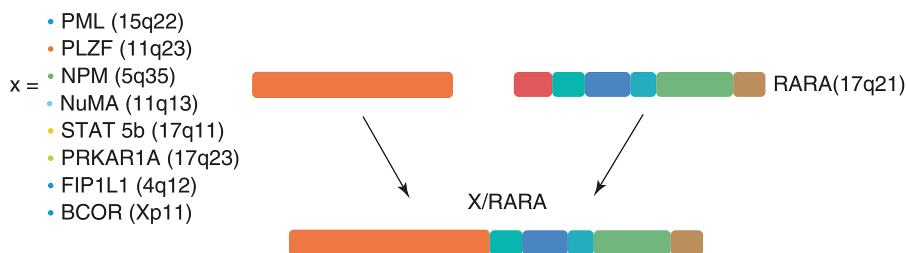

Fig. 12.5 *Identified chromosomal translocations associated with APL.* Acute promyelocytic leukemia (APL) is the result of chromosomal rearrangements in which part of the retinoic acid receptor alpha (*RARA*) gene is linked to the amino-terminal domains of eight genes (*X*) that encode different nuclear proteins. All of the translocations produce a chimeric protein (X/RARA) that disrupts the normal function of RARA and arrests the maturation of myeloid cells at the promyelocyte stage. The most common translocation, t(15;17), involves a break in chromosome 15 and disrupts the promyelocytic leukemia (*PML*) gene, producing the *PML/RARA* fusion

be that the loss of one allele of the partner protein combined with the effects of the X/RARA or reciprocal RARA/X fusion protein, which compromises normal partner protein function, contributes to the development of leukemia.

Core Binding Factor Rearrangements

Core binding factor (CBF) leukemias refer to a subset of AML bearing t(8;21)(q22;q22), which generates the RUNX1/CBFA2T1 fusion protein (previously known as AML1/ETO) and inv.(16)(p13q22), which generates the CBFB/MYH11 fusion protein. These genomic rearrangements are characterized by disruption of the *RUNX1* gene at 21q22 and the *CBFbeta (CBFB)* gene at 16q22, respectively. These are two of the most prevalent cytogenetic subtypes of AML.

Native RUNX1 and CBFB form a heterodimeric transcription factor [32] which regulates the transcription of genes required for the development of definitive hematopoiesis, including macrophage colony-stimulating factor (CSF) receptor [33], granulocyte-macrophage CSF [34], myeloperoxidase [35], and interleukin-3 [36].

RUNX1/CBFA2T1

The chromosomal translocation t(8;21) fuses the DNA-binding runt domain from RUNX1 (previously known as AML1) to almost the entirety of the CBFA2T1 (previously known as ETO) repressor protein [37]. The t(8;21)(q22;q22) translocation is present in 10–15% of AML cases and is associated with the M2 subtype of AML. Expression of the resulting fusion protein, RUNX1/CBFA2T1, in mouse models induces a pre-leukemic state, but requires cooperating mutations for full leukemogenesis [38–41]. An early hypothesis for the pathogenic role of RUNX1/CBFA2T1, postulating that it functions as a transcriptional repressor, was dervied from models based on the archetypal leukemiaassociated transcription factor, PML/RARA, and are supposrted by several lines of evidence:

1. Repression by RUNX1/CBFA2T1 is mediated by the CBFA2T1 moiety, which recruits co-repressors, such as HDACs 1–3, NCoR, SMRT, and mSin3A [42–44], and produces the secondary effect of altering the chromatin structure of target promoters.
2. RUNX1/CBFA2T1 binds to the promoters of tumor-suppressor genes which are normally activated by RUNX1, such as p14^{ARF} [45] and CCAAT/enhancer-binding protein alpha (C/EBPA) [46], and represses their transcriptional activation.
3. Treatment of t(8;21)-positive AML cell lines with HDACis [47] and DNMT inhibitors relieves the repressive effects of RUNX1/CBFA2T1 on chromatin, gene expression, and cell differentiation [48].

However, evidence has suggested that the model of RUNX1/CBFA2T1's leukemogenic effect through repressive transcriptional activity needs to be broadened. Microarray data shows that RUNX1/CBFA2T1 activates as many genes as it represses, including genes not normally under the control of wild-type RUNX1. Many of the genes upregulated by RUNX1/CBFA2T1, for example *JAG1* [49], play a role in promoting stem cell renewal. Furthermore, RUNX1/CBFA2T1 is a potent transcriptional activator of the anti-apoptotic *BCL2* gene [50]. Thus RUNX1/CBFA2T1 expression may result in leukemia by two opposing effects on transcription: by simultaneously repressing tumor-suppressor genes while upregulating genes that drive expansion or prolong the survival of t(8;21) early multipotent progenitors.

Furthermore, researchers have identified, in patients, a spliced isoform of the RUNX1/CBFA2T1 fusion protein, called AE9a, which is coexpressed with the full-length fusion and is capable of inducing leukemia in a murine transduction/transplantation model [51]. High levels of AE9a in patients are associated with poor disease outcome [52] and it was recently demonstrated that binding of AE9a to CBFB, leading to dysregulation of Notch target genes, is necessary for AML initiation [53].

Finally, an alternative explanation for the pathogenesis of t(8,21) acute myeloid leukemia is the loss of function of lineage-program-transcription factors [54]. These transcription factors strictly control gene expression during hematopoiesis, and instruct a precursor cell to commit to a certain differentiation program by initiating expression of a characteristic set of lineage-specific target genes in response to diverse signals [55]. There are four central hematopoietic transcription factors that are functionally repressed by RUNX1/CBFA2T1 through protein-protein interactions: PU.1 [56], CEBPA [57], GATA-1 [58], and the E proteins [59]. These inhibitory interactions with RUNX1/CBF2AT1 may expand stem cell pools by promoting stem cell renewal and blocking commitment to the various lineages. The expanded stem cell pool may then be primed for leukemic transformation through acquisition of additional mutations. The development of these secondary mutations is again facilitated by RUNX1/CBFA2T1 expression through the fusion protein's ability to repress DNA repair genes [49].

CBFB/MYH11

Inversion of chromosome 16, inv.(16), or the related t(16;16) is associated with the M4Eo subtype of AML, and results in the fusion of *CBFB* with *MYH11*, the gene encoding smooth-muscle myosin heavy chain. The resulting fusion protein CBFB/MYH11 is composed of the heterodimerization domain of CBFB fused to the C-terminal coiled-coil domain from MYH11. Studies suggest that CBFB/MYH11 has a higher affinity for RUNX1 than wild-type CBFB [60], and at the molecular level, CBFB/MYH11 has been suggested to alter

the normal transcription program by several mechanisms. These include the tethering of RUNX1 outside the nucleus [61, 62], recruitment of HDACs/co-repressors [63, 64], and inhibiting RUNX1 activity [65]. However, most of these studies were based on in vitro and overexpression experiments.

Furthermore, there are data suggesting that CBFB/MYH11 has activities independent of RUNX1/CBFB repression. CBFB/MYH11 expression has been shown to reduce levels of CEBPA protein, which is crucial for normal granulopoiesis, without affecting mRNA levels, but rather by the translational inhibition of CEBPA [66]. Additionally, microarray analyses have determined that CBFB/MYH11 expression results in a significant upregulation of many genes, including those involved in DNA replication, cell cycle regulation, and proliferation [67], again indicating that CBFB/MYH11 has RUNX1/CBFB repression-independent activities that may contribute to leukemogenesis.

CBFB/MYH11 rearrangements co-occur with RAS gene, or RAS-regulating gene mutations that lead to RAS pathway activation, in more than 90% of CBFB/MYH11 patients, indicating that changes to this pathway play an important role in AML pathogenesis [68]. In addition to RAS genes, whole-genome and whole-exome sequencing analysis of adult and pediatric leukemia samples identified recurrent stabilizing mutations in *CCND2* [69], the gene encoding cyclin D2. All the mutations surrounded the codon for a conserved phosphorylation site (Thr280) that regulates ubiquitination of Lys270 and degradation by the proteasome [70]. The mutations led to increased stability of the CCND2 protein [69] and suggest that stabilization of CCND2 is a previously unidentified and potentially targetable mutation in CBF-AML.

BCR/ABL

The BCR/ABL gene fusion is the result of the t(9;22), and although present in approximately 20% of B-ALL cases is most often associated with chronic myelogenous leukemia (CML). The translocation generates the BCR-ABL fusion protein, in which the N-terminal domains of BCR are combined with almost the entirety of ABL, a nonreceptor tyrosine kinase, whose activity is tightly regulated in normal cells. The oligomerization domain contributed by BCR constitutively activates ABL tyrosine kinase activity and is essential for BCR-ABL transformation.

Depending on the site of the breakpoint in the *BCR* gene, the fusion protein can vary in size from 190 to 230 kDa. Each fusion protein contains the same portion of the ABL protein but differs in the length of the BCR portion. In two-thirds of ALL cases with BCR/ABL, the breakpoint in *BCR* occurs in the region known as the minor-breakpoint cluster region (m-bcr), resulting in a fusion protein of 190 kDa (p190). In CML, however, the *BCR* breakpoint occurs further upstream, in a region referred to as the major breakpoint cluster region (M-bcr), resulting in a protein of 210 kDa (p210). A constitutively active ABL is produced by both the p190 and p210 fusion. Due to the well-characterized mechanisms of BCR/ABL oncogenicity in CML, this fusion will not be discussed further in this chapter and readers are instead directed to other chapters within this textbook which deal specifically with CML.

ETV6/RUNX1

The t(12;21) translocation is the most common genetic lesion in pediatric ALL [71], occurring in 17% of patients. The translocation generates a fusion between *ETV6* and *RUNX1* and occurs prior to the onset of immunoglobulin gene rearrangement, giving rise to leukemic blasts that appear to be blocked at the pre-B stage [72]. As noted in the introduction to this chapter, evidence from twin studies has demonstrated that the *ETV6/RUNX1* fusion is most likely an initiating event in ALL, but expression of the fusion alone is insufficient to cause leukemia. Most cases of ETV6/RUNX1 also have deletions in the wild-type *ETV6* allele [73], and mutations in *PAX5* [74, 75].

The fusion gene encodes a chimeric protein that contains the helix–loop–helix domain of the ETV6 transcription factor fused to nearly all RUNX1. The molecular mechanisms underlying ETV6/RUNX1-induced leukemogenesis remain poorly understood; however, there are some commonalities with the other fusions previously discussed, with ETV6/RUNX1 seemingly to inhibit wild-type RUNX1 transcriptional activity through the aberrant recruitment of HDACs and other transcriptional co-repressors [76, 77].

E2A Fusions

B-cell commitment and development require the sequential action of transcription factors positioned within a hierarchical network and which activate or repress genes to specify the B-cell-specific transcriptome. The *TCF3* gene encodes two basic helix–loop–helix (bHLH) transcription factors, E12 and E47, through alternative splicing and both of these proteins play an indispensable role in the earliest defined stages of B lineage development [78, 79]. Known collectively as the E2A proteins, E12 and E47 form heterodimers with other bHLH proteins and bind to the regulatory regions of many genes expressed in early- and late-stage B cells [80–82]. In common lymphoid progenitors, E2A lies in the middle of the transcription factor hierarchy. E2A expression is induced by the macrophage and B-cell-specific transcription factor and E2A itself then stimulates expression of *EBF1* [83]. EBF1, in turn, remodels the promoter region and thereby activates the expression of *PAX5* [84], which definitively

commits lymphoid progenitors to the B-cell pathway. Data from E2A-deficient cells substantiate the pivotal role of E2A in B-cell commitment; E2A$^{-/-}$ cells possess stem-cell-like properties, including promiscuous expression of genes that are normally associated with non-B-cell lineages.

Approximately 5% of all B-lineage ALLs and 25% of cases with a pre-B phenotype possess the E2A-PBX1 chimera. This translocation fuses the transactivation domain of E2A to the majority of the homeobox protein, PBX1, including its DNA-binding domain. While it is speculated that the E2A/PBX1 chimera blocks differentiation of B cells, no leukemic property of E2A/PBX1 has been identified in pre-B cells. It is possible, considering the central role of E2A in the B-cell transcription cascade, that the E2A/PBX1 oncoproteins may act via a dominant-negative mechanism in which they sequester coactivators, thereby disrupting the function of endogenous E2A proteins. Additionally, the fact that the E2A/PBX1 fusions found in human pre-B acute lymphoblastic leukemia all contain the PBX1 DNA-binding domain suggests that direct gene targeting by E2A-PBX1 is critical for the development of ALL.

Nucleophosmin

Mutations in *NPM1* represent the most common genetic change in adult patients with cytogenetically normal AML, and are seen in approximately 35% of cases [85, 86]. The latest WHO classification of AML recognizes AML with *NPM1* mutations as its own separate category [biological and clinical consequences of NPM1 mutations in AML (2017), 2]. *NPM1* mutation, when present alone, is associated with a more favorable outcome, and when co-expressed with *FLT3-ITD*, it is associated with an improved clinical outcome over *FLT3-ITD* mutations alone [87]. Interestingly, *FLT3-ITD* is about twice as frequent in *NPM1*-mutated AML compared to *NPM1* wild-type AML, which may suggest a mechanistic link between these two mutations [85, 86, 88–92]. Recently, whole-genome or whole-exome sequencing of the genomes of 200 adult cases of de novo AML revealed that the most prominent co-occurring mutations in AML are *NPM1, FLT3*, and *DNMT3A* and the combination of the three mutations is associated with extensive loss of DNA methylation, occurring mostly in coding regions. This observation, along with the fact that this co-occurrence occurs at higher frequency than expected by chance, suggests that harboring mutations in all three genes represents a novel subtype of AML [9]. In AML where all three mutations are present, evidence has shown that the *DNMT3A* mutation occurs first, then *NPM1*, and lastly *FLT3* [93, 94]. *NPM1* mutations are usually stable throughout disease and disappear with remission; therefore these could potentially be used to monitor residual disease, or to detect relapse [88, 91, 95].

The protein product of *NPM1*, nucleophosmin (NPM), is normally an abundant, ubiquitous, and highly conserved phosphoprotein that resides primarily in the nucleolus, although it shuttles rapidly between the nucleus and cytoplasm. By shuttling between these subcellular compartments, NPM plays a role in diverse processes including the regulation of centrosome duplication, transport of preribosomal particles and ribosome biogenesis, maintenance of genomic stability, participation in DNA repair processes, and regulation of DNA transcription (reviewed in [92]). In addition, within the nucleolus, NPM has been demonstrated to bind the important tumor suppressor, p53, and to its regulatory proteins, including ARF [96, 97]. The numerous functional domains of NPM (Fig. 12.6) account for its diverse biochemical functions in both cellular proliferation and growth suppression.

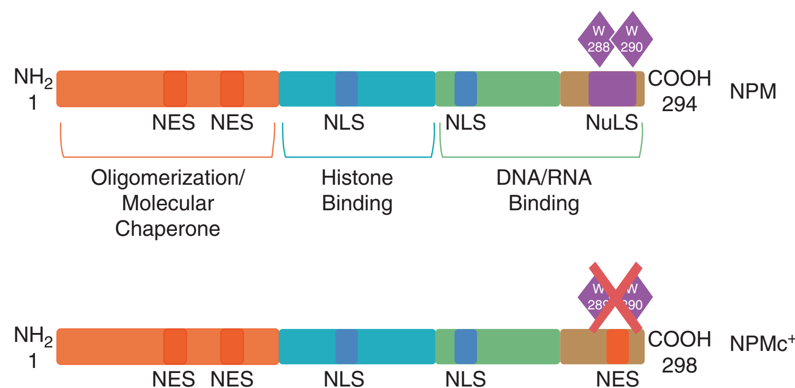

Fig. 12.6 *The functional domains and motifs of wild-type and mutant nucleophosmin*. Wild-type nucleophosmin (NPM, top panel) consists of 294 amino acids that can be subdivided into various functional domains. The cellular localization of NPM1 is dictated by three functional motifs: (1) two leucine-rich nuclear export signals (NES) located in the N-terminal domain (oligomerization domain), (2) a classic bipartite nuclear localization signal (NLS, residues 152–157 and 190–197), and (3) a C-terminal nucleolar localization signal (NuLS) containing two tryptophan residues (W288, W290) which are critical for its nucleolar localization. The mutated NPM1 protein (NPMc$^+$, bottom panel) in AML acquires a new NES at the C-terminus and loses at least one of the two tryptophans in the NuLS. Both alterations are responsible for the exclusion of NPMc$^+$ from the nucleus and its aberrant accumulation in the cytoplasm

In AML, the most common mutations of *NPM1* involve the insertion of four base pairs at the C-terminal portion of the protein. These mutations are unique to AML, and are not seen in other cancers where NPM is usually upregulated through genetic translocations [98]. The C-terminal mutations are usually heterozygous and result in an inability of the protein to perform its usual nuclear-cytoplasmic shuttling function. The cytoplasmic mutant (NPM^{c+}) has been isolated from leukemic blasts [85].

It has been shown that NPM^{c+} relocalizes ARF to the cytoplasm, thus inhibiting its functional interaction with the p53-negative regulator, MDM2, and blunting ARF-induced activation of the p53 transcriptional program. Despite this, the inactivation of ARF by NPM^{c+} is insufficient to cause oncogenesis [97]. This may be because of its dual role as an inactivator of ARF, and an inducer of cellular senescence, as discovered in experiments where NPM^{c+} is overexpressed in fibroblasts [99]. A transgenic mouse model of AML with NPM^{c+} has been generated by placing NPM^{c+} under the human myeloid-specific *MRP8* promoter. In this experimental setting, the cytoplasmic mutation of NPM induces myeloproliferation of mature monocytes and granulocytes but does not induce a maturation arrest [100]. Finally, data from in vitro, cell-free experiments using recombinant NPM^{c+}, patient NPM^{c+}, and leukemia cell lines show that NPM^{c+} reduces apoptosis through an inhibition of caspase-6 and -8 signaling, and inhibits myeloid differentiation also through a caspase-mediated process. Identifying this myeloid-specific function for NPM^{c+} may explain why this mutant is uniquely found in AML [101].

Similar to the model of cytoplasmic ARF sequestration, the $NPM1^{c+}$ mutation causes delocalization of the F-box protein, Fbw7γ, to the cytoplasm, which accelerates this protein's degradation. As Fbw7γ regulates the turnover of MYC, expression of NPM^{c+} ultimately leads to MYC stabilization [102]. MYC overexpression favors myeloid leukemogenesis in mouse models [103]; therefore the resulting elevated MYC expression might also contribute to leukemogenesis in the NPM^{c+} AMLs.

Finally, in the context of wild-type *NPM1* in acute leukemia, a novel function for NPM as a negative regulator of retinoic acid (RA)-induced gene regulation and differentiation toward granulocytes was recently uncovered. In stable RA-resistant acute leukemia cells, NPM is highly overexpressed and resistance is driven by an aberrant association with a putative co-repressor complex containing wild-type NPM and topoisomerase II beta (TOP2B) leading to recruitment of the chromatin remodeler BRG1 to RA-target genes [104].

Activated Signaling

Mutations in proteins involved in cell signaling transduction pathways typically result in the aberrant activation of these pathways, and provide a proliferative and/or survival advantage to hematopoietic progenitors.

FLT3

FLT3 (FMS-like tyrosine kinase 3) is a transmembrane receptor tyrosine kinase that belongs to the same family, the type III receptor tyrosine kinases (RTKs), as FMS, KIT, and platelet-derived growth factor receptors (PDGFRs) [105–108]. The structure of type III RTKs consists of five extracellular immunoglobulin-like domains, a transmembrane and juxtamembrane domain, and an intracellular kinase domain [109].

FLT3 has been found to be mutated in 25% of all AML, and to be overexpressed in some cases of B- and T-cell precursor ALL [110]. In AML, the recurrent mutations include in-frame internal tandem duplication (ITD) of the transmembrane domain in 95% of cases, and a tyrosine kinase domain (TKD) mutation at aspartic acid residue 835 in the remainder [111]. Other transmembrane and kinase domain mutations have been reported at a much lower frequency. For patients with AML with normal cytogenetics, the presence of an FLT3-ITD mutation is associated with a poorer response to therapy and poorer overall survival [87]. It is less clear whether TKD mutations are associated with a poor outcome (reviewed in [111]).

In normal hematopoiesis, binding of FLT3 ligand to FLT3 results in dimerization of the receptor and its activation. In combination with other growth factors, activation of FLT3 results in expansion of the hematopoietic stem/progenitor cells in vitro. For all but dendritic cells, once hematopoietic cells differentiate, the expression of FLT3 is lost [112, 113]. The proliferative role of FLT3 is further supported by knockout mouse models of FLT3 or FLT3 ligand. These mice have a normal life expectancy but show subtle deficits in hematopoietic cells, including a reduction in the number of B progenitor cells, NK cells, and dendritic cells, and reconstitute lethally irradiated mice with only 25% of the efficiency of bone marrow from wild-type mice [114, 115]. Thus, although FLT3 contributes to hematopoietic proliferation, its function is not essential.

In AML, there is constitutive activation of FLT3 due to either interference with the negative regulatory function of the juxtamembrane region with ITD mutations or changes in the activation loop with TKD mutations [116]. As a result, there is autophosphorylation and direct or indirect phosphorylation of several proteins that in turn activate the PI-3-kinase/AKT, RAS/MAPK, and STAT5 pathways, ultimately inducing cellular proliferation, and inhibiting apoptosis (reviewed in [117]).

It is postulated that FLT3 mutations allow for unrestricted growth of the leukemia stem cells. In support of this hypothesis, it has been shown that retroviral transfection of primary murine bone marrow cells with human AML *FLT3* mutation does not cause leukemia, but rather results in an oligoclonal myeloproliferative disease manifested by splenomegaly and leukocytosis [118]. Full development of leukemia occurs when *FLT3-ITD* mutations are

combined with other genetic alterations known to inhibit hematopoietic differentiation, including PML/RARA, NUP98/HOX, RUNX1/CBFA2, MLL/ENL, and MLL/SEPT6 (reviewed in [117]).

Finally, isolation of a stem cell-enriched fraction from patients with FLT3-ITD AML and subsequent injection of these primary cells into NOD/SCID mice resulted in leukemogenesis with identical FLT3-ITD mutations [119]. These data imply that FLT3-ITD mutations occur at the level of the leukemia stem cell (LSC). However, other clinical evidence suggests that the *FLT3* mutation may occur in a subclone of the LSC, including the finding that in the context of relapsed AML, there is loss of the ITD mutation 16% of the time and loss of the TKD mutation 50% of the time [120, 121].

KIT

Human KIT is located on chromosome 4 and encodes a 145 kD transmembrane glycoprotein. Like FLT3, KIT is a member of the type III RTK family [122]. The kinase activity of KIT is tightly regulated by its ligand, stem cell factor (SCF) [123–125]. SCF binding promotes KIT dimerization and transphosphorylation of KIT at specific tyrosine residues that can serve as docking sites for src-homology-2 (SH2) domain-containing signaling and adaptor proteins [108]. KIT signal transduction plays an important role in the proliferation, differentiation, migration, and survival of hematopoietic stem cells, as well as mast cells, neural crest-derived melanocytes, and germ cells [126].

Point mutations in KIT have been identified in AML. Some of the mutations localize within exon 8 [127] and result in hyperactivation of the receptor in response to SCF [128]. Other KIT mutations cluster within exon 17, which encodes the KIT activation loop in the kinase domain [129]. These mutations lead to ligand-independent activation of the kinase domain. KIT mutations are also found in other human malignancies, such as gastrointestinal stromal tumors [130], mastocytosis [131], and germ cell tumors [132].

KIT mutations are observed mostly in association with CBF-AML [133, 134]. It may be that the KIT mutations in this subset of AML provide the myeloid blasts with the necessary extra hit by conferring a proliferative and/or survival advantage, because, as discussed previously, the chimeric transcription factor blocks differentiation, but has a limited effect on cellular proliferation [38–41].

The prognostic significance of KIT mutations in CBF-AML is uncertain [135–138]. A recent meta-analysis evaluating the impact of *KIT* mutations on the prognosis of CBF-AML found that *KIT* mutations had no effect on complete remission (CR) rates, but they resulted in a significantly increased relapse risk [139].

Myeloid Transcription Factors

Hematopoietic stem cells (HSCs) are pluripotent stem cells that give rise to all the circulating blood cell types. They are defined by their ability to self-renew while generating differentiated daughter cells [140]. The maturation of HSCs into blood cells has been suggested to follow a hierarchical model, in which the stem cells undergo a reduction in self-renewal potential while simultaneously gaining functional specialization [141]. Several key transcription factors (TFs) maintain HSC self-renewal, whereas others specify differentiated hematopoietic lineages. As discussed earlier, chromosomal translocations that disrupt the normal functioning of these essential TFs are one way that hematopoiesis becomes deregulated. However, beyond fusions involving these transcription factors, mutations altering their functions have also been uncovered with new sequencing technologies [9, 75].

CCAAT-Enhancer-Binding Protein Alpha (CEBPA)

CEBPA is a tumor-suppressor gene that encodes a transcription factor associated with inhibiting cell proliferation. Mutations in this gene have been reported in 7–16% of AML patients, with a close to equal distribution of patients with either a single- or a double-*CEBPA* mutation. AML patients with a *CEBPA* mutation have improved prognosis versus wild-type patients, and those with a double mutation have better overall survival compared to those with a single mutation. Of note, this improvement in survival is lost if there is a co-occurring FLT3-ITD mutation [87, 142–148].

Mutations in *CEBPA* can occur across the whole coding region; however, two clusterings of mutation hot spots have been identified. The more common N-terminal mutations increase the use of an alternative initiation codon that then leads to the formation of a short p30 isoform, which inhibits the function of the full-length protein by a dominant negative mechanism [145]. C-terminal mutations are generally in-frame insertions/deletions in the DNA-binding or basic leucine zipper domains that disrupt binding to DNA or dimerization. The less frequent C-terminal mutations are generally in-frame insertions/deletions that prevent CEBPA DNA binding via alteration of the protein's basic-leucine zipper (bZIP) domain [149].

Recently, whole-exome sequencing detected a high frequency of *CEBPA* mutations in a subtype of AML, acute erythroid leukemia (AEL) [150]. Significantly, the biallelic *CEBPA* mutations co-occur with *GATA2* mutations. GATA2 is a transcription factor that is crucial for hematopoietic development. Considering the prominent expression of GATA2 and CEBPA in early hematopoietic progenitor cells and the direct protein-protein interaction between GATA2

and CEBPA proteins, further studies are needed to clarify whether and how mutations of both genes contribute to the pathogenesis of AEL [151].

Paired Box Protein 5 (PAX5)

B-progenitor acute lymphoblastic leukemia (B-ALL) is a common pediatric malignancy. A genome-wide analysis of leukemic cells from B-ALL patients using high-resolution single-nucleotide polymorphism arrays and DNA sequencing was performed to identify cooperating oncogenic lesions in this disease. *PAX5* was found to be the most frequent target of somatic mutations, with lesions found in ~30% of the cases analyzed [75]. PAX5 is the essential regulator of B-cell identity and function. Consistent with this view, *PAX5*-deficient pro-B cells, unlike their wild-type counterparts, exhibit promiscuous gene expression and a lack of lineage commitment [152]. Additionally, *PAX5*$^{-/-}$ pro-B cells have the capacity to differentiate into a variety of non-B-cell lineages, including functional macrophages, osteoclasts, dendritic cells, granulocytes, and natural killer cells, when stimulated with the appropriate cytokines [152]. Similarly, in mice, the absence of PAX5 results in the arrest of B-cell development at a pro-B-cell-like stage [153].

The *PAX5* gene encodes a 52 kDa transcription factor, expressed within the hematopoietic system exclusively in the B-lymphoid lineage. By recognizing DNA through the highly conserved paired domain characteristic of the PAX family of transcription factors [154], PAX5 functions both as a transcriptional activator and a repressor. PAX5 activates expression of B-lineage-specific genes such as *CD19* [155], *BLK* [156], and *CD72* [157] while concurrently repressing lineage-inappropriate genes such as *NOTCH1* [158], *M-CSFR* [152], and *FLT3* [159].

The overall effect of the *PAX5* alterations seen in B-ALL is to reduce or inhibit the level of normal PAX5 functional activity, either because of monoallelic deletions or the generation of altered forms of the PAX5 protein [75]. In the context of leukemogenesis, it is important to note that during the normal development of B cells, *PAX5* is subjected to allele-specific regulation, being predominantly transcribed from only one allele in early progenitors and then switched to a biallelic transcription mode as B cells begin to differentiate [160]. It is tempting to speculate that this allelic type of regulation has been imposed because the levels of PAX5 need to be finely tuned, as subtle decreases or increases may dramatically modify B-cell development. Therefore, the loss of wild-type *PAX5* allele due to the identified mutations would eliminate the possibility to turn on normal biallelic transcription, which may directly contribute to the arrest in differentiation arrest seen in ALL [75].

Chromatin Modifiers

Epigenetic information is deposited by “writer” proteins, such as histone methyl lysine and arginine transferases; removed by “eraser” proteins, such as histone deacetylases and demethylases; and decoded by “reader” proteins adapted to bind to chromatin marks using specific structures such as chromo, bromo, and PHD domains [161]. Together, these “chromatin modifiers” help to integrate signals that lead to meaningful changes in gene expression. Several alterations in chromatin modifiers, such as the “readers” ASXL1 [162–164]; the “writers” NSD1 [165, 166], MLL [167, 168], and EZH2 [169, 170]; and the “eraser” KDM6A [171], repeatedly occur in acute leukemia.

MLL Fusions and MLL-PTD

The MLL (mixed-lineage leukemia) gene is located on chromosome 11q23, and fusions involving this gene are seen in both de novo and therapy-related acute myeloid and lymphoid leukemia. MLL is a large DNA-binding protein ubiquitously expressed in hematopoietic cells, including stem and progenitor populations. Using chromatin immunoprecipitation (ChIP) analysis, MLL has been found to be associated with a subset of transcriptionally active human promoters [172, 173] and with RNA polymerase II, suggesting that MLL has a specific role in the regulation of transcription. A SET domain is located at the carboxy-terminal of MLL, and this domain mediates methylation of histone H3 lysine 4 (H3K4), a histone modification which is associated with transcription at active gene loci [174]. Importantly, in mammals, MLL positively regulates the expression of the homeobox (*HOX*) genes. *HOX* genes are transcription factors that participate in the development of multiple tissues, including the hematopoietic system.

Some of the roughly 50 characterized MLL fusion partners (FPs) can be grouped into families based on cellular localization and function (Table 12.1) [175, 176]. All identified MLL fusions contain the first 8–13 exons of *MLL* and a variable number of exons from the FP gene. Furthermore, another type of *MLL* rearrangement, *MLL-PTD* (partial tandem duplication), is a result of internal tandem duplication of select exons. MLL mutant proteins are always in-frame chimeras that reside in the nucleus, regardless of whether the fusion partner is normally nuclear or cytoplasmic in origin. Despite the large number and functional diversity of the fusion partners, there are some common principles that can be applied to all MLL fusions [175]. First, all MLL fusions retain its amino-terminal domains required for the association of MLL with chromatin, so the fusion proteins are still able to bind DNA. Second, expression of the amino-terminal region of MLL (the region retained in MLL fusions) alone

Table 12.1 Classification of MLL fusion partners

Group	MLL fusion partner	Location	Function
1	**AF4**, **AF9**, **AF10**, **ENL**, **ell**	Nuclear	Putative DNA-binding proteins
2	CBP, p300	Nuclear	Histone acetyltransferases
3	AF1P, **AF6**, AFX, EEN, EPS15, GAS7, LARG	Cytoplasm	Presence of coiled-coil oligomerization domain
4	SEPT2, SEPT5, SEPT6, SEPT9, SEPT11	Cytoplasm	Septin family, interact with cytoskeletal filaments, have a role in mitosis
5	N/A	N/A	MLL partial tandem duplication of exons 5–11 (MLL/PTD)

There are more than 50 known MLL partners; therefore this table is not an exhaustive compilation. The six most common fusion partners are highlighted in bold. *N/A* not applicable

does not lead to myeloid transformation [177], indicating that the fusion partners make critical contributions to the oncogenicity of MLL fusions [178]. Third, MLL fusion proteins enforce continuous expression of the *HOX* genes, *HOXA9* and *MEIS1*, which are normally downregulated during hematopoietic differentiation. This sustained induction appears to be critical for leukemogenesis, since forced expression of *HOXA9* and *MEIS1*, in the absence of an MLL fusion, immortalizes hematopoietic progenitors in vitro and results in AML development in transplanted mice [179, 180].

MLL fusions are hypothesized to disrupt normal gene expression patterns, especially those of the *HOX* genes, maintained by wild-type MLL. However, discerning one unifying mechanism of leukemogenesis by MLL fusion proteins is difficult due to the heterogeneity of the MLL fusion partners. The putative mechanisms of MLL fusion-induced transformation may be more easily characterized by dividing the fusion partners into two broad classes based on their normal cellular localization (either nuclear or cytoplasmic). The fusion partners that are nuclear have been associated with various aspects of transcriptional regulation. Therefore, the fusions involving these proteins may lead to transcriptional deregulation of the *HOX* genes through alterations in the histone modification pattern and chromatin structure. An early insight into this possibility was provided by the characterization of the nuclear MLL/CREBBP fusion [181]. CREBBP (also known as CBP) is a well-characterized global transcriptional activator with intrinsic histone acetyltransferase (HAT) activity. Structure–function analysis demonstrated that inclusion of the portion of CREBBP that contains its HAT domain in the fusion is required for full in vitro transformation and is sufficient to induce the leukemic phenotype in vivo [182]. These data suggest that the leukemic effect of MLL/CREBBP results from the combination of the chromatin association and modifying activities of CREBBP with the DNA-binding activities of MLL. Additionally, although the SET domain, which mediates MLL's H3K4 methyltransferase activity, is consistently lost in all the MLL fusions, several MLL fusion partners, for example AF4, AF9, AF10, and ENL [183], associate with the DOT1L histone methyltransferase that methylates lysine 79 residues in histone H3 (H3K79). Methylation of H3K79 is also associated with positive transcriptional regulation [184]. As different methylation marks may positively control transcription in unique ways [185], the replacement of H3K4 activity in wild-type MLL with H3K79 activity in the MLL fusion complex could perturb transcriptional control. In the case of the MLL-PTD, where the SET domain is maintained, the characterization of a mouse model of *MLL-PTD* demonstrated that MLL-PTD facilitates histone H3K4 trimethylation as well as H3/H4 acetylation within target *HOX* gene promoters [186]. This provides further evidence for an epigenetic mechanism as the underlying cause of *HOX* overexpression.

Some MLL fusion partners are normally localized to the cytoplasm and do not display inherent transactivation properties. However, they do possess structural domains responsible for protein-protein interactions. Therefore dimerization/oligomerization mediated by these domains may create a transcriptional activator complex capable of stimulating gene expression. Experiments have been performed where fusion of the first eight exons of *MLL* to β-galactosidase (a bacterial enzyme) resulted in the development of AML in mice [187]. β-Galactosidase is known to oligomerize but has not known leukemogenic potential suggesting that the mere oligomerization of MLL is sufficient to achieve transforming potential. Examples of translocations that produce fusions where the fusion partner probably imparts oligomerization include MLL/GAS7, MLL/AF1P [188], and MLL/LARG [189]. However, when tested in animal models these fusions develop leukemia after a longer latency when compared with the nuclear fusion partners, which suggests a further specific biological contribution, beyond oligomerization, of the fusion partners in dynamics and penetrance of tumorigenesis.

EZH2

A broad class of protein complexes, known as the polycomb group (PcG), are responsible for writing the histone methylation marks that suppress gene expression. PcG is correlated with transcriptional silencing and trimethylation of lysine 27 of histone H3 ($H3K27me^3$) [190]. In mammals, there are two distinct PcG complexes, PRC1 and PRC2 (Fig. 12.1). PRC2 is the primary writer of di- and tri-methylation of H3K27 [191]. PRC2 is composed of four core components (Fig. 12.7), enhancer of zeste homologue 2 (EZH2), suppressor of zeste 12 (SUZ12), and two WD40 domain proteins, EED and RBBP4 [192, 193]. The catalytic domain of EZH2 is its SET domain, and this has

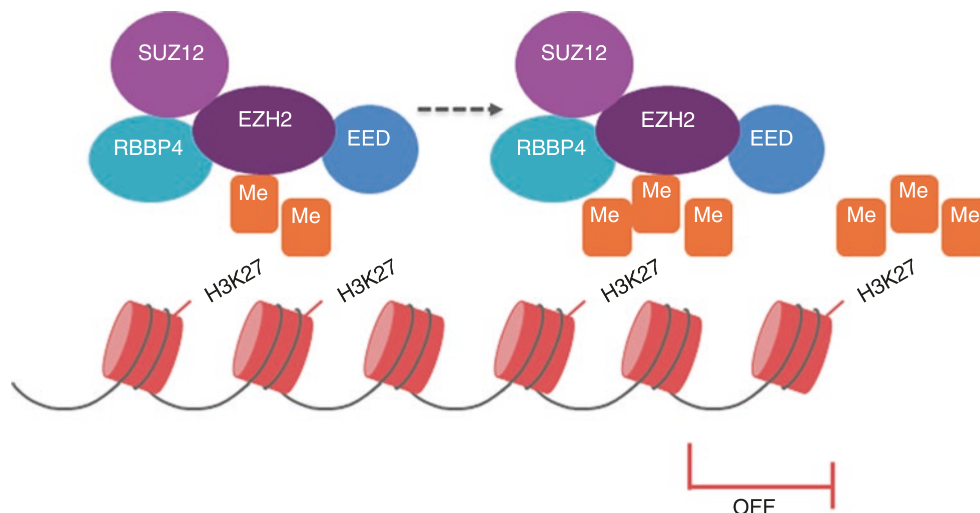

Fig. 12.7 *EZH2 is a histone methyltransferase*. PRC2 is composed of the core subunits, EZH2, SUZ12, RBBP4, and EED. EZH2 catalyzes the addition of methyl groups to histone H3 lysine 27 (H3K27me), ultimately resulting in histone H3 lysine 27 tri-methylation (H3K27me³), a mark associated with transcriptional repression

methyltransferase activity not only toward H3K27, but also weakly toward lysine 26 of histone H1 [194].

EZH2 has a complex role in cancer pathogenesis, acting as an oncogene or as a tumor suppressor, depending on the type of cancer. Evidence in leukemia suggests that it is the loss of EZH2 that contributes to tumor development. In T-cell acute lymphoblastic leukemia (T-ALL), myeloproliferative disorders, and myeloid malignancies, a range of missense, nonsense, and frameshift mutations of *EZH2* occur [169, 170, 195]. These lesions can be heterozygous or homozygous, are found throughout the gene body, and generally are predicted to ablate histone methyltransferase activity via truncation of the SET domain. Loss of EZH2 potentiates oncogenic NOTCH1 and RUNX1 signaling in T-ALL and myelodysplastic syndromes (MDS), respectively [195, 196]. Loss of EZH2 is an indicator of poor prognosis in MDS [169, 170], but the same association with de novo AML cannot be drawn, as EZH2 mutations remain comparatively rare in this setting [197]. While MDS may often progress to AML, this is not to be the case for MDS with EZH2 loss, and genetic deletion of EZH2 in a syngeneic mouse model was shown to prevent the transformation of MDS to AML [196]. Additionally, loss of EZH2 protein occurs in about 45% of relapsed AML samples due to posttranslational deregulation of EZH2 protein [198], and this loss is associated with chemoresistance toward multiple drugs. These findings indicate that inhibition of EZH2 degradation in combination with chemotherapy, and/or targeted inhibitors, may be a novel therapeutic approach in drug-resistant AML.

Cohesin

The cohesin complex is composed of four core components that hold chromatin strands in a ringlike structure that regulates sister chromatid alignment during mitosis (16). The complex has also been shown to play a role in double-stranded DNA damage repair and regulation of transcription (17). Cohesin complex mutations in all four components, STAG1/2, RAD21, SMC1A, and SMC3, have been found in AML and other myeloid malignancies [199–202]. Mutations of cohesin complex components occur in approximately 13% of AML patients [9]. The mutations are almost always mutually exclusive, and occur early in leukemogenesis, at the stage of pre-leukemic hematopoietic stem cells [199].

In most AML cases, cohesion mutations are not associated with genomic instability [9, 203], suggesting that defects in chromatid cohesion do not contribute to leukemogenesis. What, then, are the mechanistic implications of cohesion mutations in leukemia? One hypothesis put forward is that reduced cohesion function alters chromatin structure, disrupting *cis*-regulatory architecture of hematopoietic progenitors and impairing hematopoietic differentiation [204–206]. In agreement with this, using an assay for transposable-accessible chromatin combined with high-throughput sequencing (ATAC-Seq), it was shown that there was a global loss of open chromatin in cohesin-mutant-expressing cells, with a concomitant increase in accessibility at specific motifs for key hematopoietic transcription factors [205], including ERG [207], GATA2 [208], and RUNX1 [209], and enforcing stem cell transcriptional programs.

Spliceosome

The spliceosome is a large and complex cellular machine comprised of multiple protein subunits and small nuclear RNAs (snRNAs) used to remove introns from pre-mRNA during constitutive and alternative splicing [210–212]. Mutations in the spliceosome genes *SF3B1*, *SRSF2*, and *U2AF1* have been found in myelodysplastic syndromes (MDS) and myeloid malignancies, including 10–25% of

AML patients, and are enriched in patients who developed AML secondary to MDS [213–215]. The mutated spliceosome genes encode factors that are involved in the recognition of the 3′-end of the intron, and are mutually exclusive of one another in patient samples [214–217], implying that they may contribute similarly to pathogenesis or, alternatively, may not be tolerated by a cell when they co-occur.

Spliceosome gene mutations may be driving leukemogenesis by causing the mis-splicing of pre-RNA from central hematopoietic drivers. In support of this hypothesis, expression of all three mutations in human cell line models, murine cells, and patient samples results in disruption of normal splicing patterns [218–220]. Furthermore, modulation of splicing catalysis via a spliceosome inhibitor reduced leukemic burden in mouse models, indicating that targeting the spliceosome may represent a novel therapeutic strategy in genetically defined subsets of leukemia [221].

Conclusions and Perspectives

Acute leukemia represents a heterogeneous collection of diseases harboring numerous molecular abnormalities. Earlier research identified recurrent fusion proteins directly linked to the pathogenesis of acute leukemia, while more recent work has focused on the role of an ever-increasing number of specific genetic and epigenetic alterations. However, as whole-genome sequencing becomes increasingly accessible for scientists, clinicians, and patients, there is a need for clarification of the prognostic and therapeutic implications of these alterations.

13 Epidemiology and Hereditary Aspects of Acute Leukemia

Logan G. Spector, Erin L. Marcotte, Rebecca Kehm, and Jenny N. Poynter

Introduction

Recent projections for the USA estimate that 6590 patients are diagnosed annually with acute lymphocytic leukemia (ALL) and 19,950 with acute myeloid leukemia (AML), while approximately 1430 patients die from ALL and 10,430 from AML [1]. Together these forms of acute leukemia represent about 1.6% of all newly diagnosed cancers and 2.0% of all cancer deaths in the USA [1]. Advances in the understanding of immunology and molecular/genetic features of the acute leukemias along with laboratory improvements in immunophenotyping and cytogenetic characterization have led to the recognition of molecularly defined subtypes of ALL and AML, targeted therapeutics, and recognition of distinct prognostic groups. The most recent World Health Organization (WHO) classification of hematopoietic malignancies considers three major categories of acute leukemia: AML and related myeloid precursor neoplasms, precursor lymphoid neoplasms (encompassing the entities previously known as ALL), and acute leukemias of ambiguous lineage [2]. Consistent with classifications used in cancer registries, to date most epidemiologic investigations have considered all acute leukemias combined or the broad categories of ALL and AML, although an increasing number of studies, especially those of genetic risk factors, examine cases by molecular subtype. Traditionally pediatric acute leukemias, defined either as those diagnosed at 0–14 or 0–19 years of age, have been studied separately from that in adults.

ALL and AML demonstrate substantial differences in incidence patterns by age and risk factors, although some risk factors overlap (e.g., ionizing radiation). Childhood forms of ALL and AML are distinct from those occurring in adulthood with respect to certain molecular (e.g., cytogenetic) features, demographic characteristics (e.g., incidence according to racial/ethnic group), risk factors, leukemogenic susceptibility associated with certain exposures, and prognosis. There also appear to be important differences in the critical time windows for specific leukemogenic exposures [3] and in the relevant contributions of genetic and environmental factors to the etiology of childhood- versus adult-onset acute leukemias. This chapter reviews acute leukemias in terms of their descriptive epidemiology, risk factors for childhood- and adult-onset disease, and hereditary and genetic aspects. Quantitative measures of risk, described as estimated relative risks (RRs), are defined as estimates of the ratios of risks in exposed versus unexposed populations. For the purposes of this chapter, high RRs are considered to be those ≥4, moderate RRs are 2 to <4, and modest RRs are <2.

Descriptive Characteristics of Acute Leukemias Occurring at All Ages

Age-adjusted incidence of leukemia varies internationally by a factor of about six- to eightfold in women and men, respectively, with the lowest rates in Middle and Western Africa and the highest rates in Northern American and Australia/New Zealand [4]. The International Agency for Research on Cancer (IACR), the primary reporting source for international cancer trends, does not subclassify leukemias into acute and chronic, and myeloid or lymphoid, preventing international comparisons of leukemia subclassifications. Rates also vary across racial and ethnic populations within countries. In the USA, for example, rates of ALL are highest among Hispanics [5].

In the USA, the incidence of AML is 2.6 times that of ALL, with age-adjusted incidence rates of 3.6 versus 1.4 cases per 100,000 person-years, based on data from the nine long-standing cancer registry areas of the Surveillance, Epidemiology and End Results Program (SEER-9), 1975–2013 [5]. Incidence is higher among males than females—by

nearly 40% for ALL and 50% for AML—and lower among blacks than whites—by 36% for ALL and 11% for AML. Despite differences in incidence by sex and race, age-specific rate patterns are similar within each acute leukemia subtype among all sex and race groups (Fig. 13.1a). Leukemia subtypes differ notably in incidence by age: the age-specific curve for ALL is bimodal, with peaks at the youngest and oldest ages, whereas rates for AML rise consistently over the entire age range. Prior to age 20 years, ALL incidence is four times that of AML, but this pattern reverses with age, with AML incidence 11 times that of ALL among individuals ≥60 years of age. Over the past three decades in the USA, age-adjusted rates of ALL and AML have gradually increased among all sex and race groups (Fig. 13.1b).

Relative survival (RS) rates for individuals diagnosed in SEER-9 during 1975–2012 and followed through 2013 are considerably more favorable for patients with ALL than AML, with approximately 81% and 62% 1- and 5-year overall RS, respectively, for ALL, and 39% and 20%, respectively, for AML. Overall RS for ALL and AML is somewhat more favorable for females than males; overall ALL survival is slightly more favorable for whites than blacks, whereas the reverse is true for AML. Over the past three decades, overall ALL and AML survival has improved, with the greatest strides apparent among the youngest age groups. During 1975–1982, 5-year RS for ALL was 61%, 22%, 11%, and 8% for those <20, 20–39, 40–59, and ≥60 years, respectively, and this increased to 88, 47, 32, and 18% in the corresponding age groups during 2005–2012. During these same two time periods, AML 5-year RS increased prominently from 22 to 65% among those <20 years, 13–55% among those 20–39 years, and 10–40% among those 40–59 years, with a less striking improvement of 3–9% among those ≥60 years.

Risk Factors for Acute Leukemia in Children

Chromosomal translocations have been demonstrated to initiate pediatric leukemia in utero based on studies of leukemia arising in identical twins, investigations in newborn blood spots, and the short latency period characterizing pediatric leukemia [6]. Agents causing such translocations have not been identified, and it is suspected that additional molecular

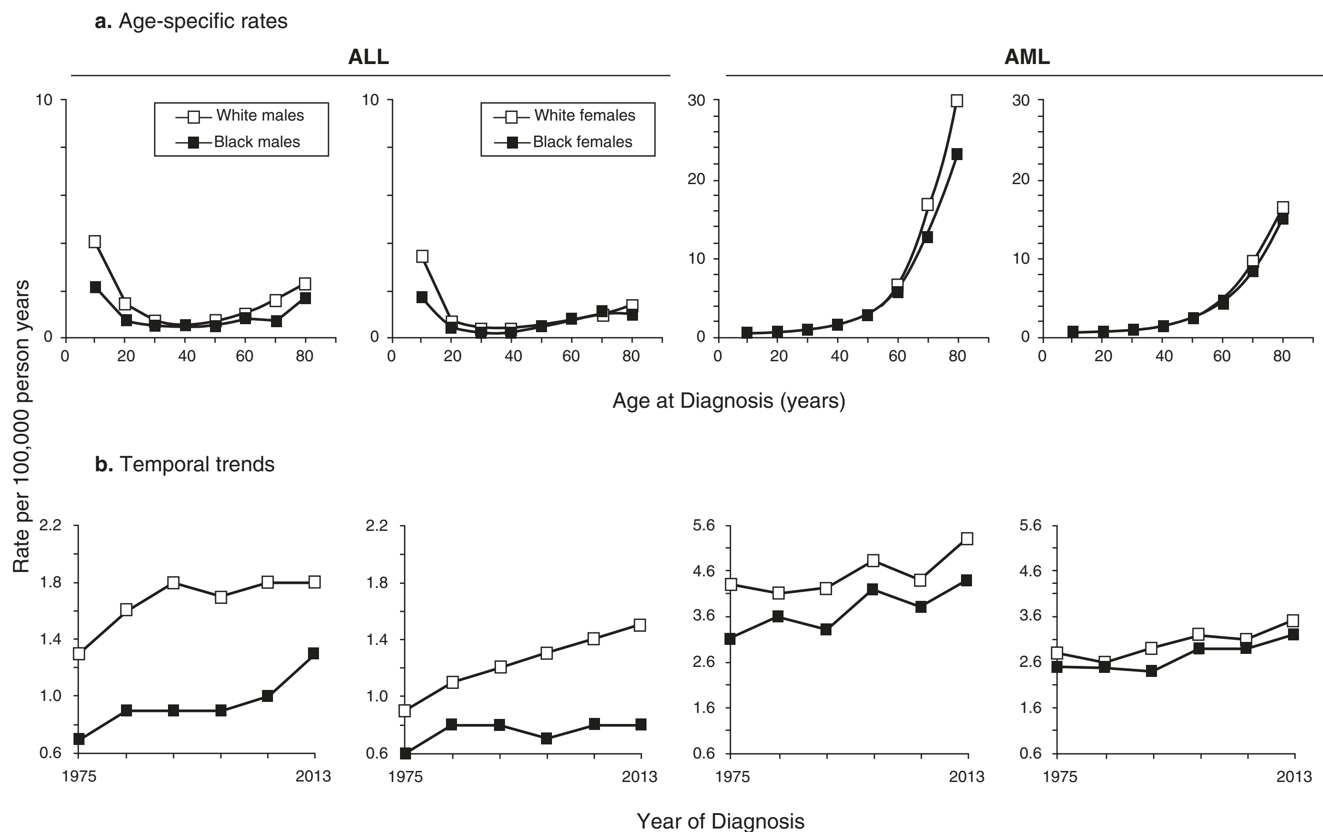

Fig. 13.1 US acute lymphocytic leukemia (ALL) and acute myeloid leukemia (AML) incidence rates (age-adjusted, 2000 US standard) by race and sex, diagnosed among residents of nine cancer registry areas of the Surveillance, Epidemiology and End Results Program, 1975–2013. (**a**) Age-specific rates (<15, 15–24, 25–34, 35–44, 45–54, 55–64, 65–74, 75+); (**b**) temporal trends (1975–1981, 1982–1988, 1989–1995, 1996–2001, 2002–2007, 2008–2013)

changes are required for pediatric leukemia to develop. Data supporting the requirement for additional events in pediatric leukemogenesis include twin concordance rates and results from animal studies. Notably, there is ongoing debate on the frequency at which these translocations occur in healthy newborns [7–9]. Next, we summarize the epidemiologic findings on preconception and prenatal risk factors followed by results for postnatal leukemogenic factors.

Prenatal and Preconception Factors

Reproductive History

Long-standing efforts to identify reproductive factors associated with risk of pediatric ALL and AML have not yielded clearly established etiologic factors. Associations of prior maternal fetal loss with increased risk of acute pediatric leukemias [10–12] were not confirmed in subsequent studies of pediatric [13, 14] or infant [15] leukemia. Although results from individual studies have been inconsistent, a recent meta-analysis reported increased risk of both ALL and AML for older maternal age and increased risk of AML for offspring of young mothers [16]. In the same analysis, older paternal age was associated with ALL while younger paternal age was associated with AML. Inconsistent findings also have been reported for birth order, although two recent large, independent pooled analyses showed slight reductions in risk for ALL with increasing birth order [17, 18].

Medical Conditions and Treatments

Decades of efforts to identify infectious agents causing pediatric ALL have been unsuccessful, and more recent studies of maternal medical conditions and/or treatments generally have not been replicated. It has long been postulated that a viral agent infecting a susceptible mother during pregnancy may play an etiologic role in pediatric leukemias [19]. However, reports linking in utero influenza infection [20] and Epstein–Barr virus [21] with pediatric leukemia and ALL, respectively, were not subsequently confirmed [22–24], and specific leukemogenic infectious agents have not been identified [24–27].

Inconsistent findings have been reported for both maternal hypertension [28–31] and diabetes [11, 28–30]. Observations requiring replication include findings of excess risks of pediatric common B-cell precursor leukemia in offspring of women with a previous molar pregnancy [14] and those receiving antibiotics [32] or mind-altering drugs during pregnancy [33], pediatric AML in offspring of mothers with polyhydramnios or anemia [14], and pediatric hematopoietic malignancies in offspring of mothers who had undergone fertility treatment [13, 34, 35]. An excess of pediatric leukemia in mothers using marijuana before or during pregnancy [36] was not confirmed [37].

Medical Radiation Exposures

Diagnostic X-ray exposures from the late 1940s through the mid-1970s have been associated consistently with modest elevation in the risk of pediatric leukemia, although risks have declined over time as radiation doses have decreased [38, 39]. Increased risk of pediatric leukemia was first linked with fetal exposure to abdominal or pelvic diagnostic X-ray of the pregnant mother nearly 60 years ago [40]. Subsequently, additional data from the large Oxford Survey of Childhood Cancers, a medical record-based study in hospitals in the northeast UK, and close to 30 other case–control studies support an overall RR of 1.4 (i.e., 40% increased risk) for pediatric leukemia associated with diagnostic ionizing radiation exposure in utero, but the interpretation of the statistical association has been debated [39]. Data are insufficient to determine risks of pediatric leukemia in offspring of women undergoing radiotherapy for cancer, and there is no evidence linking ultrasonography during pregnancy with risk of pediatric leukemia [38].

Environmental Ionizing Radiation Exposures

Data evaluating leukemia risk with in utero exposure to environmental sources of ionizing radiation are limited. The cohort study of survivors who were in utero at the time of the atomic bombings of Hiroshima and Nagasaki "… cannot provide information on the effect of radiation on the incidence of childhood cancers" in the absence of complete information for the first 5 years of follow-up and insufficient size to assess such rare outcomes [41]. Similar limitations characterize a cohort of persons who were in utero at the time of the Chernobyl accident [42]. Existing data are not informative about pediatric leukemia risks in offspring of female airline crew or women living in proximity to nuclear testing or nuclear installations [43]. However recent population-based studies have reported elevated risk of childhood leukemia associated with residential gamma radiation [44, 45], but not radon [44, 46].

Parental Occupational Radiation Exposures

A small study linking paternal preconception occupational exposure of nuclear industry workers with excess leukemia risks in offspring [47] was not confirmed in a study of 39,557 children of male nuclear workers [48]. Furthermore, there

was no excess of pediatric leukemia in offspring of female or male medical radiation workers in the UK [49] or the USA [50]. A meta-analysis of all studies of parental occupational exposure to extremely low-frequency magnetic fields (ELF-MF) revealed no association with the risk of childhood leukemia for either maternal or paternal exposure [51].

Parental Pesticide Exposures

Risks of leukemia in offspring of parents occupationally exposed to pesticides have been extensively investigated, but few investigations have identified the specific pesticides to which the fetus has been exposed. Meta-analysis of more than 30 case–control and 5 cohort studies revealed similarly increased risks for both ALL and AML (RR = 2.64, 95% CI = 1.00–5.00; RR = 2.64, 95% CI = 1.48–4.71, respectively) with maternal occupational exposure, with higher risks in studies of farm-related exposures compared with studies of mixed or unknown place of exposure [52–55]. No consistent association was observed for childhood leukemia with paternal occupational exposure to pesticides [54]. A subsequent pooled analysis of 13 case–control studies reported elevated risk of ALL following paternal occupation exposure (OR = 1.20, 95% CI = 1.06, 1.38) and increased risk of AML following maternal occupational exposure (OR = 1.94, 95% CI = 1.19, 3.18) [56]. A recent pooled analysis of home pesticide exposure found 40–55% increased risk for ALL and AML for the preconception and pregnancy time periods [57].

Parental Chemical Exposures

Findings from epidemiological studies of pediatric leukemia in offspring of parents exposed to heavy metals (including arsenic), polychlorinated biphenyls, dioxin, indices for outdoor air pollution, traffic density, drinking water disinfection by-products, and specified and unspecified solvents are generally limited by a scarcity of data available. However some pooled studies and meta-analyses have recently become available for these exposures. A meta-analysis of benzene exposure, and established risk factor for adult leukemia, revealed an association between maternal and paternal exposure and both ALL and AML, with a particularly strong effect for AML (OR = 2.34, 95% CI = 1.72, 3.18) [58]. Pooled analyses from the Childhood Leukemia International Consortium (CLIC) examining occupational [59] and home [60] paint exposure reported null associations for occupation exposures and modest positive associations for home exposure (OR = 1.54, 95% CI = 1.28, 1.85 and OR = 1.14, 95% CI = 1.04, 1.25 for exposure preconception and during pregnancy, respectively). Limited evidence has linked pediatric leukemia in offspring with parental exposure to motor vehicle emissions [61, 62], driving or inhaled particulate hydrocarbons [63], or maternal exposure to unspecified solvents [64]. Maternal exposure to petroleum products during pregnancy has also been linked to infant AML [65].

Parental Cigarette Smoking

The role of maternal smoking in the development of pediatric leukemia has been evaluated for several decades, with a few studies reporting an increased risk. However, a meta-analysis [66] and subsequent studies concluded that maternal smoking during pregnancy is not a major risk factor for childhood acute leukemia [67–69]. Paternal preconception smoking has been investigated less extensively, but a recent meta-analysis of 20 studies showed a modest association with childhood ALL (RR = 1.25, 95% CI = 1.08–1.46) [70].

Parental Alcohol Consumption

A comprehensive assessment of pediatric leukemia risk and parental alcohol consumption in 33 case–control studies did not strongly support an association [71]. Paternal preconception consumption of alcohol has also not been linked with elevated risk [72]. However, a meta-analysis of 21 case–control studies concluded that maternal consumption of alcohol during pregnancy was associated with increased risk of pediatric AML (RR = 1.56, 95% CI = 1.13–2.15), but not ALL [73]. The association between maternal alcohol consumption and AML has also been reported in a subsequent study [69]. Reasons why in utero exposure to alcohol increases AML but not ALL risk are unknown.

Maternal Diet and Vitamin Supplements

The possible role of maternal diet or vitamin supplements in risk of acute leukemia has been investigated by several studies, although heterogeneity between dietary components studied and exposure categories used makes drawing conclusions difficult. Four investigations found reduced risks of pediatric leukemia in offspring of mothers who consumed higher levels of fruits and vegetables during pregnancy [74–77]. A recent pooled analysis reported reduced risk of ALL associated with prenatal vitamin supplementation and weak evidence for a reduced risk of AML associated with maternal vitamin use [78], and a subsequent study reported similar results for both ALL and AML [79]. Other studies also found reduced risk with maternal use of iron supplements [33, 80]. Spector et al. found that maternal consumption of foods that inhibit DNA topoisomerase II was linked with increased risk

of infant AML [74]. Finally, a meta-analysis linked maternal coffee consumption to increased risk of both ALL and AML and cola consumption to increased risk of ALL, whereas tea consumption was associated with decreased risk of overall leukemia in offspring [81].

Mode of Birth

Mode of birth has recently become an exposure of interest for several long-term outcomes in offspring. Support for a role of mode of birth in immune system development includes observations that cesarean delivery alters both the composition [82] and diversity [83] of intestinal microbiota, and these differences can persist through the first 12 months of life [84]; reported associations between cesarean delivery and immune-related disorders, including type I diabetes mellitus [85], asthma [86], and allergies [87]; and evidence that infants born by cesarean delivery experience a markedly diminished stress response before birth, including reduced levels of cortisol and catecholamines [88–90]. A recent pooled analysis of 13 studies found an association between pre-labor cesarean delivery and risk of ALL (OR = 1.23 95% CI = 1.04, 1.47) but not AML [91].

Postnatal Factors

Birth Weight

High birth weight has been linked consistently with increased risk of ALL, and recent studies suggest a similar relationship for AML. A meta-analysis of 31 studies demonstrated significantly increased risks of ALL (RR = 1.23, 95% CI = 1.15–1.32) associated with birth weight of ≥4 kg, and seven of these studies showed a similar relationship for AML (RR = 1.40, 95% CI = 1.11–1.76) [92]. It has been suggested that accelerated growth rather than high birth weight per se is etiologically linked with ALL, and a recent pooled analysis of 12 case–control studies found evidence of moderate increased risk of ALL for large-for-gestational-age infants and those with a higher proportion of optimal birth weight [93]. Low birth weight (<1.5 kg) has been associated with increased risk of AML (RR = 1.49, 95% CI = 1.03–2.15) but not ALL [92].

Breast-Feeding

Large case–control studies examining the association of breast-feeding and risk of childhood acute leukemias have reported 9–20% decreased risk for ALL, but a less consistent picture for AML, ranging from no reduction to 23% reduction in risk [94, 95]. A meta-analysis found that any breast-feeding for 6 months or more was associated with an 18% reduced risk of ALL based on 11 studies and no reduction in risk of AML based on 6 studies [96]. A subsequent pooled analysis of 11 studies found a similar reduction in the risk of ALL for children who were breast-fed for 6 months or more (OR = 0.86, 95% CI = 0.79, 0.94) [17]. Although few studies have examined risks for combined breast-feeding and milk supplementation, one reported a moderately increased risk of childhood leukemia among those infants who received milk supplementation with breast-feeding more than 50% of the time [97].

Medical Conditions and Treatments: Infections, Vaccinations, Allergy, and Atopy

Clusters (a group of cases representing an excess intensity within the population at risk which is unlikely to be due to chance) of pediatric leukemia have been described for decades, but no infectious or other causal agent(s) have been linked with these clusters [98, 99]. A comprehensive, broad-based epidemiologic and laboratory investigation of the largest pediatric acute leukemia cluster to date, diagnosed in residents of Churchill County, Nevada, was unable to identify a causal agent [100].

Two mechanisms have been suggested by which infectious agents might be associated with the age peak from 2 to 5 years in the common form of pediatric ALL. Greaves postulated a two-hit model of leukemogenesis, with the first event or mutation occurring in rapidly dividing immature B cells in utero and the second event arising in early childhood as a result of delayed exposure to infectious agents [101]. Epidemiologic studies of proxy measures of early-life exposure to infections, including daycare attendance [17, 102], birth order [18], and timing of birth [103], generally support a reduced risk of ALL associated with early exposure to infectious agents. However, studies of clinically diagnosed infectious episodes during infancy are not consistent [17, 104].

Kinlen proposed that childhood ALL occurs as a rare response to a specific, albeit currently unknown, viral agent(s), particularly when there is mixing of rural (or other low-density) populations with urban (or other high-density) populations [105]. Summarizing multiple extreme examples of population mixing in Britain, Kinlen observed significant short-term excesses of pediatric leukemia [106], although others reviewing the population mixing studies have disagreed with the conclusions drawn by Kinlen [107].

A limited number of studies investigating an infectious etiology for pediatric acute leukemia have reported a protective effect from vaccination in infancy or early childhood, with risks varying according to the type of vaccine and age at

immunization [108]. A meta-analysis of epidemiologic studies examining atopy and risk of childhood leukemia revealed a 31% significantly reduced risk of ALL based on six studies and no significant association for AML based on two studies [109]. Inverse associations were seen for ALL with asthma, eczema, and hay fever, but the authors caution about overinterpretation of the results in light of the limited number of studies, substantial heterogeneity, and potential misclassification. Finally, a meta-analysis based on eight studies of allergies and ALL reported a 33% reduction in risk [110].

Medical Radiation and Chemotherapy

In general, studies of low-dose postnatal diagnostic radiographic exposures (estimated organ doses range from 0.01 to 6 mGy) have not observed increased risks of pediatric leukemia; the results were based on questionnaire responses and estimated doses were not evaluated [111]. Two reports assessing pediatric cancer risks in children who have undergone computed tomographic (CT) examinations, which are higher dose diagnostic imaging procedures (estimated organ doses from CT scans of the chest, abdomen, brain, spine, and face range from 10 to 80 mGy), reported excess risk of leukemia among children following postnatal CT, with one study reporting a threefold increase in risk (RR = 3.18, 95% CI 1.46, 6.94) for doses of 30 mGy or more [112, 113].

Earlier cohort studies of infants or children irradiated for benign conditions were generally too small to estimate the risk of pediatric leukemia accurately [114], but radiotherapy during childhood for tinea capitis was associated with a subsequent moderately increased risk of leukemia mortality (RR mortality = 2.3, estimated bone marrow dose = 30 mGy) [115]. Two of three earlier small studies found a dose–response relationship between estimated radiation dose to the bone marrow from radiotherapy for treatment of pediatric cancer and subsequent risk of secondary leukemia. A larger more recent investigation did not confirm this relationship; however, excess secondary leukemia was evident—likely due to chemotherapy treatment [116], a strong and well-established risk factor for acute leukemia. More information on the relationship between chemotherapeutic agents and acute leukemia risk is provided in the section of this chapter on adult leukemia.

Environmental Exposures: Ionizing Radiation

Environmental ionizing radiation has been examined as a potential risk factor for childhood leukemia since the establishment of the cohort of Hiroshima and Nagasaki atomic bomb survivors. Investigation of this cohort has demonstrated that survivors who were less than 10 years old at exposure had moderate-to-high relative risks for both ALL and AML [86] [117]. Relative and absolute risks were higher among children than adults, and these risks peaked within 10 years. The absolute risk for incidence was estimated to decrease by about 5% for each year's increase in age, and risk for ALL among females was about 40% of that among males. A recent analysis of this population confirmed excess risk of leukemia among children within the cohort [118].

Results from other studies of postnatal environmental ionizing radiation and risk of pediatric acute leukemias are less clear. Leukemia and lymphoma risks were found to be increased in persons under age 25 among populations living near nuclear fuel reprocessing or weapon production plants in the UK, but not among populations residing close to nuclear plants generating electricity; however, environmental radiation levels measured in proximity to these facilities were considered too low to ascribe to the radiation exposures from these plants [119]. Residential exposure to radon was linked with elevated risk of pediatric ALL in an ecological study but was not associated with an increased risk in studies in the USA [120], Germany [121], France [122], or the UK [123]. Although there was no overall association of residential radon with pediatric AML, a borderline increase was observed in children aged 2 or older [124]. The study from France also revealed no association between childhood leukemia and any type of natural background radiation, including gamma radiation [122].

Environmental Exposures: Nonionizing Radiation

Initial reports of two- to threefold excess risks of pediatric leukemia in children residing in homes with high levels of 60-Hz magnetic field exposures from residentially proximate power lines were assessed further in large studies with more extensive and direct measurements. Results from pooled analyses of these high-quality studies revealed that pediatric leukemia risks were not increased among children residing in homes with power frequency magnetic field exposures under 0.4 μT (which included more than 99% of residences internationally), but were twofold increased among the <1% of children living in homes with exposures ≥0.4 μT [125]. A recent study found that there may be some selection bias in a study of EMF, although no association was found between childhood leukemia and residential exposure to EMF even when accounting for potential biases [126]. Reasons for the suggested increased risk among children with the highest exposure levels are unclear, particularly since experimental studies have not linked power frequency magnetic fields with carcinogenesis [127].

Environmental Exposures: Chemicals

Residential use of pesticides demonstrated a relationship with total childhood leukemia [94] and ALL in two studies, including a large pooled analysis [57, 95, 128], although another study found no association between organochlorine pesticides and leukemia [129]. Exposures to insecticides in agricultural settings were not associated with risk, nor was use of herbicides or fungicides in any setting [64]. There is some evidence that supports a relationship of pediatric leukemia with childhood residential exposure to nearby high traffic density, car repair garages, or gasoline stations [64, 130, 131], and with household use of petroleum products, solvents, and paint [60, 64, 132–134]. No clear association was observed with pediatric leukemia risk and exposure to drinking water disinfection by-products, drinking water nitrate, residence near hazardous waste disposal sites, or exposure to environmental tobacco smoke [64].

Diet and Vitamin Supplements

Only a few small studies have assessed the risk of pediatric leukemia with dietary components, and replication of the results is needed. Findings were mixed for consumption of cured meats [135, 136], and reduced risks were associated with intake of bean, curd, and vegetables in a study in Taiwan [136] and with consumption of foods containing vitamin C and/or potassium in a study in California, particularly during the earliest years of life [135]. Postnatal consumption of cola has not been associated with leukemia [81]. Concern about a report linking intramuscular vitamin K with risk of pediatric leukemia [137] was dispelled following a pooled analysis showing no association [138].

Risk Factors for Acute Leukemia in Adults

Chemotherapy

The development of therapy-related myeloid neoplasms, typically AML (t-AML), is a rare but highly fatal complication of cytotoxic treatments for both malignant and nonmalignant diseases [139–143]. Exposure to such treatments is associated with RRs ≥ 3 and incidence ranging from <1 to 7% for t-AML following conventional therapy, with even higher rates following hematopoietic cell transplantation (HCT) [144].

Therapy-related myeloid neoplasms are classified as a distinct entity in the World Health Organization (WHO) classification system [145], with two types of therapy-related myelodysplastic syndromes (t-MDS) and t-AML differentiated by previous therapeutic exposure. Patients treated with alkylating agents are more prone to t-AML that is preceded by MDS, develops 5–7 years after exposure, and is characterized by loss or deletion of chromosome 5 and/or 7 [−5/del(5q), −7/del(7q)] and presence of somatically acquired loss-of-function mutations in p53 [146]. In contrast, patients treated with topoisomerase II inhibitors, including the epipodophyllotoxins, are more prone to t-AML that is rarely preceded by MDS, arises after a latency of 2–5 years, and is characterized by balanced translocations involving the *MLL* gene at 11q23 [147, 148].

Antimetabolites used for treatment of malignancies (e.g., fludarabine) and for immunosuppressive therapy for autoimmune diseases and transplantation (e.g., azathioprine) have also been shown to increase the risk of t-AML. Abnormalities in chromosomes 5 and/or 7, similar to t-AML associated with alkylating agents, have been described [149, 150]. Population-based studies showing an increased risk of MDS/AML in patients with autoimmune disease have also been published in recent years [151, 152], with evidence suggesting that the association may be attributed to immunosuppressive therapy [153]. Further, solid organ transplant recipients who received azathioprine for initial maintenance immunosuppression had increased risk for both MDS and AML [154].

Although the vast majority of therapy-related leukemias are of myeloid lineage, increased risk of ALL following exposure to chemotherapy has been reported in the literature [155–158]. Several common abnormalities are observed in these cases of t-ALL, including 11q23 abnormalities and t(9;22)(q34;q11) (Ph chromosome) [156–158]. With the introduction and increasing use of a number of new chemotherapeutic agents in recent years, future studies are needed to evaluate the acute leukemia risks and identify cytogenetic abnormalities associated with current treatments.

Medical Radiation

Most epidemiologic studies have not reported a significant association between radiation exposure from diagnostic imaging procedures and AML [159–163]. Use of the radiographic contrast medium, Thorotrast (an alpha-emitting contrast medium with a half-life of 400 years that was used in earlier time periods for cerebral angiography), has been consistently linked with an increased risk of MDS/AML [164–166]. Increased risk of AML has also been associated with radiation treatment for benign conditions, including ankylosing spondylitis [167], benign gynecologic disorders [168, 169], tinea capitis [115], and peptic ulcer disease [170]. Individuals treated with radiotherapy for non-Hodgkin lymphoma, Ewing sarcoma, or cancer of the breast, uterine cervix, or uterine corpus also have moderately increased risks of secondary AML, although the absolute risk is small [114]. Similar to the pattern for primary AML occurring among the

Japanese atomic bomb survivors, initial cases of secondary AML following radiotherapy for another primary cancer often appear within 5 years of treatment (with most cases occurring within 10–15 years) and are associated with estimated bone marrow doses ranging from 1 to 15 Gy [169].

Environmental Exposures: Ionizing Radiation

Compared with Japanese atomic bomb survivors exposed during childhood and adolescence, those exposed in adulthood had lower estimated relative risks of ALL, but the pattern was similar to that following childhood exposure, with risk peaking at less than 10 years since exposure, a declining risk for each year's increase in age at exposure, and risks for women about half the level of risks for men [117, 171]. For AML, relative risks were similar for males and females, but males had two-fold higher absolute risks. A recent analysis suggests that excess risk of acute leukemia mortality continues to persist decades after the bombings [172]. The population living on the banks of the Techa River in the Southern Urals region in Russia, who received chronic low-dose-rate internal and external radiation exposures from releases of radionuclides into the river from the Mayak nuclear weapon plant plutonium production facility, experienced excess risk of leukemias other than chronic lymphocytic leukemia (i.e., non-CLL leukemias) with an excess relative risk estimate of 0.22 per 100 mGy [173, 174].

Occupational Exposures: Radiation

Studies of radiation-exposed workers are important for clarifying the effects of protracted radiation doses, since animal studies suggest that protracted low doses may allow for DNA repair and thus lower risks of leukemia or other cancers compared with risks associated with an acute, single radiation dose [114]. Medical radiation workers were the first population observed to develop radiation-related leukemia within a few years of the discovery of X-rays due to the very high radiation exposures of early workers [175]. This increased risk was largely confined to those working prior to 1960 due to implementation of radiation protection methods in the late 1950s [176, 177]. A meta-analysis of epidemiologic studies in workers who experience low, protracted radiation exposures has shown modest increases in risk for non-CLL leukemias [178]. The International Nuclear WORKers Study (INWORKS), a large international cohort study designed to evaluate cancer risk in radiation-monitored workers, quantified this excess relative risk at 2.96 per Gy for non-CLL leukemia [179]. Leukemia mortality risks were significantly elevated and risk rose significantly with increasing external radiation dose among workers at the Mayak nuclear complex in Russia where effects of plutonium exposures have been under investigation for years [180].

Occupational Exposures: Benzene

For more than 100 years, there has been recognition that occupational benzene exposure is related to risk of leukemia. IARC has determined that benzene exposure is carcinogenic to the bone marrow and causes both AML and MDS, with several potential mechanistic explanations for this association [181]. Currently, the major occupational uses of benzene are in the manufacture of organic chemicals and chemical intermediates [181]. Benzene also occurs naturally in petroleum products and is added to unleaded gasoline [181]. Nonoccupational sources of exposure also exist, with the majority of exposure due to cigarette smoking and emissions from automobiles and industry [182]. A literature review identified 9 cohort and 13 case–control studies that included estimates of benzene exposure, excluded ecologic or proportionate mortality methods, included a comparison group, and assessed risks for one or more subtypes of leukemia [183]. High RRs and a positive dose–response relationship were seen across study designs for AML, especially in more highly exposed workers in the rubber, shoe, and paint industries. Data on ALL were judged to be sparse and inconclusive. A subsequent systematic review and meta-analysis of four studies focusing on cumulative exposure to benzene and AML found a clear dose–response pattern, with RRs of 1.94 (95% CI = 0.95–3.95), 2.32 (95% CI = 0.90–5.94), and 3.20 (95% CI = 1.09–9.45) for low, medium, and high benzene exposure, respectively [184]. A long-standing cohort study of occupational benzene exposure in China has also documented increased risks of MDS/AML in benzene-exposed workers [185–187], with the most recent report showing similar elevated risks in males and females and across different occupations after 28 years of follow-up [188].

Occupational Exposures: Farming and Pesticide Exposure

Increased risks of leukemias and lymphomas have been linked with farming, but relatively few studies have focused on risks of ALL or AML. Some data link occupation as a farmer with increased risk of ALL, but the data are not conclusive [189]. A few studies have examined risks of AML, and results have been mixed. Data from the Iowa Women's Health Study linked residence on a farm or rural area with a small but significant excess of AML, but data were not available to determine if the women worked as farmers or to assess their exposures [190]. In contrast, data from the Women's Health Initiative did not find an association between living on a farm and myeloid leukemia [191].

Exposure to a variety of agricultural chemicals has been evaluated as a risk factor for AML incidence and/or mortality [192–196]. For AML, a significant association was

reported in a meta-analysis of cohort studies evaluating pesticide exposure (OR = 1.55, 95% CI 1.02, 2.34), with evidence that this association was significant for pesticide manufacturers or pesticide applicators but not for agricultural/farm workers [194]. Data from the Agricultural Health Study suggest that the risk of leukemia overall may differ for individual agricultural chemicals, with significant associations detected between leukemia and organochlorine insecticides, fonofos, diazinon, and EPTC [197–200] while no associations being detected for other chemicals [201–203].

Cigarette Smoking

Cigarette smoking was first associated with the risk of adult leukemia in the mid-1980s. Several studies have suggested a small but consistent increased risk of acute leukemia among smokers. In a meta-analysis of studies published through 1992, the estimated relative risks for all leukemia were 1.1 (95% CI 1.0–1.2) and 1.3 (95% CI = 1.2–1.6) for case–control and cohort studies, respectively [204]. A more recent meta-analysis of smoking and AML including studies published through 2013 reported that current smokers (RR = 1.40, 95% CI 1.22–1.60) and ever smokers (1.15, 95% CI 1.15–1.36) have increased risk of developing AML when compared with nonsmokers [205]. Few studies have looked specifically at the risk of adult ALL and smoking; however, studies that have evaluated associations by subtype have typically reported stronger associations for myeloid leukemia [206].

BMI and Diet

The majority of studies have shown a modest, but statistically significant, association between obesity and leukemia, with a recent meta-analysis of 16 prospective studies yielding an adjusted relative risk (RR) for AML of 1.53 (95% confidence interval (CI) 1.26–1.85) and for ALL of 1.62 (95% CI 1.12–2.32) for individuals with a BMI > 30.0 kg/m^2 compared to individuals with a BMI < 24.9 kg/m^2 [207]. A limited number of studies have investigated dietary factors and AML [206, 208–213]. A large prospective cohort study identified higher meat intake with increased risk of AML [212], and this finding was supported by a recent case–control study [211]. Mixed evidence has been reported for associations between AML and fruit and vegetable consumption [206, 208, 211–213]. Alcohol intake has not been shown to be an important risk factor for adult acute leukemia [214–216]. The few studies conducted to date along with methodologic issues related to dietary assessment, particularly in case–control studies, suggest that additional epidemiologic research is needed.

Physical Activity

A recent pooled analysis of 12 prospective cohorts reported a significant reduction in the risk of myeloid leukemia associated with high levels of leisure-time physical activity (HR, 0.80; 95% CI 0.70–0.92) while no significant association was observed for lymphocytic leukemia (HR, 0.98; 95% CI 0.88–1.12) [217]. In contrast, a previous meta-analysis including eight published studies reported no significant association between leukemia overall and physical activity (RR, 0.97; 95% CI 0.84–1.13); however, this analysis did not stratify by subtype of leukemia [218]. Data from the prospective VITamins And Lifestyle (VITAL) study which were not included in either the pooled or meta-analysis also support an association with myeloid neoplasms [219]. Additional studies of AML and ALL will be required to clarify this association.

Nonsteroidal Anti-inflammatory Drug and Acetaminophen Use

Studies of a wide range of malignancies have demonstrated a potential chemopreventive role for frequent nonsteroidal anti-inflammatory drug (NSAID) use. Further, there is evidence that these effects may be specific to certain classes of NSAIDs. Recent evidence from case–control and cohort studies suggests that aspirin use may be associated with reduced risk of AML [220–224]. In contrast, acetaminophen use may be associated with increased risk of AML [221–224]. Given the limited number of studies conducted to date and the small sample size in some studies, further research on the topic is warranted.

Hereditary and Genetic Aspects of Acute Leukemias

Familial Aggregation and Genetic Syndromes

Familial aggregation of acute leukemias is rare. Studies of the few pure familial AML pedigrees have identified germline mutations in *RUNX1* and *CEBPA* [225]. Few studies have described familial aggregation of ALL, although novel familial syndromes involving germline mutation genes frequently somatically mutated in the disease (e.g., PAX5, ETV6) have recently been described [226–228]. Individuals having a twin with ALL have substantially elevated risk for ALL, particularly among monozygotic twins [229], although this risk is due to transplacental migration of preleukemic cells rather than genetic predisposition [230].

A much larger body of evidence regarding the hereditary component of acute leukemia derives from the study of

patients with rare genetic syndromes, but these patients also account for only a small proportion of the total population burden of acute leukemia. Among children with rare inherited bone marrow failure syndromes, including Fanconi anemia, dyskeratosis congenita, congenital neutropenia, and Shwachman-Diamond syndrome, risk of AML is strikingly elevated—often more than 100-fold [231, 232]. The molecular events that predispose to AML among these individuals are not completely understood but are thought to differ by syndrome and involve defective DNA repair, shortened telomere length, and abnormal hematopoietic differentiation and proliferation [233]. Other hereditary conditions associated with increased risk of acute leukemia include Li-Fraumeni syndrome, ataxia–telangiectasia, Bloom syndrome, Noonan syndrome, and neurofibromatosis 1 [234–238].

Myeloid proliferations related to Down syndrome (trisomy 21) have unique morphologic, immunophenotypic, clinical, and molecular features [2]. Children with Down syndrome have a 100-fold risk of AML, as well as approximately 15-fold risk of ALL [239]. Individuals with Down syndrome are disproportionately found to have somatic mutations in the hematopoietic transcription factor *GATA1*, which results in impaired hematopoietic cell differentiation [240].

Genetic Susceptibility

Numerous studies have investigated common genetic variation in germline DNA in relation to leukemia risk. Candidate gene studies of acute leukemias have frequently focused on carcinogen metabolism, folate metabolism, and DNA repair in the past, and have shown some consistency of findings [241]. However, the same genes have not been identified by agnostic methods such as genome-wide association studies (GWAS), which casts doubt on previous findings.

Rather than implicating previously hypothesized pathways or mechanisms, GWAS of childhood ALL have identified risk loci in or near several genes that regulate the transcription and differentiation of B-cell progenitors (*IKZF1*, *ARID5B*, *CEBPE, and GATA3*) and the tumor-suppressor genes *CDKN2A* and *CDK2NB*, which is also frequently somatically altered in hematologic malignancies [242–253]. Although the leukemia risks associated with these loci are low, these inherited genetic susceptibilities can be common in the general population, and it is estimated that common variants identified to date account for about 25% of pediatric ALL [254]. These common variants appear to cause ALL in children with non-European ancestries to a similar degree, but differences in allele frequency may explain a portion of interethnic differences in the disease rate [255, 256]. It is also notable that some variants discovered by GWAS are particularly associated with cytogenetically defined subtypes of ALL, for instance *GATA3* with Ph+-like disease [249]. Additional research is needed to understand the biological basis of these findings, identify other genetic loci that confer acute leukemia risk, and investigate the potential interaction of genetic susceptibility with environmental and individual risk factors.

Summary

Causes of the acute leukemias in children and adults have not been fully identified, but recent progress has provided new etiologic insights. The most well-established risk factors for acute leukemias include ionizing radiation, benzene, and cytotoxic chemotherapy, with increasing risks associated with increasing doses. Among children, risks of pediatric leukemia (ALL and AML) are modestly increased with maternal in utero exposures to diagnostic X-rays in earlier decades, moderately increased with radiotherapy treatments, and moderate-to-highly increased with childhood exposure to the atomic bombings. Among persons exposed as adults, acute leukemia risks are moderately increased among atomic bomb survivors, individuals living near the Mayak nuclear weapon plant, and patients receiving radiotherapy treatments, and AML risks are moderate-to-highly increased with occupational benzene exposure. High risks of AML occur among children and adults receiving cytotoxic treatments (e.g., alkylating agent and epipodophyllotoxin chemotherapy) for benign and malignant disease.

Although pediatric ALL has long been thought to have an infectious etiology, no infectious agent has been isolated. However, recent research has identified modest associations with other environmental, lifestyle, and medical factors for all acute leukemias. Pediatric leukemia has been linked with prenatal maternal occupational pesticide exposure (ALL and AML) and postnatal residential use of insecticides (ALL only). Modest associations have been reported for pediatric AML with maternal prenatal alcohol consumption, pediatric ALL with paternal preconception smoking, and adult AML with cigarette smoking. Anthropometric measures have also been associated with both ALL and AML in children (high birth weight) and adults (high body mass index). Dietary factors may play a role in both pediatric and adult leukemia, but more studies are needed to clarify associations. Interestingly, pediatric ALL risk appears modestly reduced among children who were breast-fed or have a history of atopy.

Recent progress has been made in understanding the germline mutations underlying familial AML, the molecular events by which rare genetic syndromes predispose to the acute leukemias, common genetic variants that confer increased susceptibility to the acute leukemias, and agents causing recurrent chromosomal and genetic abnormalities associated with acute leukemia molecular subtypes.

Although insights into etiology to date have facilitated some prevention efforts for the acute leukemias, additional epidemiologic work is needed to further impact the disease burden worldwide.

Classification of the Acute Leukemias: Cytochemical and Morphologic Considerations

14

N. Nukhet Tuzuner and John M. Bennett

Definition and Classification

The acute leukemias are a heterogeneous group of neoplasms affecting uncommitted or partially committed hematopoietic stem cells. The origin of the malignant neoplasm is almost invariably within the marrow. Replacement of the marrow pulp or repression of normal hematopoietic cells results in variable degrees of anemia, neutropenia, and thrombocytopenia.

Historically, the term acute implied not only a poorly differentiated blast population, but also a clinical syndrome that led to a rapid fatal outcome. Since it is apparent that, with modern chemotherapy, including bone marrow transplantation (BMT), patients with acute leukemia of several morphologic types can enjoy complete remission (CR), and indeed cure, the term acute can be maintained for nosologic reasons only.

Traditionally, morphology and cytochemistry identified the different involved lineages. During the past 25 years, major advances in our knowledge of the nature of acute leukemia consequent to the application of the techniques of immunology, cytogenetics, and molecular studies have taken place. The demonstration of membrane and cytoplasmic antigen or enzyme by immunologic or immunocytochemical methods and detection of the recurring chromosomal abnormalities either conventional cytogenetic or molecular methods, studies utilizing microarray analysis of gene expression, DNA copy number alterations, and next-generation sequencing provides supplementary arguments for accurate classification.

Identification of subclasses of acute leukemia is important for three reasons. First, some leukemias have clinical features that influence the therapeutic approaches; that is, central nervous system (CNS) is more frequently involved in acute lymphocytic leukemia (ALL) than in acute myelocytic leukemia (AML). Acute promyelocytic leukemia (APL) is associated with intravascular coagulation [1] and acute monocytic leukemia (AMoL) with skin and gum infiltration [2]. Second, differences in response rate and survival are observed in the treatment of acute leukemias; that is, the percentage of CR rate is higher in childhood ALL than in adult ALL. Third, classification greatly facilitates communication and cooperation around the world, and comparisons of results are possible only through reproducible definitions of the acute leukemias.

Examination of both peripheral blood and bone marrow smears is necessary for the diagnosis and the classification of acute leukemias. The most useful cytochemical stains are myeloperoxidase (MPO); Sudan Black B (SBB); specific and nonspecific esterase, such as chloroacetate esterase, naphthol ASD acetate esterase with and without sodium fluoride (NAF), α-naphthyl acetate esterase (ANAE), or butyrate esterase; periodic acid-Schiff (PAS); and acid phosphatase (Figs. 14.1, 14.2, and 14.3).

There are two instances in which the diagnosis of acute leukemia can be made on the basis of histologic material. The first occurs when there is an abundance of reticulin in the bone marrow, resulting in a so-called dry tap [3]. This can be present in any of acute leukemias and is recognized most commonly associated with acute megakaryoblastic leukemia and acute panmyelosis with myelofibrosis. Although touch preparation smears may be of help in such cases, well-prepared hematoxylin and eosin (H&E) stains of paraffin-embedded

One of the coauthors of this chapter (JMB) participated in the WHO Clinical Advisory committee on hematologic neoplasms and coauthored several of the upcoming chapters on MDS and MDS/MPN. The review article by Arber and Hasserjian (Reclassifying Myelodysplastic Syndromes: what's where in the new WHO and why. Hematol. Am. Soc. Hematol. Educ. Program. 2015:294–298) discusses many but not all of the proposed changes. Availability of the chapters was made possible by the WHO to facilitate the writing and revisions necessary.
We anticipate that the entire fascicle will be available in hard copy and via the Internet late in 2017. "We are indebted to the many authors who wrote the revised chapters and have incorporated the changes in this chapter."

material, PAS, chloroacetate esterase stains, and immunologic methods identifying antigens on cell surface (CD41, CD61 or factor VIII) may establish the diagnosis. However, the distinction between acute megakaryoblastic leukemia with myelofibrosis and acute panmyelosis with myelofibrosis may be difficult, particularly if no specimen suitable for cytogenetic analysis can be obtained [4].

The second example is hypocellular (hypoplastic) acute myeloid leukemia in which bone marrow aspirations from several sites and biopsy from one site are necessary for diagnosis [5]. The correct diagnosis depends on a representative biopsy specimen. The third example is that of an uncommon localized extramedullary mass of cells of the granulocytic–monocytic series (myeloid sarcomas) [6]. These tumors can be seen in an established diagnosis of AML, either at presentation or as the first manifestation of relapse.

Diagnosis of Acute Leukemias

The diagnosis of acute leukemia is based exclusively on the morphology of the bone marrow and peripheral blood leukemic cells in the Romanowsky-stained smears. The initial intent was to separate ALL and AML into easily identifiable cell types. In attempting to define boundaries between overlapping groups, major attention is given to the predominant cell type present. An essential cytochemical stain is one that demonstrates MPO, an enzyme restricted to the primary granules of granulocytes and monocytes [7]. Morphologic classification of acute leukemia was that proposed by the French–American–British (FAB) Cooperative group [8], widely used for over two decades. In the meantime, genetic features (cytogenetic, molecular genetic, and gene expression) as well as history of myelodysplasia and prior therapy have been shown to have a significant impact on the clinical behavior of acute leukemias. In 2001 World Health Organization (WHO) proposed a classification in which genetic information was incorporated with morphologic, cytochemical, immunophenotypic, and clinical information into diagnostic algorithms for the acute leukemias [9]. WHO 2008 classification and upcoming revised edition (expected in late 2016) expanded the number of entities with recurrent chromosomal translocations and gene mutations and included new provisional entities [10].

Acute Lymphoblastic Leukemia/Lymphoma (ALL/LBL)

ALL/LBL is one of the most common malignancies observed in the pediatric age group. It derives from the clonal proliferation of lymphoid progenitors in the bone marrow. ALL represents about 80% of cases of acute leukemia in children but only 20% in adults. The consequence of bone marrow infiltration is various cytopenias in the peripheral blood and is associated with the appearance of peripheral blast cells. In some instances, leukemic cells are not seen in the peripheral blood. Thus examination of bone marrow is usually

necessary to confirm the diagnosis. Since the CNS is infiltrated at diagnosis in 5% of patients, examination of the cerebrospinal fluid (CSF) by cytocentrifuge is also necessary.

Morphologic Features

Morphologic classification of ALL was proposed by the FAB group in 1976 [8] and widely used for over two decades. However, the WHO 2008 no longer emphasizes the morphologic classification and separation of the morphologic subtypes. The morphologic features of B- and T-ALL/LBLs are indistinguishable. The lymphoblasts in ALL/LBL vary from small blasts with high nuclear/cytoplasmic (N/C) ratio, scant cytoplasm, condensed nuclear chromatin, a small inconspicuous nucleolus, and a regular nucleus (Fig. 14.4) to larger cell with irregular nuclear membranes, one or more nucleoli, more cytoplasm, and lower N/C ratio (Fig. 14.5). A rare type of leukemia seen in approximately equal percentages in children and adults (about 3–5%) is morphologically identical to the cell characteristics of Burkitt lymphoma. The cells are large and homogeneous with round-to-oval nuclei. The chromatin is finely dispersed with prominent nucleoli. The cytoplasm is intensely basophilic with or without vacuoles (Fig. 14.6). The term B-ALL/LBL should not be used to indicate Burkitt lymphoma/leukemia since it is constantly associated with surface immunoglobulin (sIg) (mature B-ALL) [11]. In addition, an identical nonrandom chromosomal abnormality t(8;14) translocation has been described in both Burkitt lymphoma and leukemia [12]. In rare instances, terminal deoxynucleotidyl transferase-positive (TdT+) B-cell lymphoma/leukemias with BCL2 and/or MYC alterations have been reported [13–15]. These cases do not have the typical morphologic features and chromosomal translocation.

Cytochemistry

By standard definition, the peroxidase reaction is totally negative in leukemic lymphoblasts. SBB stain is also negative. However, it has been suggested that SBB is less specific than MPO because positive reactions have been reported in ALL [16]. It should be remembered that in case of negative MPO or SBB reaction, megakaryocytic, erythroid, some monocytic, and AML with minimal differentiation subtype as well as lymphoid lineage may be involved.

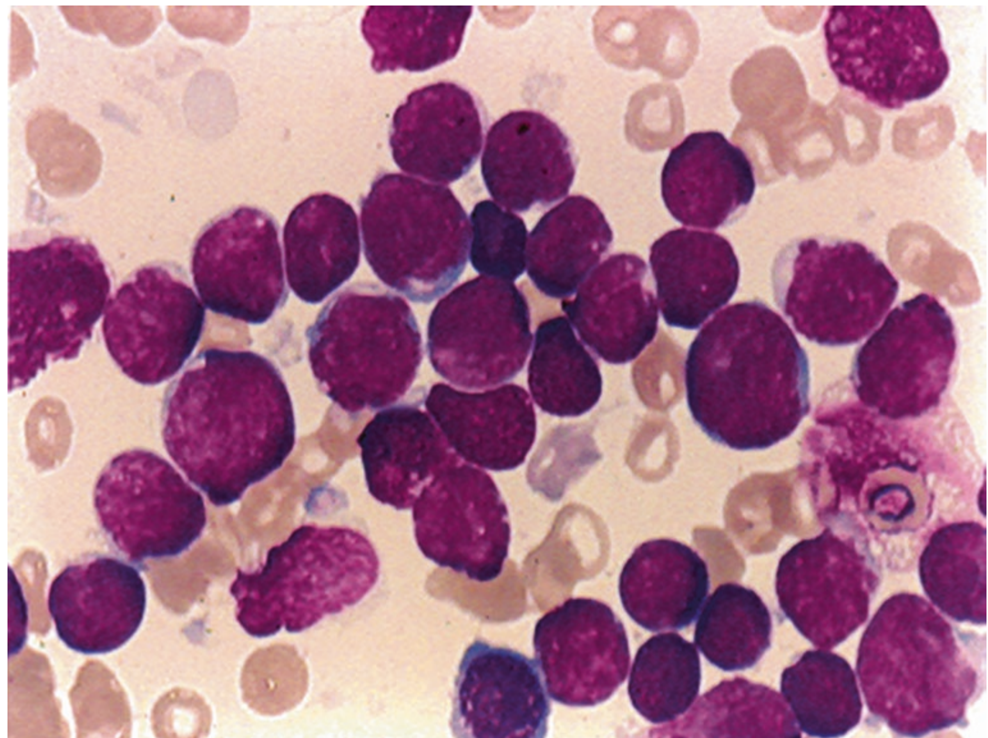

Fig. 14.4 Acute lymphocytic leukemia (ALL): agranular blasts with high nuclear/cytoplasmic ratio; smooth nuclear membrane; rare nucleoli. WG stain

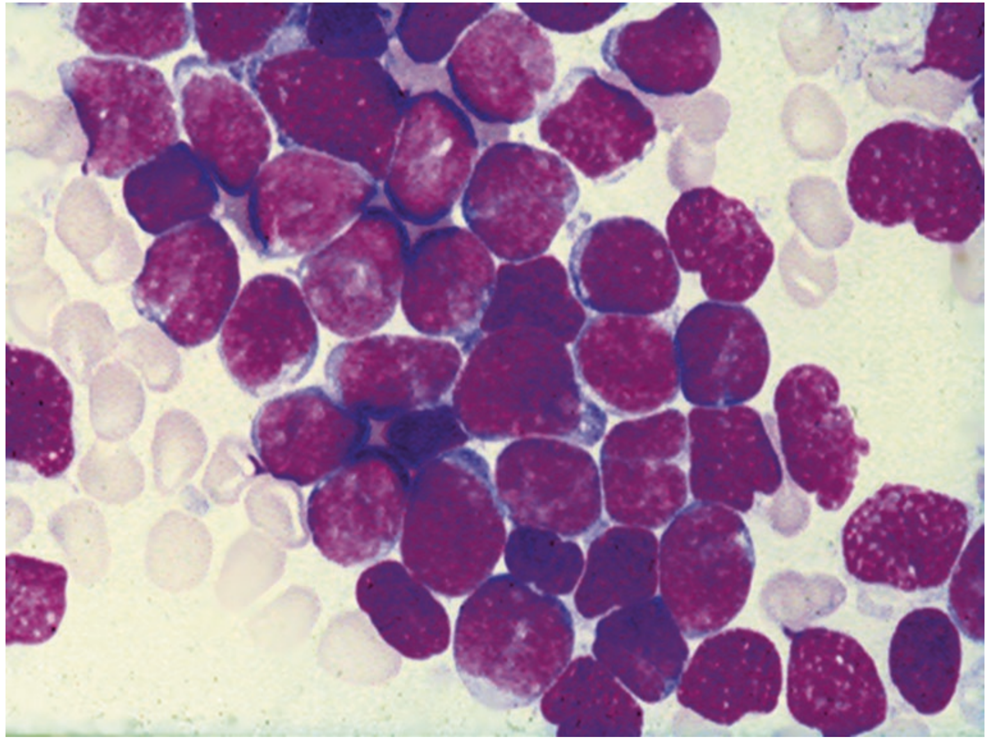

Fig. 14.5 ALL: More cytoplasm than L1 with prominent nucleoli. WG stain

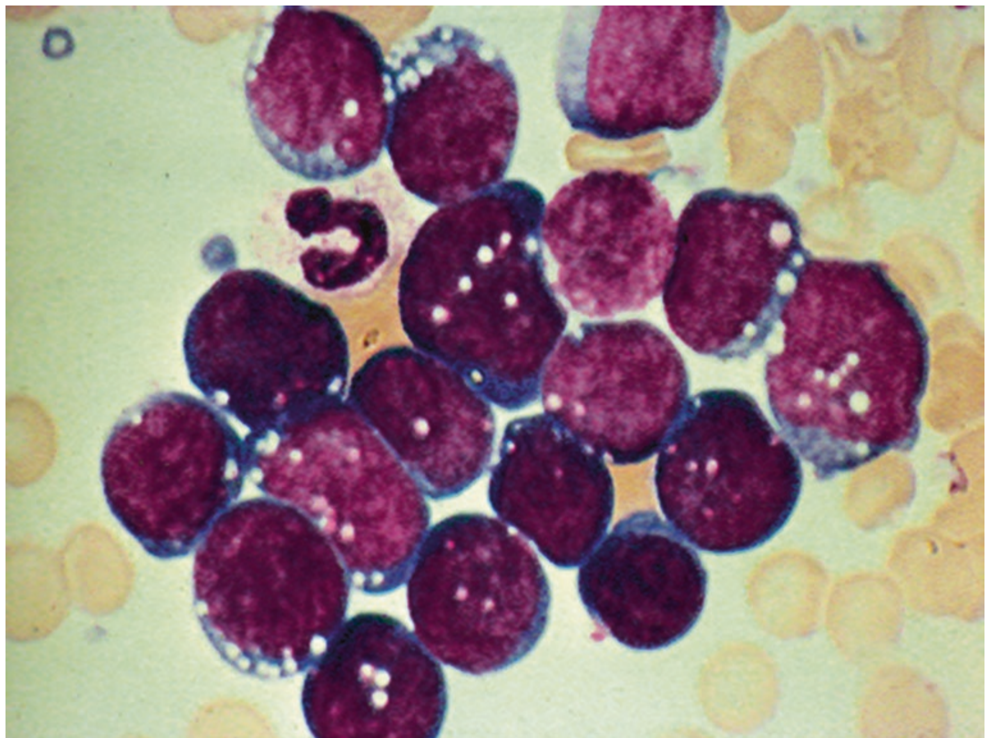

Fig. 14.6 Burkitt lymphoma/leukemia (mature B-ALL): blasts with oval nuclei, finely dispersed chromatin, basophilic cytoplasm with vacuoles. WG stain

The PAS reaction is useful in supporting the diagnosis of ALL (Table 14.1), but its importance has declined, as immunophenotyping has become more important for this purpose. Although blocklike PAS positivity is considered characteristic of ALL, only 15% of cases have this type of PAS reaction (Fig. 14.1) [17]. This pattern of PAS positivity correlates with the immunologic phenotype which is more common in B-lineage cases. The presence of both vacuolated blasts and PAS positivity correlates with reactivity of CD10 antigen [18]. It should be noted that blocklike PAS positivity can be seen in monoblasts in acute monoblastic leukemia and in erythroblasts in acute erythroleukemia [19]. Moreover, fine granular activity in blocks of PAS material can be identified in all AML cell types (Fig. 14.7). PAS stain is therefore a poor discriminator of various cell types, but it may be useful as a part of battery of stains, particularly when many of the reactions are negative or nonspecific. A strong focal (paranuclear) acid phosphatase (ACP) activity or a strong focal ANAE activity greater than 75% of blasts is characteristic of T-ALL [20]. However, it should be remembered that a localized ACP and ANAE reaction is also a feature of rare forms of acute megakaryoblastic and erythroleukemia [21].

Table 14.1 Reaction of acute leukemic cells to cytochemical stains

Stain	AML (M1–M3)	AMML (M4)	AMoL (M5)	ALL (L1–L2)
PAS	±	+	++	++
Acid phosphatase	–	±	++	+++
Peroxidase	+	+	±	–
Chloroacetate esterase	+	+	–	–
α-Naphthyl acetate esterase	±	+	++	++++

PAS Periodic acid-Schiff, − absent, ± occasional activity, + moderate activity, ++ strong activity, +++ focally strong activity in T cells, ++++ focally strong activity at acid pH in T cells

Immunohistochemistry

Indirect immunoperoxidase and indirect alkaline phosphatase anti-alkaline phosphatase (APAAP) techniques are applied to fixed cells in blood and bone marrow smears, cytospin preparations [22], or paraffin-embedded material. These methods permit the detection of surface antigens (i.e., CD19, CD20, CD3, CD1a, and CD10), cytoplasmic antigens (CD79a, MPO, or cytoplasmic μ chain), and nuclear antigens (e.g., TdT and PAX5) [23].

Genetics of Acute Lymphoblastic Leukemia/Lymphoma

Acute lymphoblastic leukemia/lymphoma is relatively homogeneous at morphologic level. However, significant heterogeneity is seen at the genetic level. These genetic lesions define disease subsets with distinct biology and response to treatment and are used in the risk stratification schemas for current protocols [10, 24]. In the last decade,

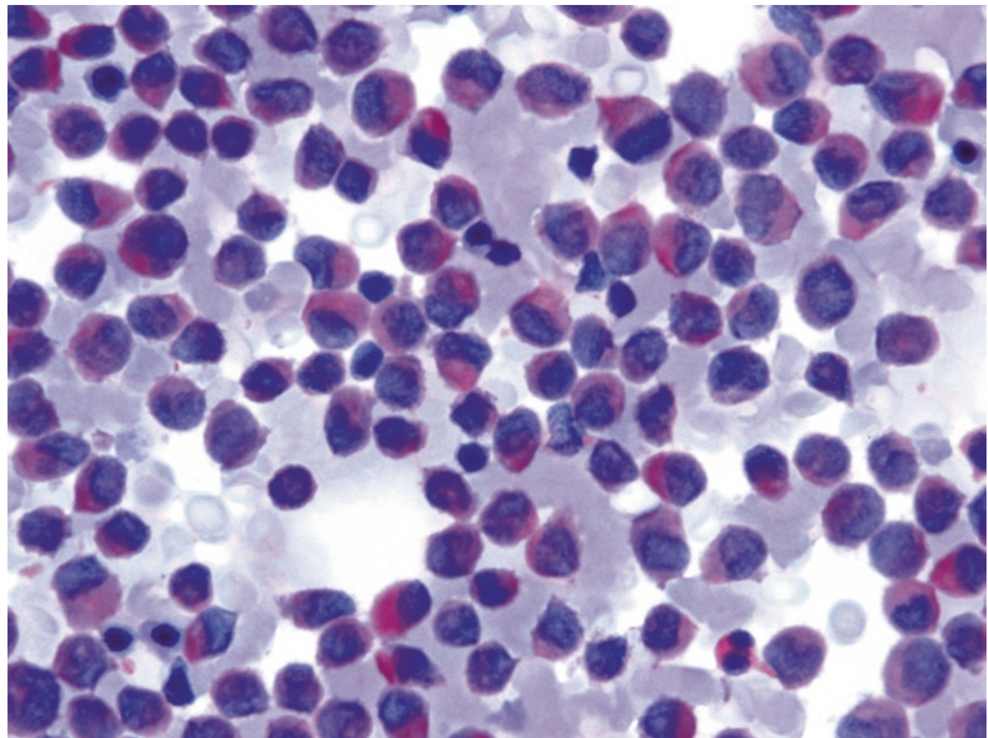

Fig. 14.7 AML: PAS reaction. Note the blush background

studies utilizing microarray analysis and next-generation sequencing have provided major insights into the pathogenesis and clinical behavior of ALL. These studies have identified new ALL subtypes. High hyperdiploidy (>50 chromosomes) occurs in 25–30% of childhood B-ALL and is associated with favorable outcome. Hypodiploidy with 44 chromosomes is uncommon (2–3% of cases) and is associated with poor outcome [25, 26]. Chromosomal rearrangements commonly involve hematopoietic transcription factors, cytokine receptors, epigenetic modifiers, and tyrosine kinases [27]. Common rearrangements in acute B lymphoblastic leukemia are as follows: the t(12;21)(p13;q22) (TEL-AML1) occurs in 15–25% of pediatric cases and is associated with excellent prognosis; t(1;19)(q23;p13) (E2A-PBX1) is seen in 2–6% of pediatric cases, associated with excellent prognosis and CNS relapse; t(9;22)(q34;q11.2) resulting in formation of the "Philadelphia" chromosome (Ph) encoding BCR-ABL1 is associated with 2–4% of pediatric and 25% of adult cases and with poor prognosis; rearrangements of MLL at 11q23 to a range of fusion partners are common in infant ALL (1–2%) with poor prognosis; rearrangement of the cytokine receptor gene CRLF2 is common in Down syndrome-associated and Ph-like ALL and with poor prognosis in non-Down syndrome-associated ALL; t(8;14)(q24;q32), t(2;8)(q12;q24), and t(2;8) (q12;q24) encoding; and MYC rearrangement is associated with Burkitt lymphoma/leukemia which is a neoplasm of mature B cells (2% of cases) and associated with favorable prognosis with short-term high-dose chemotherapy [28, 29]. Approximately 20% of childhood B-ALL cases lack one of these alterations and have alternative sentinel genetic lesions, including deregulation of the ETS family transcription factor ERG, or one of a diverse range of alterations that drive kinase signaling in Ph-like ALL.

T-ALL is also characterized by translocations that deregulate transcription factors, commonly by rearrangement to T-cell antigen receptor loci, and recurring sequence mutations and DNA copy number alterations that disrupt developmental, signaling, and tumor-suppressor pathways, including activating mutations of NOTCH1 and rearrangements of transcription factors TLX1 , TLX3, LYL1, TAL1, and MLL [9, 30, 31].

The finding of prominent eosinophilia either T or B lymphoblastic leukemia/lymphoma must be considered for a rearrangement involving PDGFRA, PDGFRB, or FGFR1. It is important to identify these cases with PDGFRA or PDGFRB abnormalities because these patients are often responsive to TKI therapy [32].

If none of the particular cytogenetic abnormalities (listed previously) are found in a case of B or T lymphoblastic leukemia/lymphoma, the designation of "B or T lymphoblastic leukemia/lymphoma not otherwise specified" is recommended.

Philadelphia-Positive (Ph) ALL and Ph-Like ALL

Cytogenetic studies suggest that Ph chromosome occurs in 2–4% of children with ALL [33], but it is as high as 30% in adults [34]. Thus, this chromosome appears to be the single most common genetic finding in adult ALL. Moreover, the presence of the Philadelphia chromosome identifies a subgroup of ALL with a poor prognosis [35]. Most BCR-ABL1-positive childhood cases express p190 fusion protein, whereas in adults, approximately 50% of the cases express p210 kDa fusion protein (more likely in chronic granulocytic leukemia). It has been suggested that Philadelphia-positive-BCR-positive ALL cases expressing p210 may be CML in lymphoid blast crisis; BCR-negative cases expressing variant p190 may be true de novo ALL [36]. However, no clinical data have been reported to substantiate this claim. One characteristic of Philadelphia-positive ALL is the expression of both myeloid and lymphoid antigens [37]. This feature supports that the cell origin is more immature than the other B-ALL cases [38]. There are no unique morphologic or cytochemical features that distinguish Philadelphia chromosome-positive ALL from other types of ALL.

Recently in about 20% of patients with B lymphoblastic acute leukemia/lymphoma that lack the BCR-ABL1 translocation but that show similar pattern of gene expression profile to B-ALL with BCR-ABL1 which are called as B lymphoblastic leukemia/lymphoma, BCR-ABL1-like or B lymphoblastic leukemia/lymphoma, Ph-like [39]. Leukemias with these properties have poor outcome and frequently have translocations involving other receptor tyrosine kinases, or alternatively have translocations involving either the cytokine receptor-like factor 2 (CRLF2) or less commonly rearrangements of the erythropoietin receptor (EPOR) [40]. Identification of these cases has clinical importance since they are potentially amenable to thyrosine kinase inhibitor (TKI) therapy [41].

There are no unique morphologic or cytochemical features that distinguish Ph-like ALL from other types of ALL. Blasts typically have a CD19+,CD10+ phenotype. The subset of cases with CRLF2 translocations shows very high levels of surface expression of this protein by flow cytometry.

Myeloid Leukemias

AMLs result from a neoplastic transformation of a single pluripotential hematopoietic stem cell. Evidence to support this statement is morphologic [42], immunologic [43], and chromosomal [44] as well as from in vitro cell culture studies. These studies have demonstrated trilineage dysplastic features or lymphoid antigen expressions in AML, monocytic, and erythroid precursors in cultures and elaboration of colony-stimulating factors (CSFs) from monocytes.

Four major types of AML have long been recognized: acute myeloid, acute myelomonocytic, acute monocytic, and acute erythroid leukemia. Despite these subtype definitions, Auer rods are the only consistent neoplastic marker demonstrating that a blast is myeloid and of leukemic origin. Auer rods are abnormal azurophilic crystalline-like granules that represent the coalescence of primary lysosomal granules of myeloid precursors as documented by cytochemical and ultrastructural studies [45, 46]. We have demonstrated that the addition of a peroxidase or another specific stain for primary granules increases the percentage of positive blast cells that contain Auer rods from 21 to 60%. The clinical relevance of these observations is uncertain at the present time.

Classification

The minimal requirements for morphologic specification of each case of AML are well-prepared peripheral blood and bone marrow smears prepared with a Romanowsky stain such as a Wright-Giemsa stain. To prove lineage, some routine cytochemical stains can be applied. These techniques are discussed next.

A uniform reproducible subtype classification in AML is necessary for several reasons; first, it permits comparison among various therapeutic regimens from different groups and from program to program within the same institution or cooperative group. Second, it allows for the potential identification of different clinical features and laboratory aspects that may be unique to certain subtypes. Finally with the increasing sophistication of chromosomal abnormalities and gene mutations in the AML, accurate description of myeloid subsets may permit a meaningful association of nonrandom rearrangements and translocations.

Morphologic classification of AML was proposed by the FAB Cooperative Group in 1976 [8] based on the morphologic and cytochemical features of the blast cells. The original proposal was revised and expanded in 1985 [47]. In the 2008 World Health Organization (WHO) classification, and in the upcoming revision, most of the morphologic FAB subgroups are retained in the AML, NOS category because they define criteria for the diagnosis of AML across a diverse morphological spectrum [48].

Morphologic classification accepts two types of blasts: type I (agranular) blasts are myeloblasts with open chromatin, distinct nucleoli, and immature cytoplasm without granules; type II (granular) blasts are similar to type I, except that they contain up to 20 delicate cytoplasmic azurophilic granules or Auer rods, or both (Fig. 14.8). Goasguen et al. [49] distinguished another type of blasts from promyelocytes, referred to as type III blasts; these lack major characteristics of the promyelocyte, especially the Golgi zone and eccentric

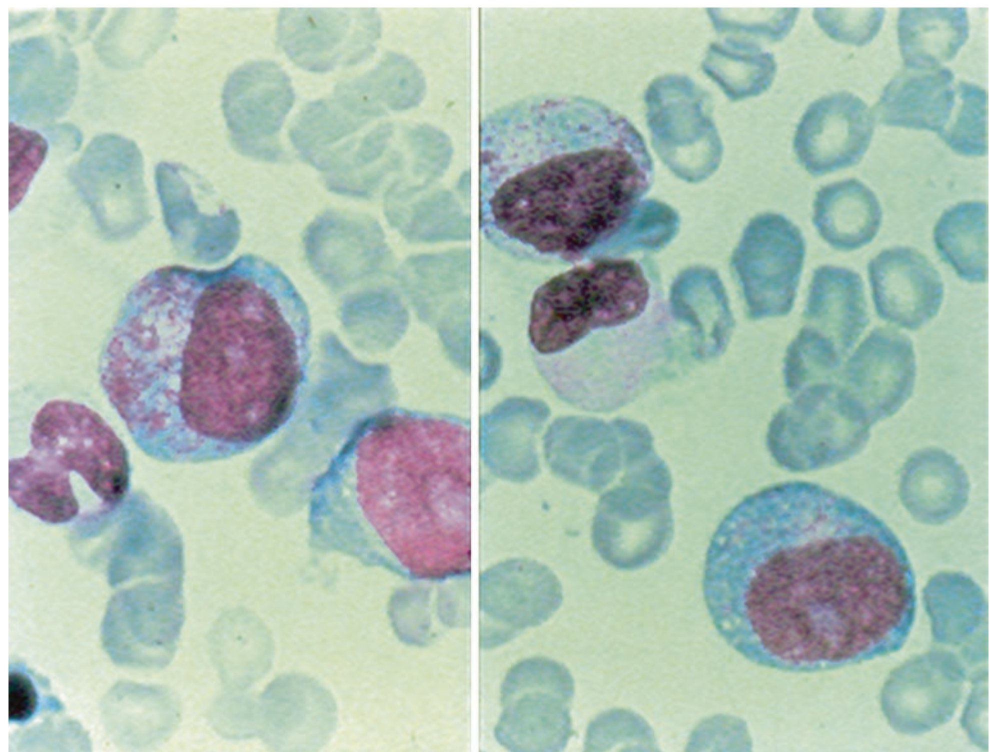

Fig. 14.8 Myeloblast morphology. *Left panel*: agranular blast and promyelocytes (note: Golgi zone); *right panel*: granular blast

nuclear location, but they have many azurophilic granules. Type III blasts are characteristically identified in AML M2 associated with t(8;21), in secondary AML and AML developing from MDS [50]. In practice, although FAB type I and type II blasts can generally be distinguished from each other it has proved difficult to distinguish FAB type II blasts from type III blasts. In addition, the enumeration of abnormal promyelocytes in MDS or AML with multilineage dysplasia remains problematic and their separation from type II and type III blasts has remained imprecise. A group of international experts in morphology has provided guidelines to assist in this regard [51].

FAB criteria identify one clinically significant type of AML, acute promyelocytic leukemia (M3); however, the remaining AML subtypes appear to be cytogenetically and immunologically heterogeneous group of diseases. AML is now classified according to the World Health Organization (WHO) Classification of Tumours of Haematopoietic and Lymphoid Tissues, which was last updated in 2008 [52]. The major categories of the current classification include AML with recurrent genetic abnormalities, AML with myelodysplasia-related changes, therapy-related AML, and AML not otherwise specified. Myeloid proliferations of Down syndrome and blastic plasmacytoid dendritic cell neoplasm are separately classified [53].

A revision of the WHO classification is under way. Changes to the section on AML with recurrent genetic abnormalities are being discussed. First, the molecular basis of inv(3)(q21q26.2) or t(3;3)(q21;q26.2) has been revisited [54]. Second, the provisional entities “AML with NPM1 mutation” and “AML with CEBPA mutation” will become entities; “AML with CEBPA mutation” will be restricted to patients with AML in whom there is a biallelic (and not a monoallelic) mutation, and third, “AML with RUNX1 mutation” [55, 56] and “AMLwith BCR-ABL1” gene [57] are being considered as provisional entities. Finally, a section on familial myeloid neoplasms, which reflects the increasing recognition of familial syndromes, is also under development [58] (Table 14.2).

In the WHO scheme, a myeloid neoplasm with 20% or more blasts in the peripheral blood or bone marrow is considered to be AML [9]. The blast count should be obtained from at least a 200-cell count of all nucleated cells in the peripheral blood and a 500-cell count of all nucleated cells in the bone marrow. In certain cases associated with specific genetic abnormalities inv (16), t(8;21), t(16;16), or t(15;17), the diagnosis of AML is made regardless of the blast count in the peripheral blood or bone marrow. Similarly, the presence of granulocytic sarcoma is diagnostic of AML even if the blast count is less than 20% in the blood or bone marrow [59].

Table 14.2 Proposed WHO revised classification of acute myeloid leukemias (AML)—2016

AML with recurrent genetic abnormalities
Acute myeloid leukemia with t(8;21)(q22;q22.1); *RUNX1-RUNX1T1*
Acute myeloid leukemia with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*
Acute promyelocytic leukemia with *PML-RARA*
Acute myeloid leukemia with t(9;11)(p21.3;q23.3); *KMT2A/MLL-MLLT3*
Acute myeloid leukemia with t(6;9)(p23;q34.1); *DEK-NUP214* 9869/3
Acute myeloid leukemia with inv.(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); GATA2, MECOM (EVI1)
AML (megakaryoblastic) with t(1;22)(p13.3;q13.1); RBM15-MKL1
AML with *BCR-ABL1*
AML with gene mutations
AML with mutated *NPM1*
AML with mutated *CEBPA*
AML with mutated *RUNX1*
Acute myeloid leukemia (AML) with myelodysplasia-related changes
Therapy-related myeloid neoplasms
Acute myeloid leukemia, NOS
Acute myeloid leukemia with minimal differentiation
Acute myeloid leukemia without maturation
Acute myeloid leukemia with maturation
Acute myelomonocytic leukemia
Acute monoblastic and monocytic leukemia
Acute erythroid leukemia
Acute megakaryoblastic leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis
Myeloid sarcoma
Myeloid proliferations related to Down syndrome
Transient abnormal myelopoiesis associated with Down syndrome
Myeloid leukemia associated with Down syndrome
Blastic plasmacytoid dendritic cell neoplasm

Cytochemistry

Myeloperoxidase and Sudan Black B

An essential cytochemical stain is one that demonstrates the presence of MPO, an enzyme restricted to the primary granules of granulocytes and monocytes [7]. This enzyme can be identified by performing a benzidine-based peroxidase reaction or SBB staining or by diaminobenzidine reaction. The benzidine method is the best available method against which other methods should be compared. However, because of the concern for its potential carcinogenicity, it should not be adopted as the reference method [60].

The SBB reaction, a general stain for intracellular lipids, can be used in the same way. This stain is present in both primary and secondary granules. Sudanophilia and MPO activity are closely parallel [61].

Specific and Nonspecific Esterases

The chloroacetate esterase reaction can also be used to identify myeloid lineage. Although it is less sensitive than either MPO or SBB in detecting myeloid differentiation, it can be useful, when combined with ANAE in double-esterase stain, in confirming a monocytic component. Because ANAE is positive both in neutrophils and in monocytes, inhibition by NAF in monocytes should be used to identify these cells [62, 63].

Periodic Acid-Schiff Reaction

All glycogen-containing cells as well as neutrophils and granulocytes at all stages of maturation stain with this reaction. Our experience in more than 200 patients has shown that fine granular PAS reaction can be identified in all AML subtypes, ranging from 60% in AML (M1–M3) to 80% in AML M5. Moreover, the latter often demonstrates a blocklike reaction pattern characteristic of ALL (Bennett J.M., unpublished observation). The blocklike pattern of PAS reactivity is seen in erythroid precursors of acute erythroid leukemia.

Electron Microscopy

Electron microscopy (EM) is used to demonstrate either MPO or platelet peroxidase (PPO). These ultrastructural studies are useful in the confirmation of myeloid (MO) or megakaryocytic (M7) origin of blasts. MPO can be demonstrated by electron microscopy in blast cells that previously had negative results (less than 3% positive blasts) by conventional criteria. It is also useful to define the myeloid component in biphenotypic leukemias [62, 63]. In megakaryoblasts, the PPO reaction is localized exclusively on the nuclear membrane and the endoplasmic reticulum, whereas in myeloblasts it occurs in the Golgi area and cytoplasmic granules.

Immunohistochemistry

Cytospin preparations or direct marrow or peripheral blood smears as well as bone marrow paraffin sections are used to demonstrate the presence of specific lineage antigens using a secondary technique (e.g., PAP, APAAP) to show antibody fixation [22]. Its advantage includes confirmation of morphologic features, the possibility of performing retrospective studies, and in situations where peripheral blood and bone marrow smears are inadequate for study such as bone marrow fibrosis or hypocellular acute myeloid leukemia. Paraffin-reactive antibodies, i.e., CD34, MPO, CD68, CD117, CD41, CD61, glycophorin A, and factor VIII-related antigen, can successfully be used to subclassify AML [64].

Acute Myeloid Leukemias with Recurrent Cytogenetic Abnormalities

All patients morphologically diagnosed with AML must have bone marrow cytogenetic studies performed. WHO 2008 classification is recommended to incorporate recently described genetic aberrations into classification and define, biologically relevant, homogeneous entities based on not only the prognostic value of a genetic abnormality but also morphologic, clinical, and phenotypic properties [59, 65]. The contribution of cytogenetics to the classification of AML and acute myeloid leukemias with recurrent cytogenetic abnormalities are briefly discussed as follows.

Acute Myeloid Leukemia with t(8;21)(q22;q22);RUNX1-RUNX1T1

AML with t(8;21) is common in children and adults accounting for approximately 7–12% of AML overall and 20–25% of AML M2. Myeloid sarcomas may be present at presentation. Cases with t(8;21) should be diagnosed as AML regardless of a blast percentage in the bone marrow. The translocation results in a fusion product involving the RUNX1 gene (also known as core-binding factor alpha or AML1) on chromosome 21 and the RUNX1T1 (also known as ETO) gene on chromosome 8 [66]. Cases of AML with t(8;21) are associated with characteristic morphologic features [67]. Blasts are large cells with a distinctive nucleolus. The cytoplasm contains abnormal heavy azurophilic granulations (type III blasts) with tiny needlelike Auer rods (Fig. 14.9). The maturing neutrophils are commonly dysplastic. However, dysplasia of other cell lines is uncommon. Background eosinophilia is variably present. Blasts may express B-lineage antigens such as CD19, CD79a, PAX5, and TdT. These findings do not indicate the presence of mixed-phenotype leukemia in the presence of t(8;21) [68]. Acute myeloid leukemia with t(8;21) is usually associated with favorable prognosis in children and adults [69]. Mutations of KIT occur in 20–30% of cases [70]. Most published reports indicate a higher relapse rate and lower overall survival when mutated KIT is present [70, 71]. Additional mutations in ASXL2 and ASXL1 were also recently described in t(8;21) AML [72]. The presence of monosomy 7 as an additional cytogenetic abnormality may adversely impact prognosis [73]. Quantitative PCR measuring of RUNX1-RUNX1T1 transcripts is useful for monitoring minimal residual disease [74].

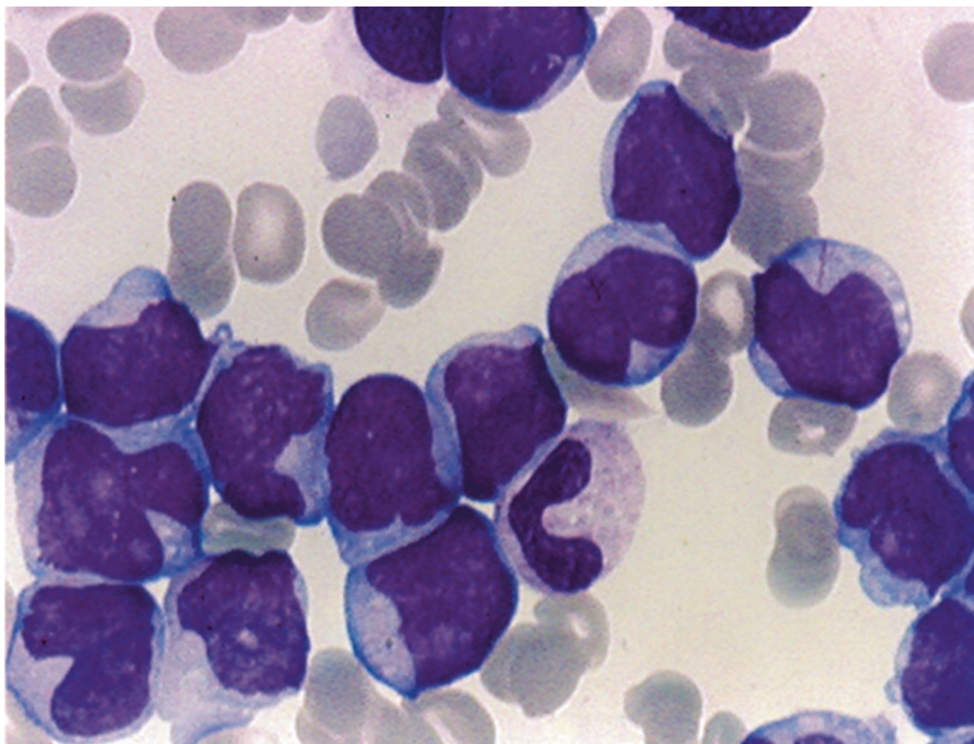

Fig. 14.9 AML –t(8;21). Note thin Auer rod in a myeloblast

Acute Promyelocytic Leukemia with t(15;17)/q22;q12, PML–RARA

APL is a distinct class of AML characterized by specific morphologic, cytogenetic, and clinical features. In most series, M3 accounts for about 10% of cases in adults and for 4–8% in children [75].

The highly specific t(15;17) translocation is present in at least 90% of all APL cases. Using molecular techniques, virtually 100% of APL cases have t(15;17). This translocation fuses the PML gene of the chromosome 15 to the retinoic acid receptor-α (RARA) gene, producing chimeric PML–RARA gene [76–78]. Cytogenetic analysis, FISH, or RT-PCR is necessary for genetic confirmation of the PML–RARA fusion. Detection of this abnormality is diagnostic of APL regardless of the blast count. The involvement of RARA at the translocation breakpoints may explain the clinical response to all-trans retinoic acid (ATRA) [79, 80].

Morphology is still highly relevant in APL diagnosis and is a very rapid modality [81]. Typical APL is characterized by the presence of hypergranular blast cells, which have the appearance of abnormal promyelocytes. The cytoplasm is dense with coarse dark-staining granules that often obscure the nucleus. The nuclear border is generally irregular and has a folded or reniform appearance (Fig. 14.10). Cells contain bundles of delicate needlelike Auer rods, giving a meshwork appearance (so-called Faggots), found in some of the leukemic blasts. These abnormal promyelocytes are strongly positive for the MPO or SBB reactions. In contrast to other AML subtypes, dysplastic features of the myeloid series associated with leukemic proliferation are not seen. In adult patients with typical APL that achieve a CR, the prognosis is better than for any category of AML.

The FAB classification recognizes a variant of APL (FAB M3v) [82], characterized by bilobate cells or by cells with reniform nucleus and cytoplasm with minimal or no granulations (Fig. 14.11). Typical M3 cells are infrequent in the bone marrow. Hypogranular promyelocytes are strongly positive for the MPO or SBB, as in typical APL. The immunophenotype of M3v is identical to that described for the typical APL (expressing of myeloid antigens in the absence of HLA-DR reactivity) [83, 84]. Special attention should be given to differentiate these cases from M4 and M5b subtypes. The distinction is important because of the well-known association of M3 with disseminated intravascular coagulation (DIC) [1]. The DIC syndrome is present equally in the M3v. In adults, the hypogranular or “microgranular” variant constitutes 25% of APL cases [85]. It may also occur in children [86]. The hematological characteristic of M3v at onset, in addition to DIC, is hyperleukocytosis (>20,000/mm^3). M3v has been associated with shorter CR and poorer overall survival, reflecting early hemorrhagic deaths [85, 86].

FLT3 mutations are common in APL with the majority being internal tandem duplication (ITD) mutations. These mutations are strongly associated with the hypogranular subtype with hyperleukocytosis [87].

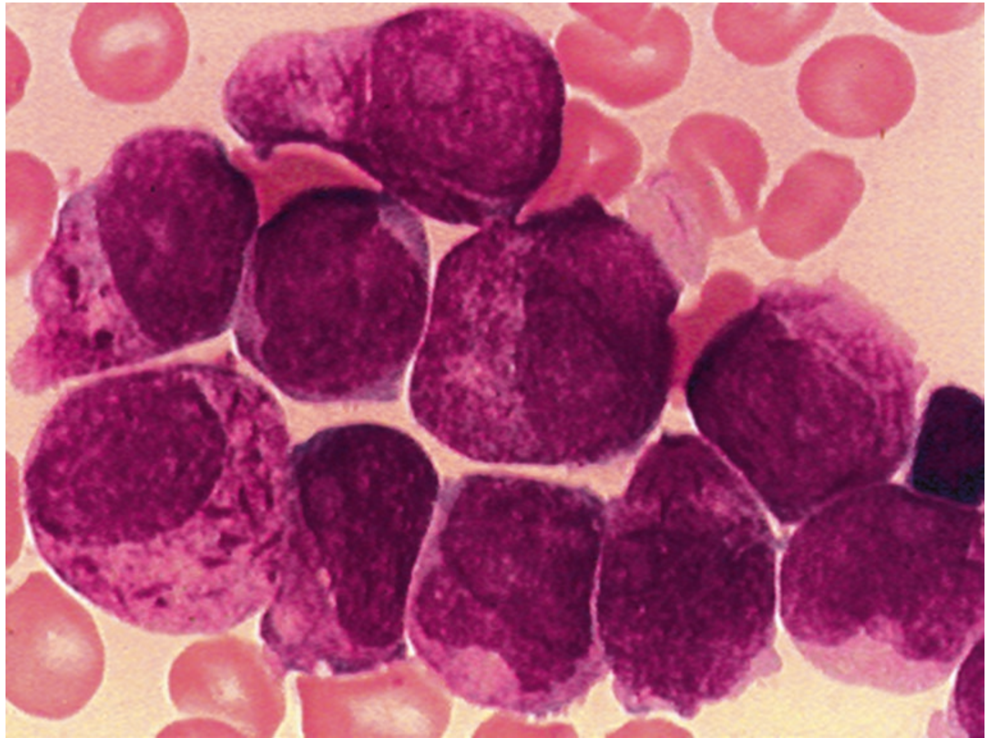

Fig. 14.10 APL (FABM3). Hypergranular promyelocytes with bundles of Auer rods

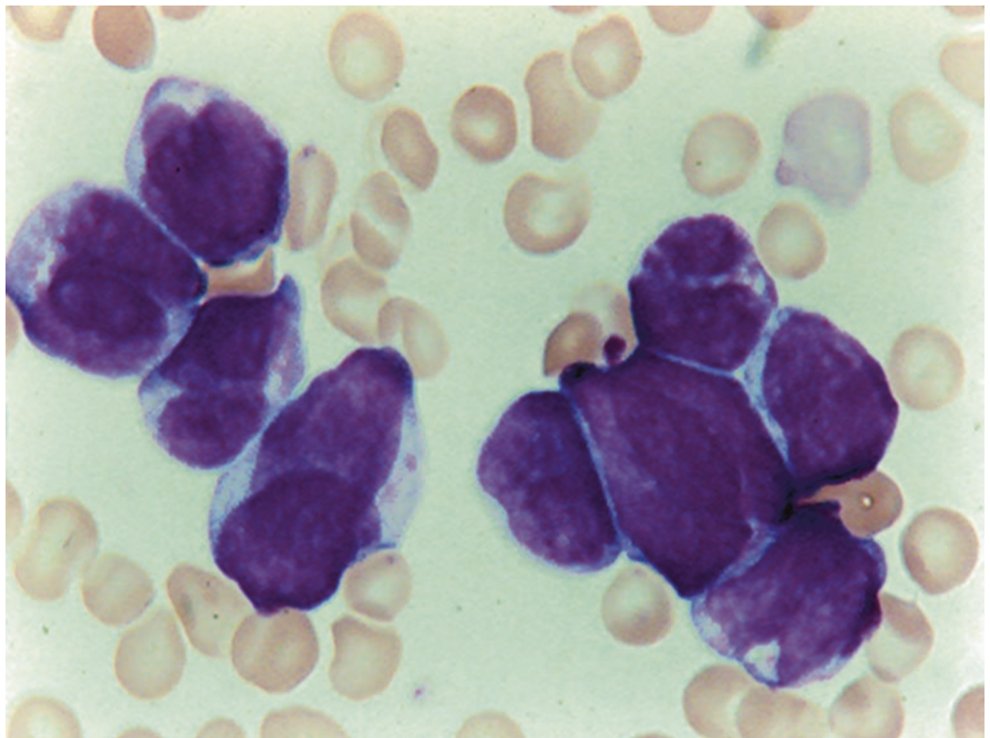

Fig. 14.11 APL variant (FABM3v). Only occasional cells have granules but prominent bilobed and reniform nuclei. WG stain

A small numbers of cases, often with morphologic features resembling APL, show variant translocations involving RARA gene on chromosome 17, but not the PML gene on chromosome 15, such as t(11;17) (ZBTB16-RARA), t(5;17)(NPM-1-RARA), and t(17;17)(STAT5B-RARA) [88]. Patients with variant RARA translocations often experience DIC. Cases with t(11;17) show morphologic differences in which Auer rods are usually absent and pelgeroid neutrophils may be seen. Importantly, some of these variant PML–RARA transcripts are associated with ATRA resistance, and some are not detected by current PCR techniques [89, 90].

Acute Myeloid Leukemia with inv(16)(p13.1q22) or t(16;16)p13.1;q22;CBFB-MYH11

AML with chromosome 16 abnormalities comprises 10% of adult and 6% of childhood AML. The inv(16) and the t(16;16) both result in the fusion of the beta-subunit of core-binding factor (CBFB) gene at 16q22 to the gene encoding smooth muscle myosin heavy chain (MYH11) at 16p13.1 [91]. The presence of this genetic abnormality is diagnostic of AML regardless of the blast count [52]. In these cases, in addition to characteristic morphologic features of acute myelomonocytic leukemia, the bone marrow shows a variable number of abnormal eosinophil components (AML-M4Eo) (Fig. 14.12). Eosinophils account for 5% or more of nonerythroid cells. The eosinophils are abnormal; in addition to the specific eosinophilic granules, they have large basophilic granules and demonstrate chloroacetate esterase and PAS (coarse granules) positivity. Often the nuclei have pseudo-Pelger features. At least 3% of the blasts show myeloperoxidase (MPO) or Sudan Black B reactivity. The monoblasts and promonocytes usually show NSE or ANAE reactivity [92]. The incidence of extramedullary disease is higher than for most types of AML, with a high incidence of CNS relapse. Patients with chromosome 16 abnormalities tend to respond to chemotherapy better, experience relatively long remissions, and have a better prognosis [69, 93]. KIT mutations are present in 30% of cases and negatively impact prognosis in older patients [70]. AML with t(8;21) or inv(16) and mutated KIT are considered as intermediate-risk AML, not favorable-risk AML [94].

Acute Myeloid Leukemia with t(9;11)(p22-q23); MLLT3-MLL

Translocations involving the MLL gene on chromosome 11q23 are seen in approximately 6% of cases of AML and secondary leukemias that occur in patients treated with topoisomerase II inhibitors [95], in patients with acute lymphoblastic leukemia, and rarely in patients with MDS [96]. However, with regard to copy number alterations (CNAs), no differences were found in the number or type of lesions between de novo and therapy-related AML with t(9;11) [97]. A number of different partners for the balanced 11q23 translocations have been identified. However, the WHO 2008 classification only recognizes t(9;11) (MLLT3-MLL) as a specific entity. This type of AML occurs at any age but is more common in children [98, 99]. Leukemic blasts containing 11q23 translocations generally have monocytic features and are subclassified as FAB M4 or M5 [100]. However, it is also detected in AML with or without maturation. Monoblasts and promonocytes show strong positive NSE reactions and often lack MPO reactivity. Extramedullary disease of the skin and gingiva and presentation with DIC have also been described.

Although pediatric cases with t(9;11) have an intermediate prognosis, leukemias associated with a different chromosome 11q23 translocations have poor prognosis [101]. Recently, within all t(11q23) AMLs, EVI1 positivity was found to be sole prognostic factor, predicting for inferior overall survival [102]. KIT or FLT3-ITD mutations are rare in AML with 11q23 translocations [59].

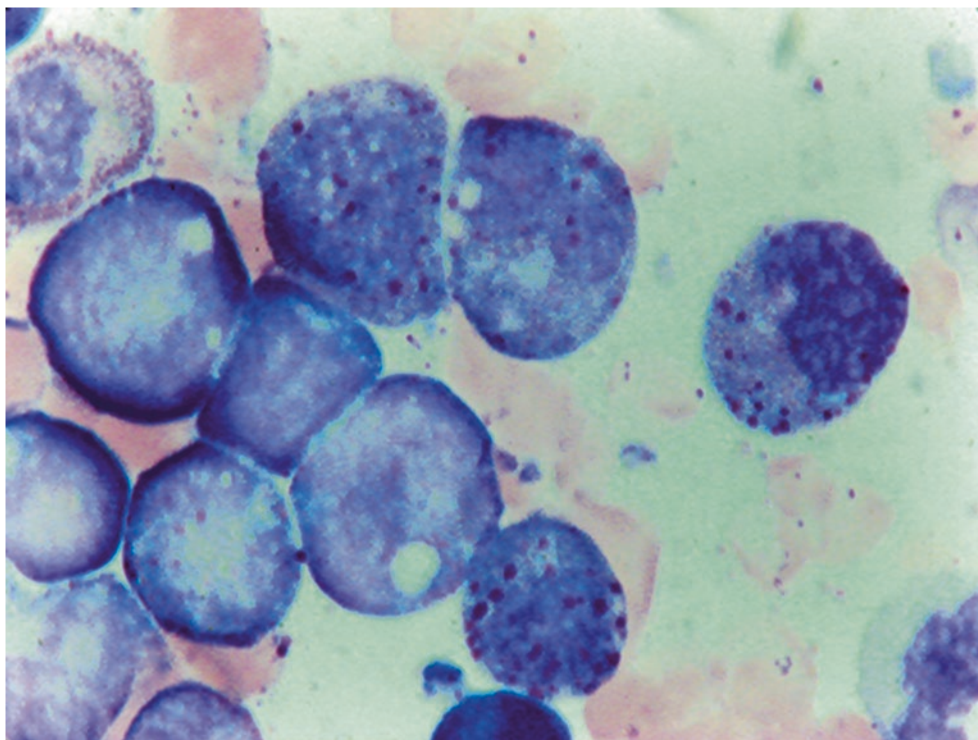

Fig. 14.12 AMML with eosinophils (FAB M4Eos). Note the magenta staining granules in the myelocyte. WG stain

Acute Myeloid Leukemia with t(6;9)(p23;q34);DEK-NUP214

The t(6;9) is detected in 0.7–1.8% of AML that occurs in both children and adults.

In this entity there are no features specific to blast cells. The blasts may show occasional Auer rods and may exhibit monocytic features. Marrow and peripheral blood basophilia defined as more than 2% is seen in half of the reported cases. Multilineage dysplasia may be evident in most of the cases [103, 104]. Blasts are MPO positive. TdT may be positive in some cases. FLT3-ITD mutations are common in this type of AML occurring in 69% of childhood and 78% of adult cases [103, 104]. AML with t(6;9)(p23;q34) represents a unique subtype of acute myeloid leukemia with a high risk of relapse, high frequency of FLT3-ITD mutations, and a specific gene expression signature including several upregulated genes involved in histone modification, and a typical HOXA/B profile, which may be a target for future therapy [105]. AML with t(6;9)(p23;q34) has poor outcome in both adults and children. However, recent smaller studies, including both adult and pediatric patients, have shown that treatment with early allogeneic hematopoietic stem cell transplantation in first complete remission may improve the outcome [106, 107].

Acute Myeloid Leukemia with inv (3)(q21q26.2) or t(3;3)(q21;q26.2);RPN1-EVI1

Various categories of 3q abnormalities in AML can be distinguished according to their genetic features. But 2008 WHO classification of hematopoietic tumors only recognizes AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2);RPN1-EVI1 as an independent clinicopathological entity, with an extremely poor prognosis. In the upcoming revised WHO classification, the molecular basis of inv(3)(q21q26.2) or t(3;3)(q21;q26.2) shows rearrangement of a GATA2 oncogenic enhancer element, rather than of the RPN1 gene, in band 3q21 with the EVI gene in band 3q26.2 [54]. High expression of the oncogene EVI1 at 3q26.2 is a poor prognostic indicator independent of 3q26 rearrangement. Deregulated expression of EVI1 is the molecular hallmark of this disease; however, when the genome-wide spectrum of cooperating mutations is elucidated it has been shown that 98% of inv(3)/t(3;3) myeloid malignancies harbor mutations in genes activating RAS/receptor tyrosine kinase (RTK) signaling pathways which may provide a target for a rational treatment strategy [108].

Acute myeloid leukemia with inv (3) or t(3;3) may represent de novo or may arise from MDS. It accounts for about 1–2% of all AML cases and occurs most commonly in adults [98, 109]. Patients typically present with anemia and sometimes thrombocytosis [110, 111]. Dysplastic hypogranular neutrophils, pseudo-Pelger cells, dysplastic thrombocytes, and naked megakaryocyte nuclei associated with or without blast cells are noted as peripheral blood changes. Bone marrow blasts may show all morphological FAB diagnoses from M0 to M7 (except M3) subtypes. MPO reactivity is often low. Multilineage dysplasia of bone marrow elements other than blast cells is a common finding. Dyserithropoesis and/or dysgranulopoiesis are frequent. Megakaryocytes may be normal or increased in number and usually have dysplastic features [111–113]. Bone marrow cellularity and fibrosis are variable.

Secondary karyotypic abnormalities including monosomy 7, 5q deletions, and complex karyotypes are present in most of the cases and associated with poor prognosis [112]. Some patients having these translocations may present less than 20% blasts in the bone marrow and should be closely monitored for development of AML.

Acute Myeloid Leukemia (Megakaryoblastic) with t(1;22)(p13;q13); RBM15-MKL1

Acute megakaryoblastic leukemia (AMKL) with t(1;22) is a rare form of AML and restricted to infants and children younger than 3 years. It commonly occurs in infants without Down syndrome (DS) [52, 114]. Non-DS AMKL is characterized by chimeric oncogenes consisting of genes known to play a role in normal hematopoiesis [115, 116]. The median age at diagnosis is 4 months. Majority of cases present with marked hepatosplenomegaly and/or osteolytic skeletal lesions with or without bone marrow involvement [117]. Patients also have anemia and thrombocytopenia with a moderately elevated white blood cell count. The morphology of the blast cells reveals that cells are very pleomorphic that may vary from very small with dense chromatin to somewhat larger with a fine reticulated nuclear chromatin and prominent nucleoli. Cytoplasmic blebs or actual platelet shedding may be found surrounding some blasts. The blasts are MPO or SBB negative. Micromegakaryocytes are common, but dysplastic features of erythroid and granulocytic cells are not present. Bone marrow biopsy may show many clusters of micromegakaryoblasts, as well as more mature megakaryoblasts (Fig. 14.13). This is associated with an increase in reticulin formation and a corresponding decrease in normal hematopoietic precursors. Patients with t(1;22) and less than 20% blasts on bone marrow aspiration should be correlated with the bone marrow biopsy. The presence of myeloid sarcoma is diagnostic of AML regardless of the marrow blast count. Megakaryoblasts express one or more of the platelet glycoproteins (CD41 and CD61). Cytoplasmic expression of these markers is more specific and sensitive than surface staining. The myeloid-associated markers CD13 and CD33 may be positive. CD36 is characteristically positive. CD34,

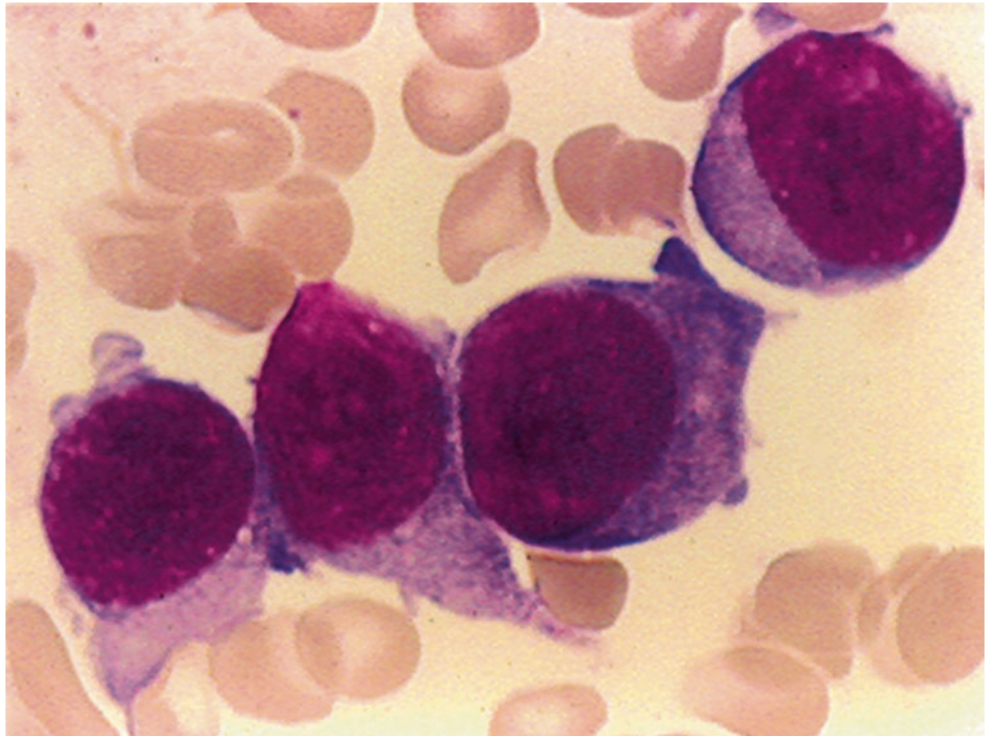

Fig. 14.13 Acute megakaryocytic leukemia. (FABM7). Large blasts with cytoplasmic projections. Immunostain for CD41 was positive. WG stain

MPO, HLA-DR, and TdT are negative [49]. The outcome of non-DS AMKL is generally poor, with lower event-free survival even in the face of intensified treatment [118]. Monitoring of MRD using RBM15-MKL1 fusion transcript would be useful in the treatment of AMKL with t(1 ; 22)(p13; q13) [119].

AML with Gene Mutations

In addition to translocation and inversions, specific gene mutations also occur in AML. Alone or in combination NPM1, FLT3-ITD, CEBPA, and KIT mutations have been reported in AML patients with a normal karyotype. However, they may also be seen in patients with translocation and inversions as well [119]. Recent studies have also shown that the mutations of ASXL1 and TP53 as well as RUNX1 have consistently been associated with an inferior outcome and they will be included in these recommendations [65, 120]. In the 2008 WHO classification [52], mutations of NPM1, FLT3-ITD, and CEBPA are listed among the most common recurrently mutated genes, and those with the NPM1 or CEBPA mutation are designated as provisional entities; in revised upcoming edition they will become entities. On the other hand, AML with CEBPA mutation will be restricted to patients with AML in whom there is a biallelic (and not a monoallelic) mutation, because only that form of AML defines a clinicopathologic entity that is associated with a favorable prognosis [121]. Finally, "AML with RUNX1 mutation" [56] is being considered as provisional entity on the basis of their characteristic clinicopathologic features. FLT3-ITD gene mutations may occur with any type of AML and MDS (20–40% of cases) but is more common in AML with t(15;17) and AML with a normal karyotype and their presence is associated with an adverse outcome [122, 123]. KIT mutations have prognostic significance in cases of AML with t(8;21), inv(16), and t(16;16) (core-binding factor leukemias), in which they are associated with a poor prognosis [70]. AML with mutated NPM1 is found in 50% of adult and 20% of pediatric AML patients with a normal karyotype [124, 125]. AML with mutated NPM1 in the absence of a FLT1-ITD mutation has a favorable prognosis [124, 126]. In adults, most of the NPM1-mutated cases show monocytic differentiation. Along with molecular techniques, paraffin sections are also used to show aberrant cytoplasmic expression of NPM by immunohistochemistry [125]. Around 10% of AML cases with normal karyotype carry the CEBPA mutation. Most CEBPA-mutated cases are double mutated (biallelic); only a few cases of AML cases with normal karyotype carry a singly mutated CEBPA [127]. There are no distinctive morphologic features of AML with biallelic mutations of CEBPA, but the vast majority of cases have features of either AML without or with maturation [127, 128]. Multilineage dysplasia is reported in 26% of cases with no adverse prognostic significance [129]. *RUNX1* mutations have been identified in a substantial proportion of AML patients with normal karyotype [55, 56] as well as in myelodysplastic syndromes [130]. AML with RUNX1 mutations

are often associated with undifferentiated morphology (M0). RUNX1 mutations are frequently associated with ASXL1 mutations; however they never coexisted with NPM1 and CEBPA mutations [56]. Since RUNX1 mutations are associated with poor clinical outcome in both younger and older patients treated with intensive induction chemotherapy [55] patients harboring RUNX1 mutations warrant novel therapies and/or early alloSCT.

Acute Myeloid Leukemia with Myelodysplastic Related Changes

Patients are assigned to "AML with myelodysplasia-related changes" if they have 20% or more blasts in the blood or marrow and (1) arise from previous myelodysplastic syndrome (MDS) or a myelodysplastic/myeloproliferative (MDS/MPN) neoplasm, (2) have specific MDS-related cytogenetic abnormalities, and/or (3) exhibit multilineage dysplasia (50% or more of the cells in two or more myeloid lineages) [49]. Patients should not have a history of prior cytotoxic or radiation therapy for an unrelated disease. The specific genetic abnormalities of AML with recurrent genetic abnormalities are absent.

This category of AML occurs mainly in elderly patients and is rare in children [131]. Although the definition of multilineage dysplasia is variable in the literature, this category appears to represent 24−35% of all cases of AML [132, 133]. Myeloid sarcomas may be present at presentation and should be diagnosed as AML regardless of the bone marrow blast percentage [52].

To classify an AML as having myelodysplasia-related changes based on morphology, dysplasia must be present in at least 50% of the cells in at least two myeloid cell lines. Morphologic dysplasias are characterized by neutrophils with hypogranular cytoplasm or hyposegmented nuclei; erythroblasts with megaloblastoid changes, nuclear irregularity, multinuclearity, and ringed sideroblasts; megakaryocytes with nonlobated or multiple nuclei; and micromegakaryocytes. Dysmegakaryopoiesis may be more easily recognized in paraffin sections [132, 134]. Some cases do not meet the criteria for a morphologic diagnosis. However, they are diagnosed as AML with myelodysplastic related changes by the detection of MDS-related cytogenetic abnormalities and/or by a prior history of MDS or MDS/MPN. Chromosome abnormalities are similar to those found in MDS and often involve gain or loss of major segments of certain chromosomes with complex karyotypes, −7/del(7q) and del(5q), and unbalanced translocations involving 5q being most common [93, 135]. Cases of AML with multilineage dysplasia may carry NPM1 and/or FLT3 mutations, or biallelic mutations of CEBPA [136]. Most NPM1-mutated or CEBPA double-mutated cases would be expected to have a normal karyotype and no history of prior MDS [137]. Prognosis of these cases is similar to cases without multilineage dysplasia [129]. Therefore, such cases are now considered as part of the respective entities of AML with mutated NPM1 or AML with double-mutated CEBPA and not as AML with myelodysplasia-related changes. Other gene mutations, such as U2AF1, ASXL1, and TP53, are fairly common in AML with myelodysplasia-related changes [9, 138]. Blasts often express panmyeloid markers (CD13, CD33), but aberrantly high or low expression is common. There is frequent aberrant expression of CD56 and/or CD7 [139].

The principal differential diagnoses are MDS with excess blasts (MD-EB), acute erythroid leukemia, acute megakaryoblastic leukemia, and other categories of AML, not otherwise specified (NOS). Careful blast cell counts, adherence to the diagnostic criteria for morphological dysplasia, and evaluation for MDS-related cytogenetic abnormalities should resolve most cases, with this category having priority over the purely morphological categories of AML, NOS. For example, a case with ≥20% total BM myeloblasts, multilineage dysplasia, ≥50% BM erythroid precursors, and monosomy 7 should be considered as AML with myelodysplasia-related changes rather than acute erythroid leukemia. Similarly, a case with 20% or more BM megakaryoblasts and multilineage dysplasia would be considered AML with myelodysplasia-related changes if AML with t(1;22)(p13.3;q13.1) and myeloid neoplasms of Down syndrome are excluded.

Although AML with multilineage dysplasia is generally associated with a poor prognosis, several studies have not found morphology to be a significant parameter when using multivariate analysis that also incorporates the results of cytogenetic analysis, high-risk cytogenetic abnormalities being more significantly associated with prognosis [136]; however, the presence of multilineage dysplasia in the absence of prior MDS or an MDS-related cytogenetic abnormality appears to remain to be a significantly poor prognostic indicator in adults [140, 141].

Therapy-Related Myeloid Neoplasms

This category includes therapy-related AML, MDS, and MDS/MPN occurring as late complication of cytotoxic and/or radiation therapy administered for a neoplastic or non-neoplastic disorder [142]. Therapy-related myeloid neoplasms account for 10–20% of all cases of AML, MDS, and MDS/MPN [143].

Two subsets of therapy-related neoplasms are recognized. The longer latency cases (5–10 years after therapy) are associated with alkylating agents and ionizing radiation. This category is commonly associated with chromosomal losses, often of −5,−7 in a setting of complex karyotype and mutations or loss of TP53 [144, 145]. Shorter latency cases may arise 1–5 years after therapy and comprise 20–30% of

patients. These cases are usually associated with topoisomerase II inhibitor therapy and majority of these cases are associated with recurrent balanced chromosomal translocations that frequently involve 11q23 (MLL orKMT2A) or 21q22.1 (RUNX1) and have morphology resembling de novo acute leukemia associated with these same chromosomal abnormalities [146]. On the other hand, division of patients according to the type of the therapy is not practical since most patients have received polychemotherapy that includes both classes of drugs [147]. The bone marrow may be hypercellular, normocellular, or hypocellular and may have been associated with fibrosis. Blast counts are variable; approximately half of the t-MDS patients will have less than 5% blasts but often exhibit poor-risk cytogenetics [148, 149]. Dysgranulopoiesis and dyserythropoiesis are present in most cases. Megakaryocytes vary in number but the majority of cases show dysplastic megakaryocytes with mono- or hypolobated nuclei. In 20–30% of cases the first manifestation of a therapy-related myeloid neoplasm is overt acute leukemia without a preceding myelodysplastic phase [146–148]. Many of these cases have monoblastic or myelomonocytic morphology. Some cases may have karyotypic and morphologic changes identical to de novo AML with recurring cytogenetic abnormalities, including t-APL with RARA-PML. Such cases should be designated as t-AML with the appropriate cytogenetic abnormality indicated [150]. The prognosis of t-MN is generally poor although it is strongly influenced by the associated karyotypic abnormality as well as the comorbidity of the underlying malignancy or illness for which the cytotoxic therapy was given [151].

Acute Myeloid Leukemia, Not Otherwise Specified

Acute myeloid leukemia, not otherwise specified (AML, NOS), encompasses those cases that do not fulfill the criteria for any of the other previously described AML categories. AML, NOS accounts for 25–30% of all cases. The subgroups of AML, NOS are not prognostically significant [132, 152] when AML with mutated *NPM1* and double-mutated *CEBPA* are removed [48]. Mutation analysis and cytogenetic studies are essential before a case can be placed into this category.

The primary basis for subclassification within AML, NOS category is the morphological and cytochemical/immunophenotypic features of the leukemic cells that indicate the major lineages involved and their degree of maturation. The defining criterion for AML is the presence of 20% or more myeloblasts in the peripheral blood (PB) or bone marrow (BM); the promonocytes in AML with monocytic differentiation are considered blast equivalents. The classification of pure erythroid leukemia is unique and is based on the percentage of abnormal, immature erythroblasts. The previous category of erythroid/myeloid type of erythroleukemia has been eliminated from AML, NOS; cases with a myeloblast count of less than 20% of total BM and PB cells are considered as myelodysplastic syndrome, while cases with greater than 20% myeloblasts will continue to be classified according to standard AML criteria.

Acute Myeloid Leukemia with Minimal Differentiation (M0)

AML M0 is a rare form of acute myeloid leukemia consisting approximately less than 5% of AMLs and may occur at any age. Morphologically, blasts are large with open chromatin and prominent single or multiple nucleoli. The N/C ratio is low. Cytoplasm is moderately basophilic. Azurophilic granules or Auer rods are not seen (Fig. 14.2). MPO- or SBB-positive blasts are less than 3% by light microscopy. Without immunophenotyping, AML M0 may be misdiagnosed as ALL based on the negative cytochemical reactions. So, it is important to stress that a diagnosis of AML M0 cannot be made on morphologic grounds alone and that always requires confirmation by immunologic techniques. Blast cells usually expressed CD13 and CD117 as well as early, hematopoietic associated antigens (CD34, HLA-DR, CD38), while expression of CD33 is found in approximately 60% of cases. Since CD13 antigen is expressed in the cytoplasm of myeloblasts earlier than on the surface, CD13 should be tested by immunohistochemistry whenever the flow cytometry on the cell suspensions is negative. Moreover lymphoid differentiation antigens should be absent, except for CD7 and TdT. TdT is positive in approximately 50% of cases and has been suggested to be of favorable prognostic significance [153]. Patients with the AML M0 subtype have a poorer response to combination therapy.

Acute Myeloblastic Leukemia with Minimal Differentiation (M1)

Poorly differentiated myeloblasts are the predominant nonerythroid cell type (type I and type II). Auer rods may be present and consistent with the diagnosis (Fig. 14.14). More than 3% of these blast cells are MPO or SBB positive by conventional cytochemistry (Fig. 14.3). The low percentage of MPO-positive (3–10%) M1 cases may constitute up to 25% of all M1 cases [154]. In such cases, M1 should be differentiated from ALL L2, acute megakaryoblastic leukemia, and acute monoblastic leukemia without differentiation (M5a). Cytochemical stains and immunophenotyping using a classic panel (MPO, CD13, CD33, CD15, CD34, CD117) to confirm the myeloid nature of blasts are necessary for the differential diagnosis. Blasts are negative for B- and T-associated

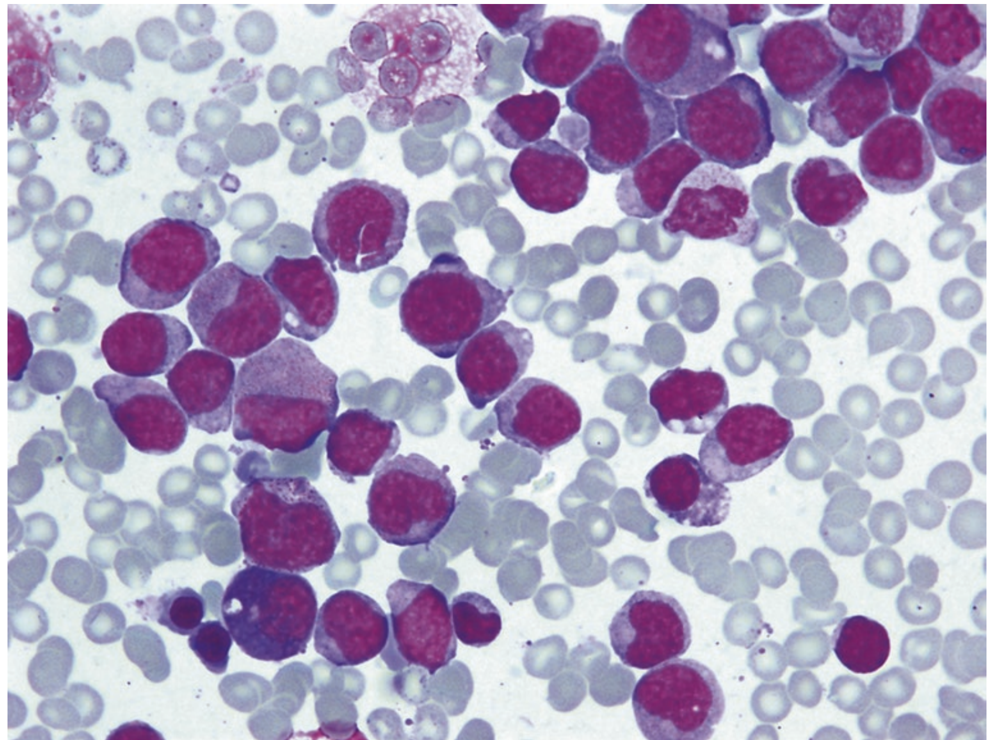

Fig. 14.14 AML (FABM1). Myeloblasts with <10% maturation of granulocytes. WG stain

cytoplasmic lymphoid markers: cCD3, cCD79a, and cCD22. CD7 is found in ~30% of cases, while expression of other lymphoid-associated membrane markers such as CD2, CD4, CD19, and CD56 has been described in 10–20% of cases.

Acute Myeloblastic Leukemia with Maturation (M2)

Acute myeloid leukemia with maturation is characterized by the presence of ≥20% blasts in the BM or PB and evidence of significant differentiation in all cells beyond the promyelocyte state (Fig. 14.15). Granular and agranular blasts are present. Auer rods are frequently seen. Monocytic precursors cannot exceed 20%. Increased numbers of eosinophilic precursors may be seen but they do not exhibit the cytological or cytochemical abnormalities characteristic of the abnormal eosinophils in acute myelomonocytic leukemia associated with inv(16)(p13.1q22) or t(16;16)(p13.1;q22). Variable degrees of dysplasia as pseudo-Pelger-Hüet cells and hypogranular neutrophils are frequently present, but no more than 50% of cells in two lineages are dysplastic. The MPO and SBB reactions are strongly positive. However, cases with a partial MPO deficiency in the granulocytic precursors and mature granulocytes have been reported [155]. Basophils are sometimes increased in this rare form and, therefore, this type of leukemia must be separated from CML in blast crisis by appropriate cytogenetic studies [156].

Leukemic blasts in AML with maturation usually express one or more of the myeloid-associated antigens, CD13, CD33, CD65, CD11b, and CD15. Early stem cell antigens like HLA-DR, CD34, and/or CD117 are also expressed. CD7 is expressed in 20–30% of cases.

Acute Myelomonocytic Leukemia (M4)

Acute myelomonocytic leukemia comprises 5–10% of cases of AML. It occurs in all age groups but is more common in older individuals; the median age is 50 years. Acute myelomonocytic leukemia is morphologically characterized by the proliferation of both neutrophil and monocyte precursors (Fig. 14.16). The PB or BM has ≥20% blasts including promonocytes; neutrophils, monocytes, and their precursors each comprise at least 20% of BM cells. This arbitrary minimal limit of 20% monocytes and their precursors distinguishes acute myelomonocytic leukemia from cases of AML with or without maturation in which some monocytes may be present. The PB typically shows an increase in monocytes, which are often more mature than those in the BM.

The monoblasts are large cells, with abundant cytoplasm basophilic cytoplasm, and have round nuclei with delicate lacy chromatin and one or more large prominent nucleoli. Promonocytes have a more irregular and delicately convoluted nuclear configuration; the cytoplasm is usually less basophilic and sometimes more obviously granulated. Monocytes and promonocytes may not always be readily distinguishable from maturing myeloid cells in routinely stained BM smears. In this regard cytochemical stains are necessary

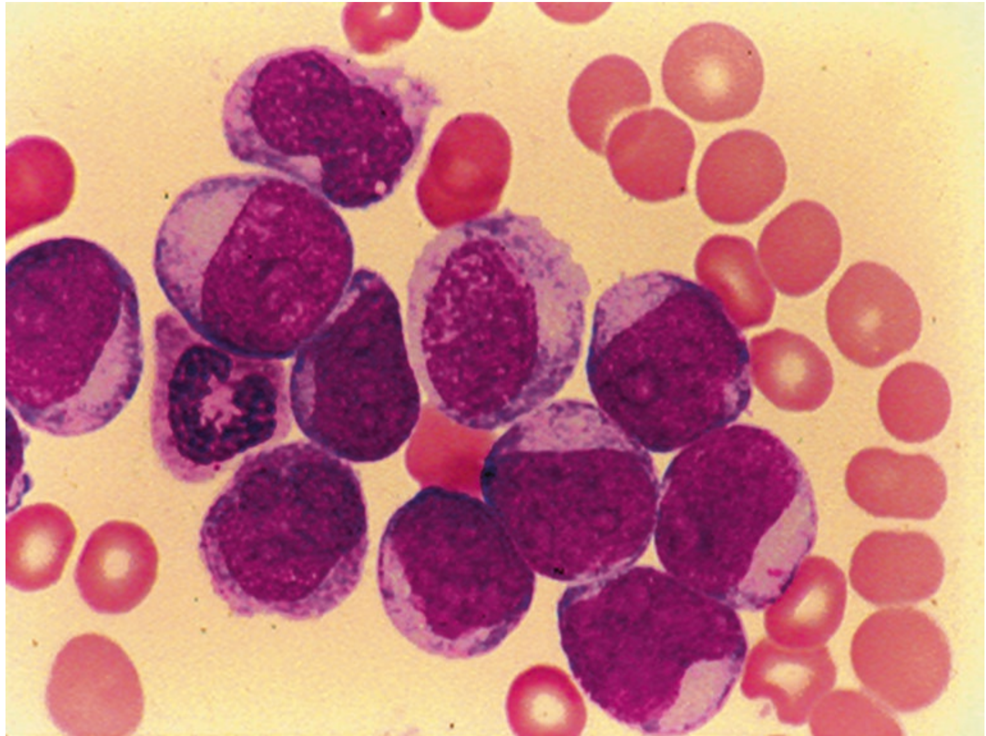

Fig. 14.15 AML (FABM2). Blasts with significant maturation of granulocytes at the promyelocyte and beyond. A single cell has an Auer rod. WG stain

for confirming the diagnosis. The monoblasts, promonocytes, and monocytes are typically nonspecific esterase (NSE) positive, although in some cases reactivity may be weak or absent. If the cells meet morphologic criteria for monocytes, absence of NSE does not exclude the diagnosis. Double staining for NSE and CAE or MPO may show dual-positive cells (Fig. 14.17). At least 3% of the blasts should show MPO positivity. Monocytic component can be identified by immunophenotyping using CD14, CD11c, CD11b, and CD68 in conjunction with other granulocyte-restricted antibodies.

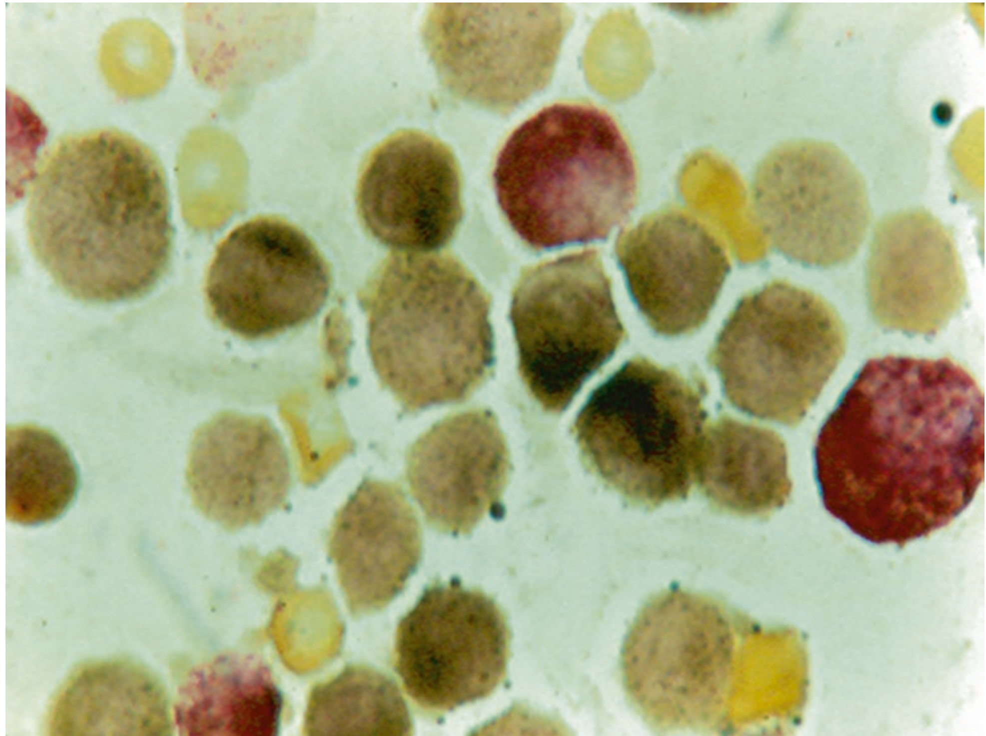

Fig. 14.17 Double-esterase reaction. *Black* product in monocytes and *brick red* color in granulocytes

Dysplastic features involving granulocytic, erythroid, and megakaryocytic lineages can be identified in approximately 20% of patients. The major differential diagnoses include AML with maturation, acute monocytic leukemia, and chronic myelomonocytic leukemia. The differential diagnosis with chronic myelomonocytic leukemia is critical and relies on the proper identification of promonocytes.

Acute Monoblastic and Monocytic Leukemia (M5a and M5b)

Acute monoblastic and acute monocytic leukemias both account for about 10% of the AML. They are clonally expressed in cells committed to differentiation to monocytic pathway [157]. The PB or BM has ≥20% blasts (including promonocytes) and in which 80% or more of the leukemic cells are of monocytic lineage including monoblasts, promonocytes, and monocytes; a minor neutrophil component, <20%, may be present.

Acute monoblastic leukemia is frequently observed in children; it can be confused with the Burkitt lymphoma/leukemia. In the bone marrow, 80% or more of all monocytic cells are monoblasts. Blast cells display abundant deep basophilic cytoplasm, which is often vacuolated and has no or few azurophilic granules and no Auer rods. The nuclei are round to oval, with one or more prominent nucleoli (Fig. 14.18). Since the peroxidase reaction may be negative in 40–50% of such cases and the PAS reaction is often strongly positive with a blocklike pattern, it is very useful to use nonspecific esterase (NSE) staining differential diagnosis. This stain will be strongly positive in more than 90% of cases. Occasionally, the SBB reaction will be positive in the absence of a peroxidase reaction. Cells with monocytic differentiation can express at least two markers characteristic of monocyte differentiation such as CD14, CD4, CD11B, CD64, CD68, and CD36 on the cell surface.

Acute monocytic leukemia is defined by the presence of 20% or more of abnormal cells being (promonocytes) with twisted or folded nuclei, gray-blue cytoplasm, and scattered azurophilic granules (Fig. 14.19). Rarely, a few cells will contain Auer rods. The percentage of mature monocytes is often much higher in the blood than in the bone marrow.

Extramedullary masses (monocytic sarcomas), cutaneous or gingival infiltration, and CNS involvement are common. MPO and CEA are typically negative, but CD68 and CD168 are often positive in extramedullary myeloid (monoblastic) sarcomas. Hemophagocytosis may be observed and is often associated with myeloid-associated, nonspecific cytogenetic abnormalities such as t(8;16)(p11.2;p13.3) [158].

The differential diagnosis of acute monoblastic leukemia includes AML without maturation, AML with minimal differentiation, and acute megakaryoblastic leukemia. Extramedullary myeloid (monoblastic) sarcoma may be confused with malignant lymphoma or soft-tissue sarcomas. However, they are readily distinguished by immunophenotypic analysis and cytochemistry. The differential

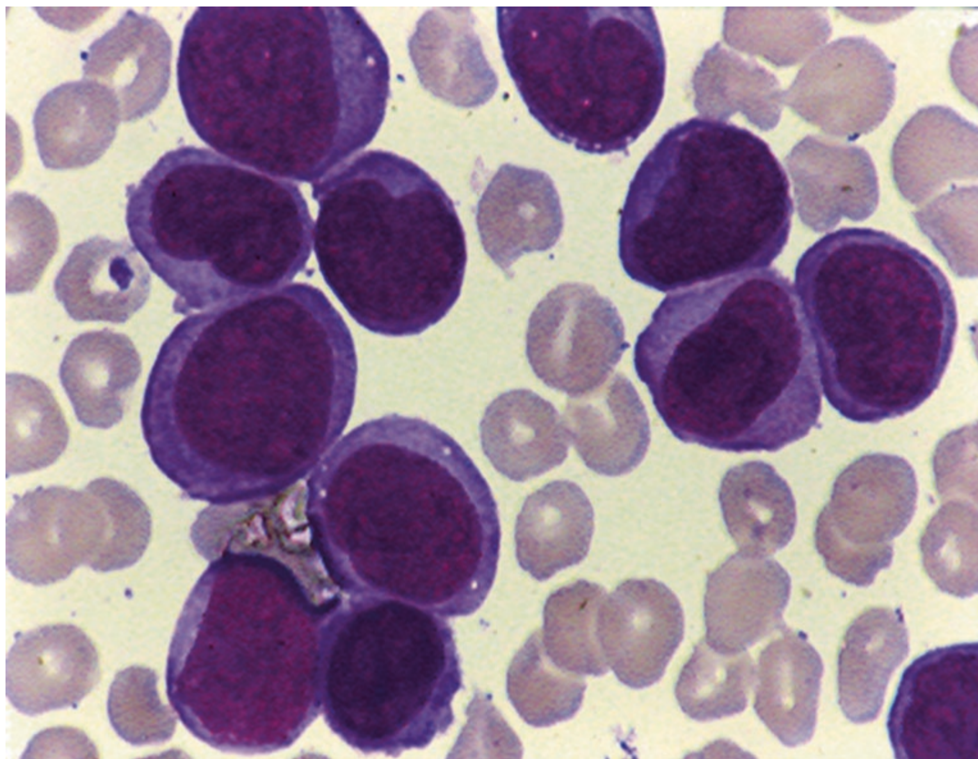

Fig. 14.18 AMOL (acute monocytic leukemia) (FABM5A). Large blasts with nuclear indentation without granules. WG stain

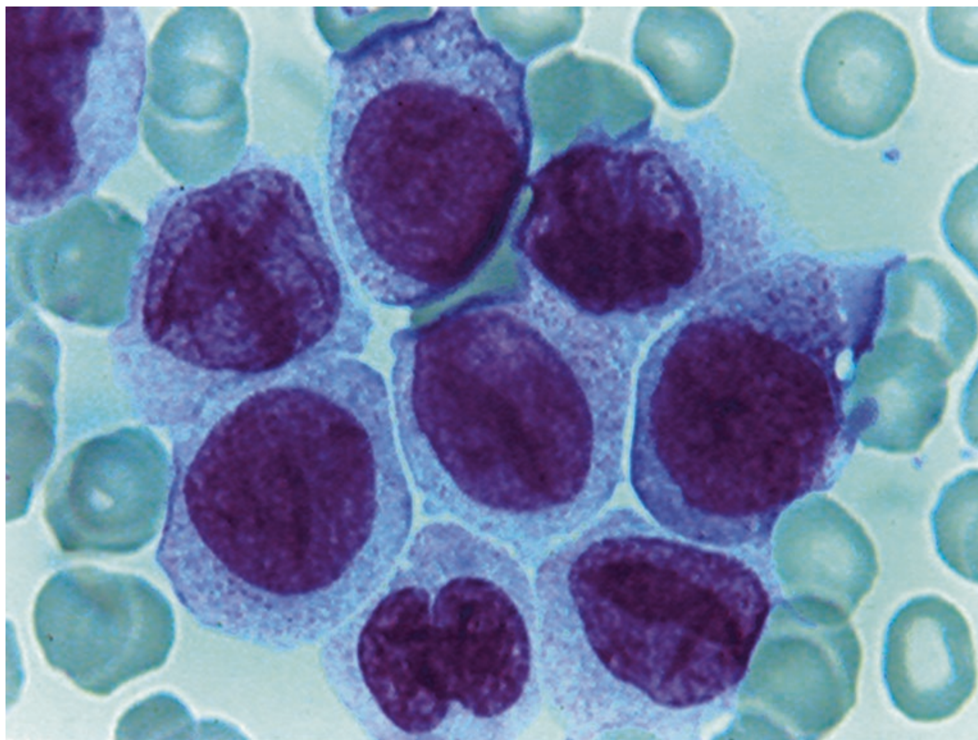

Fig. 14.19 AMOL (FABM5B). Promonocytes are apparent with occ. Azurophil granules. WG stain

diagnosis of acute monocytic leukemia includes chronic myelomonocytic leukemia, acute myelomonocytic leukemia, and microgranular acute promyelocytic leukemia (APL). These can be distinguished by careful examination of well-stained smears and by cytochemistry. The differential diagnosis with chronic myelomonocytic leukemia is critical and relies on the proper identification of promonocytes and their inclusion as blast equivalents.

Acute Erythroid Leukemia (M6)

Pure erythroid leukemia is extremely rare and defined as a neoplastic proliferation of immature (or more mature) cells committed exclusively to the erythroid lineage (80% of total nucleated cells) with no evidence of a significant myeloblastic component [159, 160]. It can occur at any age, including in childhood.

Cases previously classified as the erythroid/myeloid subtype of erythroleukemia (Fig. 14.20), based on counting myeloblasts as a percentage of nonerythroid cells when erythroid cells comprised ≥50% of marrow cells, are now classified based on the total bone marrow or peripheral blood blast cell count. Such cases are classified as myelodysplastic syndromes (usually MDS with excess blasts) when the blast count is <20% of all cells and usually as AML with myelodysplasia-related changes when blasts are ≥20% of marrow or blood cells, irrespective of the erythroid precursor cell count.

Pure erythroid leukemia may occur as a de novo disease, but more frequently occurs as progression of a prior myelodysplastic syndrome or as therapy-related disease [161, 162]. In the latter setting, the case should be diagnosed as a therapy-related myeloid neoplasm.

Morphologically, pure erythroid leukemia is characterized by the presence of medium-sized to large proerythroblasts, with round nuclei, fine chromatin, and one or more nucleoli; the cytoplasm is deeply basophilic and agranular and frequently contains PAS-positive vacuoles (Fig. 14.21). Occasionally the blasts are smaller with scanty cytoplasm and can resemble the lymphoblasts of ALL. The cells are negative for MPO and SBB; they show reactivity with α-naphthyl acetate esterase, acid phosphatase, and blocklike PAS positivity. Pure erythroid leukemia without morphologic evidence of erythroid maturation is difficult to distinguish from megakaryoblastic leukemia and ALL. Moreover, differentiation of the more differentiated forms of pure erythroid leukemia from megaloblastic anemia is difficult.

Acute Megakaryoblastic Leukemia (M7)

Acute megakaryoblastic leukemia (AMkL) in this category is probably an uncommon disease since it would not include cases with t(1;22), AML with inv(3) or t(3;3), AML of Down syndrome, and cases meeting the criteria for AML with myelodysplasia-related changes. The WHO defines AMkL as 20% or more blasts of which at least 50% are of megakaryocyte lineage. The morphologic and immunophenotypic features are those of the megakaryoblasts (Fig. 14.13) described in the aforementioned entities. Cytochemical stains for SBB, CAE, and MPO are consistently negative in the megakaryoblasts; the blasts may show reactivity with PAS and for acid phosphatase and punctate or focal nonspecific esterase reactivity. The megakaryoblasts express one or more of the platelet glycoproteins such as CD41, and/or CD61. In some cases, because of marked fibrosis resulting in a "dry tap" the percent of blasts is estimated from the biopsy.

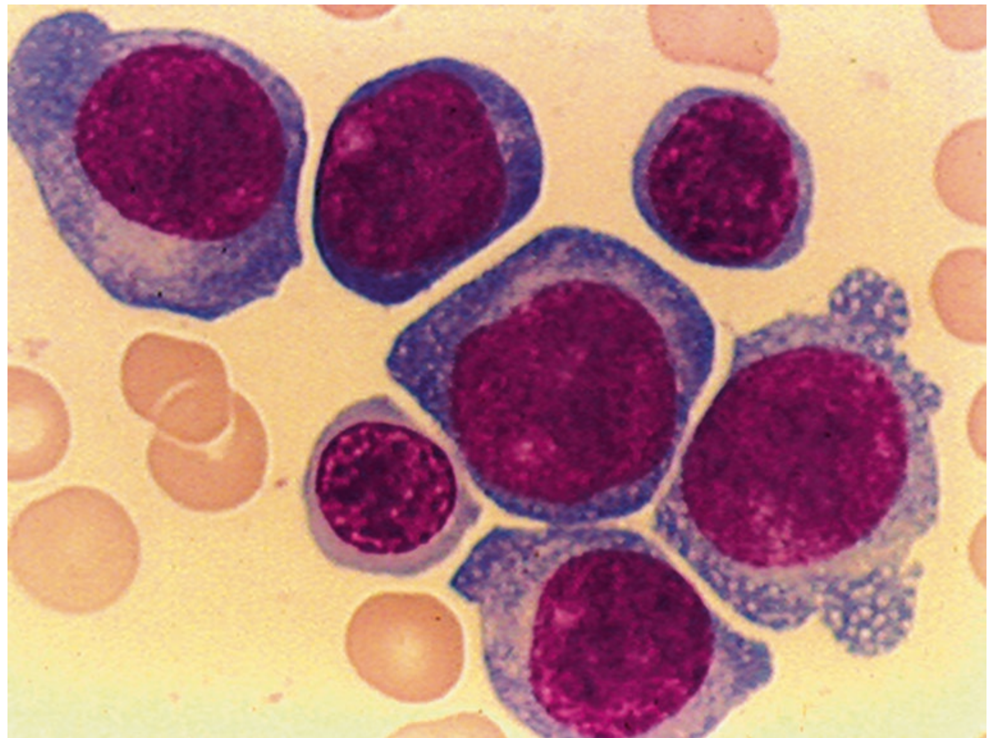

Fig. 14.21 Acute erythroleukemia (FAB M6B). No myeloblasts and many basophilic megaloblasts. WG stain

Acute Basophilic Leukemia

This is a very rare disease comprising <1% of all cases of AML. The circulating PB and BM blasts are of medium size with a high nuclear-cytoplasmic ratio; an oval, round, or bilobed nucleus characterized by dispersed chromatin; and one to three prominent nucleoli. The cytoplasm is moderately basophilic and contains a variable number of coarse basophilic granules which are positive with metachromatic stains such as toluidine blue. The differential diagnosis includes blast phase of CML, other AML subtypes with basophilia such as acute myeloid leukemia with t(6;9), AML with BCR-ABL1, and mast cell leukemia [163, 164].

Acute Panmyelosis with Myelofibrosis

Acute panmyelosis with myelofibrosis (APMF) is a very rare form of de novo AML. APMF is characterized by an acute panmyeloid proliferation with increased blasts and accompanying bone marrow fibrosis that does not meet the criteria for AML with myelodysplasia-related changes [165, 166].

The term APMF is intended to denote involvement of all three hematopoietic cell lineages. Similar features are seen in cases of MDS associated with an excess blasts and fibrosis; AML with myelodysplasia-related changes with multilineage dysplasia and fibrosis; and acute megakaryoblastic leukemia with myelofibrosis and in fibrotic phases of myeloproliferative neoplasms. The distinction between these entities and APMF may be difficult, particularly if no specimen suitable for cytogenetic analysis can be obtained.. Bone marrow biopsy supplemented with immunohistochemistry is required for diagnosis [4, 167]. Immunohistochemistry used by myeloid (MPO, CD13), megakaryocytic (CD61, CD41, factor VIII), and erythroid (glycophorin) markers confirms the presence of panmyelosis. Blasts usually express the progenitor (CD34) or more myeloid-associated (CD13, CD117) markers [4, 167, 168]. The distinction between APMF and MDS with excess blasts (MDS-EB) and myelofibrosis is very difficult since the latter cases can share most of the morphological findings seen in APMF. Cases of MDS-EB and fibrosis, except for their usually less acute clinical presentation, may be otherwise indistinguishable from APMF [4].

Myeloid Sarcoma

Myeloid sarcomas are solid myelogeneous tumors that can occur in 3–7% of AML [169], most frequently observed in children. These tumors either appear green or may become green in diluted acid because of their high MPC content (chloroma). Myeloid sarcomas can be localized in a number of locations including the skin, breast, gastrointestinal tract, lymph nodes, soft tissues, ovaries, and brain. However, most of these tumors arise adjacent to bony or neural structures [170, 171]. Myeloid sarcomas can be recognized in three types of clinical setting [6]: (1) de novo presentation without generalized bone marrow involvement (these cases should be

considered as synonymous with AML); (2) in an established diagnosis of AML either at presentation or as the first manifestation of relapse; and (3) may represent acute blastic transformation of myelodysplastic syndromes (MDS), myelodysplastic/myeloproliferative neoplasm (MDS/MPN), or myeloproliferative neoplasms (MPN) [170, 171].Myeloid sarcomas display myeloblastic, myelomonocytic, or pure monoblastic morphology [170]. The morphologic features are highly variable, ranging from little to no differentiation, where the differential diagnosis includes large-cell lymphomas and blastic plasmacytoid dendritic cell neoplasm. The histological diagnosis should be validated by immunohistochemistry (MPO, CD117, CD68, CD34, TdT, CD45, CD56 CD123, BDCA/2) [75, 172]. A more traditional stain is the specific granulocyte esterase reaction, naphthol ASD chloroacetate esterase stain on air-dried touch preparations, or non-Zenker fixed solutions. Moreover, correlation with cytogenetic and molecular genetic status is necessary to provide the correct diagnosis. AML with t(8;21), inv(16), t(1;22), and some 11q23 translocations are frequently associated with extramedullary presentations [5]. About 16% of cases carry evidence of *NPM1* mutations as shown by aberrant cytoplasmic NPM expression [173]. Inv(16) or amplification of *CBFB* has been related to breast, uterus, or intestinal involvement and possible foci of plasmacytoid dendritic cell differentiation [174].

Myeloid Proliferations Related to Down Syndrome

Patients with Down syndrome (DS) have an increased risk of leukemia. There is an approximately 50-fold increase of AML in children with DS younger than 5 years, and 70% of these neoplasms are AMKL. In contrast, AMKL comprises only 3–6% of AML in children without DS. The acute myeloblastic leukemia which occurs in children with DS has unique morphologic, immunophenotypic clinical, and molecular features [175–177] that distinguish it from other forms of AML. It commonly occurs in the first 3 years of life. Morphology of the leukemic blasts shows particular features with round nuclei and moderate amount of basophilic cytoplasm with or without blebs. Some blast contains MPO-negative coarse granules. Bone marrow core biopsy may show dense reticulin network. In these cases, antibodies to CD41 and CD61 may be particularly useful in identifying cells of megakaryocytic lineage in immunohistologic preparations. Leukemic blasts in acute megakaryocytic leukemia of DS display a similar immunophenotype to blasts in transient abnormal myelopoiesis (TAM) [178] (*positive for CD117, CD13, CD33, CD7, CD4, CD42, TPO-R, IL-3R, CD36, CD41, CD61, CD71, and are negative for myeloperoxidase, CD15, CD14, and glycophorin A*). On the other hand, TAM is a unique disorder of DS newborns in which morphologic and clinical features are indistinguishable from AML with DS [177]. The process in the majority of patients undergoes spontaneous remission within the first 3 months of life.

In addition to trisomy 21, acquired GATA-1 mutations are considered pathognomonic of TAM or AML of DS and are associated with a better response to chemotherapy and favorable prognosis compared to children with AML without DS [175]. While gene array studies have suggested differences in expression between AML of DS and TAM, however, these findings have not yet been confirmed [179].

Blastic Plasmacytoid Dendritic Cell Neoplasm

Blastic plasmacytoid dendritic cell neoplasm (BPDCN) is a clinically aggressive neoplasm derived from the precursors of plasmacytoid dendritic cells that is characterized by solitary or multiple skin lesions, often associated with regional lymphadenopathy [180]. Many cases tend to involve bone marrow and peripheral blood as well. Morphology is characterized by a diffuse monomorphous infiltrate of medium-sized blasts with scant cytoplasm, irregular nuclei, fine chromatin, and several small nucleoli. The blasts express CD4, CD56, CD43, as well as plasmacytoid dendritic cell-associated antigens (CD123, BDCA-2/CD303, TCL-1, and CLA). CD68 is expressed in 50% and TdT in 30% of cases [180–182]. In about 8% of cases CD4 or CD56 can be negative, which does not rule out the diagnosis if other PDC-associated antigens (especially CD123, TCL1, or CD303) are expressed [183, 184]. Other hematologic neoplasms especially AML with monocytic differentiation may share morphological and immunophenotypical features with BPDCN [185, 186]; an extensive immunohistochemical and/or genetic analysis is mandatory before a definitive diagnosis of BPDCN is made. On the other hand, BPDCN must be distinguished from mature plasmacytoid dendritic cell proliferation (MPDCP) in which plasmacytoid dendritic cells are morphologically mature and CD56 negative. MPDCP is invariably associated with a myeloid disorder most commonly with chronic myelomonocytic leukemia [186, 187].

Two-thirds of patients with BPDCN have an abnormal karyotype; specific chromosomal aberrations are lacking, but complex karyotypes are common [188]. Genomic abnormalities mainly involve tumor-suppressor genes [189].

The clinical course is aggressive, with a median survival ranging from 10.0 to 19.8 months, irrespective of the initial pattern of disease. Most cases (80−90%) show an initial response to multiagent chemotherapy, but relapses with subsequent resistance to drugs are regularly observed [190, 191].

Acute Leukemias of Ambiguous Lineage

Acute leukemias of ambiguous lineage show no clear evidence of differentiation along a single lineage. Cases with no lineage-specific antigens are designated as acute undifferentiated leukemia (AUL). They often express CD34, HLA-DR, and/or CD38 and TdT but lack specific myeloid and/or lymphoid antigens [192]. Leukemias that coexpress antigens of more than one lineage on the same cells or that have separate populations of blasts that are of different lineages are referred to as mixed-phenotype acute leukemia (MPAL). Some examples of MPAL blasts reveal B lineage and myeloid differentiation (MPAL, B/Myeloid) whereas other cases have both T lineage and myeloid markers (MPAL, T/Myeloid) [193, 194]. On the basis of associated cytogenetic anomalies, MPAL can be subdivided into three subgroups according to the presence of chromosome abnormalities: t(9;22)/BCR-ABL1, t(v;11q23)/MLL, or not otherwise specified (NOS) [195]. Therefore, mixed blast phase of CML must be excluded. All other unusual immunophenotypes, including early natural killer (NK) leukemias, constitute the remainder of leukemias of ambiguous origin. There may be cases that cannot be adequately classified due to insufficient immunophenotyping data or discordant expression of various markers, rendering definitive classification impossible. These cases should be designated as acute unclassifiable leukemia, which is different from AUL [196].

Central Nervous System Leukemia

Without CNS prophylaxis against CNS leukemia in ALL, isolated CNS relapse occurs in 50% of patients and is associated with subsequent systemic relapse. Therefore, CNS prophylaxis is routinely used in ALL. Although testicular and other extramedullary relapses have become exceedingly rare in ALL, in contemporary clinical trials [197] central nervous system (CNS) relapse remains a major obstacle to cure, accounting for 30–40% of initial relapses [198]. The incidence of CNS leukemia is lower in AML, and CNS prophylaxis is not usually used [199]. It should be remembered that CNS leukemia occurs frequently in patients with a prominent monocytic component (i.e., acute monocytic leukemia or acute myelomonocytic leukemia), acute promyelocytic leukemia (APL) in systemic relapse, AML with inversion or deletion of chromosome 16 (16) or chromosome 11 abnormality, hyperleukocytosis, or an elevated lactate dehydrogenase [200, 201].

The most likely explanation of CNS leukemia is direct extension from bone marrow in the skull, extending along the dura mater. Additional venules provide a direct route for leukemic infiltration of brain parenchyma [202].

Diagnostic lumbar puncture is recommended for all patients with ALL and for patients with AML who have WBC counts higher than 40,000 mm^3 [203]. Careful cytologic investigation of CNS fluid is essential to establish a diagnosis of involvement.

A CSF leukocyte count greater than 5 leukocytes/mL with the presence of unequivocal blasts on cytocentrifuge preparation is accepted as minimum cytologic criteria for CNS leukemia [204]. The two most common techniques include a cytocentrifuge preparation and a Wright-Giemsa stain or Millipore filtration technique and the Papanicolaou method. It is important to distinguish atypical but reactive cells secondary to drug-related arachnoiditis from leukemia blasts.

Evaluation of Remission

In a patient treated with acute leukemia, CR is considered when peripheral blood cell counts approach the normal range, and the bone marrow is normocellular, and shows orderly maturation of hematopoietic cells with less than 5% blast cells. The criteria for morphologic remission of less than 5% bone marrow blasts are arbitrary. The leukemic blasts in AML M3 or ALL L3, or blasts containing Auer rods, can be readily identified, even when present in small numbers. In other types of leukemia, a definitive diagnosis of residual leukemia may not be possible by morphologic examination. Persistence of dysplastic hematopoiesis in a patient who might otherwise fulfill the criteria for CR results in a much higher relapse rate. It should be remembered that the bone marrow regeneration occurs more quickly in pediatric patients (3 or 4 weeks). Therefore, one can observe a modest increase in myeloblasts and promyelocytes during recovery that may persist for 1–2 weeks. This should not be over-interpreted as a regrowth of leukemic cells.

The definition of partial remission is accepted when less than 25% leukemic cells are counted in the bone marrow smears. Relapse is defined by the presence of more than 25% leukemic cells in the bone marrow aspirate and is usually associated with peripheral cytopenias and sometimes presence of blasts.

Myelodysplastic Syndrome

Myelodysplastic syndromes (MDS) are a clonal proliferation of multipotential hematopoietic stem cells. Clinically, MDS represents a condition of bone marrow failure, usually of the elderly (primary MDS), or of patients previously exposed to prior chemotherapy or radiation or both (secondary MDS). The correlation of the biology of this clonal disorder with its clinical presentation of cytopenias is varied ranging from an incidental mild anemia stable for years to a rapidly evolving leukemia [205].

MDS is a disease of elderly, with the annual incidence of 4 cases per 100,000 in the general population.

The underlying causes in the pathogenesis of MDS remain elusive. Analyses of G6PD isoenzymes, restriction-linked polymorphisms, X-linked DNA polymorphisms of the androgen receptor (HUMARA), cytogenetic abnormalities, gene mutations, and recently targeted gene sequencing and SNP array analysis can identify somatic events in the majority of MDS patients, and have shown that MDS is a clonal abnormality of the hematopoietic stem cell characterized by defective maturation and in advanced stages uncontrolled proliferation [206–209].

Chromosomal anomalies are detected in approximately 50% of patients with de novo MDS and in up to 80% of patients with MDS secondary to chemotherapy or other toxic agent [210–212]. Balanced cytogenetic abnormalities, including reciprocal translocations, inversions, and insertions, are uncommon in MDS, in which unbalanced chromosomal abnormalities reflecting a gain or loss of chromosomal material are more prevalent [210–212]. Upcoming WHO 2008 revision recognized the importance of recent discoveries regarding the clinical significance of specific gene mutations in MDS. However, most mutations do not appear to correlate with specific disease entities with the exception for SF3B1 mutations [213, 214].

The examination of an appropriately prepared and stained bone marrow and peripheral blood smear remains the most important diagnostic approach in morphologic diagnosis [215–217]. Well-prepared thin smears with an excellent Romanowsky stains should be utilized. Iron stains are essential to address the percentage of ring sideroblasts. For an accurate differential count, at least 500 nucleated cells should be counted.

Reticulin stains prepared from bone marrow biopsy cores are recommended, since some cases will demonstrate an increased score that is viewed as impacting adversely on prognosis.

Finally, cytogenetics are critical to obtain because prognostic information is provided and is an important component of several scoring systems. Conventional cytogenetics obtained from bone marrow aspirate could be complemented by interphase FISH (with probes, i.e., 5q–,7–,8+,20q–) tests.

Morphologic Characteristics

The following discussion highlights the morphologic features used to define MDS [218–222]. In general, these features should be present in at least 10% or greater of cells of the respective lineage under consideration. The upcoming proposal is to retain the 10% threshold but provide more detailed morphologic definitions of dysplasia [217, 222–224].

Dyserythropoiesis

Morphologic bone marrow dyserythropoiesis (DysE) may include the presence of ringed sideroblasts, multinuclear fragments, bizarre nuclear shapes, internuclear bridging, mitosis, abnormal intensity of the chromatin or fine chromatin with asynchronous cytoplasm, and abnormal cytoplasmic features (intense basophilia, Howell-Jolly bodies, and ghosted cytoplasm). Marked macrocytosis (at least 100 fmol/L), basophilic stippling, anisocytosis, and poikilocytosis may be observed in the peripheral blood. Quantitative changes include the presence of ringed sideroblasts (exceeding 15% of all nucleated erythroid cells) and a number of megaloblastic erythroid precursors. However, the evaluation of dysplastic features in erythroid lineage such as megaloblastoid and cytoplasmic changes is poorly reproducible [222].

The MDS working group [51] defines three types of sideroblast: type 1 sideroblasts: fewer than five siderotic granules in the cytoplasm; type 2 sideroblasts: five or more siderotic granules but not in preinuclear distribution; and type 3 or ring sideroblasts: five or more granules in a perinuclear position, surrounding the nucleus or encompassing at least one-third of the nuclear circumference (Fig. 14.22). This definition of ring sideroblasts has been incorporated into WHO 2008 and revised WHO classification. For the definition of MDS-RS, the required number of ring sideroblasts remains at 15%.

Dysgranulopoiesis

In dysgranulopoiesis (DysG), the peripheral blood can be notable for hypogranulation and hyposegmentation of the polymorphonuclear leukocytes (PMLs) with excessive chromatin condensation (pseudo-Pelger-Hüet anomaly) (Fig. 14.23). Hypogranulation is most commonly noted and can be associated with a negative MPO reaction. The cells can be devoid of all granules, often in the more immature forms. Nuclear sticks can be seen, particularly in cases of secondary MDS or therapy-related MDS. These morphologic features may explain in part the frequency of infection in these patients (i.e., phagocytic adhesion, chemotaxis, and microbiocidal capacities may be impaired), but no correlation has been found between the loss of granules and impaired function.

Dysmegakaryopoiesis

Qualitative changes are more common in dysmegakaryopoiesis (DysM) as the number of megakaryocytes is usually normal, although hypoplasia or hyperplasia can

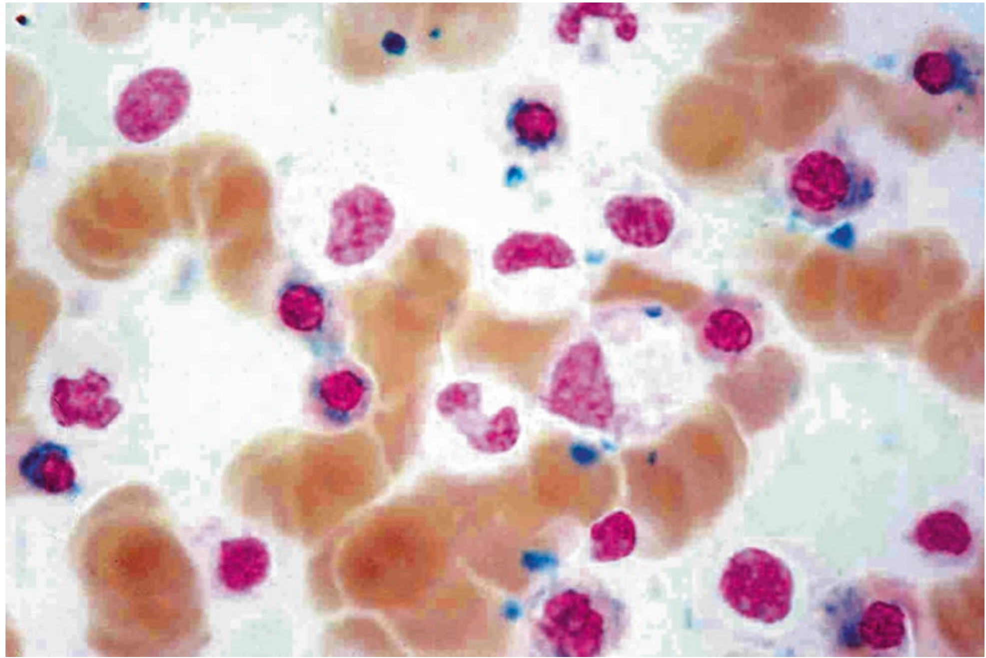

Fig. 14.22 Myelodysplastic syndrome (MDS). RARS with ring sideroblasts. Prussian *blue* reaction

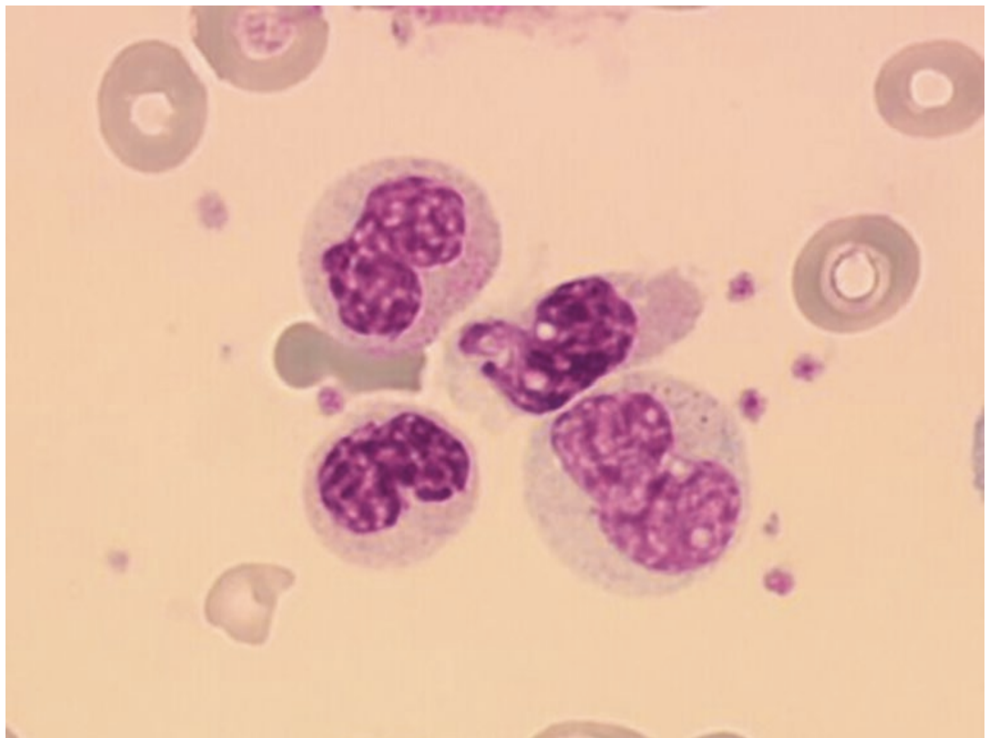

Fig. 14.23 MDS. Dysplastic granulocytes with clumped chromatin and hypogranular cytoplasm. WG stain

occasionally be seen. In the peripheral blood, large hypo- or hypergranular platelets can be found. In the bone marrow, morphologic abnormalities of the megakaryocytic precursors can be seen in half of the patients. Commonly there are micromegakaryocytes (dwarf forms) (Fig. 14.24), megakaryocytes with multiple small round, and separate nuclei and large mononuclear forms. Micromegakaryocytes can be further recognized by using CD41 and antifactor VIII antibodies on bone marrow smears with the APAAP technique. Small mononuclear megakaryocytes with a single eccentric nucleus are strongly correlated with 5q– syndrome [225].

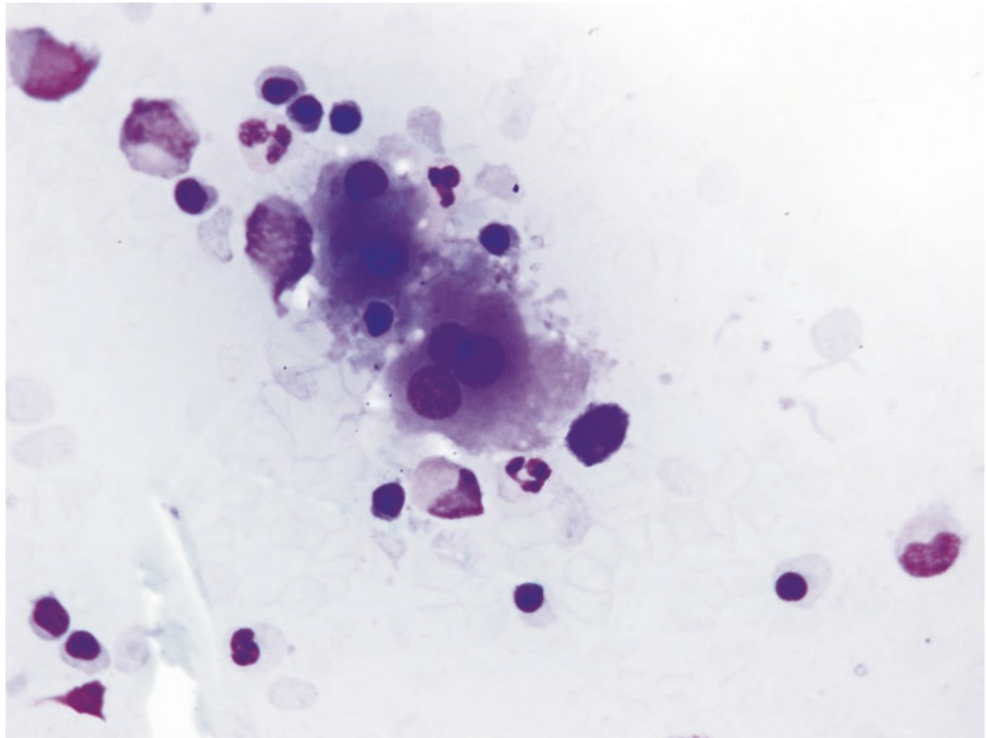

Fig. 14.24 MDS. Dysplastic megakaryocytes with separated nuclei. WG stain

Dysmonocytopoiesis

Identification of the monocyte precursors in the bone marrow is sometimes difficult, and the use of double-esterase staining may be necessary. CD14 and CD68 antibodies can also be used to identify monocytic population.

Blast Cell Characteristics

One of the most important criteria for MDS subclassification is the number (quantity) of blast cells. An area of confusion has been the identification of blasts in MDS. Recently, the international working group of morphology (IWGM) [51] recommended that myeloblasts in MDS should be classified as agranular or granular. The agranular blasts correspond to the type I blasts of the FAB classification. Granular blasts are cells that have not only the nuclear features of blast cells but also cytoplasmic granules. These cells will thus include type II blasts as defined by FAB as well as type III blasts as defined by Goasguen and coworkers [49]. Granular blasts must be distinguished from promyelocytes.

Bone Marrow Histology

The value of bone marrow biopsy in MDS is well established [64]. Bone marrow histology provides useful information on cellularity, relative proportions of three hematopoietic cell lines, architectural disorganization, and increase in the reticulin fibers.

The bone marrow cellularity should be determined as percentage of bone marrow section area according to the standard proposed by our group [226, 227]. We recommended that the bone marrow cellularity should be determined as “normocellular,” “hypercellular,” or “hypocellular” based on an age-adapted estimate.

Reticulin stain provides additional information about the degree of reticulin fibrosis which can add prognostic information.

Aggressive types of MDS (MD-EB) characterized by clusters of blast in bone marrow biopsies localized in the central part of the bone marrow away from the vascular structures and endosteal surfaces of the trabecule (Figs. 14.25 and 14.26). The blast can also be identified by immunohistochemistry using anti-CD34 antibody. Detection of blasts by anti-CD34 is especially useful in cases with fibrosis and hypocellular MDS to assess blast percentage. Previous studies have reported on the diagnostic and prognostic value of an atypical localization of immature progenitor cells (ALIP) in MDS [228]. These studies have been confirmed using anti-CD34 antibodies. In contrast to other bone marrow cells, it is possible to assess cytologic atypia of megakaryocytes in an adequately processed bone marrow sections. Megakaryocyte markers such as CD41 and CD61 are also helpful for the detection of atypical grouping or clustering and morphologic atypia of megakaryocytes. Tryptase immunohistochemistry is useful to detect coexisting occult mastocytosis [229].

Classification of MDS

In 1982, the FAB group introduced a classification system for patients with MDS [230]. The main discriminators were peripheral and medullary blast count, the percentage of ring sideroblasts, and the absolute monocyte count. This classification provided standard diagnostic procedures and became a gold standard for more than two decades.

The World Health Organization (WHO) revised and updated the MDS classification in 1997 and a revised version of the WHO classification is published in 2008 [231]. However, after 7 years, it needs to be updated. The summary of the proposed major changes to the classification related to the myelodysplastic syndromes in revised upcoming 5th edition can be summarized as follows [232]:

1- Significant changes to the morphologic criteria are not proposed. Although the current threshold of 10% to define a lineage as dysplastic may result in overcalling of dysplasia in non-MDS cases, the current proposal is to retain the 10% threshold but provide more detailed morphologic definitions of dysplasia and emphasize the importance of carefully considering non-MDS causes of dysplasia [217–224].
2. Blast cell counts resulted in no change so the classification will continue to recommend that blast cell counts should ideally be performed on well-stained, cellular bone marrow aspirate smears; although the utility of CD34 staining on a trephine biopsy may be helpful for blast cell estimates in the absence of cellular aspirate smears, such as in the setting of marrow fibrosis.

3. The use of cytopenias versus morphologic dysplasia in defining MDS subtypes is sometimes leading to confusion. It is proposed to replace the terminology of "refractory anemia" and "refractory cytopenia" with "myelodysplastic syndrome" in the revised classification [i.e., MDS with single-lineage dysplasia (MDS-SLD)].
4. The cytogenetic criteria for MDS will likely remain unchanged.
5. In WHO 2008 classification RCMD-RS was incorporated in RCMD; however this category is reinstated as RCMD-RS in upcoming edition. MDS cases with SF3B1 mutations have a distinctive gene expression pattern [233], with a large number of differentially expressed genes [234]. This combination of shared morphology (ring sideroblasts) and a shared underlying driver mutation (SF3B1) now favors separating MDS with ring sideroblasts as distinct entities, which may have single or multilineage dysplasias. Thus, MDS cases with SF3B1 mutation can be classified as RARS or RCMD-RS if any ring sideroblasts are present. Ring sideroblasts and SF3B1 mutations also occur in high-grade MDS with excess blasts and even in AML. It should be remembered that RARS or RCMD-RS only defines a specific MDS entity in cases with <5% bone marrow blasts.
6. Recent studies have shown that the del(5q) abnormality in MDS is prognostically similar whether it is isolated or occurs with one additional low-risk cytogenetic aberration [235]. Based on this finding, the category of MDS with isolated del(5q) will be expanded to encompass cases with one additional non-high-risk cytogenetic abnormality. Blasts are <5% in bone marrow, and <1% in blood; dysplasia is uni- or multilineage but cases with significant myeloid dysplasia are excluded [236].
7. The category of MDS unclassified in the revised 2008 classification is retained and includes patients with pancytopenia and unilineage dysplasia, and patients with no overt dysplasia but cytogenetic evidence of cytogenetics. Unilineage dysplasia cases with 1% blood blasts are detected on at least two separate occasions.
8. In upcoming revision erythroid/myeloid type of erythroleukemia with >50% erythroid precursors and 5–19% blasts are now considered as MDS-EB rather than AML. Acute erythroid/myeloid leukemia is linked with MDS, since they share both morphologic and genetic features [237, 238]. Cases with ≥20% blasts and >50% erythroid precursors will still be classified as AML with myelodysplastic changes. Pure erythroleukemia will remain in AML.
9. A provisional entity, refractory cytopenia of childhood (RCC), has been added in 2008 classification to include children with cytopenia(s) with less than 2% peripheral blood and less than 5% bone marrow blasts and evidence of dysplasia in two or more lineages. It remains as a provisional entity in the updated classification.

Morphologic Subtypes

MDS with Single-Lineage Dysplasia (MDS-SLD)

MDS with single-lineage dysplasia (MDS-SLD) comprises 10–20% of all cases. It is primarily disease of elderly. The vast majority of MDS-SLD cases are associated with unilineage erythroid dysplasia (RA). Anemia is the main manifestation (hemoglobin below 11 g/dL with a low reticulocyte count) with variable dyserythropoiesis. Blast cells usually are not present in the peripheral blood (<1%) and fewer than 5% in the bone marrow. Dyserythropoiesis varies from slight to moderate. The bone marrow biopsy is generally hypercellular but may be normocellular or even hypocellular. In general, RA can be considered as a "low-grade" MDS with median survival in the range of 6–7 years and only 5–10% of cases progressing to overt acute leukemia [239, 240]. Other forms of MDS-SLD are rare.

MDS with Single-Lineage Dysplasia and Ring Sideroblasts (MDS-RSSLD)

The morphologic features of MDS with ring sideroblast single-lineage dysplasia (MDS-RSSLD) are similar to those of MDS with single-lineage dysplasia (MDS-SLD) except that there are more than 15% ringed sideroblasts in the bone marrow. However, patients with ring sideroblasts but not meeting the 15% threshold used to define MDS-RSSLD will still be diagnosed if an SF3B1 mutation is detected. Macrocytosis and dysmorphic red cells are present in the peripheral blood (Fig. 14.27). MDS-RSSLD accounts for 3–11% of all MDS cases. It is primarily disease of elderly with a median age of 60–73 years [232, 239]. Ring sideroblasts represent erythroid precursors with abnormal accumulation of iron within mitochondria [51]. It should be remembered that ring sideroblasts are frequently observed in other types of MDS (i.e., MD-EB). If the platelet count is 450 × 103/μL (450 × 109/L) or greater and the megakaryocytes have features of those described in the myeloproliferative neoplasms (MPNs), an analysis for JAK2 and SF3B1 mutations is indicated. Most of these cases may be assigned to the provisional entity of RA with ring sideroblasts and thrombocytosis [241] which is considered within the MDS/MPN group.

MDS with Multilineage Dysplasia (MDS-MLD)

MDS-MLD accounts for approximately 30% of all MDS cases. It is a disease of elderly. The median age is 70 years [232]. Bone marrow aspiration and/or biopsy are usually hypercellular and characterized by erythroid, granulocytic, and megakaryocytic dysplasias. Bone marrow blasts are less than 5%. Auer rods are not seen. If present those cases should be classified as MDS-EB2. The clinical course varies. Patients with RCMD have a worse outcome (reported median survival of 17–33 months) than patients with RA [240]. The frequency of AML evaluation at 2 years is approximately 10%.

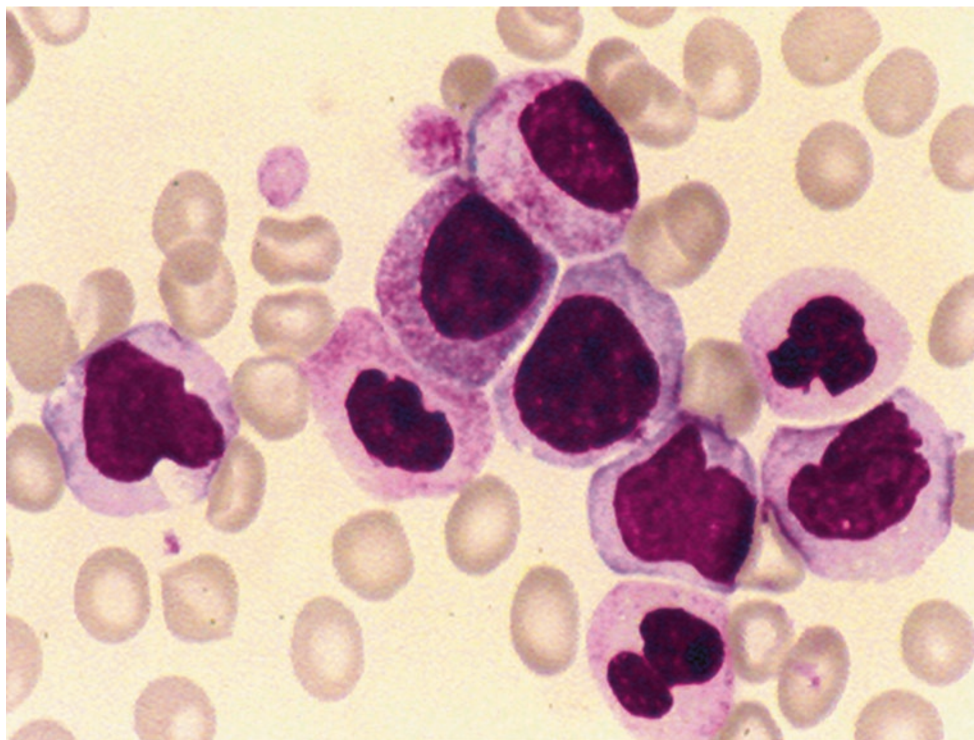

Fig. 14.27 MDS. CMML. Monocytic precursors and myeloblasts. WG stain

MDS with Multilineage Dysplasia and Ring Sideroblasts (MDS-RSMLD)

The category of RCMD-RS was originally eliminated in the 2008 WHO Classification and merged with RCMD because it was shown to be prognostically similar to RCMD lacking ring sideroblasts [242]. Although this still appears to be the case, the recent discovery of mutations in the spliceosome gene SF3B1 that are associated with ring sideroblasts provided a link between morphology and genetics in MDS [243]. Other morphologic features, except ringed sideroblasts, are similar as MDS with multilineage dysplasia.

MDS with Excess of Blasts (MDS-EB)

Conspicuous changes in all three lineages are present associated with variable cytopenia affecting two or more of the hematopoietic lines. Blasts (granular and agranular) range from greater than 5% but less than 20% in the bone marrow or 2–19% in peripheral blood. Two categories of MDS with excess of blasts (MDS-EB) are recognized: MDS-EB1, defined by 5–9% blasts in the bone marrow or 2–4% blasts in peripheral blood, and MDS-EB2, defined by 10–19% blasts in the bone marrow or 5–19% blasts in the peripheral blood [240]. The presence of Auer rods in blasts qualifies a case as MDS-EB2 regardless of the blast percentage. The bone marrow biopsy is very useful in documenting the presence of blast clusters particularly in cases with extensive fibrosis or hypocellularity. Blasts in MDS-EB tend to form cell aggregates that are usually located away from the trabecule and vascular structures. CD34 staining is helpful in their identification. Patients with MDS-EB2 have worse survival and a higher rate of disease transformation to AML. Median survival time for MDS-EB1 is approximately 18 months vs. 10 months for MDS-EB2 [240].

MDS with Fibrosis

Moderate-to-severe (Grades 2–3) bone marrow fibrosis is observed in 10–15% of patients with MDS. These cases have been referred to as MDS with fibrosis [244]. Most of these cases belong to the MDS-EB category. These cases may morphologically overlap acute panmyelosis with fibrosis (APMF). It has been shown that bone marrow fibrosis represents an independent prognostic parameter and identifies a distinct group of MDS with multilineage dysplasia, high transfusion requirement, poor-risk cytogenetics, and poor prognosis. Furthermore, the presence of CD34+ cell clusters is an independent risk factor for progression to AML [245].

Myelodysplastic Syndrome with Isolated del (5q)

Myelodysplastic syndrome with isolated del (5q) is characterized by severe anemia, absence of or mild neutropenia, and/or thrombocytosis. Blast cells usually are not present in the peripheral blood (<1%) and fewer than 5% in the bone marrow. There is marked female predominance. Bone marrow hypercellular or normocellular frequently exhibits erythroid hypoplasia. Megakaryocytes increase in number. Small mononuclear hypolobated

megakaryocytes with single eccentric nucleus and many granulations are strongly correlated with isolated del(5)q [225]. Recent studies have shown that the del(5q) abnormality in MDS is prognostically similar whether it is isolated or occurs with one additional low-risk cytogenetic aberration [246]. Based on this finding, the category of MDS with isolated del(5q) will be expanded to encompass cases with one additional cytogenetic abnormality (excluding monosomy 7).

MDS in Children

Primary MDS is very rare in pediatric population and accounts to less than 5% of all malignant hematopoietic neoplasms among children under the age of 14 years [247]. Although many morphologic and genetic features are common in adult and pediatric cases, there are some significant differences present, particularly in patients with low-grade MDS (RA, RARS, del.5q) categories. Unlike adults, children with MDS present with thrombocytopenia in approximately 75% of cases [248]. Moreover, hypocellularity of the bone marrow is more commonly observed in children than in adults [249]. For these reasons, a provisional entity, refractory cytopenia of childhood (RCC), has been added to include children with cytopenia(s) with less than 2% blasts in the peripheral blood and less than 5% in the bone marrow and evidence of dysplasia in two or more lineages. It remains as a provisional entity in the updated classification for children with 2–19% blasts in the blood and/or 5–19% in the bone marrow; the MDS subclassification should be made using the same criteria used for adults.

Hypocellular Myeloid Neoplasms

Hypocellular AML and hypocellular MDS represent small (10–15%) but significant number of patients diagnosed with myeloid malignancies [250, 251]. Hypocellular AML affects elderly and accounts for 5–12% of de novo AML. In a recent study although the outcome of hypocellular acute myeloid leukemia does not differ from that of non-hypocellular acute myeloid leukemia, hypocellular AML is characterized by prominent cytopenias, older age, a high percentage of antecedent hematologic disorders or prior chemotherapy/radiotherapy, and a low frequency of proliferative mutations [252]. Hypocellular MDS is more frequent in women and occurs with an age-related frequency which is similar to that seen in primary MDS. Bone marrow cellularity is the critical determinant to recognize hypocellular myeloid neoplasm and a bone marrow biopsy is necessary to diagnose these variants in all patients including children. According to our experience [228], by using anatomic comparisons, 13% of AML and 29% of MDS patients had hypocellular marrows. Correcting for age lowered the percentage of hypocellular marrows 2.2% and 7%, respectively. Therefore, age correction is necessary and should be considered as one of the defining criteria for such diagnoses. Bone marrow cellularity may be an important prognostic factor in hypocellular MDS. There is some controversy on survival differences between hypocellular MDS and normo/hypercellular MDS, but patients appear to do at least as well or better [251, 253, 254]. The separation between hypocellular AML, hypocellular MDS, and aplastic anemia (AA) can be problematic. Most hypocellular MDS cases fall into the categories of MD-SLD and MD-EB. The presence of easily identifiable megakaryocytes and patchy erythropoiesis with defective maturation within an architecturally disorganized marrow and the presence of reticulin fibrosis favor MDS over aplastic anemia [249, 250, 253, 255]. An important feature provided by the bone marrow biopsy is to identify blasts. In patients with myeloid neoplasia, blasts often form clusters in central marrow cavity location in contrast to paratrabecular location in reactive marrows. The presence of such clusters is mainly seen in the aggressive MDS subtypes. Immunohistochemical stains, mainly CD34, have provided additional assistance for counting blast in tissue sections. Increase in the percentage of CD34/CD117-positive blast cells and a tendency to form aggregates are useful in distinguishing hypoplastic myeloid neoplasms from aplastic anemia [256]. Although cytogenetic studies may be of particular value in this group of disorders, cytogenetic failures are frequently observed due to severe hypocellularity. FISH studies on paraffin sections or from peripheral blood may be useful for the detection of particular chromosome abnormalities (i.e., 7–, 5–). A recent study revealed that single-nucleotide polymorphisms-array (SNP-A) karyotyping in aplastic anemia and hypocellular MDS can complement metaphase cytogenetics and lead to the identification of cryptic clonal genomic aberrations in both disorders leading to improved distinction of these disease entities [257].

Myelodysplastic/Myeloproliferative Diseases

The WHO classification [9] recommends that a separate category to be formed to include disorders that have both myelodysplastic and myeloproliferative features including CMML, JMML, and aCML. These disorders have many common features including abnormalities of both granulocytic and monocytic lines and a relatively aggressive course.

Chronic Myelomonocytic Leukemia

The criterion for the diagnosis of CMML is the presence of peripheral absolute monocytosis higher than 1×10^9/L, associated with a marrow proliferation of monocytes. For most cases, the peripheral blood and bone marrow smears of patients fulfill all of the classical criteria for MDS (variable degrees of trilineage dysplasia) and show identical chromosome abnormalities. In the WHO classification [258], CMML is further divided into two subcategories, depending on the number of blasts and promonocytes found in the bone marrow and peripheral blood: CMML1, blasts and promonocytes

less than 5% in the peripheral blood and less than 10% in the bone marrow, and CMML2, blasts and promonocytes 5–19% in peripheral blood and 10–19% in the bone marrow. Presence of Auer rods qualify as CMML2 regardless of the blast percentage. The value of this approach has been validated [259].

A subset of patients with eosinophilia, which are formerly included in the CMML category associated with genetic abnormalities including PDGFR, are classified as myeloid neoplasms with eosinophilia.

The percentage of bone marrow and peripheral blasts and the presence of cytogenetic aberrations have been associated with shorter survival and a higher risk of AML evolution [260]. Moreover, the presence of EZH2 implies an unfavorable prognosis [261] while mutation of ASXL1 correlates with evolution to AML and a shorter overall survival [262]. The median survival time varies from 20 to 40 months in most reported series. Progression to AML occurs in 15–30% of cases.

Atypical Chronic Myeloid Leukemia, BCR-ABL1 Negative

This disease predominantly involves the neutrophilic series as CML but lacked Ph1 chromosome or BCR/ABL translocation. Therefore, it is renamed as atypical CML. BCR/ABL negative emphasizes importance of obtaining these tests. aCML has dysplastic and proliferative features. Dysgranulopoiesis is a constant finding. Leukocyte alkaline phosphatase score (LAP) is not useful for diagnosis. Specific and nonspecific esterase stains are useful to detect monocytic component and exclude CMML. aCML is a disease of elderly but has also been reported in young patients. Its prognosis is significantly worse than Ph1+ CML and other MDS/MPNs with a median survival of 14–30 months, and an acute myeloid leukemia (AML) progression rate of approximately 40% [263]. MPN-related mutations are either absent or very infrequent in aCML, and the detection of CSF3R T618I, MPL, CALR, or JAK2V617F mutations should prompt a differential diagnosis of chronic neutrophilic leukemia (CNL), primary myelofibrosis (PMF), or myeloproliferative neoplasm-unclassifiable (MPN-U), which can share overlapping features with aCML [264].

Juvenile Myelomonocytic Leukemia

This is a separate disorder seen in children and adolescents and distinct from adult CMML. Blasts and promonocytes account for less than 20% of cells in both bone marrow and peripheral blood. Erythroid and megakaryocytic dysplasias are frequently seen [265]. Young patient age (median 1.8 years), predominant hepatosplenomegaly, frequent skin involvement, leukocytosis, monocytosis, and presence of immature precursors in peripheral blood characterize juvenile myelomonocytic leukemia (JMML). Ten percent of patients are known to have neurofibromatosis type I by clinical criteria [266]. It is a rapidly fatal disorder; however it rarely transforms into AML. Approximately 90% of patients carry either somatic or germline mutations of PTPN-11, K-RAS, N-RAS, CBL, *or* NF1 in their leukemic cells. These genetic aberrations are largely mutually exclusive and activate the Ras/mitogen-activated protein kinase pathway [267, 268].

Immunobiology of Acute Leukemia

15

Elisabeth Paietta

Introduction

Acute leukemias are commonly defined as the expansion of immature cells that are derived from rare transformed hematopoietic progenitor cells, termed the leukemic stem cells (LSC) or leukemia-initiating cells (LIC), which have the capacity of self-renewal, a defining characteristic also of normal hematopoietic stem cells [1]. As an alternative to originating in a primitive stem cell, leukemias may be derived from transformation of a committed progenitor cell, as is the case with the PML/RAR**α** fusion gene which confers self-renewal to the promyelocyte compartment [2]. The specific cell surface phenotype of LSCs is CD34$^+$, CD38$^-$ [3]. To distinguish between normal and malignant CD34$^+$, CD38$^-$ cells, additional markers are required, such as the C-type lectin-like molecule (CLL-1) [4], CD123 [5], and CD47 [6]. Remarkably, however, even this basic LSC phenotype may vary among patients, such as in truly CD34$^-$, often *NPM1* (nucleophosmin 1)-mutated AML [7], or in leukemias with rearrangement of the *MLL* (mixed-lineage leukemia) gene, in which surface antigen expression of LSCs depends on gene fusion partners [8]. Together with the loss of long-term repopulating potential, the phenotypic features of the LSC blast cell progeny that invade the bone marrow and the peripheral blood of leukemia patients are different from those of the LSC and typically characterized by different morphology and antigen profiles. Despite limited morphologic variability, which forms the basis of the FAB classification, the genetic heterogeneity of both acute myeloid (AML) and lymphoid leukemias (ALL) is vast. With very few exceptions, namely hypergranular *PML/RARα^{POS}* acute promyelocytic leukemia (APL) associated with FAB M3, the t(8;21) and inv(16) core-binding factor (CBF) leukemias associated with M2 and M4Eo, respectively [9], and *RUNX1* mutations, which are associated with the M0 FAB type [10], the morphologic appearance of leukemic cells lacks predictive power with respect to their genetic makeup. While FAB classes may still be collected as part of the biologic characterization of study cohorts, they are no longer part of multivariate analyses establishing the prognostic significance of mutational landscapes [9–15].

For some of the cytogenetic/genetic aberrations, specific antigen profiles have been established, termed surrogate marker profiles, which, in itself, are independent of the underlying genetic lesion, e.g., for APL, for *AML1/ETO* (now termed *RUNX1/RUNX1T1*), and for *BCR/ABL^{POS}* ALL [16, 17]. For other genotypic subtypes, such as BCR/ABL1-like or Ph-like ALL, overexpression of the cytokine receptor-like factor 2 (CRLF2), found in approximately 50% of cases [18], can be reliably detected with an antibody to surface expression of CRLF2 by the leukemic B-lymphoblasts when compared to CRLF2 analysis by fluorescence in situ hybridization [19]. The 2016 revision to the World Health Organization (WHO) classification of myeloid neoplasms and acute leukemia [13] illustrates clearly the increased impact of genetic aberrations in the standardized classification of the acute leukemias. The newly defined concept of pre-leukemic cell clones which carry recurrent mutations, particularly of epigenetic regulator genes (*DNMT3A, TET2*), has revealed novel insights into the intricacies of hematopoiesis and the development of acute leukemia [20–22]. These pre-leukemic stem cells are resistant to standard chemotherapy, persist during remission, and may correspond to a patient's risk of relapse. The fact that these somatic mutations are found with astonishing high frequency in clonally expanded hematopoetic stem cells of healthy subjects [23–26], however, may challenge the notion that pre-leukemic stem cells are the most important target for minimal residual disease (MRD) monitoring.

Antigens expressed by leukemic cells are identical to those expressed by normal hematopoietic cells. To date,

there is no evidence for the existence of leukemia-specific antigens, with the exception of proteins that are encoded by novel fusion genes as a result of leukemia-specific chromosomal aberrations [27] or by mutated genes, e.g., *NPM1* [28]. The value of these antibodies to leukemia-specific proteins lies in their ability to detect genetic aberrations by alternative techniques.

The concept of surrogate marker profiles for genetic lesions [16, 17] follows the basic hypothesis that molecular features determine the cellular phenotype. For leukemic clones, this notion implies that the expression of (altered) genes associated with leukemogenesis will cause characteristic distortions of the cellular phenotype with some predictable consistency that can be exploited by sophisticated immunophenotyping. This explains the occurrence of unique antigens or antigen patterns in leukemia subtypes characterized by particular cytogenetic and/or molecular abnormalities. Examples are the typical antigen profile of AML with t(8;21) *(RUNX1/RUNX1T1*), the classical marker composition of *PML/RAR*α^{POS} APL, and the association of CD25, the α-chain of the interleukin-2 receptor, with BCR/ABL^{POS} ALL, all of which will be discussed in detail.

Unfortunately, reliable surrogate marker profiles for genetic lesions are rare and even the finding of a CD34^{-}, HLA-DR^{-}, CD11a^{-}, CD18^{-} phenotype, which is strongly indicative of APL [29], is only that, indicative of APL, and must be confirmed by the molecular presence of the *PML/RAR*α-fusion gene by the polymerase chain reaction (PCR) assay. On the other hand, elevated surface expression of CRLF2 by B-lymphoblasts is almost invariably associated with the Ph-like CRLF2 phenotype [18, 30]. It does not, however, distinguish between *IGH@-CRLF2*, *P2RY8-CRLF2*, and other kinase fusions.

The characterization of universal markers for poor treatment response with current treatment strategies is another aspect of antigen expression worth mentioning. Besides CRLF2, CD25 is one such antigen both in B-lineage ALL [31] and AML [32]. Other antigens exhibit their unfavorable prognostic significance only in association with a certain maturation stage of acute leukemia, such as the poor outcome associated with expression of the myeloid antigen CD13 in cortical, mature but not in immature T-ALL [33].

The finding that particular combinations of antigens expressed by leukemic cells may be rarely or never be seen in normal hematopoietic tissues has important implications for the detection of MRD, whether the different-from-normal approach or the concept of leukemia-associated immunophenotypes (LAIP) is used [34]. The best example is the differentiation between hematogones, normal B-cell precursor cells, and leukemic B-lymphoblasts while monitoring MRD in B-lineage ALL, which requires extensive knowledge of the intricate antigen expression by hematogones and their various differentiation stages [35, 36]. With more sophisticated immunophenotypic analyses, it has become apparent that leukemic cells differ from normal hematopoietic cells and that leukemia categorization cannot be based solely on presumed normal counterparts [37]. Of course, it is still valid to group the acute leukemias according to the major hematopoietic cell lineages (T-lymphoid, B-lymphoid, myeloid), based on the expression of lineage-specific antigens, and to distinguish between precursor and more mature subtypes based on the hierarchy of antigen expression observed in normal hematopoiesis. However, refined, clinically relevant subgrouping focuses increasingly on prognostically significant and/or therapy-determining features, which may cross lineage borders, as seen, for instance, with the CD25 antigen, mentioned above. The 2008 WHO classification of neoplastic diseases of the hematopoietic and lymphoid tissues [9] and its recent revision [13] clearly reflect this tendency by increasingly recognizing cytogenetic/molecular categories in the new nomenclature of the acute leukemias, thereby reducing those disease entities which rely on morphology and/or immunophenotype alone and invariably suffer from reduced prognostic significance. Comprehensive genomic profiling can now be performed in the clinical setting to improve the diagnosis of hematologic malignancies [38, 39] and more precisely match patients with targeted therapies [40]. The emphasis on marker compositions and single antigens which are associated with genetic features and/or carry prognostic significance irrespective of lineage affiliation should be viewed as a new role for immunophenotyping that deviates from mere lineage identification.

Clinical flow cytometrists today most commonly are still charged solely with determining the lineage affiliation of a given leukemia population to provide an immunodiagnosis which is then routinely compared with the morphologic evaluation of the same tissue under the microscope and, hopefully, with cytogenetic data, to provide the diagnostic basis for therapy. There remains the challenge of accurately interpreting the rare true bilineal (BLL) or mixed-phenotype acute leukemia (MPAL), though any controversies as to whether T/MPALs or B/MPALs [9, 13] should be treated as lymphoid or myeloid leukemias are determined by their genetic makeup rather than their presumed lineage affiliation. I am saying presumed lineage affiliation, because recognizing true lineage affiliation depends on the detection of lineage-specific, predominantly intracellular antigens, which remain to present a challenge to many. Genomic characterization of immunophenotypically distinct subpopulations from two patients with T/myeloid BLL failed to demonstrate genetic diversity, suggesting that the cells with T-, myeloid-, or T/myeloid features all derived from a common LSC with multilineage differentiation capacity [41]. This concept of inherent leukemic plasticity [37, 42, 43] emphasizes that treating BLL or MPAL leukemias according to the dominant phenotype seen at the time of testing is ill advised; genotypic features should guide the treatment decision.

Inevitably, routine clinical flow cytometry laboratories are limited in their efforts due to costs and time restraints. Even if involved in clinical trials with protocol-derived correlative studies, the laboratory must strike a balance between routine immunophenotyping for diagnostic purposes and science-driven, prognostically pertinent testing, if only limited material is available and more sophisticated correlatives, such as genomic studies, must be performed on the same tissue. Ideally, the number of cells required for mere diagnosis-confirming flow cytometry is reduced to a minimum by using multiple fluorochromes in combination and a selection of most informative antibodies. This chapter discusses the various roles of immunophenotyping and the relation between antigen expression and other biologic or clinical aspects in the acute leukemias. In particular, it emphasizes on novel developments, such as the exciting developments in immunotherapy, MRD detection, and novel genotype-driven leukemia subsets. The discussion of lineage-affiliated antigen expression and immunophenotypic classification systems, areas which have been introduced extensively in the previous editions [44, 45], this time will be touched on only peripherally, as far as they relate to the other topics.

Immunophenotyping Versus Morphology

The classification of the acute leukemias has relied on the evaluation of cell size, granularity, nuclear shape, cytoplasmic appearance, cytochemical reactions, and dysplastic features of cells surrounding the "leukemic blasts" since the introduction of the French-American-British (FAB) classification system first in 1976, followed by more recent modifications [46]. Twenty years later, when the WHO published its first proposed classification for hematopoietic tumors [47], FAB terms for ALL were no longer found relevant. For AML, the new classification encompassed four major categories: (1) AML with recurrent genetic abnormalities; (2) AML with multilineage dysplasia; (3) AML and myelodysplastic syndromes, therapy related; and (4) AML not otherwise categorized. In the 2008 WHO edition [9], category 1 was significantly expanded by incorporating more balanced chromosomal translocations and inversions as well as a list of gene mutations that had been found to be of prognostic significance and/or associated with a normal karyotype in the years between the two publications. Despite these additions, which to some extent reduced the number of cases previously left uncategorized, particularly in elderly AML [48], a large group of patients still remained in category 4, not otherwise categorized molecularly and therefore still classified by FAB criteria. Proteomic profiling confirmed the ability of the FAB classification to distinguish between the major lineages by aligning protein signatures with myeloid (M0, M1, M2), monocytic (M4, M5), or M6/M7, though without discriminating the degree of maturation [49]. This may explain why FAB classes are usually not good predictors of prognosis, with the exception of FAB M3 or hypergranular APL. Critics of the WHO classification blame it for emphasizing simplicity of classification at the expense of prognostic significance [50].

An excellent example for underappreciated discordance between information provided by FAB criteria and the actual level of maturation arrest indicated by antigen expression in a recurrent cytogenetic aberration is t(8;21) or *RUNX1/RUNX1T1*$^{\mathrm{POS}}$ AML. Incredible effort has gone into accurately identifying this AML subtype based on morphology. Nucifora et al. [51] proposed a scoring system for the identification of t(8;21) AML based on a list of morphologic characteristics—a total score of 6 or 7 would be suggestive of t(8;21). This scoring system was subsequently adjusted to capture more t(8;21) positive cases while simultaneously decreasing the false-positive rate from 12% with the Nucifera score to 7% with the weighted score [52]. This better recognition rate was accomplished simply by altering the scores assigned to the various morphologic features, reflecting the randomness of such scoring systems. Although predominantly associated with FAB M2 (AML with maturation) [9], 20% of t(8;21) AML cases presented with M1 features (AML without maturation) upon central morphology review (Bennett JM, personal communication) of a recently completed phase III trial of the Eastern Cooperative Oncology Group (ECOG) in >600 younger AML patients [53]. A characteristic feature of the t(8;21) AML immunophenotype is a striking myeloid immaturity, such as weak or absent expression of CD33 [52] and/or the more mature myeloid antigen, $\mathrm{CD65}_{(\mathrm{S})}$ (Paietta E, personal observation), and failure to detect myeloperoxidase by antibody binding [54], and consistent with the suggestion that the *RUNX1/RUNX1T1* fusion event occurs at an early stem/(progenitor cell stage [55]). This lack of myeloid maturation has mostly gone unnoticed due to the continuing tendency of pathologists to place more weight on morphology rather than immunophenotype, particularly in AML. The unique B-lymphoid antigenic features of t(8;21) AML, with expression of PAX5, CD19, and CD79a [56], are a further indication for focusing on refined immunophenotyping, especially since immunostaining for PAX5 is a valuable diagnostic tool for t(8;21) AML presenting with extramedullary masses, which occur frequently in this disease [9]. The absence of expression of the T-lymphoid antigen, CD7, in t(8;21) AML was reported many years ago [52, 57]. More recently, however, we described a subtype of AML which resembles closely the phenotype of t(8;21) AML but expresses CD7 together with CD19 [58]. Strikingly, this novel AML presents with a normal karyotype, lacks *RUNX1/RUNXT1* transcripts, but instead contains internal tandem duplications of the *FLT3* gene (*FLT3ITD*^{POS}) and mutated *NPM1* (*NPM1MUT*^{POS}).

An intriguing observation is the application of immunophenotyping in the discovery of the genetic diversity of morphologically defined APL. Flow cytometry recognizes the characteristic cellular structures of hypergranular (FAB M3) APL by producing a scattergram that reflects cells of large size (high forward-angle light scatter, FSC) with a high degree of granularity (high 90° angle scatter or side scatter, SSC). However, for variant hypogranular APL cells (FAB M3v), the scatter signal can be quite variable and misleading [59]. In a report from the Europena Working Party [60], the majority of cases with FAB M3 or M3v morphology contained t(15;17)(q22;q12)/PML/RARα or other cytogenetic aberrations involving the RARα gene. To account for a small subgroup of morphologic APL patients apparently lacking a RARα rearrangement, a new morphological subclass was introduced and termed "M3r," which also covered APL presenting with PLZF/RARα transcripts. Although the immunophenotype of M3r cases shared the negativity for CD34 and HLA-DR, which is part of the surrogate marker profile for t(15;17) APL [29], M3r patients lacked response to all-trans retinoic acid (ATRA) in vivo. In other words, the main rationale for classifying APL, namely to recognize ATRA-responsive disease, was invalid in this morphologic subtype. The other lesson that should have been learned from these data was that the standard CD34- and HLA-DR-negative marker profile, still widely accepted as sufficient for the diagnosis of APL, is unreliable in predicting the disease. Contrary to this overzealous attempt to define APL by morphology, t(15;17) leukemia without M3/M3v features is often ignored. Among larger studies [59, 61], the incidence of such APL cases ranges between 1 and 2%. For these as well as patients with cryptic t(15;17) [59], the improved surrogate antigen profile for PML/RARα^{POS} APL applies, consisting of negativity for HLA-DR, CD11a, and CD18 [29]. While this antigen combination pertains to both M3 and M3v morphologies, there are immunophenotypic peculiarities that are limited to M3v and/or leukemic promyelocytes containing the S-isoform of PML/RARα transcripts; these are expression of CD34 and of the T-cell-affiliated antigen, CD2 [29]. In fact, CD2^{POS} leukemic promyelocytes frequently lack all of the antigenic properties associated with APL. In such cases, expression of CD2 by myeloid blasts per se is the strongest indication that one is dealing with an APL. It is important to remember that CD2 expression in AML is rare and if present most commonly suggests APL or AML FAB M4Eo with inv(16)(p13q22) resulting in the *CBF*β*/MYH11* fusion transcript [62]. In confirmation of a biologic heterogeneity within the APL phenotype, results from gene expression profiling demonstrated that M3 and M3v APL were clearly separable [63]. Furthermore, the origin of CD2^{POS} APL has been localized to a progenitor cell more immature than that of CD2^{NEG} APL [64].

The role of morphology in the diagnosis of "acute leukaemias of ambiguous lineage" [9] is difficult to assess, since this leukemia subtype is frequently erroneously diagnosed. Occasionally, two morphologically distinct blast populations are readily distinguishable in individual patients; still, even in such cases, the demonstration of lineage-specific antigens is essential for the differential diagnosis of "mixed" (distinct expression of lineage-specific antigens in the two morphologically different populations) versus "biphenotypic" leukemia (expression of lineage-specific antigens by one and the same blast cell irrespective of morphology). More common is the finding of antigens specific for more than one cell lineage in a morphologically homogenous blast cell population, e.g., myeloperoxidase and cytoplasmic CD22 (cCD22) or myeloperoxidase and cytoplasmic CD3 (cCD3), the antigens specific for the myeloid, B-lymphoid, and T-lymphoid lineage, respectively. An instructive example for such a true biphenotype is that of CD117^{POS}, FLT3-gene mutated T-lineage ALL [65]. This rare leukemia subtype simultaneously expresses cCD3 and, in a subset of blast cells (5–10%), myeloperoxidase. Despite the presence of the myeloid-specific antigen in only a minor portion of the blasts, the morphology of these cases varied between FAB M2 (occasionally with Auer rods) and FAB L2, independent of the percentage of myeloperoxidase^{pos} blasts.

Minimally differentiated AML is considered to be equivalent to FAB M0, with no evidence of myeloid differentiation by morphology or cytochemistry [9]. Based on a retrospective analysis of >700 adult AML patients across all ages, ECOG defined this undifferentiated phenotype based on lack of expression of the more mature myeloid antigen, CD65(s), a carbohydrate antigen that can be expressed in an asialostate (CD65) or with a sialic acid residue in terminal position of the carbohydrate chain (CD65s) [66]. Morphologically, the majority of these patients belonged to the FAB M0/M1 classes. Important hints in the correct interpretation of this AML subtype are the following: (a) blasts must be negative for lymphoid-specific antigens, cCD22 and cCD3; (b) although blasts do not show an enzymatic reaction for myeloperoxidase, they frequently stain for the myeloperoxidase protein by antibody staining; (c) even if blasts are negative with antimyeloperoxidase antibody, they are considered myeloid given that they lack lymphoid-specific antigens; (d) in most cases, the blasts will stain for CD33 and/or CD13, the pan-myeloid antigens; (e) immature antigens, such as CD34, CD117, HLA-DR, CD133, and CD123, are common; (f) frequently, the T-lymphoid-affiliated antigen CD7 is found; (g) expression of the B-lymphoid antigen CD19 by these undifferentiated blasts suggests t(8;21)/AML1/ETO^{POS}AML. Minimally differentiated AML more often occurs in older patients and carries inferior prognosis [66].

In summary, diagnoses based on morphology cannot be easily correlated with immunophenotypic findings. With the exception of FAB-M3, morphologic subclasses rarely relate to specific immunophenotypes. The presence of monocytes and/or monocytic features in a leukemia population, however, requires special discussion. Invariably, when CD14, the prototype mature monocytic antigen, is detected on an abnormally

large fraction of white blood cells (WBC) or on blasts cells defined by the expression of immature markers, such as CD34 or CD117, the morphologic evaluation will yield FAB M4 (myelomonocytic) or M5 (monocytic), respectively. It should be emphasized here that CD123 (α-chain of the IL-3 receptor), an antigen associated with the hematopoietic stem cell [67] and expressed by >99% of AML [68], cannot be used to diagnose leukemic monocytes, because normal monocytes show weak, though persistent, CD123 expression. The strong association of CD14 with monocytic morphology stands in contrast to CD11b (Mac-1), an integrin α-subunit (adhesion molecule) [69], which in monocytic development appears earlier than CD14 [70] and which is also expressed by myeloid cells starting at the myelocyte stage [71]. Given its appearance late in myeloid maturation, one would expect CD11b expression by nonlymphoid leukemic cells to reflect monocytic features. However, in a retrospective evaluation of 382 patients with CD11b^{POS}CD14$^{NEG/LOW}$ AML, ECOG found that less than half of those patients belonged to FAB classes M4/M5, whereas the other half demonstrated FAB M1/M2 features [72].

An instructive tale relates to the "cuplike" nuclei which have been published as a distinct morphologic feature in AML with FLT3-gene internal tandem duplication (FLT3-ITD) [73]. According to Kussick et al. [73], non-APL AML-cuplike was more likely to lack HLA-DR and CD34, to express CD123 without CD133, and to have a normal karyotype. A few years later, Chen et al. [74] associated the same prominent nuclear invaginations with NPM1-mutated AML, which is characterized by negativity for CD34 and CD133, normal cytogenetics, and a high incidence of FLT3 gene mutations. These structural nuclear features prevail in NPM1-mutated AML irrespective of FAB categories, which typically span a wide spectrum in this genetic subtype. Furthermore, NPM1 mutations involve all but lymphoid hematopoietic cell lineages and, as FAB criteria, also this feature is independent of the presence of FLT3-ITD [75]. While previously [47] included in the class of "AML not otherwise characterized" and subjected to diagnosis based on FAB criteria, the newest WHO classification [13] recognizes NPM1-mutated AML as a distinct disease category rather than mere prognostic factor.

Immunophenotypes Versus Genetic Lesions

Chromosome translocations can have two distinct effects at the molecular level: either the inopportune activation of an unaltered gene or the creation and transcription of a novel gene. The first process occurs predominantly in lymphoid malignancies. The translocation places a transcriptionally silent gene under the control of the promoter of a transcriptionally very active gene, e.g., immunoglobulin or T-cell receptor (TCR) genes in B- or T-lymphocytes, respectively [76]. This leads to the inappropriate transcription of a normal gene. Alternatively, balanced translocations and interstitial chromosome deletions or inversions can lead to the creation of novel, leukemogenic fusion genes. At each of the chromosomal breakpoints, a critical gene is disrupted; fragments of the two genes are brought together as a result of the translocation. Two hybrid fusion genes are created, one on each of the two chromosomes partnering in the translocation. Even if both chimeric genes are transcribed, only one is usually suspected as the transforming gene.

The following section is limited to those leukemia fusion genes, gene mutations, and instances of aberrant gene overexpression for which immunophenotypic data are available. While some antigen combinations can be viewed as specific for certain genetic lesions (e.g., AML1/ETO^{POS} AML), others are indicative of a certain maturation stage of leukemic arrest (e.g., BAALC-overexpressing leukemias) or reflective of a specific cell of origin (e.g., NPM1-mutated AML).

Surrogate Antigen Profiles for Leukemia Fusion Genes

Specific associations have been established between the expression of single antigens or particular antigen expression patterns and cytogenetic-molecular abnormalities. While the first of such surrogate marker profiles were found rather serendipitously, i.e., that for t(15;17)/PML/RARα APL, antigen expression signatures of genetic lesions are increasingly sought in a planned fashion, in parallel to the genetic classification of the acute leukemias as well as due to developments in targeted therapy [16, 17]. Reliable surrogate marker profiles for genetic lesions are of clinical interest only when the associated genotype is prognostically significant and/or when targeted therapy for that genotype is available.

Outcome-based classification of the leukemias nowadays is based predominantly on cytogenetic aberrations and their molecular derivatives, whether recognizable by standard cytogenetics or requiring FISH analysis. Progressively, however, genetic and epigenetic profiling data provide a major source of information regarding perturbed pathogenetic pathways and potential therapeutic targets. The revolutionary discovery of BCR/ABL1-like or Ph-like B-lineage ALL is the best example for this development [18, 19, 30]. The advantage of having antigen profiles available, which can predict for the existence of, for example, gene mutation or gene silencing events, lies in the ease, speed, and low costs of flow cytometry. Appropriate situations of particular urgency arise when cytogenetics are unsuccessful or simply not performed, when chromosome structures are impaired, as in ALL, when only normal metaphases are seen, or when karyotyping, FISH analysis, and/or molecular analyses are not available at an institution. Surrogate marker profiles should not be used in lieu of molecular analyses, given that even the most reliable antigen combinations have shown

some unexpected properties: (a) sensitivity to subtle antigenic alterations outside the core marker profile; for example, the antigen profile for t(8;21)-*AML1/ETO*^{POS} AML is invalid when the T-cell marker CD7 is also present on the surface of the myeloblasts; (b) precise alterations in response to variations in the global genetic lesion; for example, striking differences were found in the expression of CD25 and dual CD33/CD13 between the *e1a2* and *e13a2(b2a2)/e14a2(b3a2)* transcript forms in *BCR/ABL*^{POS} ALL, and absence of CD33/CD13 expression in the presence of a del(9p) in addition to the t(9;22); and (c) occasionally an overpowering effect of single antigens; for example, the expression of the T-cell marker CD2 by leukemic promyelocytes occasionally obviates the finding of the typical surrogate marker profile for *PML/RAR*α APL.

t(15;17)(q22;q12)-*PML/RAR*α^{POS} APL

Given the unmistakably hypergranular features of M3 leukemic promyelocytes, which rarely cause misreadings among morphologists, APL was the first leukemia for which characteristic immunophenotypic features were described. The history of the surrogate marker profile for APL is outlined in Table 15.1. The initial definition of an APL marker profile consisted of negativity for CD34 and HLA-DR. Subsequently, the profile was refined by adding the differential reactivity of CD15/$CD15_S$ antibodies, caused by the sialylation of the CD15 carbohydrate antigen in APL, weak expression of CD38 and CD45, expression of CD9, and lack of P-glycoprotein [17]. Two developments prompted the search for an improved profile: (1) the recognition of an ATRA-unresponsive AML subtype, termed natural killer cell AML, with morphologic similarities to M3v as well as CD34 and HLA-DR negativity, while expressing CD56, the neural cell adhesion molecule [77], and (2) the observation that CD56 expression by leukemic promyelocytes conferred inferior prognosis [78, 79]. The most recent surrogate marker profile for PML/RARα APL [29] is based predominantly on (a) lack of HLA-DR and CD133, two antigens expressed at differentiation levels more immature than that of promyelocytes during normal myelopoiesis; (b) absence of several adhesive molecules, such as CD11a (α_L subunit of the leukocyte integrin LFA-1), CD18 (β_2 subunit of LFA-1), and CD11b (α_M subunit of Mac-1 integrin); (c) expression of the carbohydrate structure, CD15, only in the sialylated form, $CD15_s$; and (d) faint expression of CD45, the common leukocyte antigen, and of CD38, a bifunctional ectoenzyme catalyzing involved in cell adhesion to endothelium. In summary, APL is characterized by absence or weak expression of adhesion molecules. CD117, a progenitor molecule associated predominantly with the myeloid lineage, is invariably expressed by leukemic promyelocytes, albeit occasionally at low levels [29, 59].

Table 15.1 History of the immunophenotype of *PML/RAR*α^{POS} APL

Earliest definition	Current definition	ECOG's new definition
Myeloid	Myeloid	Myeloid
HLA-DR NEG	HLA-DR NEG	HLA-DRNEG
CD34 HLA	CD34 NEG	CD11a NEG
	CD15 NEG	CD18NEG
	CH15s POS	CD133 NEG
	CD9 POS	CD45 WEAK
	CD38 LOW	CD38 WEAK
	Pgp WEAK/NEG	CD15 NEG

"Myeloid" defines the presence of a basic myeloid phenotype with expression of CD33 and CD13, occasional expression of $CD65_{(S)}$ and/or myeloperoxidase, and absence of lymphoid-specific antigens. *Pgp* P-glycoprotein, the multidrug resistance protein; *NEG* (negative) reflects absence of antigen-expressing cells; *POS* (positive) reflects expression of antigens by >10% of gated leukemic promyelocytes; *WEAK* reflects weak intensity of fluorescence of antibody staining

The (15;17) translocation involves the retinoic receptor α (RARA) gene on the long arm (q) of chromosome 17 and the promyelocytic leukemia (PML) gene on the q arm of chromosome 15. While the breakpoints in the RARA gene occur consistently in intron 2, differential breakpoints in the PML gene lead to the L- (Long, bcr1), S- (Short, bcr3), or the V- (Variable, bcr2) transcript isoform of PML/RARα. The HLA-DR^{LOW}, CD11a^{LOW}, CD18^{LOW} surrogate marker profile is applicable to all three molecular isoforms [29, 59]. However, the isoforms can be distinguished based on specific antigenic features outside this core antigen profile. While the antigen expression patterns in L- and V-form diseases are indistinguishable, they are clearly separable from S-isoform APL. Only leukemic promyelocytes that contain S-form transcripts variably express CD34, CD2, and CD56. The expression of CD2 together with the S-isoform correlates with poorer prognosis [80]. A potential explanation could be a higher incidence of extramedullary relapse in CD56^{POS} cases [81]. Furthermore, thrombotic events in APL were found to be associated with CD2^{POS} S-form disease with *FLT3-ITD* [82]. As discussed before, CD2^{POS} APL is hypothesized to be derived from a progenitor cell with myeloid/lymphoid potential [63, 83]. Note that while CD2 and/or CD56 on a patient's leukemic promyelocytes are highly suggestive of the S-isoform, because they are never seen in L- or V-isoform, there are S-isoform patients who lack these antigens. CD34 expression may be associated with the molecular isoform or the microgranular morphologic variant (see before). Even when expressed, the density of the CD34 antigen is significantly lower on the surface of leukemic promyelocytes than on non-APL myeloblasts [84]. CD2^{POS} APL occasionally may lack APL-typical antigenic features, something never seen in L- or V-form APL, thus possibly misleading laboratory investigators or pathologists when they interpret the data [16, 17]. It is recommended that any case of CD2^{POS} myeloid leukemia be immediately tested by PCR for *PML/RAR*α versus *CBF*β*/MYH11*, since APL [59] and inv(16)(p13q22)/t(16;16)(p13;q22) AML [62], respectively, are the two major AML subtypes found to express CD2, especially since these leukemia subdiagnoses require distinct therapies.

In addition to the *PML/RAR*α fusion gene, which accounts for >98% of APL cases, a common segment 5′truncated *RAR*α has been found to fuse with alternative genes [85]. Because such variant translocations are rare, clinical information regarding their responsiveness to ATRA is scarce; recurrent cases of *PLZF/RAR*α (promyelocyte leukemia zinc finger), derived from t(11;17)(q23;q21), appear to lack ATRA responsiveness, while *NPM/RAR*α (nucleophosmin) APL, derived from t(5;17)(q35;q21), is ATRA responsive. Despite their low frequency, the limited immunophenotypic observations available suggest that the main characteristic features of *PML/RAR*α APL cells hold up for all currently known variant APL translocations that involve rearrangement of the *RAR*α gene [59]. Novel variant *RAR*α fusion genes keep appearing in the literature whereby ATRA sensitivity in individual cases appears to vary. Two pieces of evidence should prompt the search for the presence of an alternative *RAR*α fusion gene in a patient: (a) the finding of APL-specific immunophenotypic features in a patient negative for *PML/RAR*α, and (b) cytogenetic evidence of chromosome 17 abnormalities in such a patient. Occasionally, slight variations from the typical APL profile may be found. Gallagher et al. [86], for instance, found weak expression of CD133 in the only second case of *STATb/RAR*α. If confirmed in further cases, this antigenic peculiarity may serve as a diagnostic tool for this particular APL variant.

t(8;21)(q22;q22)-*RUNX1/RUNX1T1* (formerly *AML1/ETO*)^{POS} AML

Leukemias with t(8;21) or inv(16)/t(16;16) belong to the core-binding factor (CBF) AMLs, which are a diagnostically and prognostically distinct subgroup [9]. Both of these chromosomal rearrangements result in the formation of fusion proteins, *RUNX1/RUNX1T1* and *CBF*β*/MYH11*, respectively, that involve the disruption of one of the CBF transcription factor genes. The two genes involved in (8;21) translocation are the AML1 transcription factor, now called *RUNX1*, on chromosome 21q22.3, and the eight-twenty one oncoprotein (ETO) (now called *RUNX1T1*) on chromosome 8q22 [55]. The characteristic immunophenotype of t(8;21) AML allows for a correct prediction of this genetic aberration [87]. Distinctive features are expression of CD19, a B-lineage-associated antigen, and of CD56, the neural-cell adhesion molecule, by CD34^{POS} myeloblasts. Presence of CD56 may explain the increased incidence of granulocytic sarcomas observed in this disease [88, 89]. While CD19 is consistently present in the t(8;21) subtype and rarely found in other AMLs, expression of this antigen by myeloblasts is often very weak so that its detection can depend on the accurate choice of fluorochromes and an open mind on the part of the interpreting flow cytometrist. In fact, CD19 conjugated to fluorescein isothiocyanate (FITC) should be avoided at all costs. An example of CD19/CD56 double expression in a patient with *RUNX1/RUNX1T1*^{POS} AML is shown in Fig. 15.1. Although CD56 expression is promiscuous among myeloid leukemias and absent in a marked fraction of t(8;21) cases, the finding of both CD19 and CD56 against the background of a myeloid phenotype is highly suggestive of t(8;21) AML. As in the case of APL, an

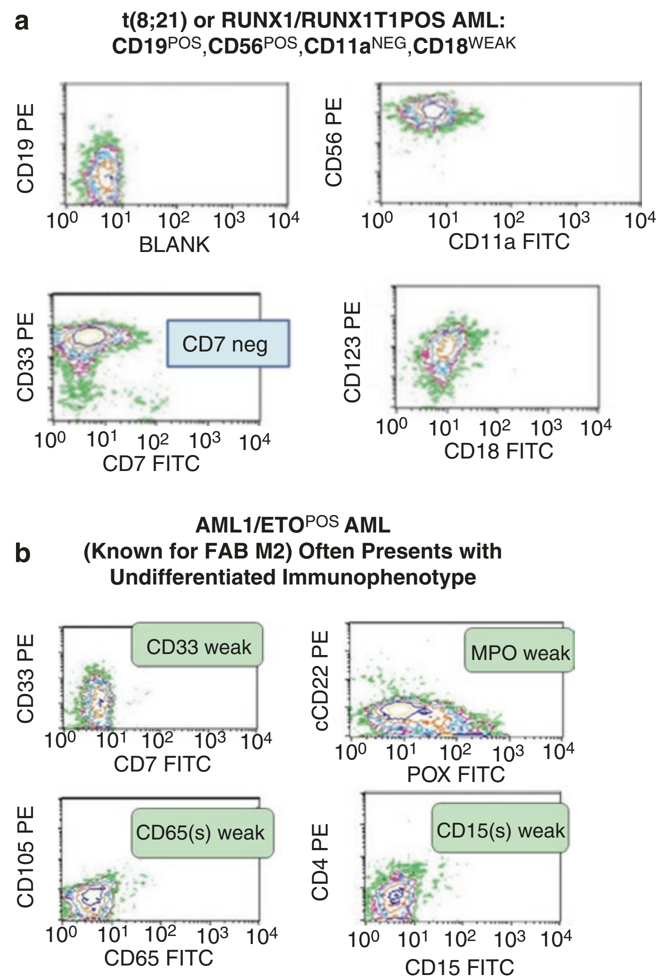

Fig. 15.1 (**a**) Dual-CD19 and -CD56 expression by t(8;21)-*RUNX1/RUNX1T1*^{POS} myeloblasts. Blasts were gated based on low side and forward scatter and all antigen expression shown reflects that of gated blasts. Antibody staining along the *X*-axis demonstrates fluorescence intensity of FITC-conjugated antibodies, whereas the *Y*-axis represents PE-conjugated antibody staining. (*A*) This contour plot demonstrates the weak though definite expression of CD19. (*B*) The same weakly CD19^{POS} blasts also strongly express CD56 but lack CD11a. (*C*) CD33 expression in this particular case of *RUNX1/RUNX1T1*^{POS} AML is strong, but notably there is no CD7 expression. (*D*) The blasts express the stem cell marker, CD123, but lack CD18. (**b**) This case of *RUNX1/RUNX1T1*^{POS} AML demonstrates the frequently found immature myeloid phenotype. Blasts were gated as described under 1.A. (*A*) Blasts only weakly express CD33 and lack CD7. (*B*) Myeloperoxidase expression is weak but there is no evidence of intracytoplasmic CD22. (*C*) Mature myeloid antigens $CD65_{(s)}$ and CD15 (*D*) are absent. The blasts also fail to stain for CD105, a marker of immature hematopoietic cells, and CD4, which is frequently expressed by monocytic cells. In the presence of CD19 staining (not shown for this case), this pattern of antigen expression may be confused with CD10^{NEG} B-lineage ALL. To exclude B-lineage ALL, myeloperoxidase and intracytoplasmic CD22 must be evaluated. Furthermore, CD10^{NEG} B-lineage ALL blasts preferentially express CD65/CD15 rather than CD33

increasingly accurate surrogate marker profile for t(8;21) AML has evolved over time. One particularly helpful diagnostic tool is the diminished or absent expression of CD11a/CD18 [59, 90], a member of the β2 integrin subfamily [69]. With the exception of t(8;21) or t(15;17) (and its variants), >90% of AML demonstrate expression of CD18. The absence of CD11a in t(8;21) AML is explained by the inhibition of Runx1-dependent CD11a transcription by the *RUNX1/RUNX1T1* fusion product [90].

Variable expression of CD11a is seen in AML with dual expression of CD19 and CD7, a T-lineage-affiliated antigen [58]. Previously, the incompatibility of t(8;21) with expression of CD7 had been reported [57]. More recently, CD19/CD7 double-positive AML has been associated with a predominantly normal karyotype and *FLT3-ITD* and *NPM1* mutations [58] (Fig. 15.2).

Aside from CD19, t(8;21) myeloblasts can also express two other B-lineage antigens, CD79a and PAX5 [56]. The *PAX5* gene encodes a paired box domain transcription factor, which is considered a crucial mediator of B-cell identity [91]. Tiacci et al. [56] hypothesized that the PAX5-dependent expression of CD19 and CD79a in t(8;21) AML results from the interaction and functional cooperation between the PAX5 and AML1/ETO proteins. Expression of CD56 is also not limited to the myeloid lineage [92] and in B-lineage ALL appears to be associated with BCR/ABL transcripts [93]. Taken together, these findings can lead to a misdiagnosis of B-lineage ALL, especially in view of the immaturity of the myeloid phenotype frequently encountered (as discussed before), as long as karyotypic and molecular data are unavailable. While in t(8;21) AML, the same blast population will co-express myeloperoxidase or surface myeloid antigens, e.g., CD13, weak CD33, and CD19, these blasts will not stain for cCD22. It is important to remember that dual absence of myeloperoxidase and cCD22 is consistent with AML.

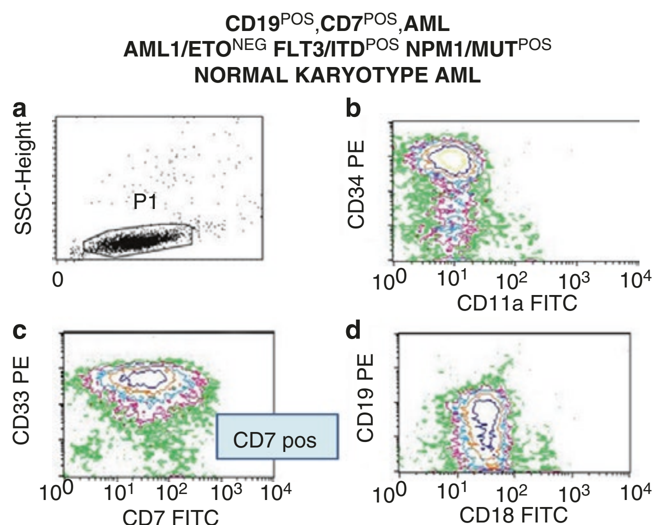

Fig. 15.2 Expression of CD7 by CD19^{POS} myeloblasts rules out t(8;21)-*RUNX1/RUNX1T1^{POS}* AML. (**a**) P1 is drawn around suspicious cells with low side (SSC) and forward scatter (FSC), reflecting lack of granularity and small-to-intermediate cell size. (**b**) In this biparametric contour plot, cells within gate P1 are found to contain a major population with high-intensity CD34 expression and a minor population with variable, weak CD34 expression; both populations lack CD11a. (**c**) Further characterization of gated cells reveals that both CD34^{HIGH} and CD34^{WEAK} cells belong to the leukemic population as they all express both CD33 and CD7. (**d**) These CD33^{POS}CD7^{POS} myeloblasts also express CD19 and lack CD18. In graphs b–d, a small population of residual normal T-lymphocytes is seen. In graph b to the right of the main CD34^{POS} cell population is a very small component of CD11a^{POS} cells; in graph c there is a small component of CD7^{POS} but CD33^{NEG} cells, and in graph d, there is a small population of CD18^{POS} but CD19^{NEG}, suggesting that they reflect a small number of normal T-lymphocytes, which had been inadvertently included in the P1 gate

t(9;22)(q34;q11)-*BCR/ABL^{pos}* ALL

The Philadelphia chromosome, t(9;22), which results in the *BCR/ABL* fusion gene, is the dominant negative prognostic factor in ALL [94]. Its incidence increases with age, accounting for 2–5% in children and up to 28% in adult patient cohorts [95]. The disappointing response of *BCR/ABL^{POS}* patients to standard therapy and the availability of specific inhibitors for the constitutively activated tyrosine kinase in BCR/ABL fusion proteins [96] have prompted separate trials for *BCR/ABL^{POS}* and *BCR/ABL^{NEG}* ALL, making it imperative that these patients are recognized accurately. It is important to differentiate between *BCR/ABL^{POS}* ALL and BCR/ABL1-like (or Ph-like) ALL (18,19), which will be discussed later.

Cytogenetic analyses in lymphoblasts are hampered by suboptimal chromosome structure [97], and, furthermore, approximately 10% of *BCR/ABL^{POS}* ALL lack evidence of the t(9;22) by chromosome banding [95]. Both karyotyping and molecular analyses by PCR require time, 1–2 weeks and, in most laboratories, at a minimum, 24 h, respectively. The first alleged antigenic signature for *BCR/ABL^{POS}* ALL relied solely on differences in staining intensity of antigens commonly found in B-lineage ALL, such as strong expression of CD10 and CD34 and weak expression of CD38 [98–100]. However, in 1997, a preliminary analysis of 144 patients enrolled in ECOG's phase III adult ALL trial, E2993, demonstrated an association between *BCR/ABL* positivity and expression of CD25, the α-chain of the interleukin-2 receptor [101]. This observation confirmed an earlier report of the incidental finding of CD25 in four patients with *BCR/ABL^{POS}* ALL [102]. The final analysis of E2993 [31] solidified the surrogate marker profile for *BCR/ABL^{POS}* lymphoblasts as CD25^{pos}CD34^{high} with frequent dual expression of myeloid antigens, CD33 and CD13. Despite the frequent expression of two myeloid antigens by *BCR/ABL^{POS}* lymphoblasts, this phenotype must not be considered biphenotypic, since *BCR/ABL^{POS}* lymphoblasts unequivocally belong to the B-cell lineage (cCD22^{POS}, myeloperoxidase^{NEG}). Approximately 60% of *BCR/ABL^{POS}* ALL cases (pediatric and adult) express additional cytogenetic aberrations [103, 104]. Rieder et al. [105] and Primo

et al. [106] reported that patients with del(9)(p21), in addition to the t(9;22), lacked both CD33 and CD13. Among 11/156 *BCR/ABL*^{POS} patients with del(9)(p11), del(9)(del(9)(p13), or del(9)(p21) on E2993, 8 lacked both CD33 and CD13, whereas the other 3 only showed decrease or loss of CD13 expression, thus supporting and expanding Primo's observation (Paietta E, personal observation). Wetzler et al. [104] could not confirm this association between myeloid marker expression and abnormalities of 9p. Of potential interest, a report from the pre-tyrosine kinase inhibitor (TKI) era indicated that *BCR/ABL*^{POS} children with loss of the p-arm had a particularly poor outcome [103], confirming an early report from adult *BCR/ABL*^{POS} patients [105].

The dual expression of myeloid antigens, CD33 and CD13 by *BCR/ABL*^{POS} lymphoblasts, is not surprising, given that these blasts most commonly express immunophenotypic features of early pre-B-ALL (CD10^{POS}). Ludwig et al. [107] have proposed that the expression of myeloid antigens in adult B-lineage ALL differs according to the level of B-lymphoblast maturation, analogous to what has been reported from pediatric ALL [108, 109]. Analysis of E2993 [110] confirmed but also expanded these associations. While pro/pre-pre-B-ALL, the immature CD10^{NEG} maturation stage, typically expressed $CD65_{(S)}$ and $CD15_{(S)}$, the CD10^{POS} early pre-B stage preferentially expressed the pan-myeloid antigens CD33 and CD13, which in normal myelopoiesis appear before $CD65_{(S)}$/$CD15_{(S)}$ on maturing myeloid cells. However, these relationships did not hold up in *BCR/ABL*^{POS} cases; as given in Table 15.2, the paired expression of CD33/CD13 persisted irrespective of the maturation stage of BCR/ABL^{POS} lymphoblasts. CD33/CD13 positivity was seen whether *BCR/ABL*^{POS} blasts lacked CD10 (pro/pre-pre-B stage) or expressed intracytoplasmic μ chains (pre-B stage). Importantly, *BCR/ABL*^{POS} lymphoblasts never expressed $CD65_{(S)}$/$CD15_{(S)}$ even in those instances in which CD33 and/or CD13 were not expressed. It is important to realize that *BCR/ABL*^{POS} cases with CD33/CD13 expression do not represent MPAL B/myeloid, as defined by the WHO classification [9], given that *BCR/ABL*^{POS} ALL cells invariably contain intracytoplasmic CD22 (B-lineage-specific marker) and lack myeloperoxidase (myeloid-lineage-specific marker).

Table 15.2 *BCR/ABL*^{POS} B-lineage ALL blasts frequently express both CD33 and CD13, irrespective of the maturation stage of the B-lymphoblasts (shown in **bold**)

BCR/ABL	B-ALL maturation	CD33	CD13	CD65	CD15
Negative	Pro-B /Pre-Pre-B	neg	neg	pos	pos
Positive	Pro-B/ Pre-Pre-B	**pos**	**pos**	neg	neg
Negative	Early Pre-B	*pos*	*pos*	neg	neg
Positive	Early Pre-B	**pos**	**pos**	neg	neg
Negative	Pre-B	neg	neg	neg	neg
Positive	Pre-B	**pos**	**pos**	neg	neg

While *BCR/ABL*^{NEG} immature, CD10^{NEG} pro-B/pre-pre-B blasts commonly express CD65 and/or CD15, *BCR/ABL*^{POS} pro-B/pre-pre-B blasts express CD33/CD13. The more mature pre-B blasts in *BCR/ABL*^{NEG} ALL typically lack myeloid antigen expression

The (9;22)(q34;q11) translocation results in the actual Philadelphia chromosome, the derivative chromosome 22, in which the *BCR/ABL* fusion gene is located, and the derivative chromosome 9, where the reciprocal *ABL/BCR* fusion gene resides, which does not appear to contribute to the pathogenesis of this disease. Various isoforms of the *BCR/ABL* fusion gene are created dependent on the variable breakpoints in the *BCR* gene. All translated BCR/ABL proteins share a similar carboxy-terminal ABL tyrosine kinase domain (TKD), but differ in the portion of the BCR protein included in the fusion product, due to multiple breakpoint cluster regions in the *BCR* gene. In the majority of chronic myeloid leukemia (CML) cases and in one-third of *BCR/ABL*^{POS} ALL, the break within the *BCR* gene occurs in the major breakpoint cluster region (M-bcr), resulting, when joined with a portion of *c-ABL* from chromosome 9, in a *e13a2 (b2a2)* or *e14a2 (b3a2)* fusion transcript encoding a protein of 210,000 Da molecular weight (p210$^{BCR-ABL}$). A break in the minor breakpoint cluster region (m-bcr) forms the *e1a2* transcript encoding a 190,000 Da protein (p190$^{BCR-ABL}$), found mostly in *BCR/ABL*^{POS} ALL [111, 112]. Castor et al. [113] proposed a distict pattern of hematopoietic stem cell and committed B-cell progenitor involvement for major and minor *BCR/ABL* fusion ALLs, respectively.

The most striking observation with respect to CD25 and *BCR/ABL*^{POS} ALL is that expression levels of CD25 are of prognostic significance predicting for a lower likelihood to achieve complete remission [31], and shorter overall (OS) [31] or event-free survival [114] among *BCR/ABL*^{POS} patients. In other words, CD25 is unique in its dual function as a dependable marker of *BCR/ABL*^{POS} ALL and an independent prognostic factor for outcome in this disease. Most recently, the mechanism of action of CD25 in *BCR/ABL*^{POS} ALL was elucidated in detail [115]. The group of Markus Müschen [115] found that CD25 is a critical feedback regulator of the B-cell receptor (BCR) and a biomarker of tumor clones driven by oncogenic BCR mimics, including *BCR/ABL* and other *ABL1* fusion genes present in Ph-like ALL cases. This predicts that CD25-expressing B-cell malignancies may be sensitive to small-molecule inhibitors of the BCR signaling pathway (e.g., ibrutinib). In murine models for B-cell tumors, CD25 was crucial for the initiation of B-cell leukemia. Phosphorylation of the cytoplasmic tail of CD25 by protein kinase C δ (PKCδ) causes surface expression of CD25 which in turn coordinates a negative feedback by shuttling inhibitory phosphatases from the cytoplasm to the cell membrane (e.g., SHIP1). This recruitment of phosphatases stabilizes oncogenic tyrosine kinase signaling and mediates drug resistance. The mechanism of CD25 in BCR-driven lymphoid cells is illustrated in Fig. 15.3. Most importantly, CD25 inhibition sensitized CD25-expressing cells to conventional drug treatment. These preliminary data have

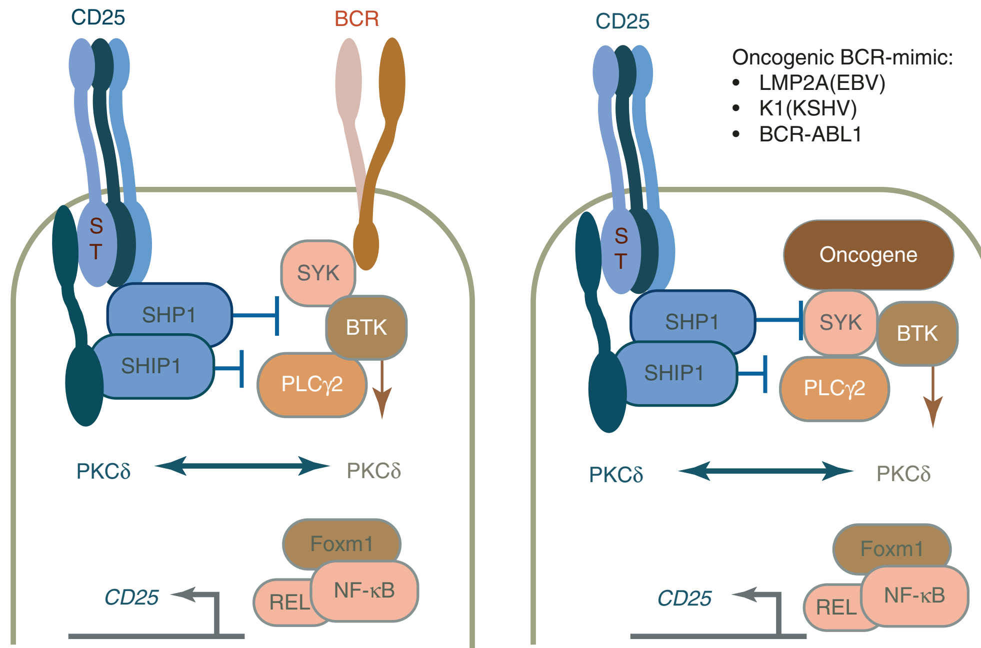

Fig. 15.3 *Left graph*: The left graph represents pre-B-cell receptor (BCR)-mediated signaling in normal B-cells. BCR signaling involves rapid activation of spleen tyrosine kinase (SYK), Bruton's tyrosine kinase (BTK), and phospholipase C γ-2 (PLCg2), which convert protein kinase C δ (PKCδ) from an inactive (*yellow*) to an activation state through phosphorylation (*blue*). Activated PCKδ (*blue*) is translocated from the cytoplasm to the plasma membrane. BCR also activates the proto-oncogene Foxm1, which encodes Forkhead box protein M1, and nuclear factor kappa B (NF-κB), a transcription factor which resides in the cytoplasm in an inactive complex. Müschen et al. have found that the genomic region of CD25 was occupied by several components of NF-κB, such as RELA and RELB, and able to interact with Foxm1. Once activated, NF-κB, and potentially also Foxm1, transcriptionally increases CD25 expression. Plasma membrane-located PKCδ (blue) recruits the newly synthesized CD25 to the cell surface via phosphorylation of the serine and threonine (ST) motif appended to the CD25 cytoplasmic tail. The now surface-located CD25 recruits phosphatases, such as Src homology region 2 domain-containing phosphatase-1 (SHP1) and phosphatidylinositol-3,4,5-triphosphate 5-phosphatase 1 (SHIP1), which counteract and stabilize BCR signaling. In normal pre-B- or B-cells, BCR signaling is transient and must be quelled by phosphatases such as SHP1 and SHIP1. *Right graph*: The right graph represents an ALL blast. ALL typically originates from pre-B-cells which critically depend on survival signals emanating from a functional pre-B-cell receptor (BCR). Oncogenes such as Epstein-Barr virus latent membrane protein 2A (LMP2A), the K1 protein of Kaposi's sarcoma-associated herpesvirus (K1), or BCR-ABL1 deregulate B-cell signal transduction by mimicking activated BCR. This "false" BCR signaling leads to constitutive activation of SYK, BTK, PLCg2, and NF-κB, which requires upregulation of surface CD25 expression via activation of PKCδ to stabilize signaling strength. With BCR mimics, BCR signaling is constitutive and excessive, a critical factor in the development of BCR-addicted leukemia and lymphoma (courtesy Dr. Markus Müschen)

led to a clinical trial using of ADCT-301, a human monoclonal antibody to CD25, linked to a pyrrolobenzodiazepine dimer toxin, in relapsed/refractory CD25^{POS} acute leukemias [NCT02588092]. As will be discussed later, CD25 also represents a most powerful prognostic factor in AML [32].

Though isolated case reports of *BCR/ABL*^{POS} ALL with T-lineage phenotype are still occasionally posted, all of the larger studies have reported that BCR/ABL rearrangements in pediatric and adult ALL are restricted to the B-cell lineage [31, 96, 116–118]. A substantial cohort of pediatric patients studied from various European groups found 3 T-ALLs among 61 *BCR/ABL*^{POS} patients [119]; unfortunately, no details were provided on the immunophenotypic diagnosis of those T-lineage cases, though it is apparent that cCD3 and cCD22 were not tested. The lack of demonstration of these lineage-specific antigens is the most likely reason for misdiagnosed *BCR/ABL*^{POS} T-cell phenotypes. A potential alternative cause is an apparent Philadelphia chromosome translocation by conventional karyotyping that does not yield the ABL-BCR juxtaposition on chromosome 9 [120]. While in the report by Fossa et al. [120] the leukemic phenotype was unequivocally T-lymphoid (cCD3^{POS}), an analogous case was seen in ECOG's E2993 trial, with a (9;22)(q34;q11.2) translocation that by FISH did not result in the *BCR/ABL* fusion but, as in Fossa's case, disrupted the *BCR* gene (ECOG Cytogenetics Committee, personal communication). The E2993 patient, however, expressed immunophenotypic features of pre-B-ALL. In summary, caution is definitely warranted when t(9;22)^{POS} or *BCR/ABL*^{POS} T-ALL cases are published.

t(4;11)(q22;q23)-*KMT2A (former MLL)/AF4*^{pos} B-Lineage ALL

The myeloid/lymphoid or mixed-lineage leukemia (*MLL*) gene has been renamed *KMT2A* gene, located at 11q23. *KMT2A* in humans encodes histone-lysine N-methyltransferase 2A. *KMT2A/AF4*^{POS} ALL is typically found in early infancy

and also represents the most prevalent of the diverse *KMT2A* fusion genes in adult ALL [121–123]. Despite improved complete remission rates with modern treatments, overall survival in adults remains poor due to short remission duration [122–125]. There exists a striking difference in outcome by age group with the worst prognosis found in infants less than 6 months old as well as in adults [124]. *KMT2A/AF4*^{POS} ALL is associated with the immature pro/pre-pre-B-ALL maturation stage, defined by negativity for CD10. As a unique immunophenotypic feature among all ALL phenotypes, *KMT2A/AF4*^{POS} lymphoblasts show a tendency to express the more mature myeloid carbohydrate antigens, $CD65_{(S)}$ and $CD15_{(S)}$, while lacking CD33 and CD13, the pan-myeloid antigens expressed earlier in normal myelopoiesis [93, 123, 125, 126]. Overexpression of immature antigens, CD133 and CD135, further supports the immature state of this subtype [125]. On the other hand, CD33 and/or CD13 are found preferentially in CD10^{pos} early pre-B-ALL. Burmeister et al. [126] demonstrated that lymphoblasts from *KMT2*-rearranged adult ALL patients in general (55% with *KMT2A/AF4*) demonstrated significantly lower expression of CD10, CD33, and CD13 and more frequent expression of $CD65_{(S)}$ and $CD15_{(S)}$ irrespective of B-lineage differentiation stage. This report confirmed the observations from the E2993/UKALLXII trial [125]. Together with the myeloid antigen expression pattern in *BCR/ABL*^{POS}ALL, discussed before, these observations suggest that myeloid antigen expression in B-lineage ALL is determined by the underlying genetic defect rather than B-lymphoid developmental stage.

Cryptic t(12;21)(p13;q22)-*TEL(ETV6)/AML1(RUNX1)*^{POS} B-Lineage ALL

The cryptic (12;21)(p13;q22) translocation that results in the *TEL/AML1* fusion gene is the most common genetic aberration in pediatric ALL (>20%) and carries a favorable prognosis, especially with high-intensity therapy [127, 128]. In adults, this hybrid gene only accounts for <1–3% of ALL [95, 100, 129], thus precluding prognostic predictions. In children, the *TEL/AML1* fusion occurs exclusively in early pre-B-ALL with certain characteristic markers: high intensity of HLA-DR, CD40, and CD10 expression (early pre-B phenotype), commonly CD13^{POS} and/or CD33^{POS}, but CD9^{NEG}, CD20^{NEG}, and low expression of CD45, CD135, and CD86 [130–132]. A striking characteristic feature has recently been added, namely absence of CD11b, an integrin reported to confer poor response to therapy in B-lineage ALL [133]. Given the low incidence of *TEL/AML1*^{POS} ALL in adults, immunophenotypic information in this age group is scarce. The nine *TEL/AML1*^{POS} cases found among ECOG E2993 patients (1.4%) demonstrated the characteristic CD10^{POS} early pre-B phenotype, lacking CD20 and predominantly CD34, and frequently expressing CD33+CD13. However, in comparison to early pre-B-ALL with normal cytogenetics and molecularly negative for *TEL/AML1, BCR/ABL, MLL/AF4, and E2A/PBX1*, there was no difference in CD45, and the CD40 intensity was higher than the median value in normal karyotype controls in only half of the patients (Paietta E, unpublished observation). Although based on small numbers of patients, the most predictive immune profile applicable for both pediatric and adult *TEL/AML1*^{POS} B-lineage ALL, to date, is CD10^{POS}, CD20^{NEG}, CD34^{NEG}, cIgM^{NEG}, frequently CD33+CD13^{POS}, and possibly CD11b^{NEG}.

Inv(7)(p15q34) and t(7;7)(p15;q34)-*TRB@/HOXA*

As a result of two cryptic cytogenetic aberrations, inv(7)(p15q34) or t(7;7)(p15;q34), the TCRB locus (*TRB@*) at 7q34 is juxtaposed to the *HOXA@* at 7p15 (approximately <5% of pediatric and adult T-ALL), leading to transcriptional activation of several *HOXA* genes [134, 135]. The typical antigen expression patterns associated with the *TRB@/HOXA* rearrangement include negativity for CD2 and single expression of CD4, without CD8. It is important to emphasize that among surface antigens, CD7 is the only T-cell antigen universally expressed by T-cell lymphoblasts.

Antigens and Antigen Profiles Associated with Prognostic Gene Expression

FLT3 Mutations in AML

The *FLT3* gene encodes CD135, the FMS-like tyrosine kinase 3 (FLT-3) or receptor-type tyrosine-protein kinase FLT3, a cytokine receptor which belongs to the type 3 receptor tyrosine kinases and is expressed on the surface of normal hematopoietic progenitors and the leukemic blasts of most cases of AML. Upon binding of the FLT3 ligand, the receptor undergoes dimerization and subsequent autophosphorylation of the tyrosine kinase domains, leading to the induction of multiple intracellular signaling pathways involved in cell growth, differentiation, and survival [136]. There are two major clusters of mutations of the FMS-like tyrosine kinase-3 (*FLT3*) gene, those in the juxtamembrane domain that lead to internal tandem duplications (ITD) and point mutations in the tyrosine kinase domain (TKD. Both result in the activation of the transforming potential of *FLT3* [136, 137]. Activating mutations of the *FLT3* gene are the most common known genetic abnormalities in pediatric and adult AML, with *FLT3-ITD* found in approximately 20–35% of adults and 15% in children (ranging from 1.5% in infants to 20% at teenage age), while *FLT3-TKD* are present in about 7% of AML irrespective of age group. With respect to cytogenetic links, distinct differences are seen between *FLT3-ITDs* and *FLT3-TKDs*; *FLT3-ITDs* are particularly frequent in AML with normal cytogenetics, while *FLT3-TKDs* frequently occur in cases with inv(16)-*CBFβ/MYH11*. Both types of mutations are found in a large percentage of t(15;17)-*PML/RARα* APL with minimal impact on outcome, if treated according to modern strategies [138, 139]. In non-APL AML, the suggested negative clinical implications for *FLT3-*

ITD (e.g., increased relapse rate) vary with therapeutic intensities, allelic ratio (mutational burden), and size of ITD, and according to its genetic context [140, 141]. *FLT3-TKDs*, on the other hand, failed to confer unfavorable prognosis [142]; in fact, patients with high-level mutations (more than 25% mutant) experienced improved outcome [143]. The introduction of novel FLT3 inhibitors will certainly change the prognostic outlook of patients with FLT3 gene alterations [144].

The earliest description of a unique immunophenotype for *FLT3-ITD*^{POS} AML suggested a combination of increased CD123, decreased CD38, "mildly" decreased CD117, and loss of CD133 [145]. Subsequently, the same authors described the distinctive, cuplike nuclear morphology in *FLT3-ITD*^{POS} AML (which was discussed before) in association with loss of HLA-DR, CD34, and CD133 [73]. Falini et al. reported this paired absence of CD34/CD133 in *NPM1*-mutated AML in their groundbreaking publication in 2005 [146]. The frequent association of *FLT3-ITD* with *NPM1* mutations [114, 140, 141], therefore, suggests that the lack of CD34 and CD133 in *FLT3-ITD*^{POS} AML may be the result of the concomitant presence of mutated *NPM1*. Gönen et al. [32] reported that CD123 expression, but not CD34 or CD133, was significantly higher in CD25^{POS} AML which demonstrated a characteristic genotype of triple *FLT3-ITD/NPM1/DNMT3A* mutations. Co-association of *FLT3-ITD* with *DNMT3A* and *NPM1* mutations is well established [14, 147]. In mice, concurrent expression of *FLT3-ITD*, mutated *DNMT3A*, and mutated *NPM1* resulted in a fully penetrant leukemic phenotype, whereas any single or paired alleles led to incompletely penetrant disease [148]. Angelini et al. [149] also reported the combined expression of CD123 and CD25 as characteristic for *FLT3-ITD*^{POS} AML and, added CD99 (MIC-), a potential LSC marker, highly expressed in the LSC-enriched CD34^{POS}/CD38^{NEG} fraction compared to the bulk of blasts [150]. CD25^{POS} *FLT3-ITD*^{POS} AML patients on phase 3 trial E1900 [NCT00049517] had a significantly shorter overall survival than CD25^{NEG} FLT3-ITD^{POS} patients, whose survival did not differ from that of the *FLT3*-wild-type cohort [32].

FLT3-ITD^{POS} T-Lineage ALL

The rare subtype of CD117^{POS} T-lineage ALL with activating *FLT3* gene mutations [65, 151] belongs to the few known examples of gene mutations, which are predicted by the presence of a unique antigen expression pattern.

In pediatric ALL, *FLT3-TKDs* are common in cases with *KMT2A/MLL* rearrangements and those with hyperdiploid karyotype, while *FLT3* length mutations are extremely rare; still, high levels of FLT3 protein expression provide a target for therapeutic intervention [136, 140, 152, 153]. While in infant *KMT2A/MLL*-rearranged ALLs the presence of a *FLT3* mutation negatively affected outcome, there was no such effect seen in hyperdiploid cases [152]. *FLT3* mutations are even rarer in adult ALL. The analysis of ECOG study E2993 revealed an incidence of 1.9% *FLT3-ITD* among 511 patients [151]. Of the ten E2993 *FLT3-ITD*^{POS} patients, three belonged to the B- and the remaining seven to the T-cell lineage. No consistent immunophenotypic or cytogenetic features were shared by the three early pre-B patients. On the other hand, all *FLT3-ITD*^{POS} T-ALLs expressed a unique immunophenotype: CD5^{NEG}; surface CD3^{NEG}CD4^{NEG}CD8^{NEG} (triple-negative); positive for CD117, CD34, CD2, CD7, TdT, CD62L, CD13, CD135 (FLT3 protein); and positive for T-cell lineage-specific cCD3 [65]. CD117, the stem cell factor receptor, is much more frequently expressed by leukemic myeloblasts than lymphoblasts [154, 155]. In normal lymphopoiesis, a fraction of CD3/CD4/CD8-triple-negative CD34^{POS} thymocytes express high levels of CD117 [156, 157]. In these thymocytes, expression of CD117 coincides with that of CD135, the FLT3 receptor tyrosine kinase [136, 158]. Occasionally, up to 10% of cCD3^{POS}CD117^{POS}*FLT3-ITD*^{POS} blasts expressed myeloperoxidase, thus representing truly biphenotypic features [65]. This profile fits the most immature category of T-ALL [159–161], resembling earliest thymic precursors with both T- and myeloid lineage potential [162]. In further support of a T-lineage affiliation, FLT3-mutated T-lymphoblasts overexpressed *LYL1* and *LMO2* oncogenes [160]. In pediatric T-ALL, the LYL1-overexpressing, most immature cases demonstrate relative resistance to standard chemotherapy [160]. To the contrary, the *FLT3-ITD*^{POS}CD117^{POS}CD13^{POS} T-cell phenotype in adults does not carry inferior prognosis, though numbers were small [151]. This observation is remarkable given the negative prognostic impact of CD13 expression in CD117^{NEG} adult T-lineage ALL [151]. Neumann et al. [163] subsequently confirmed the CD2^{POS}/CD5^{NEG}/CD13^{POS}/CD33^{NEG} phenotype as a surrogate for mutated *FLT3* in T-cell ALL. They expanded the distinct gene expression pattern (aberrant expression of *IGFBP7*, *WT1*, *GATA3*) and mutational status (absence of *NOTCH1* mutations and a low frequency, 21%, of clonal TCR rearrangements). Despite the low frequency of *FLT3* gene mutations in adult ALL overall, the availability of a variety of FLT3-kinase inhibitors suggests a potential targeted approach in the treatment of this patient cohort. The potential of targeted therapy is the clinically important aspect in this ALL subtype and should supersede any discussions as to whether *FLT3*-mutated T-ALL represents a biphenotypic leukemia or an example for MPAL T/myeloid as defined by the WHO classification [9].

Van Vlierberghe et al. [164] reported that in pediatric T-ALL CD117 mRNA (not protein) expression was not invariably associated with *FLT3* gene mutations in that most pediatric cases expressed CD117 mRNA; this suggests that, similar to what has been reported for myeloperoxidase transcripts [165], CD117 mRNA might undergo posttranscriptional downregulation in ALL. Immunophenotypic profiles of the two pediatric *FLT3-ITD*^{POS} T-ALL patients identified by Van Vlierberghe et al. [164] were surface CD3^{NEG} but CD5^{POS}CD4^{POS} with partial CD13 expression. Furthermore, the authors stated that these blasts carried a "*HOX11L2*

translocation," presumably leading to aberrant HOX11L2 expression. Taken together, these findings suggest arrest at an immature, though already single, CD4^{pos} differentiation level, distinct from the triple-negative stage seen in the adult cases [65]. Remarkably, another pediatric T-ALL case with *FLT3-ITD*, the only one among 59 children tested, identified by Ferrando et al. [160] belonged to the LYL^{POS} cluster, consistent with the findings in the adult cases.

Hoehn et al. concluded that the absence of CD117 expression in T-ALL precluded the presence of *FLT3* mutations, whereas the positive predictive value of CD117 for mutated *FLT3* was only 35% [166]. CD117^{pos} T-ALL lacking *FLT3* gene mutations were found in 2% of patients on E2993 [93]. Aside from CD117, their immunophenotype differed from that in *FLT3-ITD*^{POS} cases subtly but distinctly: the T-lymphoblasts expressed CD5, occasionally were single CD8^{POS}, frequently expressed CD33 instead of CD13, often were CD56^{POS}, and commonly lacked CD34 and CD62L, both markers of immaturity. A close association between CD117 and CD13 expression in surface CD3^{NEG} T-ALL has been previously reported [167]. Thus, while CD117 expression in adult T-lineage ALL might be considered a surrogate marker for *FLT3* gene mutations, this concept only applies for T-lymphoblasts arrested at the most immature stage of differentiation.

CD117^{POS}/*FLT3-ITD*^{POS} T-ALL represents a subtype of early T-cell precursor (ETP) leukemia, which, particularly in adults, has been demonstrated to be widely heterogeneous both in immunophenotype and genetic alterations [168–172].

Early T-cell Precursor (ETP) Leukemia

ETP ALL was initially characterized solely based on its immunophenotypic features, CD1a^{NEG}CD8^{NEG}CD5^{WEAK} with myeloid (e.g., CD33, CD13, CD11b, or CD65), and stem cell markers (e.g., CD34 and CD117), suggesting that this leukemia subtype may be part of a spectrum called stem-cell-like leukemias [173]. The name ETP was given to these leukemias because their immunophenotype appeared closely related to that of early T-cell precursors which retain their multilineage differentiation potential [162, 174, 175]. ETP-T-ALL accounts for approximately 10–15% of pediatric T-ALL [170] but has a much higher prevalence of 50% in adult T-ALL in some studies [168] but not others [176]. Though early data suggested that this subtype of T-ALL carried a very poor prognosis [173, 176–178], more recent results are encouraging [179–181].

Genetic alterations fueling ETP-ALL suggest that this leukemia has more in common with AML than with other types of ALL [168–170, 172, 182]. ETP-ALLs contain mutations in myeloid-specific oncogenes and tumor-suppressor genes, including *IDH1, IDH2, DNMT3A, FLT3, GATA3, ETV6*, and *NRAS.* On the other hand, ETP-ALLs showed a low incidence of alterations commonly seen in T-ALL, such as activating mutations in the *IL7R* gene and *NOTCH1*, while approximately 25% demonstrated co-occurrence of myeloid and T-typical mutations. In an analysis of ECOG trial E2993, Van Vlierberghe et al. [33] found that in these ETP-ALLs, mutations in *IDH1/IDH2* and *DNMT3A* were associated with poor prognosis. As much as ETP-ALL represents a grey zone with respect to its genetic affilations, it presents a challenge to us flow cytometrists. How many cases of ETP-ALL are indeed enrolled on AML treatment protocol because they were diagnosed as AML based on antigen profile? It has been suggested that ETP-ALL may benefit from myeloid therapy, though we will never get the answer to this if we do not establish a clear guideline for the immunophenotypic diagnosis of this subtype. I would like to suggest the following: any case with expression of surface CD7, CD2, and intracytoplasmic CD3; absence or weak surface expression of CD5; lack of surface CD3; expression of CD34, CD13, and/or CD33; and whether or not CD117 or myeloperoxidase are found should be considered ETP-ALL.

Whether or not an ETP ALL patient should be treated as ALL or AML is currently unclear. ALL COG study AALL0434 (NCT00408005) suggested that there was no difference in outcome between ETP, near-ETP, and not-ETP patients, whereby the distinction of near-ETP was based on elevated CD5 expression in otherwise ETP patients [179]. Induction failure, based on >25% blasts by morphology at the end of induction, was significantly higher in ETP and near-ETP patients. Day 29 bone marrow MRD levels of >0.01% were present in 81.4%, 64.8%, and 30.5% of ETP, near-ETP, and not-ETP patients. Day 29 MRD levels were used for risk stratification, whereby intermediate- (MRD <1%) and high-risk patients (MRD >1%) were randomized to receive or not receive nelarabine, delayed intensification, and maintenance. With this MRD-targeted approach, ETP patients had outcome identical to not-ETP patients.

However, there is the caveat when interpreting this study in that the immunophenotypic analysis for ETP-ALL status on AALL0434 was not completely assessed for all patients [183]. But can we solely rely on immunophenotypic features in defining ETP-ALL? Retrospective analyses of T-ALL samples with ETP-gene signature have not consistently been found to express the ETP-ALL immunophenotype [184, 185]. But what is the best way to identify ETP-ALL, or more importantly ETP-ALL with poor outcome? [186]. Bond et al. [187] reported that deregulation of homeobox (*HOX*) factor A was highly predictive of phenotypic immaturity, glucocorticoid resistance, and early treatment failure in T-ALL. However, while the entire *HOX*-activated group did not have an inferior outcome, poor prognosis was restricted to those patients who also had an ETP-like immunophenotype. Vice versa, ETP-ALL patients without *HOXA*-activation fared equally well as non-ETP patients. A subset analysis of AALL0434 [183], which included 10 patients who had failed induction therapy, corroborated the notion that *HOXA*-activated ETP-ALL, frequently acquired in *MLL (KMT2A)*-rearranged cases, is

associated with induction failure, refractory disease, and relapse. Unfortunately, the detection of *HOX*-activated ETP-ALL carries its own pitfalls.

To date, alternative treatment options for ETP-ALL are limited. One could foresee, however, that a precision medicine approach be suggested in the near future, e.g., using a histone methyltransferase inhibitor to target *HOX* gene expression [188]. A phase 1 trial using EPZ-5676, an inhibitor of the DOT1-like histone H3 methyltransferase, in relapsed/refractory leukemia with *KMT2A* rearrangements has recently been completed (NCT02141828). So, when the time comes and a precise definition of ETP-ALL is important for targeted therapy, the burden will be in part on the flow cytometrist, the first one who could raise a suspicion of ETP-ALL in a new case of leukemia.

Association of T-ALL Differentiation Stages with Gene Expression

The changes brought about in the classification of T-cell ALL over the last 15 years have been dramatic, considering that where we started from was a mere distinction between CD2^{POS} and CD2^{NEG} T-ALL. In 2002, Ferrando et al. published gene expression signatures in pediatric T-ALLs which correlated with leukemic arrest at specific stages of normal thymocyte differentiation [160]. This elegant model was based on the unique, aberrant expression of oncogenic transcription factors in T-ALLs as a result of chromosomal translocations which typically juxtapose strong promoter and enhancer elements associated with *TCR* genes to a finite number of T-cell transcription factors. This T-ALL classification distinguished the early immature double-negative CD4^{NEG}CD8^{NEG}surface CD3^{NEG} stage with overexpression of transcription factor *LYL1* and *LMO2*, which corresponds to ETP-ALL with a transcriptional program related to hematopietic stem cells and specific genetic aberrations, as previously discussed. In contrast, the early cortical stage is characteristically CD1a^{POS} CD4^{POS}CD8^{POS}CD3^{WEAK}CD10^{POS} and frequently associated with cytogenetic translocations inducing activation of the *TLX1/HOX11* family of homeobox transcription factor oncogenes. Finally, the late cortical CD4^{POS}CD8^{POS}CD3^{HIGH} CD2^{POS}TCR^{POS} stage shows expression of the TAL1 transcription factor oncogenes. All of these stages precede that of mature single positive with either surface CD4 or CD8 expression. Constitutive expression of *TLX1*/*HOX11* has been associated with favorable prognosis in pediatric and adult T-lineage ALL [160, 189–191]. In the analysis of a large series of adult T-ALL enrolled on E2993 [151] all cases were tested for cCD3 and myeloperoxidase. Aside from cCD3, only surface CD7 was universally present. Attempts to stratify patients according to their maturation stage based on expression of CD3, CD2, or CD34, as suggested by the WHO classification system [9], failed to provide prognostic subsets. While the myeloid antigens CD13 and/or CD33 were found in approximately half of the patients, the carbohydrate antigens, CD65$_{(S)}$ and CD15$_{(S)}$, were detected in a minority of cases. The entire patient cohort could be divided into two prognostic subsets based on CD1a and CD13 expression: CD1a^{POS} T-ALL predominantly lacked CD34, CD13/CD33, and CD11b. These T-lymphoblasts, representative of intrathymic differentiation, frequently expressed the CD62L selectin and CD10, and were double positive for CD4 and CD8. CD1a^{POS} T-ALL did exceedingly well with an overall survival at 5 years of 64% (95% CI 48–80%). The other subtype with clinical significance was CD13^{POS} T-ALL. While the complete remission rate was similar to that of CD13^{NEG} patients, overall survival at 5 years was significantly shorter than for CD13^{NEG} patients ($p = 0.0005$). CD13^{POS} or double-CD13/CD33^{POS} T-lymphoblasts preferentially expressed CD34 and CD11b and showed a tendency to be negative for CD4, CD8, surface CD3, or CD2. CD117^{POS} T-ALL was diagnosed in 18% of patients. Only 6/107 patients with unequivocal staining for cCD3 and negativity for cCD22 expressed CD19, occasionally in combination with CD10. Of potential interest, merely 17% of these patients survived for 5 years. In a follow-up analysis, Van Vlierberghe et al. [33] performed microarray gene expression profiling of these immunophenotypically characterized patients and described two clusters. The first corresponded to early immature leukemia (ETP) with a gene expression signature related to that of hematopoietic stem cells and myeloid progenitors. In contrast, the second cluster contained leukemias with gene expression signatures of cortical and mature thymocytes. Overall, the immature cohort was associated with poor prognosis and reduced overall survival compared with cortical/mature T-ALL ($p = 0.0112$). Notably, the poor prognostic effect of CD13 expression was restricted to the cortical/mature T-ALL, thus identifying a high-risk subgroup in an otherwise good prognosis subtype.

NPM1-Mutated AML

The *NPM1*-mutated AML subtype is characterized by high frequency of *FLT3-ITD*, association with normal karyotype, negativity for both CD34 and CD133, and good prognosis, especially in the absence of *FLT3ITD* [75]. Other reports have suggested additions and/or modifications to this phenotype. Nomdedeu et al. [192] concluded that the majority of cases showed high expression of CD33, CD13, HLA-DR, and CD123, and myelomonocytic traits in the morphologic appearance. On the other hand, Kern et al. [193] suggested high expression of myeloperoxidase and CD33 but lack of CD13, CD65, CD15, HLA-DR, and CD34, combined with minimal differentiation in 20 cases of *NPM1*-mutated AML. The rare immunophwnotypic subset of *NPM1*-mutated/*FLT3-ITD*^{POS} normal karyotype AML with dual-CD7/CD19 expression [58] presents with surprisingly high CD34 expression, higher than

found in *NPM1*-mutated/*FLT3-ITD*^{POS}AML without this antigen profile or *NPM1*-mutated AML without *FLT3-ITD*. An informal analysis of the incidence of CD34^{POS} myeloblasts in 105 cases of *NPM1*-mutated AMLs suggested greater variability than previously appreciated with the percentage of CD34^{POS} blasts ranging from 0 to 99% (Paietta et al., unpublished observation). Taken together, these reports suggest that the immuneprofile of *NPM1*-mutated AML is not as homogenous as previously thought. Along the same line, LICs in *NPM1*-mutated AML have been located both in CD34^{POS} and CD34^{NEG} stem cell fractions [7]. Martelli et al. [194] reported that CD34^{POS} cells from *NPM1*-mutated cases harbored aberrant nucleophospmin expression in the cytoplasm. The *NPM1*-mutated gene and/or protein was also confirmed in the CD34^{POS} subfraction which expressed a stem cell-like phenotype, CD34^{POS}, CD38^{NEG}, CD123^{POS}, CD33^{POS}, and CD90^{NEG}. When transplanted into immunecompromised mice, these CD34^{POS} cells generated a leukemia indistinguishable from the original disease with *NPM1*-mutated CD34^{NEG} myeloblasts, suggesting that the CD34^{POS} cell fraction in *NPM1*-mutated leukemia contains cells with LIC properties.

BCR/ABL1-like or Ph-like B-lineage ALL

Just like T-lineage ALL, B-lineage ALL has undergone a major reclassification with strong prognostic and therapeutic implications. FAB classification of ALL has become obsolete [9, 47]. The standard subclassification of B-lineage ALL based on maturation stages lacks prognostic significance with modern chemotherapy [195]. The associations between level of maturation and major genetic subtype in B-lineage ALL have been discussed earlier for the historic genetic defects, *BCR/ABL, MLL/AF4,* and *TEL/AML1*. *E2A/PBX1* (now called *TCF3/PBX1*) transcripts, derived from the (1;19)(q23;p13) translocation, are more commonly associated with more mature pre-B ALL, characterized by the presence of intracytoplasmic IgM heavy chains. This subtype was previously considered as high risk, but is no longer included into the risk stratification as a result of modern treatment regimens [196]. It is difficult to distinguish mature B-ALL from the leukemic phase of Burkitt's lymphoma, as they share immunophenotypic features, clinical presentation, and cytogenetic abnormalities. In the prototype (8;14)(q24;q32) translocation, the c-myc proto-oncogene is translocated from chromosome 8 onto chromosome 14 and brought under the transcriptional control of the immunoglobulin heavy-chain locus. The variant translocations, t(2;8)(p12;q24) and t(8;22)(q24;q11), result in the positioning of portions of the κ and λ light chains, respectively, under the control of myc.

The revolution in B-lineage ALL classification started with the finding of alterations of the lymphoid transcription factor gene *IKZF1* (IKAROS) in B-ALL [170, 182]. *IKZF1* deletions and somatic mutations are the hallmark of *BCR/ABL*^{POS} ALL and confer poor prognosis in this disease [197–199]. Recently, Iacobucci et al. described surface expression of CD90 as a marker for *IKZF1* alterations in *BCR/ABL*^{POS} ALL [200]. CD90/Thy1 is a marker of hematopoietic stem cells [201]. In combination with surface CD25 expression [17, 31, 101], CD90 analysis affords the flow cytometrist to reliably predict the presence of *BCR/ABL* transcripts in B-ALL. As we discuss below, it is essential to exclude CRLF2-overexpressing *BCR/ABL1*-like ALL, which can present with both CD90 and CD25 expression [Paietta E, unpublished observation]. Noteworthy, however, neither CD25 nor CD90 will be expressed in a small percentage of *BCR/ABL*^{POS} patients, those with superior outcome [31]. The same is true for other immunophenotypic features published as associated with *BCR/ABL*^{POS} ALL, such as high CD34 and low CD38 expression and dual expression of CD13 and CD33 [98–100]. While in a case with B-lineage ALL, an immune profile with expression of both CD25 and CD90 and absence of CRLF2 expression, is highly predictive for the presence of *BCR/ABL* transcripts, I always advise to run the *BCR/ABL* PCR assay to confirm the immunophenotypic findings, if at all possible.

IKZF1 can also be deleted in *BCR/ABL*^{NEG} B-ALL, likewise associated with inferior outcome [199, 202]. Many of these *BCR/ABL*^{NEG}, *IKZF1*-mutated cases exhibit a gene expression profile similar to that of *BCR/ABL*^{POS} ALL with novel kinase-activating mutations (e.g., *JAK2*, *ABL1, PDGFRB, CSF1R*) or genetic alterations in signaling pathways (e.g., *EPOR, IL7R, SH2B3*), giving birth to the novel subtype of *BCR/ABL1*-like ALL (Ph-like ALL), which is incorporated into recent WHO revisions as a provisional category [13]. With continuously extended sequencing, the full repertoire of kinase-activating lesions and other rearrangements in Ph-like ALL awaits to be identified. Ph-like ALL has been characterized independently by two groups [199, 203]. Characteristically, these patients show high levels of MRD after induction and overall poor outcome. MRD-guided, risk-directed therapy, including allogeneic transplantation, may be able to abolish the adverse prognostic significance of Ph-like ALL, at least in children [204]. However, a recent report from German Multicenter ALL Working Group (GMALL) trials 06/99 and 07/03 suggested that adult Ph-like ALL patients, although they achieve complete hematologic remission (CR), relapse very rapidly after induction therapy, thus precluding stem cell transplantation in first CR, as had been stipulated in the protocols [205]. Fortunately, there are exciting genomic and preclinical findings which suggest that many patients with Ph-like ALL could be successfully treated with currently available lesion-specific kinase inhibitors [170, 182, 206, 207]. Tasian et al. [207] demonstrated the need for combinatorial treatment strategies which hit or ablate an entire multifaceted pathway affected in these patients using patient-derived xenograft models. About 15% of children present with Ph-like ALL and, just like with *BCR/ABL*^{POS} ALL, the incidence of Ph-like

ALL showed increase with age in a large study across various National Cancer Treatment Network groups in the USA [19]. In contrast, GMALL investigators reported the peak of Ph-like ALL among adolescents and young adults and a dramatic decrease in the incidence of Ph-like ALL with more advanced age [208].

Of utmost relevance to flow cytometrists, approximately 50% of Ph-like ALL patients harbor a rearrangement of *CRLF2* (cytokine receptor-like factor 2 or thymic stromal lymphopoietin receptor), either as an *IGH@-CRLF2* rearrangement or a focal deletion proximal to *CRLF2* that results in expression of the *P2RY8-CRLF2* fusion, both causing overexpression of *CRLF2* on the surface of the leukemic cells [209, 210]. Half of *CRLF2*-rearranged cases harbor concomitant activating *JAK1/2* mutations [209–211], and *CRLF2*-rearranged cases exhibit constitutively active JAK-STAT signaling and activation of the P13K/mTOR pathway making them sensitive to JAK mTOR inhibitors [170]. It is important to realize that CRLF2 overexpression occurs only in B-ALL cases which lack rearrangements of *TEL, MLL (KMT2A), TCF3*, and *BCR/ABL*. Rare cases of *CRLF2* overexpressing ALL patients without the molecular features of the Ph-like phenotype have been seen predominantly in children (Roberts K, personal communication). There are inconsistent data on the prognosis of *CRLF2*-rearranged Ph-like ALL cases [30, 212–214]. Whatever the prognostic power of CRLF2 overexpression, these patients may be treated with biologic treatment strategies and spared a stem cell transplant. Thus, the recognition of these cases is important and it is possible using a monoclonal antibody to CRLF2. This antibody must be included into any antibody panel used routinely by clinical laboratories in the evaluation of B-cell leukemias.

Antigens and Therapy

Acute leukemias provide a suitable testing environment for therapy with antibodies, which represent drugs with a clearly defined target, the specific antigen. There are several aspects to antigens and antibodies and their usefulness in therapy. Selected expression of antigens by leukemic cells is a first prerequisite. In the majority of cases, antibodies to antigens expressed by the leukemic cells are administered in in vivo treatment. Recently, adoptive immunotherapy with autologous chimeric antigen receptor-engineered T-cells (CAR-T-cells) has become a major focus of leukemia therapy, particularly in ALL. Antibodies are being incorporated into first-line therapies, to eliminate MRD, or during salvage attempts in relapsed/refractory patients [215–221]. Undoubtedly, with the documented benefits of antibody therapy, particularly in ALL, and ongoing optimization of CAR-T-cell therapy, antigen-specific immunotherapy strongly contributes to targeted or personalized therapy, thereby changing the paradigm of treatment of the acute leukemias.

Treatment with Monoclonal Antibodies

In vivo therapy with monoclonal antibodies aims at a specific antigen, which otherwise may be a part of a very diverse immunophenotype. Targeted delivery of these agents based on recognition of their relevant antigen on the surface of the leukemic cells improves efficacy and, optimally, minimizes off-target toxicity, provided that antigen distribution in normal tissues is well known (cytotoxic effects may be more widespread than intended). While there is a plethora of potential antibody targets on leukemic cells, only a select few have emerged as clinically successful. Reasons are multiple and include specificity of antigen expression on target tissue (i.e., the leukemic cell) and the question whether the target antigen is expressed by the LIC in individual patients. Monoclonal antibodies can be used naked, in unconjugated form (e.g., rituximab) and exert their effect via various mechanisms, including antibody-dependent or complement-dependent cytotoxicity or induction of apoptosis. Alternatively, conjugated antibodies are used, whereby they function as vehicles carrying immunotoxins or chemotherapeutic agents (e.g., calicheamicin-conjugated CD33 antibody), which requires knowledge that the target is internalized upon binding of the antibody [222]. Radioimmunotherapy, which adds radiobiological cytotoxicity to immunologic cytotoxicity by using monoclonal antibodies (e.g., CD45, CD33, CD22) conjugated to radioactive molecules, has been tested in AML or ALL, predominantly for its efficacy in intensifying the antileukemic effects of conditioning regimens prior to various types of stem cell transplantation [223]. T-cell engaging bi-specific antibodies use the host's cytotoxic T-cells to eliminate leukemic cells [215, 216, 219, 224].

CD20 Antibodies in B-ALL

In B-lineage ALL, CD20 expression depends on the maturation stage of malignant B-lymphoblasts with CD10^{NEG} pro-B/pre-pre-B lymphoblasts generally lacking CD2 [125], while CD20 expression by CD10^{POS} early pre-B-ALL blasts is variable [226]. But even when expressed, antigen density is usually quite low [110, 225]. Importantly, both the percentage of CD20^{POS} blasts and the intensity of staining are greatly affected by the choice of fluorochrome used in CD20 antibody binding in that CD20 antibody conjugated to fluorescein isothiocyanate (FITC) will yield much lower numbers than CD20 antibody conjugated to phycoerythrin (PE). This important information is not paid attention to in publications

regarding the prognosis of CD20 expression in B-lineage ALL or the result of rituximab treatment [215, 216, 227]. Since the report of the trial, the Group for Research on Adult Acute Lymphoblastic Leukemia 2005 (GRAALL 2005), on rituximab in *BCR/ABL*^{NEG} CD20^{POS} B-lineage ALL at the plenary session of the American Society of Hematology meeting in 2015 and recently published in the New England Journal of Medicine [228], the addition of rituximab to the treatment of ALL has been accepted as standard of care. In this seminal trial, patients with <20% CD20^{POS} blasts were excluded and only those with at least 20% CD20^{POS} blasts were assigned to rituximab treatment or not. In this setting, and giving rituximab to all treatment phases, the rituximab group showed improved event-free survival and a reduction in the cumulative incidence of relapse when compared to the control group. Of note, CR rates were identical and MRD levels post-induction were comparable in the two groups suggesting that rituximab addition to induction therapy did not improve the quality of response. This is in contrast to the results of the GMALL Study 07/2003 [229] which also showed a comparable morphologic CR rate between patients treated with rituximab and those not receiving the antibody but in which the MRD load, measured by PCR, reduced significantly faster in the rituximab group. Interestingly, Thomas et al. [230] found that the benefit of rituximab addition to hyperCVAD therapy did not extent to patients ≥60 years old, suggesting that the high-risk features (e.g., unfavorable cytogenetics) more often encountered in the older patient population cannot be overcome with rituximab. Despite an upper age limit of 59 years, Maury et al. [228] also observed that older age remained significantly associated with shorter event-free survival in the rituximab group.

Unfortunately, in all of these studies, the definition of CD20 positivity was based on the arbitrary cutoff point of 20% CD20^{POS} blasts. There is no biologic basis for using a 20% cutoff level; this custom simply refers to a time when blast cells were not gated based on CD45 intensity and other means and the 20% threshold was used to account for contaminating normal cells [231]. Second, the choice of fluorochrome used in the CD20 conjugate is essential information. It is the common experience of flow cytometrists that CD20-FITC will yield fewer CD20^{POS} blasts than CD20-PE. This is particularly obvious in chronic lymphocytic leukemia (CLL) where the leukemic B-cells express CD20 at significantly lower density than normal B-lymphocytes. As a result CD20-FITC staining on B-CLL cells is frequently too weak for accurate quantification [232]. These comments do not advise against the use of CD20 in B-lineage ALL, they merely emphasize the importance of cautiously selecting fluorochromes and knowing the consequences of the particular selection. However, in clinical trials which use a certain threshold of antigen expression to leukemic cells to trigger the use of in vivo therapy with the relevant antibody, it is imperative to declare which fluorochrome was, is, or should be used to establish that threshold of antibody binding. Ideally, a trial should be designed to give rituxan to all patients with B-lineage ALL, irrespective of their CD20 expression which should be measured using various CD20 conjugates simultaneously; subsequently, a retrospective response-driven analysis would define the prognostically significant CD20 expression level with the various CD20 fluorochromes. UKALL14 (NCT01085617), conducted by the UK NCRI Adult ALL group, is a randomized trial which adds rituximab to the treatment of B-lineage ALL irrespective of the level of CD20 expression and the correlation of response with CD20 expression will be of great interest. There is evidence that the effectiveness of rituximab correlates with the level of CD20 expression by target tissues, at least in chronic B-cell leukemias [233]. In fact, Maury et al. [228] observed a more pronounced effect of rituximab in patients with higher CD20 expression. Dworzak et al. [225] found that a cutoff value for CD20 positivity at diagnosis of 20% was insufficient to predict rituximab-induced complement cytolysis of pediatric B-lymphoblasts in vitro. These investigators also reported upregulation of CD20 expression in a significant portion of patients by glucocorticoids as early as on day 8 of therapy. Stimulation of CD20 expression has also been reported with histone deacetylase inhibitors (e.g., valproic acid), demethylating agents (e.g., azacytidine), and farnesyltransferase inhibitors [234]. On the other hand, other therapies have been found to down-modulate CD20 expression (e.g., lenalidomide, bortezomib) [234]. Rituximab binding itself leads to the depletion of CD20-expressing B-cells which, just as up- and downregulation of the molecule, occurs through a variety of mechanisms [234]. In addition to surface CD20 expression, other factors may influence the clinical benefits of rituximab treatment and contribute to antibody resistance [235]. All of these considerations further question the use of arbitrary or any cutoff points of CD20^{POS} B-lymphoblasts for defining CD20 positivity, at least with respect to the decision to add rituximab to a treatment regimen. Biologic differences between patients may also account for the inconsistent data on the prognostic significance of CD20 expression in B-lineage ALL [236–240]. Similar to early findings in pediatric B-lineage ALL [241], our analysis of the adult E2993 trial found progressively higher intensity of CD20 staining, but not the percentage of CD20-expressing B-lymphoblasts, to be associated with increasingly reduced 5-year event-free survival [Paietta E, unpublished].

Second-generation CD20 antibodies, such as obinutuzumab [242], which act through mechanisms of action different from that of rituximab, have shown activity in rituximab-resistant patients [215, 216, 227]. Of potential importance with all anti-CD20 antibodies is the occurrence of soluble CD20 antigen, since high levels of circulating soluble antigens reduce the bioavailability and thus efficacy of administered antibody [243].

CD22 Antibodies in B-ALL

In contrast to CD20, CD22 is equally expressed across all maturation stages of B-lineage ALL [244, 245]. CD22 belongs to sialic-acid-binding immunoglobulin-like lectins (siglecs), which are endocytic receptors. As a result, cytotoxic agents conjugated to a CD22-antibody are immediately internalized without shedding into the extracellular environment [245]. Another advantage is that, when compared to CD20 antibodies, CD22 expression is maintained in patients treated with CD22-targeted therapy and levels of soluble CD22 are low [245]. Thus, CD22 is an ideal target for antibody-based therapy in B-cell malignancies.

Humanized CD22 antibody, epratuzumab, has been used both unconjugated and radiolabeled form. It has a unique mechanism of action in that it modulates B-cell activation and signaling rather than eliciting direct cytotoxicity [246, 247]. Re-induction chemoimmunotherapy with epratuzumab in relapsed ALL in COG trial ADVL04P2 (NCT00098839) did not improve the clinical response when compared to historical controls, but there was a trend towards improved MRD response when epratuzumab was administered more frequently [248]. Various trials in relapsed ALL are currently ongoing (www.clinicaltrials.gov).

Inotuzumab ozogamicin (INO) is a humanized CD22 antibody attached to a toxic natural calicheamicin, a potent DNA-binding cytotoxic antibiotic via an acid-labile linker. INO has shown encouraging results in relapsed/refractory B-lineage ALL [249, 250].

CD33 Monoclonal Antibodies

CD33 is a myeloid differentiation antigen which is expressed by the majority of blasts in AML, though with variable intensities [251, 252]. Unconjugated CD33 antibodies (e.g., lintuzumab) have shown disappointing activity (rev in [252]). However, though an antigen with endocytic properties, internalization is slow, making CD33 a challenging target. Several approaches to address this problem exist [252]. Nonetheless, I will focus on gemtuzumab ozogamicin (GO) as a humanized CD33 antibody, linked to a calicheamicin derivative, given its controversial history and biologic interests. In 2000, GO was granted accelerated approval by the US Food and Drug Administration for use in relapsed AML patients ≥60 years of age. GO was voluntarily withdrawn from the US marker in 2010 due to concerns of lack of efficacy in the presence of enhanced toxicity, which emerged during an interim analysis of S0106 [NCT00085709], a SWOG-led phase 3 trial in data untreated AML [253]. While there appears to be no beneficial effect of GO on the achievement of CR, there are compelling data suggesting that GO improves survival in cytogenetically favorable (CBF leukemias) and intermediate-risk leukemias [253–255], suggesting that reapproval of GO for risk-defined subsets of AML patients, as well as APL, may be warranted [256, 257]. Various additional biologic factors affect GO efficacy, such as the presence and activity of spleen tyrosine kinase (Syk) [258], CD33 expression levels [251, 259, 260], CD33 single-nucleotide polymorphisms [261], drug efflux, toxin release, and others (rev in [262]). Increasing Syk expression, e.g., with 5-azacytidine, can indirectly enhance CD33 antibody toxicity. Along the same line, the engagement of the SHP-1 tyrosine phosphatase in Syk regulation could be pharmacologically exploited by combining CD33 antibody with cytosine arabinoside and idarubicin [222]. There are case reports on the potential efficacy of GO in CD33^{POS} ALL, but no controlled studies have been conducted.

Of note, in a recent reanalysis of trial ALFA-0701 (NCT00927498), when the level of CD33 expression by myeloblasts was correlated with the outcome with GO, the cutoff of interest was found to be 70% CD33^{POS} blasts, in that a beneficial effect of GO was only observed in this response-defined high-CD33^{+} group [260]. Once again, this data strongly supports the view that cutoff points for defining the clinically relevant levels of antigen expression in immunotherapy can only be defined after the fact when response data are available. Whether or not such defined cutoff levels will hold true for other patient populations in future trials remains to be proven.

CD52 Antibody

CD52 is expressed on virtually all lymphocytes, monocytes, and natural killer cells. In ALL, the density of CD52 antigen expression varies by lymphoid lineage, with T-lymphoblasts demonstrating significantly lower amounts of CD52 on the cell surface [110]. Data with alemtuzumab in ALL are scarce, but suggestive of antileukemic activity [263, 264]. Gorin et al. [265] tested alemtuzumab together with G-CSF (to boost antibody-dependent cytotoxicity mediated by neutrophils) in refractory and heavily pretreated relapsed ALL (NCT00773149) and saw some responses though of short duration. ECOG performed a phase 2 trial of chemotherapy combined with alemtuzumab in relapsed/refractory ALL (NCT00262925); results have not yet been published.

CD25 Antibody

CD25, the α-chain of the interleukin 2 receptor, is a powerful negative prognostic indicator both in ALL [31] and AML [32]. Until recently, the mechanisms of action of CD25 in either of these diseases have been unknown, given that CD25 does not work as part of the interleukin-2 receptor on either

lymphoblasts or myeloblasts [114]. CD25 is a transmembrane protein with a short, 13-amino acid-long cytoplasmic tail. Recent work by the Müschen group [114] has demonstrated that CD25 is a feedback regulator of the B-cell receptor (BCR) and a biomarker for disease driven by oncogenic BCR mimics. The tail of CD25 contains PKCδ substrate motifs. As a result, BCR signaling induces CD25 expression by PKCδ phosphorylation of the CD25 cytoplasmic tail which in turn leads to the membrane recruitment of phosphatases and robust oncogenic signaling (Fig. 15.2). Pharmacological activation of PKCδ, e.g., with the PKCδ agonist, diterpene ester ingenol-3-angelate (PEP005), induces rapid CD25 membrane translocation in patient-derived ALL cells. CD25 thereby mediates negative feedback signaling to stabilize oncogenic tyrosine kinase signaling and mediates drug resistance. Combinational treatment of CD25^{POS} leukemic B-lymphoblasts with PEP005- and CD25-directed immunotoxins may be a useful new approach to overcome drug resistance, for instance, in *BCR/ABL^{POS}* ALL. ADCT-301 is a human monoclonal antibody targeting CD25 linked with a pyrrolobenzodiazepine dimer toxin (CD25-ADC). CD25-ADC overcomes drug resistance in vivo when mice engrafted with CD25^{POS} human leukemic lymphoblasts are treated with this antibody conjugate. Based on this data, a clinical trial has been initiated using CD25-ADC in relapsed/refractory CD25-expressing ALL or AML (NCT02588092).

Bi-specific Antibodies

Bi-specific antibodies target leukemia-associated antigens while simultaneously activating antigens on cytotoxic effector cells or may otherwise potentiate the signaling events that will eventually lead to inhibition of leukemia cell growth. Bi-specific T-cell engagers (BiTE) form a new class of constructed antibodies, which direct the body's cytotoxic T-cells against tumor cells. One BiTE representative is blinatumomab (MT103), consisting of four immunoglobulin variable domains, of which two form the binding site for CD3 on the surface of T-cells, and the other two form the binding site for CD19 on the surface of the targeted B-cells [266]. Blinatumomab enables a patient's T-cells to recognize malignant B-lymphocytes and works by temporarily bridging these two cell types and activating the T-cells to exert cytotoxic activity against the malignant B-cells, causing redirected cell lysis, while nonspecific collateral killing effects have not been observed [267]. BiTE antibodies activate T-cells only in the presence of target cells, and nonspecific collateral killing effects have not been observed.

Blinatumomab [268] is currently indicated for *BCR/ABL^{NEG}* relapsed/refractory B-lineage ALL based on a single-arm study (NCT01209286) conducted by Topp et al. [269]. The US National Cancer Treatment Network leukemia groups are currently conducting a randomized phase 3 trial whereby patients with *BCR/ABL^{NEG}* B-ALL are randomized to blinatumomab or not at the time of complete hematologic remission based on MRD status (E1910/NCT02003222). The severe neurotoxicity seen in some blinatumomab-treated patients is not correlated with active CNS disease. Instead, variable expression of CD19 in neurons may make neurons susceptible to the inflammatory response from CD19-engaging T-cells [268]. Loss of the CD19 antigen, though rare, may contribute to resistance to blinatumomab as does extramedullary disease which probably reflects disease in sanctuary sites not penetrated by blinatumomab [268]. Duell et al. [270] recently reported that the frequency of CD4/CD25/FOXP3-expressing regulatory T-cells (Tregs), which inhibit T-cell proliferation, prior to blinatumomab administration, was able to predict blinatumomab responders. The authors also reported upregulation of CD69, CD25, and programmed death-1 (PD-1), an immune checkpoint receptor, by Tregs when incubated with blinatumomab and primary ALL blasts, suggesting a potential role of immune-inhibiting molecules, such as PD-1, in resistance to blinatumomab.

CD33/CD3-bi-specific T-cell-engaging antibody AMG 330 has shown promising ex vivo activity (rev in [271]) and has recently entered into a phase 1 trial in relapsed/refractory AML (NCT02520427). A dual-affinity-retargeting (DART) molecule generated from antibodies to CD3 and CD123 was designed to redirect T-cells against leukemic myeloblasts (also referred to as MGD006/S80880) [272]. CD123, the interleukin 3 receptor α, is highly expressed on the surface of AML blasts. Based on promising preclinical data, this antibody has entered into a phase 1 study in relapsed/refractory AML and high-risk MDS (NCT02152956).

Chimeric Antigen Receptor (CAR) T-Cells

CARs involve genetic engineering of a patient's own cells. In these molecules, an extracellular single-chain antigen recognition domain, usually derived from the variable fragment of a specific monoclonal antibody, such as CD19 (CART-19), is linked to the intracellular signaling domains of the T-cell receptor (TCR) [273]. Unlike the TCR, immunoglobulins can bind any antigen they encounter, independent of antigen processing and major histocompatibility complex. First-generation CARs, linked only to the intracellular CD3ζ signaling domain, were unable to adequately activate T-cells in vivo, and had limited clinical activity. Second-generation CARs contain costimulatory intracellular domains, such as CD28 or CD137 (4-1BB) in addition to CD3ζ [221, 274]. Third-generation CAR-T-cells which use two tandem costimulatory domains have also been reported [275]. Further improvement in efficacy and persistence of CAR-T-

cells may derive from modifying these cells to express the proinflammatory cytokine, interleukin-12, or costimulatory ligands, 4-1BB and CD40L, thus "armoring" CAR-T-cells [276]. CART-19 cells have produced promising results in various B-cell malignancies, including B-ALL [221, 277–280].

Leukemia Escape After CD19-Targeted Therapies

Fascinating data are emerging concerning the potential adaptation of leukemia cells to CD19-directed immunotherapies, both with CD19/CD3 BiTE and CART-19. Relapses with CD19^{NEG} blasts have been seen both after blinatumomab and CART-19 treatment (rev in [281]). This experience demonstrates the potent selective pressure of these therapies that drives extreme and specific escape strategies by leukemic blasts. Alternatively, anti-CD19 treatment may result in the emergence of a CD19^{NEG} clone that had been present all along as a minor undetectable subclone among predominantly CD19^{POS} blasts, following the concept of oligoclonality [282, 283]. The loss of CD19 per se has a definite impact on MRD detection in these patients. Relying on side scatter characteristics, CD45 staining intensity and CD34 expression have been suggested as a way around third problem [284]. The National Cancer Institute initiated MRD Working Group has suggested gating strategies in these patients which do not rely on CD19 alone by combining CD20, CD22, CD10, and CD24, given that CD34 is frequently not expressed in B-ALL. Of course, it is essential to make sure that myeloid cells do not contribute to the gate, given that CD24 and CD10 are expressed by normal myeloid cells and CD22 by basophils.

The diversity of mechanisms which potentially contribute to the loss of the CD19 epitope on the cell surface is astounding. Sotillo et al. described *CD19* gene mutations and appearance of *CD19* splice variants which lacked the CAR-recognizing epitope after CART-19 treatment [285]. A complete loss of antigen, rather than epitope loss or splice variant, was suggested by Braig et al. [286] who did not detect CD19 by flow cytometry using CD19 antibodies with differential epitope recognition in one case of CD19^{NEG} relapse studied in detail. In that patient, the *CD19* gene had no mutations, and full-length CD19 messenger RNA was detected, excluding transcriptional regulation and splice variants for the loss of CD19. On flow cytometric analysis, ALL blasts lacked expression of CD81 and CD21, two molecules that form the B-cell co-receptor signal transduction complex with CD19 and CD225 on the cell surface of B-cells. CD81 regulates CD19 protein maturation and acts as a chaperone of CD19 during trafficking from the Golgi apparatus to the cell surface. Rather than caused by a genetic defect, as described in antibody deficiency syndrome [287], the lack of CD81 expression in the CD19^{NEG} relapse case was attributed to posttranscriptional regulation [286]. The finding of hypoglycosylated or deglycosylated CD19 indicated that in this case of CD19^{NEG} immune escape was the result of lack of CD81 expression, resulting in defective transport and/or maturation of CD19.

To date, the other escape variation described is myeloid lineage switch [281, 288]. While the exact mechanisms of lineage switch are still to be elucidated, it is important to note that the myeloid relapses appear to be clonally related to the pretreatment disease. Gardner et al. [289] described two distinct mechanisms leading to the myeloid relapse in two cases of *MLL (KMT2A)*-rearranged ALL treated with CART-19 therapy. Secondary therapy-related AML was excluded by the identification of cytogenetic abnormalities by conventional karyotyping or FISH which were shared between lymphoid blasts before and myeloid blasts after CAR-T-cell therapy. In one case, an identical rearranged *IGH* gene sequence that was identified in both lymphoid and myeloid blasts suggested a contribution from cell reprogramming or dedifferentiation of previously committed B lymphoid blasts. However, in the second case, absence of the original *IGH* rearrangement in the myeloblasts was consistent with myeloid differentiation of a non-committed stem cell clone or selection of a preexisting myeloid clone. These authors discussed as another alternative the outgrowth of a CD19^{NEG} myeloid clone in response to cytokines. Both patients with phenotypic switch had presented with severe cytokine release syndrome (CRS), including high serum levels of interleukin-6, a well-known complication of CAR-T-cell therapy [220, 221, 290, 291]. Other patients in the same treatment cohort, who did not experience phenotype switch, did not experience severe CRS [289]. In vitro IL-6 supplementation has been found to be a key factor in driving myeloid differentiation of a t(4;11) *MLL(KMT2A)*-rearranged B-ALL line [292], suggesting that high serum cytokine levels during CRS might contribute to the myeloid switch phenomenon encountered after CART-19 therapy. On the other hand, a clonal phenotypic switch was also described in a t(4;11) ALL patient following blinatumomab without any obvious sign of cytokine contribution [293].

How to deal with CD19 loss therapeutically or how to avoid it is a work in progress [221, 274, 281] and beyond the scope of this chapter.

Minimal Residual Disease Determination by Flow Cytometry

The topic of MRD in leukemia is comprised of several aspects, including (1) the most advantageous methodology for MRD assessment, (2) the selection of peripheral blood

versus bone marrow and the issue of sample quality, (3) the timing of MRD assessments, (4) the clinically relevant level of MRD, and (5) the association of flow cytometry with other prognostic factors, in particular, genetic aberrations. This section of the chapter focuses on the flow cytometric detection of MRD and biologic parameters associated with or predictive of MRD.

MRD by definition refers to persistent disease after treatment that remains at levels too low to be detected by the human eye with light microscopy. MRD reflects the quality of response, serves as one of few post-therapy prognosticators, and has been found to prognostically significant at all time points though at different thresholds; furthermore, MRD thresholds will change with novel therapies and must be established with the introduction of new treatment strategies. The optimal way for detecting MRD has yet to be established, particularly in AML. Despite a lack of assay standardizations and the use of variable thresholds for defining MRD positivity, the prognostic effect of MRD has been confirmed universally indicating that this parameter is not easily swayed by technological aspects. There exist standard pre-therapeutic prognostic features, including cytogenetic aberrations, gene mutations, and immunophenotypic characteristics, which predict for the occurrence of MRD after therapy. However, within each conventional risk category, MRD status adds independent prognostic information. For example, patients with favorable cytogenetics will do much more poorly if they remain MRD^{POS} after therapy than favorable-risk patients who become MRD^{NEG}. On the other hand, intermediate-risk patients who become MRD^{NEG} with induction chemotherapy may do as well as MRD^{NEG} favorable-risk patients. In theory, early MRD assessment in the treatment course allows for refined risk stratification and tailored treatment. There are numerous reviews on MRD of which only a few recent ones are listed here, a list which by no means claims to be inclusive [34, 294–303].

New Definition of Complete Remission

It has almost become the standard of care to determine MRD in patients who after induction chemotherapy achieve a morphologic complete remission (CR). The implication that MRD might exist at the time of morphologic CR was raised by Bradstock et al. in 1981 [304] in patients with T-ALL, using the limited antibodies available at that time. It is quite unbelievable that despite 35 years of increasing evidence in favor of a prognostic significance of MRD in morphologic remitters, most clinical trials still define CR as the absence of blasts in the blood, normal trilineage hematopoiesis, ≤5% blasts in the marrow as recognized by the human eye with light microscopy, and absence of extramedullary disease [305]. We will discuss some of the reasons for this lag in reaction time, most of which appear to stem from lack of reliability in MRD measurements. Current CR subcategories, CR with incomplete blood count recovery (CRi), and its subset, CR with incomplete platelet recovery (CRp) [305], are associated with inferior long-term survival than patients in morphologic CR [306]. Chen et al. [307] found that MRD levels in marrows from CRi patients are significantly higher than in those from morphologic CR or CRp patients. Freeman et al. [308] had previously suggested a high incidence of MRD positivity in CRp patients and the loss of prognostic power for insufficient platelet count recovery in multivariate analysis after adjustment for MRD status. A major step in the direction of MRD has been taken by the European LeukemiaNet recommendations 2017 for the diagnosis and management of AML in adults [309] by introducing new response criteria, CR without MRD and the conventional morphologic CR with unknown or positive MRD. They also recommended that both multiparameter flow cytometry (MFC) and molecular techniques can be used to monitor MRD in AML. These recommendations will hopefully impact response criteria in clinical trials and individual patient treatment plans.

Of great importance are results from COG trial AAML03P1 [NCT0007017], which suggest that about 30% of children with AML who have a morphologically positive marrow after induction and are, therefore, considered induction failures are negative for MRD by MFC [310]. These children have an outcome superimposable to that of patients who were negative for MRD by both methods. Inaba et al. [311] similarly reported some AML patients who by morphologic examination of the bone marrow after induction had >5% blasts, while MFC-MRD did not detect residual leukemia. Percentage of myeloblasts by morphology did not affect the relation between MFC-MRD and treatment outcome marrows. These authors hypothesized that MFC-MRD negativity in morphologically positive marrows was due to therapy-induced differentiation of leukemic cells, resulting in the observed discordance between antigen expression and morphologic appearance. Since maturing blasts are doomed to undergo apoptosis, such patients would be expected to have a favorable outcome indistinguishable from that of MRD^{NEG} patients. In APL patients treated with all-*trans* retinoic acid, early MRD assessment by PCR for the *PML/RARα* transcript is not informative because the transcript persists in leukemic promyelocytes which undergo retinoic acid-induced maturation [312]. Such complication of MRD measurements does not occur in APL treated with arsenic trioxide [313]. However, a similar interference with MRD detection can be expected from other differentiation-inducing therapies, such as with inhibitors targeting *IDH2*-mutant AML [314]. Using real-time quantitative (RQ-PCR) for somatic receptor gene rearrangements, O'Connor et al. [315] analyzed end-of-induction MRD in pediatric ALL from

MRC trial, UKALL2003 [NCT00222612]. Of >3000 patients, only 1.9% were morphologic induction failures, and of those 59 patients, 6 had between 5 and 25% blasts by morphology (M2 marrow) but <0.01% MRD by PCR. These MRD$^{\text{VERY LOW}}$ patients had a 5-year event-free survival of 100%. These findings are surprising. What is surprising is the fact that despite the known limitations of morphology, these studies have not been done earlier and are still not being done in major trials. Going forward, every patient with AML and ALL, whether an induction failure by morphology or a morphologic remitter, must be evaluated for MRD by more sensitive methods to confirm or negate the morphologic result. Only then can we make sure that patients are treated according to their true depth of induction response.

The Choice Between Bone Marrow and Blood for MRD Detection

MRD determination by MFC invariably finds a lower percentage of blasts in bone marrow aspirates than in blood, provided that the aspirate is not diluted with blood. While this statement clearly applies to B-ALL, there may not exist such difference between marrow and blood in T-ALL [316]. This is in agreement with the fact that B-ALL (and AML, see below) are malignancies of the bone marrow, while T-ALL is of thymic origin. We have found in a large fraction of adult B-ALL patients that MRD by MFC was undetectable in the blood when up to 5% of blasts were measured in the marrow [317] and this experience continues in ongoing trial, E1910 [NCT02003222] (Paietta E unpublished observation). Along the same line, van der Velden et al. [318] found that RQ-PCR monitoring of immunoglobulin and T-cell receptor rearrangements yielded up to 1000 times higher levels of MRD in the bone marrow of children with B-ALL compared to levels in the blood. On the other hand, levels in the two tissues were comparable in T-ALL patients. Based on the available literature, MRD levels in the blood are 1–3 logs lower than in bone marrow in B-ALL and comparable or 1 log lower in T-ALL. Consequently, for both leukemia subtypes, bone marrow sampling was pronounced a prerequisite for accurate MRD monitoring (rev in [294, 297]).

Remarkably, a recent review stated that studies in ALL have already proven that assessment of bone marrow MRD could be replaced by peripheral blood MRD, without giving a reference or eluding further on the subject [296]. As stated above, this is not the case. However, there are some additional interesting data on this issue. Coustan-Smith et al. [316] reported from a small number of pediatric B-ALL that those patients with detectable MRD in both blood and marrow at the end of induction had a significantly higher incidence of relapse than patients with MRD in bone marrow only. It is important to mention here that their flow cytometric assay at the time only detected 1 leukemic cell in 10,000 normal cells, a sensitivity 10 times lower than what we are used to seeing now. Despite this limitation, their results suggested that peripheral blood MRD in B-ALL, though significantly lower than in the marrow, could provide prognostic information. An analysis of >2000 children with B-lineage ALL by Borowitz et al. [319] revealed that detection of bone marrow MRD at the end of induction helped to identify patients at high risk of relapse, but was not as useful for identifying patients at low risk. In multivariate analysis, MRD positivity (>0.01%) by MFC on day 29 (end of induction) was the most significant prognostic factor across all risk groups. While peripheral blood MRD was not equivalent to bone marrow MRD, the presence of MRD on day 8 in peripheral blood was associated with adverse outcome, with an increasingly bad outcome seen with progressively higher MRD levels. Strikingly, day 8 blood MRD$^{\text{NEG}}$ patients had a better prognosis than patients who were bone marrow MRD$^{\text{NEG}}$ on day 29. And the group of patients with the best outcome were MRD$^{\text{NEG}}$ in blood on day 8 and had favorable cytogenetics. This prognostic significance of early blood MRD was also confirmed in a small study by Volejnikova et al. [320] using RQ-PCR for somatic receptor gene rearrangements. Once again, these authors confirmed a poor correlation between MRD levels in marrow and blood in B-ALL. However, they also found that a negative MRD result in the blood on day 15 identified a group of patients with excellent relapse-free survival. In summary, MRD levels in the blood are not equivalent to those in the marrow. Blood MRD status early on during induction chemotherapy in B-ALL, however, carries prognostic significance.

Measuring blood MRD on day 8 with MFC presents with a major challenge in that WBC counts will be markedly suppressed by chemotherapy. Rarely will it be possible to acquire the desired number of events (500,000–1 million), thus reducing sensitivity of MRD detection [319]. One clear advantage of blood when compared to bone marrow for MRD detection in B-ALL is the absence of normal B-cell precursor cells (hematogones) which occur in increased numbers in the marrow especially after consolidation therapy as part of marrow regeneration and which can be mistaken as persistent MRD [35, 297, 321]. In other words, the sensitivity of the blood MRD assay is lower compared to that of marrow MRD determination, while blood MRD has higher specificity due to the relative absence of normal progenitors in the blood. Next-generation sequencing (NGS)

in paired bone marrow and blood samples from patients with B-lineage ALL also found that the leukemia burden in the blood was sixfold lower than in marrow [323]. However, due to the extremely high sensitivity of NGS, only 17% of paired samples had disease detectable in marrow but not peripheral blood and those were predominantly cases with marrow MRD ≤0.01% of total cells. These data suggest that with NGS, blood might be an alternative source tissue to marrow for MRD detection.

Regarding AML MRD, comparative data in blood and marrow are scarce. In 2007, Maurillo et al. [324] reported a strong concordance between MRD levels in blood and marrow by MFC and determined that a blood MRD level of 0.015% post-induction or post-consolidation correlated with outcome. Of the 50 patients studied, 43 had blood MRD levels higher than 0.015% after induction and 77% of those relapsed after a median of 10 months. Regarding biologic characteristics of this patient cohort, there was an overrepresentation of intermediate-risk karyotypes and cytogenetics had no effect on outcome. It is noteworthy that seven patients with detectable blood MRD after consolidation have remained in continuous remission, questioning whether the cutoff of 0.015% may be clinically relevant. There was no difference in overall survival between patients positive for blood MRD after induction and those with MRD >0.015%, though relapse-free survival was significantly shorter in the MRD^{POS} group. The same group of investigators use a threshold of 0.035% to define MRD positivity in the marrow [325]. Maurillo et al. [324] mentioned three patients in whom MRD levels in the blood were tenfold higher than in the marrow and these patients were monoblastic leukemias with extramedullary disease at the time of study. Zeijlmaker et al. [326] also reported one case with FAB M5 leukemia in whom MRD levels in the blood were 6.9 times higher than in the marrow, though extramedullary disease was not present. These investigators analyzed paired marrow and blood samples from 114 AML patients and found blood MRD levels to be 4–5 times lower in the blood based on MFC. Blood MRD was an independent predictor of response duration using a threshold of post-induction and post-consolidation MRD of 0.04% to distinguish between MRD^{NEG} and MRD^{POS} status, which was based on optimal specificity. This threshold agreed with the median of primitive marker-positive cells (CD34^{POS}, CD117^{POS}, or CD133^{POS}) in the blood of healthy individuals (0.038%) as compared to a median percentage of 0.88% in the marrow of these controls. Although the frequency of the primitive cell population itself was lower in the blood of AML patients, expression of aberrant markers by the primitive cells was not. With regard to the use of blood as an alternative source to marrow for MRD detection, they made the reasonable suggestion to monitor MRD in the blood and to assume that a patient is at high risk for relapse if the blood is MRD^{POS}. In cases in which the blood is MRD^{NEG}, an additional marrow aspiration should be performed to evaluate the true MRD status.

The Sample Quality Conundrum in MRD Determination

I cannot emphasize enough that it is the quality of the aspirate that determines the accuracy of MRD results. Several factors affect bone marrow quality and can be detrimental to accurate MRD determination. Many of those are out of the hands of the laboratory eventually performing MRD analysis. Those pre-analytical factors are sample storage after collection, delay in transport to the laboratory, or damaging conditions during transport (e.g., heat), resulting in degenerative changes with preferential loss of cell populations, possibly including the blasts in question. Hemodiluton of bone marrow samples, however, is probably the most significant and unfortunately too common problem. In an elegant, though mostly overlooked study, Helgestad et al. [327] demonstrated that the technique of bone marrow aspiration dramatically influenced MRD levels in ALL. Even the second pull from the same aspiration site reduced the leukemic fraction in the aspirate by almost 50% due to dilution with blood containing much fewer blasts. As a result, clinical trials in pediatric as well as adult B-ALL now emphasize the need of a first pull aspirate for MRD evaluation, or a separate pull from a distinct aspiration site after redirecting the needle, to avoid hemodilution at all costs as it leads to underestimation of leukemia involvement. Loken et al. [328] suggested a method to normalize aspirates for hemodilution flow cytometrically based on the proportion of dim-staining CD16^{POS} maturing myeloid cells, which, however, has not found widespread application. An intriguing suggestion as to how to resolve the problem of hemodilution in MRD detection was made by Terwijn et al. [329]. These investigators related the fraction of malignant primitive cells, those expressing aberrant markers (e.g., CD7) (aPC), to the total population of primitive cells, based on the dim expression of CD45, low side scatter characteristics, and expression of primitive markers, CD34, CD117, or CD133. In their experience, in contrast to MRD, the aPC fraction did not decrease upon dilution of the marrow with blood, because aPC fractions in peripheral blood and bone marrow were comparable.

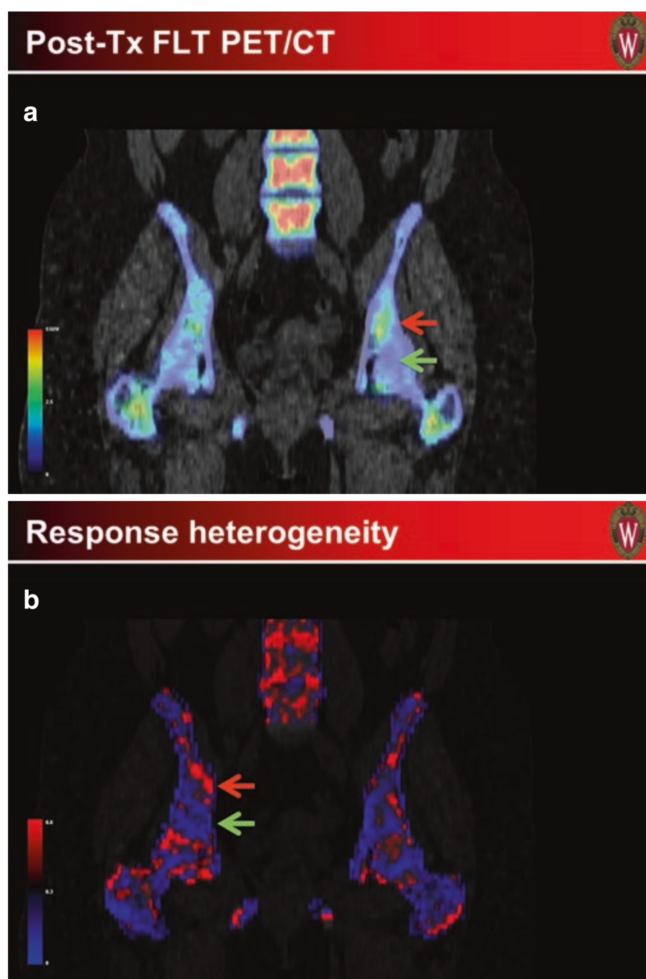

Fig. 15.4 FLT PET/CT images of posttreatment bone marrow in an AML patient. The patient was injected intravenously with 5 mCi FLT and scanned using a GE Discovery LS PET/CT scanner at the University of Wisconsin. PET/CT imaging began 45 min post-injection and extended inferiorly from the top of the skull to the distal femora. The pelvic region was chosen for display in this figure given that the iliac cristae are the most commonly used site for bone marrow aspiration and biopsy. PET activity concentrations were converted to standardized uptake values (SUV) by dividing the activity concentrations by the injected activity per patient mass. FLT PET images of bone marrow proliferative activity were extracted from full FLT PET/CT scans by first using the CT scans to extract the bone. These CT bone volumes were expanded to include the marrow resulting in bone and marrow CT masks. These masks were applied to the FLT PET images to isolate FLT PET voxels (volume elements of a scan) representing proliferative activity of bone marrow. An SUV threshold of 0.5 was applied to the masked FLT PET images to extract marrow FLT PET voxels, yielding FLT PET images of bone marrow proliferation. (**a**) Shows the FLT PET/CT of bone marrow in the pelvis and lower lumbar spine in an AML patient post-induction therapy. The SUV color bar reflects high proliferative activity in red (*red arrow* and red areas in the vertebrae) and low proliferative activity in blue (*blue arrow*). This scan demonstrates the heterogeneity of proliferative activity and thus distribution of residual disease in the pelvic regions. (**b**) Shows the spatial heterogeneity of bone marrow response to therapy in the same AML patient. The image represents a voxel-by-voxel ratio, whereby the values in the posttreatment FLT PET/CT were divided by the values in the pretreatment FLT PET/CT after co-registration of the pre- and posttreatment scans. Regions in red contained about 60% of the pretreatment activity, regions in black contained about 30%, and those in blue represent complete response. As can be seen from both images, there was substantial heterogeneity of residual bone marrow, as well as bone marrow response throughout the pelvic region, emphasizing the issues with a single-site bone marrow biopsy to assess treatment efficacy and response (courtesy Dr. Robert Jeraj)

Differential, heterogeneous distribution of the tumor load in different parts of the bone marrow, especially after treatment, could result in erroneously low MRD levels. In ALL, two independent bone marrow punctures at different locations showed comparable levels of MRD [330] strongly suggesting an equal distribution of ALL cells and indicating that it is sufficient to analyze MRD in a single bone marrow sample only. Substantial spatial heterogeneity in the bone marrow response after treatment for AML has been revealed by positron emission tomography (PET) with the proliferation marker, 3′-deoxy-3′-[^{18}F]fluoro-l-thymidine (FLT), in that response varied considerably throughout the pelvic region and in relation to other parts of the bone marrow [331]. Both during and after therapy, FLT uptake in the bone marrow of patients with residual disease, as assessed by bone marrow biopsy on day 14, was much higher and much more heterogeneous than in patients who achieved a morphologic CR. Figure 15.4 demonstrates the heterogeneous distribution of non-proliferating and actively proliferating bone marrow in the pelvis of an AML patient after induction chemotherapy (Fig. 15.4a). Figure 15.4b shows considerable spatial heterogeneity in the bone marrow response of an AML patient with refractory disease visualized by comparing pre- and posttreatment proliferative activity (disease) throughout the pelvis. Interestingly, there was a suggestion that elevated pretreatment FLT uptake may be predictive of poor response to induction, in agreement with data from Buck et al. who observed the highest FLT uptake in bone marrow of patients with refractory leukemia [332]. In other words, the accepted practice of performing single-point measurements for MRD in the bone marrow of treated AML patients could yield a false-negative result due to the heterogeneity in disease distribution. A similar study by Weindel Ibar Cribe et al. [333] also found a high degree of consistence between bone marrow response in AML patients to induction chemotherapy and the results of ^{18}F-fluorodeoxyglucose PET scans. These investigators speculated that a suboptimal PET response may be a predictor for an early relapse. The ECOG-ACRIN Cancer Research Group (Eastern Cooperative Oncology Group [ECOG], American College of Radiology Imaging Network [ACRIN]) is currently performing a trial to formally assess the value of FLT imaging in comparison to flow cytometric and morphologic MRD assessment in the marrow on day 28 of induction (EAI141, registered as NCT02392429).

A packed or concentrated marrow can be fully replaced by malignant cells at 100% cellularity leading to dry taps or the inability to obtain a suitable aspirate with spicules. Another etiology of dry taps can be reticulum fibrosis. Bone marrow fibrosis at diagnosis, as measured by reticulin fiber density, has been found to be more common in B- than T-ALL and has been associated with higher MRD levels on day 29 in B-ALL [334]. Packed marrows are much more common at diagnosis than after treatment and thus have less impact on MRD detection than hemodilution due to incorrect marrow aspiration.

MFC-MRD Versus Molecular MRD

The detection of MRD by MFC is based on the principle that leukemic cells express aberrant patterns of antigens which allow us to distinguish them from normal cells of same lineage and similar maturation stage [335–339]. The optimal method of MRD quantification and the best way to incorporate MRD information into risk-adapted strategies remain to be determined. The big advantage of MFC-based MRD assessment is its broad applicability. Leukemic blasts from approximately 90–95% of acute leukemia patients present with one or more antigen profiles which differ from the ordered pattern of antigen expression usually seen in normal hematopoiesis.

Flow cytometry looks at viable cells, which is an advantage over molecular techniques that may detect residual disease stemming from apoptotic or partially differentiated blast cells which have lost both aberrant phenotype and clonogenic potential. Inaba et al. [311] demonstrated this phenomenon when they compared MRD detection by MFC and qualitative PCR in CBF leukemias in which MRD by MFC after induction improved risk assessment, whereas the mere detection of the relevant transcripts by PCR did not. Low levels of molecular MRD may be compatible with long-term survival in CBF leukemias, again suggesting persistence of fusion transcripts in pre-leukemic cells or in differentiating leukemic cells without leukemogenic potential [340]. Complementary roles of MFC and RQ-PCR for the monitoring of MRD in CBF leukemias have been recently suggested [341].

With continuous improvements in the MFC methodology for MRD detection, differences in sensitivities between MFC and molecular techniques are diminishing. The standardized eight-color MFC-MRD procedure developed by the EuroFlow Consortium has proven a 98% concordance between MFC and RQ-PCR of immunoglobulin/TCR rearrangements in B-ALL [303], whereby the increased sensitivity of MFC was due to the availability of <4 million cells per antibody tube. Initially discordant cases were either due to overinterpretation of MFC-MRD (calling actually MRD^{NEG} cases MRD^{POS}) which were resolved by reanalysis or due to nonspecific amplification leading to false-positive RQ-PCR data. In those false-positive RQ-PCR cases, qualitative NGS analysis could not detect the involved leukemia-specific immunoglobulin/TCR rearrangements. The EuroFlow Consortium has reached extreme standardization of pre-analytical and MRD procedures (www.EuroFlow.org). Their EuroFlow quality assurance program helps to identify technical failures and inconsistencies [342]. Up until now, they have recommended using the Infinicyt software for analysis, which compares leukemic B-lymphoblasts with the nearest-normal B-cell precursors using automated population separator plots. Still, Theunissen et al. [303] concluded that interpretation of MFC-MRD, especially at very low levels, remains expert based. Being true to the term EuroFlow-based next-generation flow (NGF)-MRD strategy [294], EuroFlow now strives at developing new software tools to reduce subjectivity in MRD interpretation. The main limitation for MFC-based MRD evaluation, in fact, is the need for data interpretation which, in the hands of the untrained, is as subjective as the morphologic assessment of bone marrow smears. In other words, detailed knowledge of normal maturation for cells of the relevant lineage is an absolute prerequisite for the correct recognition of MRD by MFC [343, 344]. A recent first effort by the National Cancer Institute to standardize MFC-MRD for B-ALL in North America, using the COG-protocol for B-ALL as the gold standard, has demonstrated that a standardized methodology and continuous educational feedback helped improving the performance of participating laboratories [345]. While the COG protocol is based on the different-from-normal (DFN) approach, similar experience was reported by Feller et al. [346] who aimed at concordance of data in AML among five centers utilizing leukemia-associated immunophenotype (LAIP)-based MFC (DFN versus LAIP concepts of MFC-MRD determination will be discussed below). In both attempts, discordances were interpreter dependent, as previously observed in earlier European standardization efforts for B-ALL MRD assessments in multicenter settings [347, 348]. Since participants in all of these trainings were experienced in standard diagnostic flow cytometry of leukemias, these results suggest that immunophenotypic MRD assessment requires additional guided schooling.

Molecular studies are limited by the requirement of predefined targets, such as leukemia-specific, recurrent translocations leading to the creation of fusion transcripts (e.g., *BCR/ABL*), somatic gene mutations (e.g., *NPM1, FLT3, DNMT3A*), or, in ALL, creation of patient-specific primers for immunoglobulin and/or TCR gene rearrangements unique to the abnormal clone present at diagnosis. Good correlation has been found between RQ-PCR amplification of most frequent fusion transcripts in B-ALL and MFC-MRD [349]. Discordance between RQ-PCR MRD and MFC-MRD in *ETV6/RUNX1* (*TEL/AML1*) ALL affected only early time points of induction chemotherapy. It is possible that RQ-PCR detected *ETV6/RUNX1* carrying pre-leukemic clones (CD34^{POS}CD38^{NEG}CD19^{POS} pro-B-cells), which by MFC were not recognized as leukemic B-lymphoblasts [350]. Molecular signals may have derived from fusion transcripts present in nonviable or differentiating blast cells [340]. Huang et al. [349] speculated that the sensitivity of their six-color MFC-MRD assay could have been increased by adding additional antibodies to newly described markers to their panel [351]. Eight-color flow cytometry has yielded improved concordance with molecular MRD in BCR/ABL^{POS} ALL [352].

Ravandi et al. [353] reported that >50% of MRD specimens from their *BCR/ABL*^{POS} ALL patients were *BCR/ABL*^{POS} by PCR but negative by MFC. These findings are in agreement with those of others who found that MRD levels by MFC and/or PCR amplification of antigen receptor genes are largely equivalent but different from *BCR/ABL* transcript quantification [354]. It is conceivable that multi-lineage involvement with the presence of *BCR/ABL* in non-ALL

cells is in part responsible for this finding [355]. More recently, the suppression of BCR/ABL protein translation in LSCs which carry *BCR/ABL* transcripts has been reported in imatinib-refractory chronic myeloid leukemia, resulting from the modulation of LSC metabolism by the environment in the stem cell niche [356]. The detection of MRD which is represented by residual LSCs is essential for long-term outcome in *BCR/ABL*^{POS} disease. A potential marker of *BCR/ABL*^{POS} LSC, dipeptidyl peptidase IV (CD26), has been proposed as a follow-up parameter at least in TKI-treated CML and lymphoid blast crisis of CML [357].

Correlations between MFC-MRD and molecular MRD in ALL have mainly focused on immunoglobulin/TCR gene rearrangements [340, 351, 358–360]. The two strategies were found to be complementary and (almost) comparable when properly standardized and the choice between these two methods is primarily dictated by costs, time, and expertise available. While fusion transcripts represent very stable targets for MRD determination, clonal evolution of immunoglobulin and TCR gene rearrangements is a frequent occurrence with therapy [361]. NGS, but not allele-specific oligonucleotide (ASO)-PCR, allows for the tracking of the evolution of all gene rearrangements during therapy [362–364]. Not surprisingly, deep sequencing by NGS measuring immunoglobulin heavy-chain variable, diversity, and joining DNA sequences proved superior to six-color MFC-MRD when tested prior to and early post-allogeneic stem cell transplantation [365]. With a sensitivity level 1000-fold lower than that of optimal MFC-MRD, pre-transplant NGS-MRD negativity, but not MFC-MRD negativity, was strongly correlated with relapse-free survival, raising the question whether the potential toxicities of allogeneic transplantation could be avoided in this patient cohort.

With respect to common gene mutations in AML, PCR- and sequencing-based MRD monitoring confirmed heterogeneity and clonal instability between diagnosis and relapse with selective outgrowth of mutated clones (oligoclonality), in particular, for *FLT3-ITD* [366], while *NPM1, DNMT3A*, and *IDH2* mutations were found to be more stable [282, 367–369]. Salipante et al. [369] reported *NPM1*-mutation-positive MRD by NGS in six out of six randomly selected AML patients after therapy though they were MFC-MRD negative, possibly reflecting persistence of mutated *NPM1* in a pre-leukemic clone, carrying also mutations in epigenetic landscaping genes (e.g., *DNMT3A, IDH1/IDH2*) [22]. Ivey et al. [370] found that in patients in molecular remission according to the *NPM1* mutation RQ-PCR assay, the coexisting *DNMT3A* mutations at arginine 882 (*DNMT3A*^{R882}) persisted, suggesting that they drive relapse [21]. The presence of *DNMT3A*^{R882} mutations predicted MRD measured by six-color MFC in AML patients in first remission, treated on phase 3 trial, E1900 [NCT00049517], underscoring their role in chemoresistance [148]. In that study, none of the other gene mutations analyzed, including mutated *NPM1* and *FLT3-ITD*, was associated with MFC-based MRD.

The relationship between *BCR/ABL1*-like genotype and MFC-MRD was studied by Roberts et al. in the St. Jude Total Therapy XV trial [204]. In that study, the majority of patients with *BCR/ABL1*-like ALL had an inferior initial response to treatment which triggered them being treated with intensified therapy. This MRD-guided risk assessment yielded comparable clinical results in *BCR/ABL1*-like and other B-ALL. Based on these findings, the authors proposed for centers that lack the capability to identify *BCR/ABL1*-like ALL that excellent overall treatment results can still be achieved, provided that reliable methods for monitoring MRD are available.

How to Define MRD Positivity and Negativity

In the study by Pulsipher et al. [365], ALL patients with even the lowest levels of residual disease by NGS (10^{-6} to 10^{-7}) benefitted from the allotransplant as patients with such low MRD levels who did not get a graft-versus-leukemia effect from the transplant relapsed. A strict correlation between the presence of quantifiable MRD pre-transplantation and outcome in ALL has also been reported by others [181, 371, 372], whereas this absolute need for MRD reduction may [373] or may not apply to AML [371, 374]. The power of pre-allotransplant MRD in AML has been demonstrated by a meta-analysis which demonstrated a strong relationship between pre-transplant MRD and post-transplant relapse and survival which was independent of the methodology used to determine MRD, the MRD threshold, as well as the conditioning regimen used [375].

MFC-MRD levels (threshold 0.01%) correlated with the outcome of myeloablative allogeneic stem cell transplantation in pediatric ALL with 3-year estimates of relapse being 17% and 38% and estimated 3-year overall survival being 68% and 40% for patients without and with MRD prior to transplant, respectively [376]. While these differences were highly statistically significant, they indicated that 17% of patients with <0.01% MFC-MRD relapsed within 3 years after transplant. This observation suggests that prognostic heterogeneity exists within the MRD^{NEG} group when defined by the 0.01% threshold. That the commonly used threshold of 0.01% to define MRD positivity in ALL, while usually achievable by MFC, may be set too high for clinical relevance in all ALL patients has also been suggested by PCR amplification of antigen-receptor genes at the end of remission induction [377]. On the other hand, in the first clinical trial in pediatric ALL that used MRD levels prospectively during and after remission induction therapy to guide risk-directed treatment, the St. Jude Total Therapy XV study (NCT00137111), the threshold for determining 10-year event-free survival was

≥1% of MFC-MRD on day 19 of induction [378]. However, at later time points of therapy, including prior to allotransplant, MRD^{NEG} status was defined with <0.01%. As pointed out by Campana and Coustan-Smith [340], the proportion of MRD^{POS} samples at any given time point during the course of treatment is highly dependent on the preceding therapy. Using a threshold of ≥0.01% to define MRD positivity, these authors stated that the prevalence of MRD positivity at the end of remission induction for ALL ranged from 19.4 to 83.5% in a variety of studies. This implicates that clinically meaningful MRD levels need to be determined with every new therapy. There is evidence that end-of-induction MFC-MRD is not as useful a determinant of outcome in T-lineage as in B-lineage ALL [379], consistent with PCR data which showed that T-ALL patients with MRD at the end of induction and even end of consolidation had a favorable outcome [380].

For MFC-based MRD in AML, the cut point used to define MRD positivity is, in general, ten times higher than in ALL (≥0.1%) [325, 381, 382]. To determine the cutoff of MRD positivity most relevant for relapse-free survival early during induction therapy, at the time of aplasia, Köhnke et al. [383] calculated hazard ratios for different cutoff values from 0.01 to 1% and arrived at 0.15% patients with ≥0.15% of mononuclear cells exhibiting the leukemia phenotypes(s) that were considered MRD^{POS}. Utilizing the same method, a cutoff of 0.3% was determined as to represent MRD positivity post-induction. Lowering the cutoff to 0.1% at that time point resulted in a nonsignificant correlation with survival.

In the pediatric AML02 trial (NCT00136084) [384], a rare example of MRD-guided therapy in AML, an MRD level of ≥1% after the first course of induction therapy was the determining factor for outcome in these high-risk patients, despite treatment intensification triggered by MRD results, suggesting that novel therapies might be indicated for this cohort. Patients with low MRD levels after induction 1 (0.1 to <1%) did as well as MRD^{NEG} patients, whereas any detectable MRD (>0.1%) after induction 2 was associated with poor outcome. Buccisano's group [385, 386] suggested that the clinically relevant threshold of MRD will differ with the intensity, in other words, the efficacy, of the therapies administered. In their experience, the MRD level that discriminated MRD^{NEG} from MRD^{POS} AML patients decreased from 0.1 to 0.035% in the bone marrow after intensification of the therapeutic schedule. On the other hand, high-dose versus low-dose cytarabine during induction did not affect post-induction MRD levels in pediatric AML, though this study demonstrated an MRD-lowering effect of gemtuzumab ozogamicin, the anti-CD33 antibody, when given after the first course of induction [384], and neither did doubling of the daunorubicin dose in adults [387], although the latter resulted in prolonged overall survival [388]. Similarly, there was a significantly better outcome in relapsed ALL children induced with mitoxantrone versus idarubicin without apparent difference in post-induction MRD levels [389]. Butturini et al. [390], however, warned about applying a definition of MRD status which was established in a given clinical situation in a random fashion to other settings. In other words, MRD thresholds that are prognostically significant in children with de novo ALL treated with standard therapy may not be applicable to children in relapse treated with experimental regimens. Yang et al. [391] identified germline variations which distinguished children at risk of relapse despite an excellent early response to therapy. Of the 134 single-nucleotide polymorphisms associated with relapse, 14 were associated with unfavorable pharmacokinetics of commonly used antileukemic drugs.

Intensification of induction chemotherapy may indeed lower the threshold to be used for defining MRD negativity to undetectable, given that patients who remain with detectable disease after highly cytotoxic therapy must be considered as having a low likelihood of benefitting from further cytotoxic therapy, most likely including transplantation [392]. Araki et al. [373] demonstrated that AML patients in MFC-MRD^{NEG} remission prior to myeloablative allogeneic transplantation had a cumulative risk of relapse of only 20–25% compared with a relapse risk of 65–70% for patients who underwent transplantation while in MRD^{POS} remission or patients with morphologically visible disease. Importantly, MRD negativity was defined as the absence of detectable MRD with ten-color MFC and the different-from-normal (DFN) MRD assay approach. Outcomes in patients with MFC-MRD^{POS} were unrelated to the level of MRD (<0.1% to >1%). The reason why about one-quarter of remitters relapsed posttransplant despite having been MRD^{NEG} prior to the procedure might at least in part be explained by the threshold of 0.1% to determine MRD negativity which falsely identified these patients as free of MRD.

Given the complex heterogeneity of AML, in addition to methodological disparities in MRD assays, it is probably reasonable to propose that the absence of detectable MRD, at any time point of treatment, should determine MRD negativity [393]. One of the main clinical uses of MRD determination is monitoring the kinetics of MRD reduction with treatment, rather than a single-time-point assessment. The usefulness of detecting recurring MRD in patients in continuous hematologic remission will depend on the availability of MRD-targeting preemptive therapeutic strategies [381].

Sample Preparation for MFC-MRD Determination

If MRD negativity is to be determined by the inability to detect MRD, then the lowest level of detection will dictate this definition. Consequently, unless everybody utilizes the same methodology for MFC-MRD assessment, it will continue to be impossible to compare studies. In addition to the

caveat of threshold determination for MRD status and the choice of MRD assay, as discussed below, there are differences in sample preparation which can markedly affect results: for example, MRD determination in mononuclear cells versus whole bone marrow. While MFC-MRD data from mononuclear cells may be better comparable to those from molecular MRD analysis (nucleic acids are always prepared from mononuclear cells), there is the possibility that MRD cells are lost during density gradient centrifugation and/or antigen expression is altered during the procedure. Furthermore, Gaipa et al. [394] found that the impact of using either monucleated or total nucleated cells on the concordance of MFC with PCR results was minimal, and rather influenced by the time point at which MRD was measured. While direct antibody staining of MRD cells in whole, unseparated tissues is the preferred method nowadays, a no-wash procedure [395] is ill advised. It is imperative that excess antibodies be washed away after incubation and before red cell lysis and fixation prior to acquisition [297].

Optimally, a cluster of ten clearly aberrant cells can be sufficient for the recognition of MRD in a well-controlled assay. In that setting, for a limit of detection of 0.01%, the threshold currently utilized in B-lineage ALL to define MRD status, 1 million events must be acquired. Notably, in the presence of platelets, red cell fragments, tissue debris, or nonnucleated cells more events must be acquired, unless this noise can be excluded from the MRD enumeration. Other factors which can contribute to a suboptimal assay are nonspecific antibody binding or insufficiently cleaned flow cytometers. There is a lack of standardization of the denominator used for MRD enumeration. COG ALL-MRD assays maintain as denominator nucleated mononuclear cells [297], while others either relate MRD cells to total nucleated cells or total white cells, based on CD45 expression [396]. Dworzak et al. [347, 397] introduced the use of a live-cell-permeant nucleic acid-binding dye, such as Syto 16, a green fluorescent dye, to correct for nonnucleated cells and debris.

There are several other aspects of MRD determination, such as the choice of anticoagulant (EDTA or heparin is preferred) for the aspirate, use of cocktailed antibody combinations, and optimal ammonium chloride red cell lysis for white cell enrichment in the case of hypocellular marrow aspirates, a crucial step which is usually not paid attention to sufficiently. There are commercially available ACK (ammonium-chloride-potassium) lysing buffers and there are several home-brew recipes, which vary by temperature used during lysis (room temperature versus ice), speed during cell centrifugation after lysis, concentration of EDTA (ethylenediaminetetraacetic acid), and type of protein-containing buffer used to wash the white blood cells after lysis. I can only recommend that laboratories find the ACK buffer and lysing conditions which work best for their MRD assay, especially which avoid cell clumping.

The Two Philosophies of MFC-MRD Assays

MRD assays are widely applicable but require interpretive expertise. This notion is true whether MRD is based on leukemia-associated immunophenotypes (LAIP) [294, 303, 346, 382, 390, 396, 398, 399] established in the diagnostic specimen or the different-from-normal (DFN) approach [297, 301, 310, 343–345], which does not require knowledge of the presenting immunophenotype and relies on the recognition of cellular features that differ from those seen on normal cells of similar lineage and maturational stage. Cells that cluster in sites where normal cells are absent (the so-called empty spaces) are consequently defined as residual leukemic cells irrespective of the diagnostic phenotype of leukemia. Independent of the baseline phenotype, fixed antibody panels for leukemia population identification are used. Details regarding the methodology and antibody panels for all lineages have been published by B. Wood [399]. Which strategy to use is personal preference and a combination of the two might be the way to go. In fact, the contrast between these two philosophies appears to reflect more an individual conviction than actual scientific evidence. As Brent Wood [297] recently formulated, the use of LAIP is a simplified version of the DFN approach.

Preferentially, LAIPs consist of cell surface markers and combine antibodies which distinguish leukemic blasts from normal precursors; detect expression of lineage-foreign markers, e.g., lymphoid antigens on myeloblasts; detect altered density or lack of antigen expression; detect asynchronous expression of antigens (co-expression of antigens that are not concomitantly present during normal differentiation); or recognize antigens associated with particular genotypes (e.g., CD25 in BCR/ABL^{POS} ALL). Because of the dependence of LAIPs on the diagnosis immunophenotype, baseline and follow-up samples are ideally processed the same way and antibody combinations as well as fluorochrome choices for essential antibodies must be those used at diagnosis. LAIP-based MFC-MRD detection in the UK National Cancer Research Institute AML16 trial (NCT00454480) was performed in four reference laboratories with identical standard operating procedures, antibody panels, instrument type, and controls [400]. Still, these laboratories produced MRD values which were not identical. Especially in AML, multiple leukemic clones are frequently found requiring that equally multiple LAIPs be used in the MRD assay. However, it is recommended that only LAIPs expressed by a minimum of 10% of the leukemic blast population be monitored [401]. Though explained by the limits of sensitivity of MRD detection, this rule ignores the possibility that minor clones at presentation may dominate the remaining leukemia population at the time of MRD assessment or at relapse [282, 402]. Instability of even one of the LAIPs after treatment poses the risk of a false-negative MRD result.

The DFN-based analysis approach circumvents the problems of false negatives from phenotypic shifts and emerging subclones after treatment by using a fixed antibody panel. Most importantly, this approach avoids rigid gating predefined by the baseline specimen. Its independence from the diagnostic immunophenotype is very conveniently used in referral centers or commercial enterprises, when they receive samples for MRD determination without accompanying information on the baseline antigen profile. Both strategies are used in ALL and AML.

To reach satisfactory sensitivity against the background noise of antigen expression by normal bone marrow cells, leukemic immunophenotypes must be sufficiently aberrant to be present on less than 0.1 to 0.01% of normal lymphoid or myeloid marrow cells, so that in an adequate sample an MRD detection sensitivity threshold of 10^{-3} to 10^{-4} (1 in 1000 to 1 in 10,000 cells) can be achieved. However, for both LAIP and DFN methods, this signal-to-noise ratio is not a constant and varies with both treatment stage and leukemia subtype. The degree of abnormality in the population of interest is patient dependent. For leukemic phenotypes with a low degree of abnormality, the sensitivity of the MRD assay can be increased by acquiring more events (1,000,000 or even more) and the number of fluorochromes used per cell [303]. Furthermore, interference with the detection of MRD by normal cells will change with treatment stage. A simplified MRD assay in B-lineage ALL was based on the hypothesis that CD19^{POS}CD10^{POS}CD34$^{POS/NEG}$ cells detected early after initiation of treatment should be leukemic rather than normal, since normal bone marrow B-cell precursors (hematogones) with this phenotype are exquisitely sensitive to corticosteroids and thus eradicated during remission induction [403].

Hematogones and MFC-MRD Detection in B-lineage ALL

Hematogones are present in increased numbers during periods of hematopoietic regeneration, potentially causing interference with the detection of MRD [35, 36, 322]. In normal bone marrow, all differentiation stages of hematogones are present, whereby they exhibit a typical continuous differentiation spectrum that defines the normal evolution of B-cell precursors [35, 297, 322, 404]. This contrasts with discrete clusters of leukemic cells arrested at a certain stage of differentiation. In most studies, hematogones are differentiated from leukemic blasts by their expression pattern of CD45/CD19/CD10/CD20/CD38/CD22/CD34/CD58. As expected from normal B-lymphopoiesis, CD34 (and TdT) are present in the most immature stage of hematogones when CD10 is the highest and CD45 the lowest. With increasing maturation, hematogones lose CD10, and gain CD45, CD22, and some CD20. Zeidan et al. [405] demonstrated that the less mature hematogones express CD34 and lack CD123, whereas the more mature hematogones, with higher CD45 expression, lack CD34 but always express CD123. Given that the majority of B-ALL cases express both CD34 and CD123, this differential expression pattern was suggested to be helpful in distinguishing hematogones from leukemic blasts. As a side note, CD123 has been found to be overexpressed in B-lineage ALL patients with hyperdiploidy [351, 406]. It is also important to remember that leukemic lymphoblasts frequently express myeloid antigens, especially CD13 and/or CD33, which clearly allows the distinction from hematogones [407]. Based on differential gene expression between B-ALL and hematogones, Coustan-Smith et al. [351] found 22 markers which by flow cytometry were differentially expressed in the large majority of ALL cases tested, among them CD24, CD123, CD200, CD44, CD73, CD86, CD99, and BCL2. CD73 and CD86 have recently been confirmed as useful in differentiating B-lymphoblasts from hematogones [407]. While hematogones have been extensively studied in bone marrow, they are occasionally found in the blood (0.01–1.3%) according to Kroft et al. [408]. Chen et al. [409] identified a handful of proteins that were expressed in leukemic B-lymphoblasts at higher densities than in normal CD19^{POS}CD10^{POS}CD34^{POS} progenitors, including CD58 (LFA3), a ligand for CD2. Veltroni et al. [410] confirmed CD58 to be overexpressed by leukemic B-lymphoblasts when compared to regenerating and mature B-lymphocytes and no significant modulation of CD58 expression with treatment was noted.

While MRD detection in CD10^{POS} B-lineage ALL is plagued by the presence of hematogones, that in CD10^{NEG} B-ALL deals with the discrimination between leukemic cells and CD19^{POS}CD10^{NEG} plasma cells and plasmablasts. If one is lucky enough that the CD10^{NEG} leukemic blasts were CD34^{POS} at diagnosis, then CD34 negativity by suspicious cells together with high CD38 expression will definitely characterize those cells as plasma cells. CD38 expression by plasma cells exceeds by far that of leukemic B-lymphoblasts (or hematogones). CD138 (syndecan-1), a very useful marker of plasma cells, is usually not part of any MRD assay antibody panel. Plasmablasts, which may be found in marrow aspirates due to hemodilution, express CD38 at lower intensity than mature plasma cells, comparable to cases of CD10^{NEG} leukemic B-lymphoblasts, thus adding to a potential confusion. CD10^{NEG} pro-B or pre-pre-B-ALL blasts [44] vary in their expression of other B-cell differentiation antigens, such as CD22 and CD24, and CD20. Plasmablasts are CD20^{POS}, while plasma cells are CD20^{NEG}, CD24^{NEG}, but variably positive for CD22. Adding to a potential misinterpretation of CD10^{NEG} MRD is the infrequent finding of CD19 expression by natural killer cells [411]. Because MFC-based MRD identification is more difficult in CD10^{NEG} than CD10^{POS} ALL, standardized multicenter MRD testing demonstrated the highest discordant results between MFC- and PCR-MRD in CD10^{NEG} disease [348].

MFC-MRD Detection in T-lineage ALL

As mentioned before, the kinetic pattern of MRD response in T-lineage ALL is different from that in B-ALL with a slower rate of blast cell clearance in T-ALL, making end-of-induction MRD data less useful [379, 380]. Roshal et al. [412] reported that the main T-cell-associated antigens, surface CD3, CD2, CD4, CD5, CD7, and CD8, as well as CD45 remain relatively stable with treatment and thus can be reliably used in MRD detection. It is important to discriminate T-lymphoblasts from natural killer cells, which have variable expression of some T-cell antigens (especially CD7). Furthermore, the natural killer cell markers, CD16 and/or CD56, are occasionally expressed by T-ALL cells [413]. CD99 has been shown to be overexpressed in T-ALL when compared to hematopoietic stem cell and normal T-lymphocytes [412, 414, 415]. During T-lymphopoiesis, CD99 is downregulated with increasing expression of surface CD3 [416]. As a result, CD99 has been suggested as a very useful tool in MFC-MRD for T-ALL [414]. However, CD99 can be lost during therapy [412]. In fact, other markers of immaturity, such as TdT and CD34, dramatically decline during therapy of T-ALL as well [412].

MFC-MRD Detection in Myeloid Leukemias

Normal immunophenotypic patterns of maturation of hematopoietic lineages have been well described and they form the basis of MRD detection by the DFN approach [343]. While in lymphoid acute leukemias, the neoplastic population can be identified in most instances accurately even when present at very low levels, using either of the analysis approaches discussed, the situation is much more complicated in AML due to the heterogeneity of nonlymphoid acute leukemias and the multitude of differentiation stages to be encountered in follow-up samples [343]. A multitude of LAIPs have been proposed and utilized [346, 382, 417] and the DFN panel for MRD in AML has been published [399]. In APL, MFC-MRD determination is not very useful given the rather mature phenotype of leukemic promyelocytes and the ready availability of PCR-MRD monitoring for *PML/RAR*α transcripts. Theoretically, one could utilize the expression (albeit often weak) of CD117 and the differential expression of CD15s and CD15 by leukemic and normal promyelocytes, respectively [29]. Monocytic leukemias present the biggest challenge because leukemic monocytes show considerable overlap in antigen expression with normal monocytes. Van Lochem et al. [418] have suggested various immunostainings for studying aberrant monocytic differentiation, which, however, also delineate their potential pitfalls. The European LeukemiaNet reported that the most common aberrations observed in AML are $CD33^{POS}CD7^{POS}$ ($\pm CD34^{POS}$) and $CD34^{POS}/CD11b^{POS}$ ($\pm CD117^{POS}$) [395]. Together with low CD45 expression and side scatter characteristics, it was suggested that a combination of four or five surface markers could reliably detect MRD in AML. The biggest handicap to this LAIP-based MRD approach is the multitude of LAIPs often present at diagnosis and the challenge to monitor all of them. While the DFN-based MRD approach has the definite advantage of not worrying about presenting LAIPs and being flexible enough to detect phenotypic changes, there is still a substantial incidence (about 25%) of false-negative MRD reports even with this methodology [310].

That tumor heterogeneity in AML makes this disease a moving target for the detection of MRD has been well described [402]. Despite its genetic and biologic heterogeneity, a common most primitive cell population with the $Lin^{NEG}CD34^{POS}CD38^{NEG}$ phenotype was shown to be able to transfer AML to NOD-SCID mice [419]. Since these early studies, other markers have been detected on these LICs, including CD123, which is expressed by LICs at much higher levels than by normal hematopoietic stem cells [420]. Other differentiating markers of LICs are C-type lectin-like molecule-1 (CLL-1), CD96 (tactile), a member of the immunoglobulin gene family, CD47, the ligand for signal regulatory protein α, whose expression by LICs protects them from phagocytosis by macrophages and dendritic cells, and others [421]. However, there is marked variability in LIC antigen expression profiles among AML patients. LICs in *KMT2A(MLL)*-rearranged leukemias have variable surface antigen expression patterns dependent on gene fusion partners [8], also suggesting that the $CD34^{POS}CD38^{NEG}$ cell pool may not uniquely contains LICs. Most importantly for MRD detection, the LIC compartment in AML is more heterogeneous than previously anticipated and includes cells with the surface phenotype of committed progenitors [421, 422]. This suggests that measuring $CD34^{POS}CD38^{NEG}$ stem cells, as putative culprits of relapse, may not be entirely sufficient, although the frequency of these cells at diagnosis predicts for high MRD levels [423–426]. It is indeed surprising, though, that commonly used MFC-MRD assays, which solely measure residual cells from the original leukemic bulk, provide any clinically relevant information. The pre-leukemic stem cell clone, which has lost the major phenotype of bulk AML but contains the driver or founder mutations which led to the disease in the first place, survived standard treatment, thus persisted during remission, and eventually will lead to relapse (rev in [427]); this clone cannot (yet) be identified based on antigen expression. The mere evidence, however, that apparently mature myeloid cells in remission may be derived from leukemic progenitor cells [428, 429] makes MFC-based MRD measurements extremely difficult in AML.

Changes in Blast Cell Immunophenotypes with Treatment

Stability of LAIPs is a prerequisite for reliable LAIP-based MRD tracking. Despite the fact that differences in antigen expression levels between longitudinal studies during the treatment course of a patient may be due to technical aspects, like differences in analysis strategies or sample preparation, there is convincing evidence for true phenotypic changes. There is the reduction or disappearance of individual antigen expression and increments or gains in antigen expression; some phenotypes completely disappear while new abnormalities appear. The potential consequences of this phenomenon for MRD detection both in AML and ALL have been reviewed [402, 430]. Without question, changes in the immunophenotype of leukemic blasts with treatment and/or disease progression contribute to the approximately 25% of patients who relapse despite having been MRD$^{NEG/LOW}$ after induction or consolidation therapy.

Modern sequencing techniques have allowed us to prove beyond any doubt that the genetic landscape of leukemic subpopulations in a patient continues to evolve, either due to natural progression of the disease or in response to selective pressure from treatment [431, 432]. It is therefore not surprising if changes in surface phenotypes are observed between presentation and relapse but also early on during induction chemotherapy. Gaipa et al. [433] found the downregulation of CD10 and CD34, while CD19, CD11a, and CD20 were upregulated during the initial phase of induction treatment for pediatric B-lineage ALL, indicative of progressive maturation. These changes, which were found to be caused by glucocorticoid administration, were transitory. Remarkably, normal B-lymphocytes present in the specimens were equally affected. Rather than due to subclone selection or apoptosis-related artifacts, these changes (except for CD11a) were a direct result of drug-induced modulation [434]. Interestingly, the extent of phenotypic shift correlated positively with sensitivity to drug treatment [433]. Nonetheless, phenotypic shifts of highly relevant MRD antigens, like CD10 and CD34, returned to their initial aberrant expression levels after glucocorticoid-containing therapy was discontinued [434]. In addition, phenotypic modulation creates new combinations of aberrant expressions during follow-up, in particular based on upregulation of CD20. Genome-wide gene expression analysis revealed that glucocorticoid administration for 8 days resulted in decreased proliferative activity of the blast cells and a differentiation shift towards normal B-cells, both developments which may be the cause for the persistence of these blasts at day 8 of therapy as a result of drug resistance [435]. Rhein et al. [435] also reported increased expression of CD11b (MAC-1) integrin and CD119 (interferon gamma receptor-1) on day 8 B-lymphoblasts. The expression of CD11b in B-lineage ALL was found to confer a high risk of MRD when present on B-lymphoblasts at diagnosis [133]. Similar to B-lineage ALL, also leukemic T-lymphoblasts lose markers of immaturity during therapy, such as CD34, TdT, and CD99 [412].

Borowitz et al. [430] reviewed diagnostic and relapse immunophenotypes in children with ALL and found that although phenotypic shifts are common, they do not interfere with MRD detection, especially when the DFN approach is used. Of interest, these authors reported that the MRD-positive population at day 29 resembled the diagnostic specimen in 63% of cases, whereas in one-third of patients the day 29 MRD resembled the relapse phenotype, and in 2 out of 29 cases, day 29 MRD was unrelated to either phenotype. Surprisingly, time to relapse was identical in these groups. Contrary to what has been observed in ALL, phenotypic changes from diagnosis in AML point to a more immature state, through loss of CD11b and CD15 and frequent gain of CD34 and CD117 [298, 402]. A unique occurrence has been reported by Slamova et al. [436], a switch from CD2^{POS} B-ALL to acute leukemia of the monocytic lineage, associated with demethylation of the CEBPα gene and upregulation of this gene.

Epigenetic diversity within the LIC population and its progeny is an interesting alternative to permanent genetic modification as a cause of phenotypic changes, given that epigenetic modifications are dynamic and transient and allow the epigenetic status to return to its original status after selective pressure has been overcome. Although the actual mechanisms by which phenotype changes occur are unclear, the two most favored options are (1) spontaneous gains or loss of mutations in the primary tumor clone(s) present at the time of diagnosis and occurring during or after therapy and (2) selection of minor therapy-resistant subclones, already present but not routinely detected at diagnosis, which survived therapy and grew out to cause relapse [431].

With the increase in monoclonal antibody therapy, flow cytometrists face a novel situation, the potential of antigen loss or downregulation due to therapeutic antibody exposure. In patients treated with gemtuzumab ozogamicin, CD33 expression persisted at relapse in most cases [437]. In contrast, after rituximab therapy, more than one-third of cases lost CD20 expression [438]. With the bi-specific CD3/CD19-targeting antibody, blinatumomab, loss of CD19 expression occurred with treatment and at the time of relapse [439]. The mechanisms of CD19 loss after CD19-directed therapy have been discussed before.

As true for flow cytometry in general, MFC-based MRD determination cannot function in a vacuum, isolated from all other aspects of leukemia biology. Mooreman et al. [440] demonstrated that a subgroup of genetically good-risk ALL patients remained MRD^{POS} after induction, which was associated with more incidences of relapse but an overall survival of >90%. Rather than superseding other prognostic factors [441], MRD complements the power of genetic factors for risk stratification of patients with acute leukemia.

Cytogenetics of Acute Leukemia

16

Nyla A. Heerema and Susana Catalina Raimondi

Introduction

Cytogenetic abnormalities are an important factor in patient diagnosis, risk assessment, and treatment in acute leukemia. Characteristic genetic abnormalities are recognized as essential for disease classification and are a significant element of the 2008 World Health Organization (WHO) classification [1]. Some aberrations are involved in the initiation whereas others participate in the progression of different acute leukemias. Cytogenetic aberrations occur in most malignant cells, revealing acquired genomic changes that may have diagnostic and prognostic significance. This chapter reviews the most important cytogenetic and molecular genetic lesions in acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL).

In acute leukemias, the bone marrow is the sample of choice to detect cytogenetic aberrations in malignant cells because cells of the bone marrow divide spontaneously; however, peripheral blood may also be studied if there is a significant number of circulating blasts. It should be noted that normal chromosomes in the periphery do not necessarily reflect a cytogenetically normal marrow because reactive rather than malignant cells may be dividing. Cytogenetic analysis involves either a direct procedure or culture of cells overnight to obtain dividing cells, which are necessary to observe chromosomes. Cells are exposed to colchicine to arrest the cells in division, when chromosomes are sufficiently contracted for visualization. The cells are fixed, banded, and analyzed. As only 20 completely analyzed metaphases are required for a cytogenetics evaluation, metaphase cytogenetics is limited in its sensitivity to detect abnormalities.

The sensitivity of cytogenetics has been greatly enhanced by the application of fluorescence in situ hybridization (FISH). FISH has notably advanced the field of cytogenetics by enabling the detection of numerical and structural aberrations in both hematologic malignancies and solid tumors. FISH is a molecular cytogenetic technique which uses a DNA probe to evaluate cells in either metaphase or interphase. Various types of probes are commercially available and are applied to detect gains, losses, and different types of cytogenetic rearrangements. The probes vary in size and can detect aberrations as small as 200 kb, although most clinically applied probes are much larger. This is in contrast to metaphase cytogenetics, in which most aberrations must be at least 2 Mb for detection. Technically, both the probe and the chromosomes are "denatured" (made single stranded), hybridization of the fluorescently labeled probe to its matching DNA on the chromosomes is allowed to occur, the excess probe is removed with several washings, and the preparations are analyzed using a fluorescence microscope. In addition to detecting much smaller aberrations, FISH is more sensitive than metaphase analysis because 200 interphase cells are generally analyzed. Furthermore, dividing cells are not required, so neither culturing nor live cells are necessary as for metaphase cytogenetics, making application to a wider range of tissues possible.

Different FISH probe "strategies" are used to detect different types of abnormalities. The ones commonly used in analysis of acute leukemias include probes for detection of rearrangements, gains, and losses. These include probes designed to detect specific loci, such as *TP53*, to detect centromeres, and to detect whole chromosomes (chromosome paints—metaphase analyses). The use of dual-color dual-fusion probes is another strategy to detect translocations. The breakpoints of each of the translocation partners are labeled in different colors, generally a red and a green, such that both probes are split when there is a translocation. Fusion of the two probes indicates the rearrangement, and since most

translocations are reciprocal, two fusions are typically present in addition to the two normal alleles. Thus, the pattern observed in abnormal cells with the translocation queried is two fusions, one red and one green signal. Break-apart probes have been designed to detect rearrangements of genes that frequently have different partners, such as *KMT2A* (formerly *MLL*). These probes are labeled with one color 5′ of the breakpoint, and a second color 3′ of the breakpoint, yielding two fusion signals in a normal cell. If the gene has been rearranged, one signal is split and one red, one green, and one fused signal will be detected in abnormal cells. In many cases, FISH should be performed on metaphase chromosome preparations, because there are many variations of each genetic abnormality at the DNA level and because analysis of only interphase nuclei can lead to misinterpretation of results. Furthermore, FISH analysis has shown that in several cases "balanced" translocations detected by conventional cytogenetics are not actually balanced, but rather associated with submicroscopic deletions. However, the clinical significance of these deletions remains unknown [2]. Use of FISH has become very common in the cytogenetic laboratory, as it is rapid and precise and gives a quick and accurate diagnosis. Because of its sensitivity, FISH is also useful to detect cytogenetically cryptic aberrations, such as the t(12;21)(p13;q22) found in ~25% of pediatric ALL. It also is frequently utilized to help define a complex karyotype or to confirm an abnormality suspected in a karyotype. However, FISH can only give results concerning the specific probes applied; the presence or absence of other aberrations is not detected.

Conventional cytogenetic methods, FISH and reverse transcriptase-polymerase chain reaction (RT-PCR), are complementary and can reliably identify clonal rearrangements of genes and aid in subclassification of disease subtypes in acute leukemias [3]. RT-PCR may be a useful adjunct to FISH when cytogenetic analysis is not possible because of a lack of dividing cells. For example, the cryptic t(12;21) generates an *ETV6–RUNX1* chimeric fusion that is easily identified by FISH or RT-PCR. Cytogenetic analyses of t(8;21), inv(16), or t(15;17) in patients with AML yield a low rate of false positives, but false negatives occur in rare cases when cryptic, complex rearrangements are not detected [4, 5]. Thus, it is clinically important to use FISH and RT-PCR separately or in combination to detect cryptic abnormalities, especially for disease subtypes such as acute promyelocytic leukemia (APL) wherein optimal therapy differs.

In some subgroups it may be difficult or not feasible to detect all translocations because of the diversity of partners (e.g., *KMT2A* with multiple partners) or because the genes involved are located near the telomeric regions of the chromosomes [e.g., *NUP98*(11p15.5), *RUNX1*(21q22), *ABL1*(9q34.1), *JAK2*(9p24), *ETV6*(12p13.2)]. For *KMT2A* cases, a long-distance inverse PCR method has been successfully used to identify any type of *KMT2A* rearrangement at the molecular level [6]. The rapid amplification of cDNA end PCR method can also be used to clone breakpoints of partner genes such as of *KMT2A*, or of *PDGFRB* in chronic myeloproliferative disorders or of *NUP98* in myeloid leukemias.

At present, newly developed methods such as array-comparative genomic hybridization (aCGH) and single-nucleotide polymorphism (SNP) arrays quantitatively analyze DNA copy number at high resolution and systematically detect changes on a genomic scale. The implementation of these technologies has improved the resolution with which genetic alterations, especially changes in copy number, can be localized to the human genome [7]. With novel emerging technologies aimed to genetic, immunophenotypic, epigenetic, and proteomic classification, as well as next-generation sequencing (NGS) approaches to aid the identification of new molecular subsets, the classification of acute leukemias will likely evolve to provide informative prognostic and biologic guidelines to clinicians and researchers.

Acute Myeloid Leukemia

AML, a malignant disorder of the bone marrow, develops because of the clonal transformation of a multipotent stem cell through the acquisition of chromosomal rearrangements and multiple mutations. Cure rates for AML have improved only moderately over the past few decades compared with those for ALL. Clonal, nonrandom chromosomal abnormalities have been observed by conventional cytogenetics in blast cells of 80% of children and adolescents and 60% of adults with AML.

Cytogenetic analysis is a primary component in the diagnosis and treatment of AML. According to the World Health Organization classification (WHO-2008) [1], results of diagnostic studies should correlate with clinical findings and be reported in a single, integrated report that includes the cytogenetic profile. In addition, a minimum of 20% blasts is typically required for the disease to be classified as AML. However, with t(8;21), inv(16)/t(16;16), and t(15;17), the disease is considered AML even if less than 20% blasts are present. WHO-2008 expanded the number of recognized chromosomal abnormalities associated with AML and for the first time included specific gene mutations (*CEBPA* and *NPM1)* as provisional categories [1] (Table 16.1). *FLT3* internal tandem duplication (*FLT3*-ITD) is included because of its recognized prognostic significance. In addition to cytogenetic abnormalities, with the advent of powerful high-throughput tools, these and other recurrent genetic mutations have been incorporated into clinical practice. A revision of the WHO classification

AML acute myeloid leukemia; *APL* acute promyelocytic leukemia
[a]Newly defined entities by WHO-2008 [1]

is under way to include the many lesions identified by genomic methods, which are either targetable for therapy or useful for prognostication. This update is expected to improve the risk classification for AML [8].

Favorable prognostic factors for patients with AML include low white blood cell (WBC) count; inv(16)/t(16;16); t(8;21); t(15;17); *NPM1* mutation (in the absence of *FLT3*-ITD or *DNMT3A* mutation); biallelic *CEBPA* mutation; Down syndrome (DS) in children up to 4 years old, mostly with acute megakaryoblastic leukemia (AMKL, AML-M7); and early response to treatment. Unfavorable prognostic factors include –7, –5/5q, t(6;9)(p23;q34), t(6;11)(q27;q23), and 3q abnormalities; complex karyotypes (≥3 unrelated cytogenetic abnormalities, excluding the categories described by WHO-2008); cryptic lesions mostly observed in children such as t(5;11)(q35;p15.5)/*NUP98–NSD1*, t(6;11)(q27;q23)/*KMT2A–MLLT4(MLL–AF6)*, inv(16)(p13.3q24.3)/*CBFA2T3–GLIS2*, t(11;12)(p15.5;p13.3)/*NUP98–KDM5A*, and t(7;12)(q36.3;p13.2)/*MNX1–ETV6*; as well as lesions found in all age groups, 17p/*TP53* deletion or mutation; *KMT2A*(*MLL*)-PTD and *FLT3*-ITD, particularly with a high allelic ratio; and *DNMT3A, ASXL1,* and *RUNX1* mutations. Intermediate-risk factors include normal and other karyotypes and genetic lesions excluding favorable and unfavorable abnormalities [1, 9–12].

AML represents 15–20% of all childhood leukemias and approximately 33% of adolescent and 50% of adult leukemias. The prognostic value of cytogenetics has been well established for all age groups [9, 10, 12, 13]. However, the distribution of recurrent chromosomal abnormalities observed in AML differs by age groups. In infants (<2 years old), chromosomal abnormalities most frequently include a breakpoint in 11q23 and involve *KMT2A*(*MLL*) in 60% of cases. The incidence decreases to 30% in children (2 to <13 years) and to 13% in adolescents (13 to <21 years), and is even lower in young adults (8%; 21 to <30 years) and adults (3%; ≥30 years) [13]. The t(1;22)(p13;q13) is specific for AMKL and is mostly seen in children younger than 2 years and rarely in adults. In older children (>10 years) and young adults (<60 years), the most frequent abnormalities are t(15;17), t(8;21), and inv(16). In older patients (>60 years) with AML, there is a low frequency of favorable core-binding factor chromosomal abnormalities but a higher incidence of complex aberrant karyotypes, which is attributed to both disease biology and host factors [14]. A previous study evaluating the effect of age on outcome of AML in children 21 years or younger suggested that age is an independent prognostic factor in childhood AML and that children younger than 10 years benefit more than older children from newer intensive therapies [15].

The following section describes the associations among specific recurring cytogenetic and molecular abnormalities in AML, distinct clinical subtypes of diseases, and treatment outcomes.

Specific Recurring Cytogenetic and Molecular Abnormalities

t(15;17)(q24;q21)/*PML–RARA*

The t(15;17)(q24;q21) is associated with APL, a distinct subtype of AML that is treated differently from other types of AML because of its marked sensitivity to the differentiating effects of all-*trans* retinoic acid (ATRA). The t(15;17) is found in 9% of children with AML; it is rarely observed in infants, and the incidence decreases with age in adults (rarely seen in adults 45 years or older) (Fig. 16.1). The t(15;17) generates the fusion gene *PML–RARA* to produce a chimeric protein. Patients with the t(15;17) and APL respond well to the combination therapy of ATRA and the chemotherapy agent arsenic trioxide (ATO) and have a favorable prognosis (cure rate 80%) [16–19].

A suspected diagnosis of APL should be treated as a medical emergency because immediate measures are needed to counteract coagulopathy and initiate ATRA therapy. Thus, a prompt genetic diagnosis by conventional cytogenetics, FISH with *PML–RARA* probes, RT-PCR, or anti-PML monoclonal antibodies, is essential for patients with suspected APL [18]. *Conventional G-banding* has helped to identify the t(15;17) in more than 90% of patients with APL, but it cannot detect the *PML–RARA* fusion resulting from cryptic rearrangements. However, cytogenetics facilitates the identification of rare variant translocations, including three-way translocations affecting *PML* and *RARA* or other aberrations affecting only *RARA*. FISH with commercially available probes is a rapid, highly sensitive, and specific method to confirm the presence of the *PML–RARA* fusion. However, in rare instances, fusion

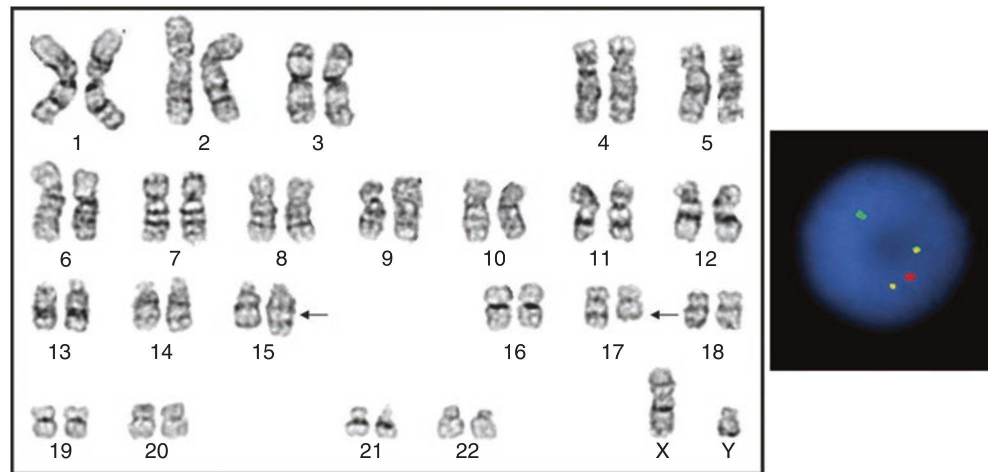

Fig. 16.1 *Left*: Karyogram of a cell from a patient with APL and the typical translocation between chromosomes 15 and 17 (*arrows*). The karyotype is 46,XY,t(15;17)(q24;q21). *Arrows* indicate abnormal chromosomes. *Right*: FISH with the dual-color dual-fusion *PML–RARA* probes (Abbott Molecular) showing 2 fusion (*yellow*), 1 *red*, and 1 *green* signals

signals might be different from those expected, because of deletion of sequences at translocation junctions or where *PML–RARA* is formed as a result of an insertion or a complex translocation [5]. FISH using *RARA* break-apart probes is useful to evaluate rearrangements in suspected cases that lack the *PML–RARA* fusion. *RT-PCR* is important to establish the type of *PML–RARA* isoform fusion transcript that will be the target to reliably monitor minimal residual disease. *Immunostaining* with anti-PML monoclonal antibodies on dry smears is also useful to establish a rapid diagnosis.

Small *PML–RARA* insertions can be missed by FISH when using very large probes; in such cases, it is more appropriate to use relatively small cosmid probes. Patients with APL in whom the *PML–RARA* fusion is generated due to variant three-way translocations or cryptic insertions respond to ATRA combination regimens in a similar manner as those with APL with the typical t(15;17) [5].

Other rare translocations involving *RARA* can also result in APL. Approximately 1% of patients with APL have variant translocations involving only *RARA*. The most common is t(11;17)(q23;q21)/*PLZF*(*ZBTB16*)–*RARA* (~20 patients) [20]. These patients and another patient with a rare inv(17)(q11.2q21)/*STAT5B-RARA* were partially resistant to ATRA [21]. Other variant translocations with *RARA* include *OBFC2A (NABP1)* (2q32), *TBL1XR1* (3q26), *FIPIL1* (4q12), *NPM1* (5q35), *NUMA1* (11q13), *ZBTB16* (11q23), *PRKAR1A* (17q24.2), and *BCOR* (Xp11.4) [20, 22, 23]. It is important to identify patients with such translocations, as the sensitivity for ATRA or ATO may vary.

Children with APL have a higher incidence of hyperleukocytosis (WBC count $\geq 10 \times 10^9$/L) than adults with APL, but the high WBC count is associated with poor outcome in both groups [18, 19]. *FLT3* mutations [either internal tandem duplications (ITDs) or kinase domain mutations] occur in up to 40% of patients with APL and are associated with high WBC counts; however, there is no clear correlation between the presence of *FLT3* mutations and outcome [19, 24, 25].

Core-Binding Factor Leukemias

In children and adults with AML, the highest complete response rates and longest survival times are associated with the two common aberrations, t(8;21) and either inv(16) or t(16;16). Both aberrations disrupt the core-binding protein complex, which plays a vital role in hematopoiesis, and are designated core-binding factor (CBF) leukemias. The t(8;21) targets *RUNX1*, and the inv(16)/t(16;16) targets *CBFB*. Several studies have shown an association between cooperating mutations and CBF leukemia; the most prevalent are *KIT* and *NRAS* mutations, but their prognostic significance remains debated [26].

t(8;21)(q22;q22)/*RUNX1*(*AML1*, *CBFA2*)-*RUNX1T1*(*ETO,MTG8*)

The t(8;21)(q22;q22) is among the most frequent recurrent abnormalities in AML (12% of children and 6% of adults). The t(8;21) juxtaposes *RUNX1* to *RUNX1T1* on the derivative chromosome 8, generating a chimeric gene *RUNX1–RUNX1T1* (*AML1–ETO*), which inhibits transcriptional activation by wild-type *RUNX1*. RT-PCR and *RUNX1–RUNX1T1* FISH probes are available to detect the t(8;21) and are useful especially when submicroscopic rearrangements are suspected or the sample does not yield metaphases for analysis. Additional cytogenetic aberrations are present in 68% of patients with t(8;21). The most frequent additional change in cases with t(8;21) is loss of a sex chromosome in approximately 40% of patients; the Y chromosome is lost in males more frequently (55%) than the X chromosome (33%) in females [27, 28]. A del(9q), rearrangement of 7q, +4, or +8, can also occur, but does not significantly affect the overall survival. However, a del(9q) was associated with lower complete remission and +4 with inferior outcome in a recent study [27]. The t(8;21) is associated with a favorable

outcome, especially when the disease is treated with regimens containing high-dose cytarabine [27].

Presence of the *RUNX1–RUNX1T1* transcript in the bone marrow in adults and cord blood cells of children who do not have AML suggests that the t(8;21) is generated early in hematopoiesis. Some people may acquire secondary genetic alterations that lead to the development of AML [29], which is supported by the detection of *RUNX1–RUNX1T1* in neonatal blood spots of infants in whom AML subsequently developed (after >10 years) [30]. The most frequent genetic lesions identified are *KIT, ASXL2,* and Ras-pathway mutations [31].

inv(16)(p13.1q22) and t(16;16)(p13.1;q22)/*CBFB-MYH11*(*SMMHC*)

The inv(16) and t(16;16) result in fusion of *CBFB* at 16q22 to the smooth muscle myosin heavy-chain gene (*MYH11*) at 16p13.1. *CBFB* is the heterodimeric partner of *RUNX1*, which together form the transcriptional activating factor designated as CBF. The inv(16)/t(16;16) is strongly associated with the FAB M4Eo subtype and is observed in approximately 6% of children and adults with AML. FISH probes and RT-PCR are available to evaluate the status of fusion genes in patients with AML and can aid in the diagnosis of this subtle chromosomal abnormality. Additional abnormalities in leukemic cells with an inv(16) are found in up to 40% of patients, with +22, +8, and +21 being the most frequent. The inv(16)/t(16;16) confers a good prognosis in both children and adults with AML. The most frequent genetic lesions identified with inv(16)/t(16;16) are *KIT*, Ras-pathway mutations, and *FLT3*-ITD [32].

Other *RUNX1*(*AML1*,*CBFA2*) (21q22) Rearrangements

The *RUNX1* gene encodes a transcription factor that is important for hematopoiesis and is one of the most frequently mutated genes in acute leukemias. Chromosomal abnormalities include the t(12;21)(p13;q22)/*ETV6–RUNX1*(*TEL–AML1*) in ALL and many other *RUNX1* partner genes identified in AML, but several of them are reported for single cases (<1% of pediatric AML). One of the most frequently identified *RUNX1* partner genes is *MECOM(EVI1,MDS1)*, involved in the t(3;21)(q26.2;q22) associated with therapy-related MDS and CML in blast crisis [33]. The t(3;21) can generate fusion of *RUNX1* with several genes such as *EVI1, EAP*, and *MDS1*. In addition, other rearrangements of 3q26 (such as inv(3)(q21q26)) often lead to overexpression of *EVI1*, which is associated with poor prognosis, suggesting its role in the pathogenesis of AML [34]. Determination of *EVI1* expression is likely important, because it is overexpressed in cases with cryptic 3q26 rearrangements [35]. Another rare but recurrent translocation is the t(16;21)(q24;q22), mostly observed in patients with therapy-related acute leukemias and MDS but also in children and adults with de novo AML. The t(16;21) generates the fusion gene *RUNX1–CBFA2T*(*MTG16*), which is similar to the *RUNX1–RUNX1T1* generated by the t(8;21). Of interest, a t(16;21)(p11;q22)/*FUS–ERG* is a rare recurrent abnormality associated with poor prognosis in AML. *RUNX1* mutations have been identified in AML with noncomplex karyotype and confer an unfavorable prognosis [36].

Other 3q26.2/*MECOM*(*EVI1*, *MDS1*) and 3q21.3/*GATA2*/*RPN1* Rearrangements

These aberrations are more frequently observed in adults with AML than in children with AML and are adverse prognostic factors [37, 38]. *EVI1*-rearranged AML is characterized by distinct molecular alterations [38, 39]. The molecular basis of inv(3)(q21q26.2) and t(3;3)(q21;q26.2) (observed frequently with –7) has been revised with the rearrangement of a *GATA2*(3q21.3) oncogenic enhancer element rather than of the *RPN1* gene with *MECOM(EVI1)* [8, 40]. Of interest, a recent study identified *GATA2* mutation as the most common germline defect predisposing to pediatric MDS, with a very high prevalence in adolescents with –7, but did not confer poor prognosis [41].

11q23/*KMT2A* (*MLL*, *MLL1*, *ALL1*, *TRX*, *HTRX1*)

Most myeloid blasts with an 11q23 abnormality have a *KMT2A* rearrangement and are associated with monocytic differentiation. Every *KMT2A* translocation results in gain of function by generating novel chimeric proteins coded by the N-terminus of *KMT2A* fused in-frame with one of many partner genes coding for diverse functions, and each oncogene is associated with a distinct form of leukemia. More than 120 translocations target *KMT2A* in acute leukemias, and approximately 80 partner genes for *KMT2A* have been cloned [42, 43]. Despite the diversity of chimeric proteins created, *KMT2A* fusions generate a characteristic gene expression profile, including upregulation of developmental homeobox genes such as *HOXA9* and *MEIS1*, suggesting that partner genes for *KMT2A* might be involved in regulating transcription elongation and chromatin structure remodeling.

Chromosomal rearrangements involving *KMT2A* in AML and in ALL include balanced and unbalanced translocations, inversions, insertions, amplifications, and partial tandem duplications (*KMT2A*(*MLL*)-PTD). These genetic

mechanisms convert *KMT2A* into a chimeric transcription factor with leukemogenic properties. Some *KMT2A* gene rearrangements are not detected by conventional cytogenetic methods. In other *KMT2A* rearrangements, the precise breakpoint or gene partner is difficult to assign because different genes are mapped on chromosome regions with limited banding resolution, such as 10p and 19p [42]. FISH using commercially available dual-color *KMT2A* probes allows evaluation of derivatives of a translocation involving *KMT2A* in metaphase chromosomes and the splitting of signals in interphase nuclei (Fig. 16.2). In rare instances, FISH with this probe detects not only the reciprocal translocation but also a deletion of at least 190 kb from the 3′ region of *KMT2A*.

A *KMT2A* rearrangement is observed in up to 25% of children with AML, is prevalent in infants (~60%), and declines to less than 10% in older children with a median age of ~2 years. Pediatric patients with t(6;11)(q27;q23) and t(11;17)(q23;q21) are significantly older at presentation (12 years and 9 years, respectively). In contrast to the poor prognosis of infants with 11q23/*KMT2A*⁺ ALL, the outcome of infants with 11q23/*KMT2A*⁺ AML is not poorer than that of infants who do not have this rearrangement. The specific fusion partner of *KMT2A* may influence prognosis [44]. WHO-2008 has classified the t(9;11) as a separate category and recommends that partner genes be determined for patients with *KMT2A* rearrangements [1]. Several studies have reported a more favorable prognosis for children with t(9;11)(p22;q23)/*KMT2A-MLLT3* (50% of patients with *KMT2A* rearrangements) than children with other *KMT2A* rearrangements, but other studies have refuted these observations.

In a recent collaborative group study of 756 children with AML and an 11q23/*KMT2A* rearrangement, the overall 5-year event-free survival (EFS) was 44% [44]. The outcome of the subgroups varied greatly; for example, patients with a t(1;11)(q21;q23) (~3% of patients with *KMT2A* rearrangements) had an excellent outcome (5-year EFS, 92%), whereas those with a t(6;11)(q27;q23) (~9%) had the worst outcome (5-year EFS, 11%). Subgroups with a t(10;11)(p12;q23) (15%), t(4;11)(q21;q23) (<1%), and t(10;11)(p11.2;q23) (<1%) had 5-year EFS of 31%, 29%, and 17%, respectively [44]. A follow-up study by the international group reported that additional chromosomal abnormalities further influenced the outcome of children with *KMT2A* rearrangements, with complex karyotypes and trisomy 21 predicting poor outcome and trisomy 8 predicting a more favorable outcome [45].

A *KMT2A*-PTD is detected in approximately 10% of patients with AML, particularly those with trisomy 11 or a normal karyotype, and confers a poor prognosis [46]. In the 1990s, the use of epipodophyllotoxins was associated with the development of therapy-related AML (t-AML) with 11q23 abnormalities. The most frequently observed translocations were t(9;11)(p22;q23), t(11;19)(q23;p13.3), and t(11;16)(q23;p13.3). The t(11;16)(q23;p13.3), affecting *CREBBP*(*CBP*), was rarely seen in de novo AML. Subsequently, the dose and schedule of topoisomerase II inhibitors for treatment of acute leukemias were modified, which has reduced the occurrence of t-AML with a *KMT2A* rearrangement. Leukemias with *KMT2A* rearrangements are sensitive to BET, hDOTIL, and CDK6 inhibitors, which are currently being tested in an early clinical trial [12].

t(10;11)(p12;q14)/*PICALM*(*CALM*)–*MLLT10*(*AF10*)

The t(10;11)(p12;q14) is a rare recurrent abnormality seen in both adult and pediatric patients with AML or T-ALL and is often associated with a poor prognosis [47–49]. The t(10;11)(p12;q14) lacks a *KMT2A* rearrangement and can be difficult to differentiate microscopically from the t(10;11)(p12;q23)/*KMT2A–MLLT10*, and FISH or RT-PCR analysis is usually required to distinguish these two translocations with accuracy.

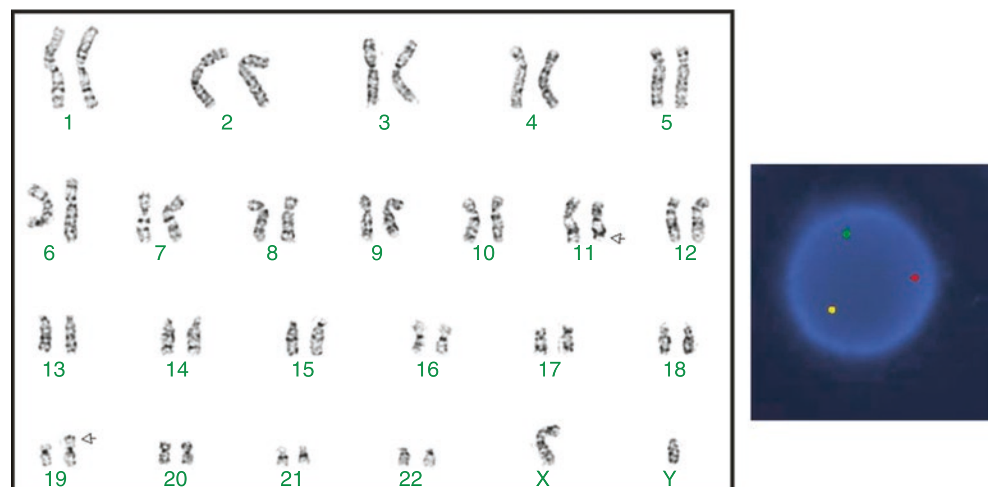

Fig. 16.2 *Left*: Karyogram of a cell with a t(11;19)(q23;p13.3), which occurs in both AML and ALL. *Arrows* indicate abnormal chromosomes. The karyotype is 46,XY,t(11;19)(q23;p13.3). *Right*: FISH with a *KMT2A* break-apart probe (Abbott Molecular) shows the separation of the 2 *KMT2A* signals (1 *red* and 1 *green*) and a normal fused (*yellow*) signal indicating a rearrangement of the *KMT2A* gene

t(1;22)(p13;q13)/*RBM15*(*OTT*)–*MKL1*(*MAL*)

The t(1;22)(p13;q13) is restricted to patients with AMKL and occurs in 33% of this subgroup, mostly in infants and young children. The t(1;22)(p13;q13) is rare in children with DS who develop AMKL. The t(1;22) juxtaposes the *RBM15(OTT)* on 1p13 to *MKL1(MAL)* on 22q13. Patients with this translocation present with hepatosplenomegaly and bone marrow fibrosis and can have high-hyperdiploid karyotypes. These patients were earlier classified as high risk, but the use of intensive therapy has significantly improved the prognosis [50–52].

t(3;5)(q25;q35)/*NPM1–MLF1*

The t(3;5)(q25;q35) is rare in young patients with AML and can present with trilineage dysplasia. However, patients with the t(3;5) have good outcomes [53, 54].

t(6;9)(p23;q34)/*DEK–NUP214*(*CAN*)

This translocation leads to formation of a leukemia-associated fusion protein DEK–NUP214(CAN), which occurs in up to 2% of children with AML. It is associated with relatively late onset (median age, 10.4 years) and male predominance. The t(6;9) presents with trilineage dysplasia and bone marrow basophilia and is the sole abnormality in 80% of the patients; the most common secondary changes are +8 or +13. The t(6;9) is strongly associated with *FLT3*-ITD mutations (up to 70% of patients), and has a poor prognosis [55]. Outcomes might improve with stem cell transplantation [56, 57].

t(X;6)(p11.2;q23.3)/*GATA1-MYB*

The t(X;6)(p11.2;q23.3) generates an *MYB–GATA1* fusion. The translocation is very rare, with few cases reported worldwide. It is predominantly seen in male infants presenting with basophilic leukemia, and most patients were in long-term complete remission at the time of reporting [58].

Recurrent Abnormalities of Chromosomes 5 and 7

Cytogenetic aberrations associated with unfavorable outcomes include monosomy 5 (−5) and del(5q)/5q–, monosomy 7 (−7), and complex abnormalities. These abnormalities occur more frequently in adults than in children. Patients with del(7q)/7q– are no longer considered to be at high risk of treatment failure [59]. Monosomy 7 is observed in approximately 2% of children with AML. The majority (72%) of adolescents with MDS and –7 carry an underlying *GATA2* deficiency, which does not confer poor prognosis [41]. In a large pediatric series, the prevalence of –5/del(5q) was 1.2%, the abnormality occurred in older children (median age, 12.5 years), it had a high incidence of undifferentiated blast morphology, and most patients had additional chromosomal abnormalities. The study confirmed the very poor prognosis of children with a –5/5q– [60].

t(8;16)(p11.2;p13.3)/*KAT6A*(*MOZ/MYST3*)–*CREBBP*(*CBP*)

Disruption of *KAT6A* at 8p11.2 is rare (~1%) and is seen in children (median age, 1.2 years), younger adults (median age, 45 years), and t-AML. It is associated with a poor prognosis [61]. The most frequent translocation is t(8;16)(p11.2;p13.3), which fuses *KAT6A* to *CREBBP*. Blast cell morphology is similar to that of acute myelomonocytic or monocytic leukemia, with the blast cells frequently (70%) displaying erythrophagocytosis. Patients with t(8;16)(p11.2;p13.3) can present with leukemia cutis (58%) and disseminated intravascular coagulation (39%); the coagulopathy may mimic that seen in APL [62, 63]. Importantly, spontaneous remissions occur in a subset of neonatal patients [28% of patients with a t(8;16) are diagnosed in the first month of life] and warrant a watch-and-wait strategy before initiating therapy [62]. The t(8;16) has a unique gene expression profile that clusters close to 11q23/*KMT2A* [62, 63]. Other *KAT6A* fusion partners are *NCOA2*(*TIF2*) in inv(8)(p11.2q13), *NCOA3* in t(8;20)(p11.2;q12), and *EP300* in t(8;22)(p11.2;q13.2). These partner genes encode proteins that have histone acetyltransferase activity and likely contribute to leukemogenesis by altering chromatin-mediated transcriptional control of unknown target genes. The *CREBBP*(*CBP*) (16p13.3) gene is also involved in other translocations in AML—t(10;16)(q22;p13.3)/*MYST4*(*MORF*)–*CREBBP* and t(11;16)(q23;p13.3)—which results in *KMT2A–CREBBP*(*CBP*) fusion and is strongly associated with treatment-related hematologic malignancies [64].

Complex Karyotype

The definition of a complex karyotype has not yet been standardized, but the current trend is to consider patients with three or more unrelated chromosomal abnormalities (excluding those recognized as categories by WHO-2008) in this category; adults with AML who have complex karyotypes have a significantly poorer prognosis than those without a complex karyotype [65]. The loss of 17p is among the most frequent abnormalities observed as part of a complex

karyotype in hematologic disorders in adults, and it is strongly associated with abnormalities of chromosomes 5 or 7, or both [66]. The loss of 17p consistently creates a monoallelic loss of *TP53* and may be associated with *TP53* mutation or lack of expression, which is associated with a very poor prognosis; risk-adapted targeted therapies are being evaluated for patients in this category [67–69].

Cryptic Chromosomal Abnormalities and Submicroscopic Lesions

NUP98 (11p15.5)

Numerous partners have been identified for the *NUP98* (11p15.5) gene, and most partners are cryptic if the translocated genes are at the telomeric regions of the chromosomes involved. Chromosomal translocations involving *NUP98* occur in a wide range of hematopoietic malignancies. Patients harboring the cryptic t(5;11)(q35.2;p15.5)/*NUP98–NSD1* fusion usually present with a very high WBC count, have a high frequency of *FLT3*-ITD mutations, and have a dismal outcome. The overall prevalence of t(5;11)(q35.2;p15.5)/*NUP98–NSD1* is approximately 5% in children and 3% in adults with AML. Although most patients have normal cytogenetics, some can harbor +8 and del(5q) as secondary aberrations. In a large series of patients with *FLT3*-ITD, *NUP98–NSD1* was found in children (16%; median age, 10 years) and adults (8%; median age, 45 years). Among patients with normal karyotypes, *NUP98–NSD1* occurred in 8% of children and 4% of adults [70, 71]. The *NUP98–NSD1* has a distinct *HOXA/B* gene expression pattern and is associated with upregulation of other genes, including overexpression of *PRDM16(MEL1)* (mapped at 1p36.1) [72]. Of note, a cytogenetically cryptic t(11;12)(p15.5;p13.3)/*NUP98–KDM5A(JARID1A)* was recently identified in 11% of children with non-DS-AMKL (median age, 2 years). The cryptic translocation had a distinct *HOXA/B* gene overexpression signature and was associated with a poor outcome [50]. Of interest, a novel t(11;12)(p15.5;q13)/*NUP98–RARG* gene fusion was observed in a patient with AML, which resembled that seen in APL [73]. A frequent translocation in AML is the t(7;11)(p15.4;p15.5)/*NUP98–HOXA9*, with a preponderance in young adults (median age, 35 years) [74].

t(7;12)(q36.3;p13)/*MNX1–ETV6*

The t(7;12)(q36.3;p13) is seen in 20% of infants with AML, and patients harboring this translocation are younger than 2 years. The t(7;12) and *KMT2A*(*MLL*) rearrangements are mutually exclusive. The t(7;12) is a subtle chromosomal aberration and can be difficult to recognize; however, FISH with the *ETV6* probe can identify the rearrangement and detect the abnormality. Most patients with this translocation have an extra chromosome 19. The fusion predicts a poor clinical outcome in patients with AML [75, 76].

***ETV6* (12p13).** Other chromosomal abnormalities of 12p, such as deletion, balanced translocations, and unbalanced translocations, which may include the loss or rearrangement of *ETV6*, are rare in patients with AML (~3%) but have been associated with poor prognosis in children with AML [54, 77–79].

inv(16)(p13.3q24.3)/*CBFA2T3(MTG16/ETO2)–GLIS2*

The *CBFA2T3–GLIS2* fusion generated by the cryptic inv(16)(p13.3q24.3) was initially identified in 30% of children with non-DS-AMKL but not in adults. Subsequently, it was found in all morphological subtypes of AML, with an overall prevalence of 8% in pediatric AML, and in larger series, in 17% of patients with non-DS-AMKL [80, 81]. The *CBFA2T3–GLIS2* fusion occurs with normal karyotypes in 8% of children; it is rarely observed with other recurrent abnormalities such as 11q23, t(8;21)(q22;q22), or inv(16)/t(16;16)(p13.1;q22). There are very few common AML-associated mutations in these children, and the *CBFA2T3–GLIS2* fusion predicts an adverse outcome [80].

***CBFA2T3* (16q24.3)**. The *CBFA2T3* gene is also fused with *RUNX1(AML1)* in the t(16;21)(q24;q22), which is rarely identified in de novo and therapy-related AML [82]. The t(1;16)(p31;q24)/*NFIA–CBFA2T3* has been detected in young males with erythroleukemia [83].

14q32/*BCL11B*

The *BCL11B* gene is sometimes involved in mostly cryptic 14q32 translocations in AML; patients with *BCL11B* rearrangements concomitantly express myeloid and T-cell-specific biphenotypic markers and harbor *FLT3*-ITD. FISH with a break-apart *BCL11B* probe can reveal rearrangements of the 14q32 locus fused to different partner chromosomes (2q22, 6q25.3, and 8q24.21) [84, 85].

Acute Megakaryoblastic Leukemia

AMKL accounts for up to 15% of pediatric AML patients, but it is extremely rare in adults. AMKL can be divided into two subgroups: DS-AMKL and non-DS-AMKL. Non-DS-AMKL includes a heterogeneous group of patients who have poor outcomes despite receiving intensive chemotherapy

[51]. Many patients carry recurrent genetic lesions [86]. The t(1;22)(p13;q13)/*RBM15(OTT)–MKL1(MAL)* (13%) is the signature lesion for non-DS-AMKL. Other recurrent abnormalities include inv(16)(p13.3q24.3)/*CBFA2T3–GLIS2* (17 %), t(11;12)(p15.5;p13.3)/*NUP98–KDM5A(JARID1A)* (11%), and 11q23 *(KMT2A)(MLL)* (10%) [50, 80]. In general, DS-AMKL includes the majority of patients with DS who are younger than 4 years and develop AML. DS-AMKL is considered by WHO-2008 as a distinct subgroup [1]. The *GATA1* (Xp11.23) mutation is present in most patients with DS-AMKL, but it is rare in children with DS and other types of leukemias or in children with non-DS-AMKL. In patients with DS-AMKL, *GATA1* mutations confer increased sensitivity to regimens containing cytarabine. The therapy for these children is less intensive than that for AML, which results in superior outcomes (EFS > 80 %) [87, 88]. Children with DS-AMKL who are older than 4 years are usually treated on standard AML regimens and have a very poor prognosis [89].

Transient Abnormal Myelopoiesis

DS with transient myeloproliferative disorder (TMD) is observed in infants with DS and is characterized by a clonal expansion of myeloblasts that can be difficult to distinguish from that seen in AML. Most cases of TMD regress spontaneously within the first 3 months of life. TMD blasts are most commonly megakaryoblastic and have distinctive mutations involving *GATA1* (Xp11.23). TMD can occur in phenotypically normal infants with genetic mosaicism in the bone marrow for trisomy 21. Although patients with TMD rarely have other chromosomal abnormalities in addition to the +21, the presence of an aberration can predict an increased risk for developing AML [87, 90]. Approximately 20% of infants with DS and TMD eventually develop AML, most being diagnosed within the first 3 years of life [91]. This transformation likely occurs through the acquisition of additional mutations and clonal selection [86, 92].

Genetic Mutations and Cytogenetic Subgroups

Some recurrent mutations that are frequent in AML are mutually exclusive of the transcription-factor fusions generated by translocations or other structural aberrations, suggesting that a cooperating mutation such as *FLT3* might activate signal pathways important in triggering leukemogenesis. Mutations such as *NPM1*, *DNMT3A*, *IDH1,* and *TET2* are initiators of leukemogenesis. Clinically relevant mutations are usually not detected in the first years of life, but their prevalence increases with age.

FLT3 (13q12) Mutation

FLT3, a receptor tyrosine kinase expressed on hematopoietic progenitors, is frequently mutated in AML, mainly in patients with a normal karyotype and is associated with poor prognosis [93]. Mutations include internal tandem duplication (*FLT3*-ITD) and a less frequent mutation involving the region encoding the activation loop (tyrosine kinase domain, *FLT3*-TKD), leading to ligand-independent constitutive activation of FLT3 signaling. *FLT3*-ITD mutations occur in children (12%; rare in children younger than 10 years) and adults (30%) with AML. *FLT3*-TKD mutations have been identified in less than 10% of children and adults with AML, but their clinical significance is not clear [94, 95]. These mutations are particularly significant when both alleles are mutated or there is a high ratio of the mutant allele to the normal allele [96, 97]. Approximately 10% of *FLT3* mutations are either gained or lost at relapse, which suggests that they can be late subclonal events and are not always the driver mutation of prognosis and response [98]. *FLT3*-ITD mutations are particularly prevalent in APL (up to 40% of children and adults), but their prognostic impact is minimal [24]. There is also a strong association of *FLT3*-ITD mutations with t(6;9)(p23;q34)/*DEK–NUP214* (~70%) and t(5;11)(q35;p15.5)/*NUP98–NSD1* (~82%). Both abnormalities are associated with dismal outcome, but this is independent of the presence of *FLT3*-ITD [57, 71].

Isolated trisomy 13 is extremely rare in children, but has been reported in a low incidence in adults with AML or MDS. Such patients have a poor outcome; however, recent reports have shown that these patients may be sensitive to lenalidomide as are patients with low-risk MDS with the 5q- cytogenetic abnormality [99]. Trisomy 13 (chromosome 13 harbors *FLT3*) is strongly associated with *RUNX1*(*AML1*) mutations and increased *FLT3* expression in AML.

NPM1 (Nucleophosmin) (5q31) Mutation

The NPM1 protein has diverse functions in the cell, such as chromatin remodeling and ribosomal complex assembly. *NPM1* mutations are detected by immunohistochemical methods that show its cytoplasmic localization [100]. NPM1 mutations are found in up to 35% of adults and 8% of children with AML. These mutations are most frequent in cytogenetically normal AML (45–60% of patients), but can be associated with +4, +8, and del(9q) and additional gene mutations such as *FLT3*-ITD, *DNMT3*, *IDH1,* and *IDH2* [101]. *NPM1* mutations are a good marker to assess MRD [102]. *NPM1* mutations are associated with good prognosis if *FLT3*-ITD or *DNMT3* mutations are absent [103].

CEBPA (19q13.1) Mutation

CEBPA encoding a transcription factor involved in normal myelopoiesis is mutated in 10% of adults younger than 60 years and in 5% of children with AML [57]. *CEBPA* mutations are found in approximately 10% of patients with normal karyotypes and can occur in patients with abnormal karyotypes, but are mutually exclusive of recurrent chromosomal aberrations [104]. Reports suggest that only biallelic mutations of *CEBPA* associated with a normal karyotype predict a favorable outcome in the absence of *FLT3*-ITD mutations [105–107].

Summary

Conventional and molecular cytogenetics are among the most important features currently used to direct treatment randomization in AML. In the last 30 years, many recurrent genetic lesions have been identified, but no single mutation has been shown to be sufficient to cause leukemogenesis. Instead, cooperating mutations are believed to promote proliferation and survival of aberrant cells or block the differentiation necessary for leukemic transformation. Most of the recurrent chromosomal abnormalities identified in myeloid blast cells generate chimeric oncoproteins that inhibit differentiation. Recent molecular genetic studies have shown that the common molecular markers for subclasses of AML include genetic lesions that may or may not be associated with chromosome abnormalities as determined by conventional cytogenetics [108–110]. The advent of novel technologies available for the genomic sequencing of leukemic blasts will help enhance our understanding of the pathophysiology of acute leukemias and identify novel therapeutic targets. Collaborative trials are needed given the rarity of childhood AML, its biological heterogeneity, and the prospect of targeted therapeutics for small genetic subgroups [10, 111].

Acute Lymphoblastic Leukemia

ALL is the most common leukemia in children, where 80–85% of leukemias are ALL, and is much rarer in adults where only 20% of acute leukemia is ALL. The cytogenetics of ALL has long been known to be of prognostic relevance, and both the number of chromosomes (modal number) and some structural abnormalities are prognostic in both adult and pediatric ALL [112].

Both cytogenetic aberrations and outcome differ between children and adults with ALL. Children with ALL have a very good prognosis, with 5-year EFS rates approaching 90% [113]. On the other hand, adults with ALL have a much poorer outcome with an overall EFS of 40% [114]. This difference in outcome can in part be attributed to the different biology of ALL in the two age groups, some of which is demonstrated by cytogenetics. The frequencies of "good prognosis" cytogenetic aberrations are higher in children than in adults with ALL, and "poor prognosis" cytogenetic abnormalities are more frequent in adults than in children with ALL.

ALL also is differentiated by the cell type that becomes leukemic. Approximately 85% of children and 75–80% of adults with ALL have B-cell precursor (BCP) ALL, and the remaining have T-cell ALL (T-ALL) [115, 116]. The cytogenetics of BCP and T-ALL differ, although there are some overlaps, and will be discussed separately. (See Table 16.2 for summary of ALL cytogenetic aberrations.)

B-Cell Precursor ALL

Chromosome Numbers in ALL

Modal number (mn) is defined as the number of chromosomes in the most prevalent abnormal clone. However, in ALL, the mn for classification is considered the number of chromosomes in the simplest abnormal clone, regardless of the prevalence of the clone. The mn is prognostic in ALL. Modal number classification in ALL includes high hyperdiploidy (HH, 51–67 chromosomes), low hyperdiploidy (LH, 47–50 chromosomes), near-triploidy (68–79 chromosomes), near-tetraploidy (>79 chromosomes), pseudodiploidy (46 chromosomes with an abnormality, usually, although not always, structural), normal chromosomes, and hypodiploidy (HO, <46 chromosomes).

As per mn classification, patients with HH have the best outcome. About 35% of children with ALL have HH [unpublished Children's Oncology Group (COG) data], whereas <10% of adults have HH [117, 118]. Chromosomes X, 4, 6, 10, 14, 17, 18, and 21 are preferentially present in extra copy number in HH ALL [119, 120] (Fig. 16.3). Furthermore, the excellent prognosis of HH ALL can be attributed to the presence of specific extra chromosomes. The COG found that the simultaneous presence of extra copies of chromosomes 4, 10, and 17 was associated with an excellent prognosis [121], and the Medical Research Council (MRC) of the United Kingdom found that extra copies of chromosomes 10 and 18 were associated with an excellent prognosis [119]. The significance of specific extra chromosomes has not been studied in adults with ALL. Approximately 50% of children with HH ALL have a structural abnormality, most often a duplication of 1q, which does not have prognostic significance [122]. The only other recurring structural abnormality frequently found in pediatric HH ALL is a t(1;19)(q23;p13.3), which frequently does not have a *TCF3-PBX1* rearrangement. Adults with HH ALL, however, frequently have recurring structural abnormalities that are associated with an adverse outcome [118].

Table 16.2 Common recurring aberrations in ALL

B-cell precursor ALL						
	Frequency (%)					
Aberration	Adult	Pediatric	Genes	Prognosis	Cytogenetic variants	Comments
Numerical aberrations						
Hyperdiploidy, mn > 50	<10	25–30		Good		
Hyperdiploidy, mn > 46 < 51	15	15		Intermediate		Usually have structural abnormalities, ~50% recurrent
Pseudodiploidy				Intermediate		
Near-triploidy and mn 30–39	Rare			Poor		
Hypodiploidy, mn 44–45		7		Intermediate		Usually have structural abnormalities
Hypodiploidy, mn <44		1.7		Poor		Few structural abnormalities, frequent doubling in mn <40
Structural aberrations						
t(9;22)(q34.1;q11.2)	25	<4	*BCR-ABL1*	Intermediate with TKI therapy	5% complex	Frequency increases with age
t(12;21)(p13;q22)	Very rare	25	*ETV6-RUNX1*	Good		Cytogenetically cryptic. Many other *ETV6* rearrangements may differ in clinical characteristics and prognosis
t(4;11)(q21.3;q23)			*KMT2A-AFF1*	Poor	Insertions, three-way translocations	Frequent in infants. Outcome may differ with age
t(11;19)(q23;p13.3)			*KMT2A-MLLT1*	Poor		Also in T-ALL and AML
t(9;11)(p22;q23)			*KMT2A-MLLT3*	Adults better than other 11q23; children poor		
Other 11q23	5	5 >1 year 80 <1 year	*KMT2A/other*	Poor		Frequent in infants. Outcome may differ with age and partner
t(1;19)(q23.3;p13.3)	3	6	*TCF3-PBX1*	Not prognostic	der(19)t(1;19)(q23.3;p13.3); t(17;19)(q22;p13.3)	*HLF-E2A* in t(17;19)—poor prognosis
der(21)/add(21)			*RUNX1*	Poor	der(21) appears in many guises	Amplification of *RUNX1* or near gene
del(9p)	30	6	*CDKN2A*	Unknown		
dic(9;12)(p13;p11.2)	Rare	Rare	50% *PAX5-ETV6*	Good		Not all have PAX5/ETV6 rearrangement
dic(9;20)(p12-p13;q11.2)	Rare	Rare	*Some PAX5-ASXL1*	Good		
dic(7;9)(p11.2;p13)	Rare	Rare				
t(8;14)(q24;q32.3)			*IGH-MYC*	Intermediate		Usually Burkitt leukemia/lymphoma
t(8;14)(q11.2;q32.3)			*IGH-CEBPD*	Good in Down syndrome		Prevalent in Down syndrome ALL
t(5;14)(q31;q32.3)	Rare	Rare	*IGH-IL3*	Poor		Associated with hypereosinophilia
Other 14q32.3			*IGH*			
del(6q)	7	1.5	*MYB* some cases	Not prognostic		Frequent in *ETV6-RUNX1* cases
del(5q)	Rare	Rare				
del(7p)	4	4		Poor		
del(12)(p11.2-p13)			*?ETV6*	Not prognostic

[a]When frequencies do not differ between children and adults, they are displayed in the adults column

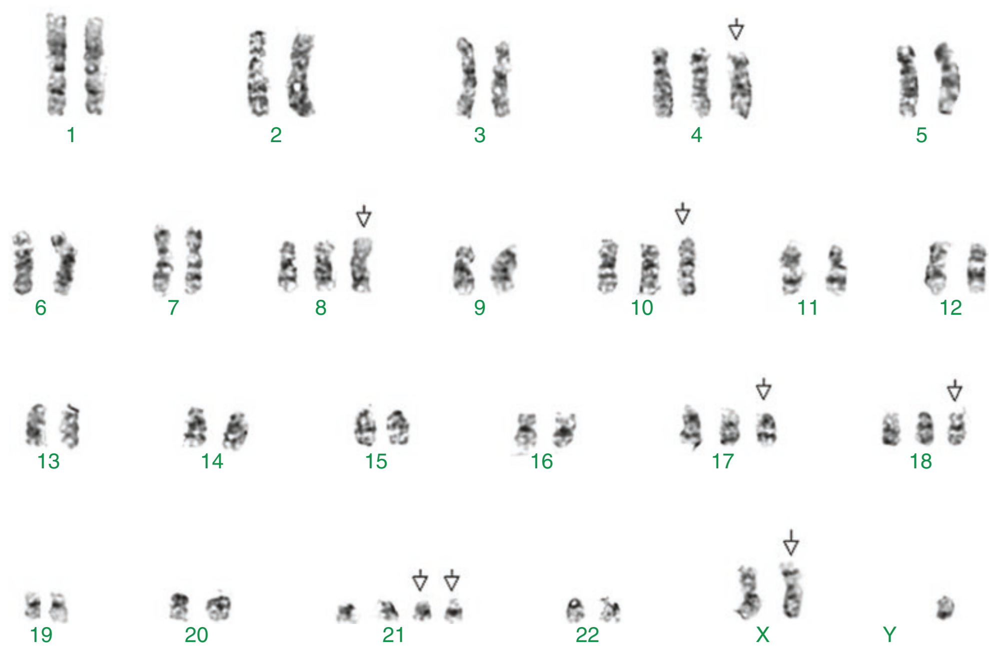

Fig. 16.3 Karyogram from a child with high hyperdiploid ALL. *Arrows* indicate extra chromosomes. The karyotype for this patient is 54, XY, +X, +4, +8, +10, +17, +18, +21, +21

Low hyperdiploidy is present in approximately 15% of both pediatric and adult ALL. These patients frequently have a recurring structural abnormality, and prognosis is associated with the recurring structural abnormality. The remaining patients with LH ALL have an intermediate prognosis [123, 124].

Near-tetraploidy is rare, occurring in <1% of pediatric and adult BCP ALL. It is more frequent in T-ALL. In pediatric BCP ALL, near-tetraploidy often also has an *ETV6-RUNX1*(*TEL-AML1*) rearrangement, which is associated with excellent prognosis (see in text to come). Because near-tetraploidy is rare, its prognostic significance in the absence of an *EVT6-RUNX1* rearrangement is unknown [117, 118].

Near-triploidy is also rare (<1% of pediatric ALL and 4% of adult ALL). These cases appear to be "true" near-triploids in pediatric ALL, with three copies of most chromosomes and only rarely structural abnormalities. Adult near-triploidy appears to be associated with hypodiploidy and represents a doubling of a hypodiploid clone. Cases with this karyotypic result are classified as hypodiploid cases in pediatric ALL. The prognosis of "true" near-triploidy is not known.

Pediatric ALL with hypodiploidy is further differentiated by mn. Seven percent of children with BCP ALL have 44 or 45 chromosomes. These cases usually have a structural abnormality, and prognostic significance is associated with the structural abnormality. Overall, these patients have an intermediate prognosis [125]. Patients with 43 and fewer chromosomes (1.7% of pediatric BCP ALL) have a dismal prognosis [125]. Cytogenetically, they can be classified as those with 40–43 chromosomes, with 30–39 chromosomes, or with 24–29 chromosomes [126, 127]. Patients with 40–43 chromosomes nearly always have a structural abnormality (>86%), and do not have doubling of the abnormal clone. Karyotypes of children with 30–39 chromosomes have doubling in 30–57% of cases and often (39–57% of cases) have structural abnormalities. Patients with 24–29 chromosomes (near-haploidy, 1% of pediatric BCP ALL) frequently also have doubling of the near-haploid clone (57–64% of cases), and structural abnormalities are found in only 14–25% of cases [126, 127]. Doubling of the hypodiploid clone can be masked, with only the doubled clone present. In such cases, additional studies, such as SNP microarray, are required to detect the abnormal clone and assure correct cytogenetic classification. Recent molecular studies of pediatric hypodiploid ALL have confirmed three categories of hypodiploidy differing in both modal number and types of mutations in the different groups [128]. Near-haploid cases (mn = 24–31) frequently have mutations in the signaling pathway, particularly in *NRAS*, *NF1*, and *IKZF3*. They also tend to be younger than hypodiploid patients with higher mn. Low hypodiploid cases (mn = 32–39) have mutations in *RB1* and *IKZF2* and significantly in *TP53*. Approximately half of the latter are germ line in origin, consistent with Li-Fraumeni syndrome. Adults with ALL with near-triploidy and hypodiploidy (30–39 chromosomes) are often classified together as the near-triploid clones usually represent doubling of the hypodiploid clone [117, 118]. Near-haploid adult ALL is extremely rare, and has not been reported in patients older than 40 years [117].

Recurring Structural Abnormalities in BCP ALL

Cytogenetic classification of BCP ALL is further classified on the basis of structural abnormalities. In cases with a recurring structural abnormality and a numerical abnormality, the case is generally classified by the structural abnormality.

Rearrangements Associated with Favorable Prognosis

The most common structural abnormality in pediatric BCP ALL is t(12;21)(p13;q22), which results in an *ETV6-RUNX1*(*TEL-AML1*) fusion gene. The abnormality is cryptic by standard cytogenetics, but can be detected by FISH using probes for *ETV6-RUNX1*. This rearrangement is present in 25% of children with BCP ALL and is associated with excellent prognosis [129]. It is rarely found in adult ALL, and then with rare exception, in patients younger than 30 years [130]. Although the t(12;21) is cryptic, 80% of these patients have cytogenetically visible aberrations [131]. The *ETV6-RUNX1* rearrangement is prenatal in origin [132]. It is not sufficient to cause leukemia, but appears to be an initiating event. A second event is required for expression of the disease [132]. The second event is often loss of the second *ETV6* allele, which is frequently detected by standard cytogenetics. This may explain early studies reporting either no prognostic significance or a good prognosis for patients with deletions of 12p.

Rearrangements Associated with Adverse Prognosis

Rearrangements of *KMT2A* (formerly *MLL,* 11q23) are associated with a poor prognosis in ALL. Although *KMT2A* rearrangements occur in both ALL and AML, some rearrangements are more common to each leukemia. *KMT2A* rearrangements are present in 2–7% of ALL patients older than 12 months. However, they are particularly common in infants, and up to 80% of infants younger than 12 months who are diagnosed with ALL have an *KMT2A* rearrangement. A t(4;11)(q21;q23)/*KMT2A-AFF1*(*AF4*) occurs in ALL, but the cells may have some myeloid markers [133]

(Fig. 16.4). It is the most common *KMT2A* rearrangement in infant ALL and is associated with a very poor prognosis [134]. The t(4;11) also occurs in pediatric and adult ALL, although at a much lower frequency (<2%), and also is associated with a poor prognosis. The etiology of the t(4;11) in infants and young children is prenatal [132]. Studies of monozygous twins with t(4;11) ALL show that they share identical molecular rearrangements, and studies of infant blood spots (Guthrie spots) from children with t(4;11) ALL show that these rearrangements can be detected in blood spots [132]. Also, cord blood investigations have shown that the rearrangement is much more prevalent than the development of leukemia [132]. These studies indicate that additional mutations are required for the development of ALL; even though a t(4;11) may occur prenatally, t(4;11) leukemia does not always develop, and when it does develop there is typically a time lag. The second most frequent *KMT2A* rearrangement in infant ALL is t(11;19)(q23;p13.3)/*KMT2A-MLLT1*(*ENL*), which also portends a poor prognosis, although it may not be as poor as t(4;11) infant ALL (Fig. 16.2). This rearrangement occurs in 3–7% of children and adults with ALL as well as in AML. A third common *KMT2A* rearrangement in ALL that occurs in all age groups is t(9;11)(p22;q23)/*KMT2A-MLLT3*(*AF9*), which is also very common in AML. Other *KMT2A* partners in ALL include Xq13.1/*FOXO4* (*AFX1*), 1p32/*EPS15*(*AF1P*), 5q31/*AFF4*(*AF5q31*), 6q27/*MLLT4*(*AF6*), 7p22.1/ *TNRC18*(*KIAA18856*), 10p12/*MLLT10*(*AF10*), 11q21 /*MAML2*, 11q23.3/*BCL9L*, 15q14/*CASC5*(*AF15Q14*), 16p13.3/*CREBBP*(*CBP*), 19p13.3/ *ASAH3*(*ACER1*), 19q13/ (*ACTN4*), 20q11/*MAPRE1*, and 22q11.21/*DEPT5*(*CDCREL*) [6].

Secondary ALL is a rare event, and most frequently has an *KMT2A* rearrangement. These secondary ALL generally occur after a patient has been treated with epipodophyllotoxins; they have a short lag time of 2–4 years and no preceding preleukemic phase. Patients with secondary ALL typically respond to therapy, but remissions are short and prognosis is poor. A t(4;11) is the most common *KMT2A* rearrangement in therapy-related ALL, but other *KMT2A* rearrangements, particularly t(9;11), also occur [6].

Philadelphia Chromosome (Ph+) and Philadelphia-like ALL

A Philadelphia chromosome (Ph), resulting from a t(9;22)(q34.1;q11.2) and a *BCR-ABL1* fusion, in ALL was associated with a very poor outcome in the past [114, 135] (Fig. 16.5). However, the poor outcome has been ameliorated by treatment with the tyrosine kinase inhibitor, imatinib mesylate [136, 137]. This translocation is present in less than 4% of children with ALL, but in 25% of adults with ALL. Its frequency increases with age, at least up to the fourth decade [117].

Philadelphia-like or *BCR-ABL1*-like ALL has an expression signature very much like that of Ph+ ALL, but without a t(9;22)(q34.1q11.2) [138, 139]. It is 3–4 times more common than Ph+ ALL in children, and its frequency increases with age. Outcome with traditional treatments is very poor. It is associated with *IKZF1* deletion, *CRLF2* rearrangements, and *JAK2* mutations. There are two different types of Ph-like ALL: those associated with *CRLF2* overexpression [140] and those with a variety of gene fusions targeting kinase

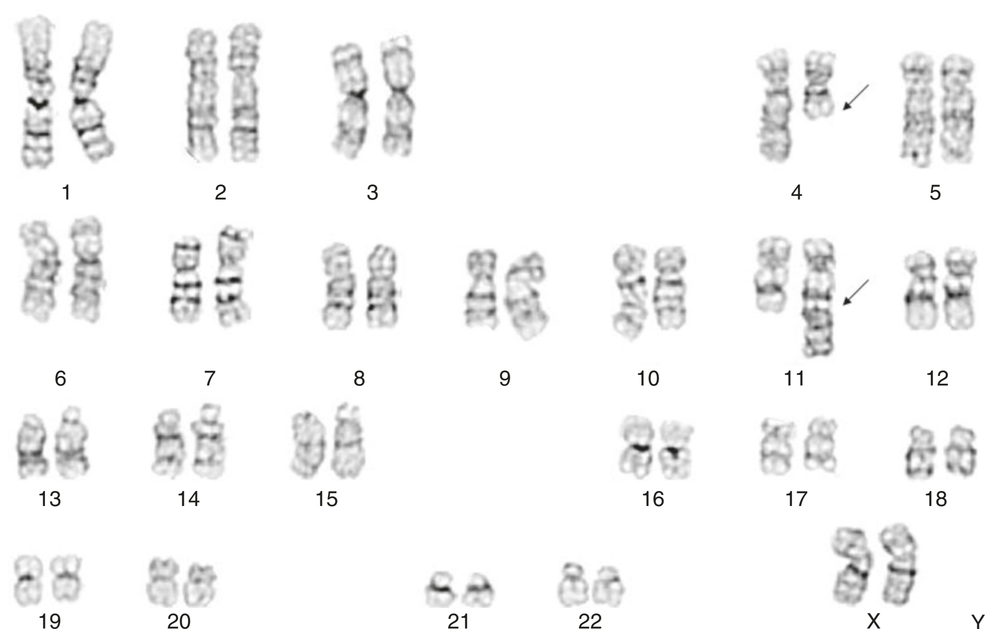

Fig. 16.4 Karyogram of patient with ALL and a t(4;11). *Arrows* indicate the abnormal chromosomes. The karyotype for this patient is 46,XX,t(4;11)(q21;q23)

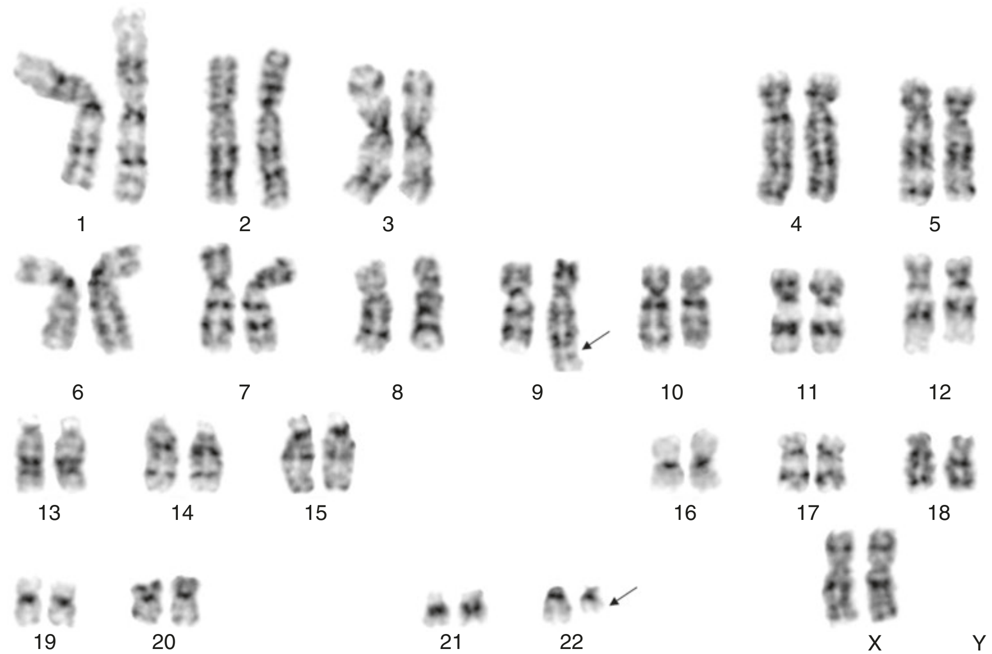

Fig. 16.5 Karyogram from a Philadelphia chromosome-positive ALL patient. *Arrows* indicate the abnormal chromosomes. The karyotype for this patient is 46,XX,t(9;22)(q34.1;q11.2)

genes, including *ABL1*, *ABL2*, *CSF1R*, *PDGFRB*, *EPOR*, and *JAK2* in a significant percentage of the remaining cases. Patients with these aberrations may be sensitive to tyrosine kinase inhibitors [141, 142]. Many of these gene fusions are cytogenetically cryptic, and molecular techniques are required to detect them. *CRLF2* is located in the pseudo-autosomal region of the X and Y chromosomes. CRLF2 overexpression results from a translocation with *IGH* or from a deletion of the sequences between *CRLF2* and *P2RY8*; both are cytogenically cryptic, and FISH or other molecular techniques are required for their detection. The *P2RY8-CRLF2* deletion is particularly common in children with DS [143]. Patients with a *CRLF2* rearrangement may be sensitive to ruxolitinib [142].

In addition to a t(12;21), the *ETV6-RUNX1* probes detect amplification of the *RUNX1* gene, resulting in an abnormality designated *iAMP21*. This may be detected with array studies, but is typically detected by FISH. By definition, amplification requires at least three extra copies of *RUNX1* on a single chromosome, usually an abnormal chromosome 21, resulting in a total of at least five *RUNX1* signals. It is not known whether the significant gene amplified in this region is *RUNX1*, as *RUNX1* is not overexpressed, although aCGH studies have shown that *RUNX1* is always included in the amplified region. The abnormality has been associated with a poor outcome [144, 145]. This aberration is more common in older children, but is rarely seen in adults with ALL [146].

Rearrangements Associated with Uncertain Prognostic Significance

A t(1;19)(q23.3;p13.3)/*TCF3*(*E2A*)-*PBX1* occurs both as a balanced t(1;19) and an unbalanced der(19)t(1;19) with two normal chromosomes 1. It is found in 6% of pediatric and 3% of adult ALL, typically with a pre-B-cell phenotype. It is only rarely prenatal in origin [132]. Early reports indicated an adverse prognosis for children with this aberration, but subsequent studies showed that it did not influence outcome, most likely due to more intense treatment in subsequent studies [130]. However, a t(1;19) may portend an adverse prognosis in adult ALL [147].

Deletions of 9p are frequent in ALL, occurring in up to 30% of adult ALL and up to 6% of pediatric ALL. Some are seen by traditional cytogenetics, but many are cryptic and cannot be detected by cytogenetics, so the frequency of this aberration may be much higher. The clinical significance of this abnormality has been controversial, with some studies showing an adverse prognosis [148] and others no impact on outcome [149]. The abnormality is thought to result in loss of the oncogene *CDKN2A*, which can be detected by FISH.

Interestingly, dicentric chromosomes are frequent in ALL, and they most often involve a chromosome 9. Although all dic(9;V) result in loss of 9p, the significance of dic(9;V) may be associated with a fusion gene rather than a deletion of 9p. A dic(9;12) is one of the more frequent dicentric chromosomes in ALL, although it is seen in less than 1% of

children with ALL and very rarely in adults with ALL (usually in young adults) [150]. Approximately 50% of cases with dic(9;12) have a *PAX5-ETV6* rearrangement [151], and the remaining have an *ETV6-RUNX1* rearrangement instead [152]. The chromosome 12 involved in the dic(9;12) is not involved in the *ETV6-RUNX1* rearrangement, and the genes involved in the dic(9;12) in these cases have not yet been identified [152]. There is no consensus on the outcome of patients with dic(9;12); early reports of dic(9;12) indicated an excellent outcome [150], but studies by the Children's Cancer Group did not confirm this good prognosis [148].

A dic(9;20)(p12–p13;q11.2) is another frequent dicentric chromosome in ALL. This aberration is subtle and may be missed by traditional cytogenetics; cases with monosomy 20 need to be tested for the presence of this dicentric chromosome by FISH with probes for the centromeres of chromosomes 9 and 20 on either metaphases or interphases or using chromosome paints for chromosomes 9 and 20 on metaphases. The dic(9;20) has a peak incidence at age approximately 3 years and has a female predominance. It occurs in approximately 0.5% of adults and 2% of children with ALL and appears to have a favorable prognosis [153]. The molecular breakpoints of both partners of the dic(9;20) are heterogeneous—some 9p11–13 breakpoints occur in the repetitive region near the centromere and some involve *PAX5*. The 20q breakpoint frequently involves *ASXL1* [154].

Rearrangements of 14q32, usually involving the *IGH* gene, are recurrent in ALL. The t(8;14)(q22;q32.3)/*IGH-MYC* and its variants t(2;8)(p12;q22)/*IGK-MYC* and t(8;22)(q22;q11.2)/*IGL-MYC* generally indicate Burkitt leukemia. Although this aberration can occur in patients with BCP ALL, most are considered mature B-cell leukemias. Several rearrangements of 14q32.3, in addition to t(8;14)(q24;q32.3), are recurrent in ALL. They result in overexpression of the *IGH* partner gene. One such rearrangement is a t(8;14)(q11.2;q32.3)/*IGH-CEBPD*, which is more frequent in children with DS and ALL. In non-DS cases, trisomy 21 is often a secondary abnormality. Patients with DS and ALL who have this abnormality have an excellent prognosis [155]. Another *IGH* rearrangement in ALL is t(14;19)(q32.3;q13)/*IGH-CEBPA*. Additional *CEBP* genes also rearrange with *IGH*, indicating that overexpression of any of the several members of a gene family can contribute to ALL [156].

Recurrent Deletions and Single-Chromosome Aneusomies

Deletions of 12p are frequent in ALL. A del(12p) has been detected by cytogenetics in 9% of children and 4% of adults with ALL [118, 157]. It often includes deletion of *ETV6* and is sometimes associated with t(12;21) in pediatric ALL. When examined regardless of the presence of t(12;21), it has no prognostic significance [157]. Its clinical significance in the absence of t(12;21) remains to be investigated.

Deletion 6q is more frequent in adults (7%) than in children (1.5%) with ALL ([124] and COG unpublished data). It is often cryptic, and therefore its true incidence is not known. Whether the *MYB* oncogene is the significant gene deleted is controversial. When detected by traditional cytogenetics, del(6q) does not have prognostic significance in pediatric ALL [158], although it may have an adverse impact on prognosis in adult ALL [117, 159].

Deletions of 5q in ALL are rare (<2% of both children and adults). They do not appear to have prognostic significance in adults [160]. Children with ALL and a del(5q) have an adverse EFS, but not overall survival, indicating that they may respond to salvage therapy [161]. Whether the significant region of 5q lost in ALL is the same as that in AML remains to be investigated.

Monosomy 7 is rare but recurrent in ALL. It is frequently a secondary abnormality in Ph+ ALL. Deletions of chromosome 7 also occur, most frequently of 7p. When Ph+ cases are excluded, monosomy 7 or chromosome 7 deletions occur in approximately 5% of adults and children with ALL. Deletions of 7p appear to be an adverse prognostic factor in children but not adults with ALL [118, 162].

Trisomy 8 as a sole abnormality is also rare but recurrent in ALL, seen in approximately 3% of cases ([124] and COG unpublished data). There is no agreement on its prognostic significance: some studies have shown no prognostic significance [118], and others have shown an adverse outcome for patients with ALL and this abnormality [159].

Gain of an X chromosome in non-HH ALL is also recurrent, often in conjunction with another abnormality, such as the t(8;14)(q11.2;q32.3). As a sole cytogenetic abnormality, it is found in less than 1% of children with ALL (unpublished COG data), and its frequency in adults as a sole abnormality has not been reported. It does not appear to influence prognosis in adults when all cases with an extra X chromosome are considered [118].

Trisomy 21 in non-HH ALL is also recurrent. As with an extra X chromosome, it often occurs in conjunction with another abnormality, such as the t(12;21), wherein it is a frequent secondary abnormality. Sole trisomy 21 is rare in pediatric ALL, occurring in less than 1% of cases (unpublished COG data). Its frequency in adult ALL or its prognostic significance as a sole aberration in ALL has not been investigated.

Deletions of 13q and monosomy 13 occur in 5% of adults with ALL, and 2% of children with ALL have breakpoints in 13q12–14 [163]. In children, these aberrations contribute to a higher risk of treatment failure and are also associated with other adverse clinical features. Deletion 13/monosomy 13 does not appear to have prognostic significance in adults [118].

B-Cell Precursor ALL Summary

Frequencies of cytogenetic aberrations known to have the most significant impact on outcome differ in children and adults with ALL. The differences in frequencies of a Ph, an *ETV6-RUNX1* rearrangement, and HH contribute to the differences in outcome between pediatric and adult ALL. HH and an *ETV6-RUNX1* rearrangement, both rare in adults, have the best prognosis among all ALL cytogenetic aberrations. However, a Ph, which is much more common in adults than in children with ALL, predicts a poor prognosis, especially before the advent of treatment with tyrosine kinase inhibitors specific for this rearrangement. The frequencies of aberrations with less prognostic impact differ only slightly between adults and children with BCP ALL. Additional research is needed to elucidate the etiology of the differences in frequencies of ALL cytogenetic subsets between adults and children with ALL. Although the genes involved in many aberrations are known, many have not been identified. Identification of new aberrations, such as Ph-like ALL and development of treatments specific for genetic subsets of ALL will contribute to improved outcomes for these patients in the future.

T-Cell ALL

T-ALL is less common than BCP ALL, accounting for 10–15% of pediatric ALL and 25% of adult ALL, and is more frequent in males than in females [116]. It is cytogenetically distinct from BCP ALL, although both subtypes have some aberrations in common. It is typically subdivided according to the maturation status of the leukemic cells. Normal metaphase cytogenetics in T-ALL may in part be due to a high frequency of cryptic aberrations in T-ALL. Molecular approaches have shown that 90% of adults with T-ALL have aberrations [164]. Numeric changes are rare in pediatric T-ALL (<8%; unpublished COG data), but are more common in adult ALL (~30%) [118].

The most common cytogenetic aberrations in T-ALL involve the T-cell receptor (TCR) loci, *TRA/TRD* at 14q11.2, *TRB* at 7q34, and *TRG* at 7p14, and occur in 35% of cases of T-ALL [165]. Any of the TCRs can rearrange with each of the partner loci, and some partners appear to preferentially rearrange with different TCRs. As a result of these rearrangements, the translocation partner of the TCR is juxtaposed to the promoter or enhancer element of the TCR and is overexpressed. A t(1;14)(p32;q11.2)/*TRA/TRD-TAL1* results in overexpression of *TAL1*. This aberration is rare (3%) in T-ALL. However, a cryptic deletion of 1p, which results in loss of *SCL* and juxtaposition of *STIL* and *TAL1*, is much more common (17% of T-ALL) and also causes deregulation of *TAL1*. This rearrangement is associated with a good prognosis [166]. Other recurring translocations with the TCR loci are with 10q24/*TLX1*(*HOX11*), 9q34.3/*NOTCH1*, 11p13/*LMO2*, 11p15/*LMO1*, 7p15/*HOXA* cluster, 9q32/*TAL2*, 8q24/*MYC*, 19p13/*LYL1*, 1p34/*LCK*, 14q13/*NKX2.1*, and 12p13/*CCND2*. *TLX1* expression is generally associated with an improved outcome, and its expression also occurs in the absence of a *TLX1* rearrangement [167]. The prognostic significance of the other genes rearranged with TCR loci is not well established. The recurrent t(7;9)(q34;q34.3) led to the identification of Notch1 signaling in T-ALL pathogenesis, and *NOTCH1* activating mutations are now known to occur in 60% of T-ALL [168, 169]. Notch1 is important in regulating hematopoietic progenitor commitment to the T-cell lineage, consistent with *NOTCH1* mutations in 50–70% of T-ALL [170, 171].

Chimeric or fusion genes also recur in T-ALL, including *KMT2A* rearrangements, although these are rare (<5%; COG unpublished data and [116]). Interestingly, a t(11;19)(q23;p13.3) (*KMT2A-MLLT1*) rearrangement in T-ALL is associated with a relatively good prognosis [172] (Fig. 16.2). A t(10;11)(p12;q14)/*PICALM*(*CALM*)-*MLLT10* occurs in 2–3% of patients with T-ALL. It can be mistaken for a *KMT2A* rearrangement, as the breakpoints of different t(10;11) can be difficult to distinguish. These abnormalities can be detected by FISH. Patients with a *PICALM-MLLT10* fusion have a relatively good prognosis [116]. A t(5;14)(q35;q32)/*BCL11B-TLX3* is another cryptic rearrangement in T-ALL. *TLX3* also rearranges with other partners, including 14q11.2/*TRA/TRD*), 7q21/*CDK6*, and 5q34/*RANBP17*. As a result of these rearrangements, *TLX3* is overexpressed. The rearrangements are rare and previously appeared to predict a poor prognosis; however, with current therapies these patients may not have a poor prognosis [116, 173]. In most cases with *TLX3* expression, a chromosome 5 abnormality is present [173]. Amplification of a cryptic rearrangement of *NUP214-ABL1* is seen in 2–6% of patients with T-ALL. *NUP214* is slightly distal to *ABL1* on chromosome 9 band q34. This rearrangement is unique in that it is present as an episome (a small extrachromosomal circular body) with juxtaposition of these genes. The episomes are in the nucleoplasm. Although not detected by metaphase cytogenetics, this rearrangement can be detected by FISH with either a fusion probe for *NUP214-ABL1* or a probe for *ABL1* [174]. This aberration is also found in Ph-like B-precursor ALL [141]. There is some preliminary evidence that patients with this aberration may respond to imatinib therapy [175].

Deletions of 9p are very frequent in T-ALL; they are often cryptic and not detected by cytogenetics, and therefore FISH or PCR is needed for their detection. The genes deleted are *CDKN2A*, the primary target, and *CDKN2B*, also very frequently deleted. They are often homozygously deleted (65% of T-ALL) and less frequently hemizygously deleted (23%) [176]. In addition, they may be inactivated by methylation;

up to 93% of *CDKN2A* and 99% of *CDKN2B* may be inactivated at the protein level [177]. This aberration appears to have no prognostic significance [116]. Similarly, deletions of 6q are common, occurring in 30% of cases, but their prognostic significance is uncertain.

Although complexity has not been shown to be prognostic in BCP ALL, it may be prognostic in T-ALL, particularly in adults; 5–8% of adults with T-ALL have five or more abnormalities, and 15% have three or more abnormalities. In a large study, adults with T-ALL who had five or more abnormalities had a poor outcome [116].

T-ALL Summary

In normal development, T-cell progenitors originate in the bone marrow and migrate to the thymus, where they complete antigen-independent maturation. The thymus is encapsulated and has cortical and medullary areas. T-cell precursors enter the subcapsular cortical area where they proliferate and begin to differentiate. As the cells differentiate, they move from the cortex toward the medulla where differentiation continues, TCR rearrangement begins, and cells progress through differentiation stages; first expressing neither CD4 nor CD8, then expressing CD4 and CD8, and then either CD4 or CD8. The cells move to the cortico-medullary junction and maturation continues. When the cells are mature, they leave the thymus and enter the periphery.

Expression array studies of T-ALL have shown five different expression signatures, which correspond to differentiation stages and to cytogenetic aberrations [178]. The *TAL1/LMO* subgroup includes all rearrangements involving these genes (Table 16.2) and the T-cells are in an early stage of development, when neither CD4 nor CD8 is expressed. The *TLX1* subgroup includes cases with *TLX1* (10q24) rearrangements, typically affects cells at the early cortical thymocyte stage, and is associated with a good prognosis. The *TLX3* subgroup currently includes only *TLX3* (5q35) rearrangements. Although they do not have a unique differentiation profile, they do not have a mature immunophenotype. The fourth expression array subgroup is the *HOXA* subgroup and includes *PICALM-MLLT10*, *KMT2A*, inversion 7, and *SET-NUP214* rearrangements. *HOXA* genes are activated in this subgroup, and they generally have a mature immunophenotype. The *MYB* subgroup represents cases with expression of *MYB* through activation by a translocation with a TCR or by *MYB* amplification. The T-cell developmental stage of this subgroup has not been identified [178]. These expression array studies and their correlations with cytogenetic aberrations show a pattern of genetic lesions in T-ALL and a relationship to the differentiation status of the transformed T-cells. The different patterns of gene expression categorize many recurring T-ALL cytogenetic aberrations into groups, illustrating association of different abnormalities to each other, to T-cell differentiation, and to prognosis.

Summary

The use of conventional and molecular cytogenetics has led to many gene discoveries in cancer biology over the past several decades. The cloning of chromosome translocation breakpoints, like the t(8;21), inv(16), 11q23, t(12;21), t(9;22), and many others, has helped to identify the genes involved in these translocations and allowed the development of DNA probes for FISH and RT-PCR that are used to diagnose and monitor minimal residual disease. Many genetic lesions are currently used as tools for the diagnosis, classification, and management of patients with acute leukemia.

The advent of new DNA array and sequencing technologies has enabled the simultaneous detection of mutations, deletions, amplifications, and epigenetic changes; and RNA arrays have allowed the evaluation of associated biochemical pathways. Thus, the detection of additional tumor markers via innovative genetic technologies will help pinpoint the genes that act cooperatively in a particular malignant cell type, complementing the current WHO-2008 assignment of genetic lesions used in acute leukemias.

Currently known molecular genetic mutations as well as novel ones that remain to be identified are potential genetic markers that have clinical significance, underscoring the patient variability in and heterogeneity of acute leukemias. These genetic events alter cellular pathways and functions, which may in turn affect the clinical phenotype of the disease and treatment response, thereby facilitating individualized targeted therapy.

Acknowledgments We are unable to include the references for studies by several investigators because of limited space; only the latest references in various topics have been included in this chapter. Special thanks to Heather Breidenbach for assistance with the preparation of the chapter and to Vani Shanker for scientific editing of the chapter.

Diagnosis and Treatment of Childhood Acute Lymphoblastic Leukemia

17

Melinda Pauly and Lewis B. Silverman

Introduction

Acute lymphoblastic leukemia (ALL) is the most common malignancy of childhood, accounting for 25–30% of all pediatric cancer cases [1]. Leukemias arise from genetic changes that occur in a single lymphoid progenitor cell at various stages of maturation, resulting in a clonal expansion. The single-cell origin of ALL is demonstrated by the finding of clonal rearrangements of immunoglobulin (Ig) or T-cell receptor (TCR) genes in most lymphoblasts [2]. Malignant lymphoblasts possess the immunophenotypic and genetic characteristics of either B- or T-lymphoid precursors [3, 4]. The inability of these lymphoid progenitors to differentiate as well as their resistance to cell death leads to their accumulation in the marrow compartment and spread throughout the body. By the time of diagnosis, lymphoblasts have usually occupied much of the bone marrow microenvironment at the expense of normal hematopoietic cells, resulting in anemia, thrombocytopenia, and/or neutropenia. Effective treatment for the majority of patients consists of multiagent chemotherapy administered for 2–3 years, resulting in clonal eradication; the intensity of therapy is stratified based on presenting features, leukemia genetics, and early response to therapy.

Incidence

Of the approximately 6600 new cases of ALL diagnosed in the USA per year, 57% of cases are under the age of 20 years and 15.6% of death from ALL occur in this age group [5]. ALL is the most common malignancy diagnosed in patients younger than 15 years, representing 23% of all cancers and 76% of leukemias in this age group [6]. Over the last 30 years, the incidence of ALL in the USA and Europe has steadily increased [1, 7]. The incidence of ALL is highest between ages 2 and 5 years, and is higher in boys than in girls (especially for T-ALL), although girls have a slightly higher (1.5 times) incidence in the first year of life [8].

Predisposing Factors

Risk factors for developing leukemia include family history, underlying genetic conditions, and (rarely) certain environmental exposures. For the vast majority of cases of childhood ALL, predisposing factors cannot be identified.

Fraternal twins and siblings of children with leukemia have a two- to fourfold greater risk of developing leukemia during the first decade of life [9, 10]. The concordance rate of ALL in monozygotic twins ranges from 5 to 25%, depending on subtype and age that the first twin develops leukemia. When one twin develops infant ALL (typically with a *KMT2A* gene rearrangement), ALL almost invariably develops in the other twin with a short latency (generally within a few months), likely reflecting transfer of ALL cells via the placental circulation [11–14]. The concordance rate in twins with ALL with the *ETV6-RUNX1* fusion is much lower at 10% and the postnatal latency period is longer, suggesting that cooperating genetic events are required postnatally for leukemic transformation in this subtype of ALL [15, 16].

Only a small proportion (<5%) of cases of ALL are associated with hereditary genetic abnormalities. The most common condition associated with the development of ALL is Down syndrome (trisomy 21). Children with Down syndrome

© Springer International Publishing AG 2018
P.H. Wiernik et al. (eds.), *Neoplastic Diseases of the Blood*, DOI 10.1007/978-3-319-64263-5_17

have a 20-fold greater risk of ALL compared with non-Down syndrome children [17, 18]. The ALL observed in children with Down syndrome appears biologically distinctive, with a higher frequency of *CRLF2* overexpression and *JAK2* mutations, and a lower frequency of other recurrent genetic abnormalities, such as *ETV6-RUNX1*, high hyperdiploidy, *KMT2A*-rearrangement, and *BCR-ABL1* [19–23].

Other genetic disorders associated with an increased risk of ALL include ataxia telangiectasia and Bloom's syndrome [18, 24, 25]. Patients with ataxia telangiectasia have a 70-fold greater risk of leukemia, particularly T-ALL [26]. Nearly 90% of pediatric cases of low hypodiploid ALL (32–39 chromosomes), a rare subtype, have a TP53 mutation (compared with <5% of non-low-hypodiploid ALL); almost half of the TP53 mutations observed in low hypodiploid ALL are germline [27].

Genome-wide association studies (GWAS) have identified a number of germline polymorphisms associated with increased risk for developing childhood ALL. The first SNPs which GWAS technology identified as significantly associated with ALL were *ARIDB5, IKZF1,* and *CEBPE* [28, 29]. Additional variants in *CDKN2A, BMI1-PIP4K2A,* and *GATA3* have been identified and verified as increasing the host's risk for childhood ALL [30–32]. In addition, it is now known that specific susceptibility variants are associated with either molecular subtypes of ALL and/or ancestry. For instance, the risk alleles of *ARID5B*, a gene that encodes a transcriptional factor important in embryonic development, are associated with the development of the high hyperdiploid B-ALL subtype, and the susceptibility associated with *CEBPE* and *CDKN2A* polymorphisms is only seen in Europeans [33]. While a number of polymorphisms have been identified, the effect size of these genetic variants is relatively small, and very few childhood ALL cases are associated with them.

In utero exposure to diagnostic X-rays is associated with a slightly increased risk of ALL, proportional to the number of exposures [34]. The association between leukemia and maternal exposure to potential mutagens, parental use of medications and drugs, proximity to electromagnetic fields, parental smoking, exposure to petrochemical air pollution, and administration of vitamin K in the neonatal period have been studied, but findings have been contradictory and/or inconclusive [10, 35–40]. For instance, one study found that in utero exposure to DNA-damaging drugs, herbal medicines, or pesticides was significantly associated with infant leukemia with *KMT2A* rearrangements [41], but a Children's Oncology Group study found no association with pesticides and infant ALL [42].

Clinical and Laboratory Features at Diagnosis

Rarely ALL is detected during routine examination in the absence of signs or symptoms, but in most cases some symptoms are present for a few days to a few weeks prior to diagnosis. Patients typically present with the clinical signs of pancytopenia due to replacement of normal hematopoiesis by leukemic cells. Symptoms may include pallor, fatigue, or dizziness from anemia, and bruising and/or petechiae from thrombocytopenia. Fever is common and can be caused by infection or by pyrogenic cytokines released by the leukemic cells. In addition, leukemic infiltration of the marrow is often a painful process and patients may present with bone pain and arthralgias, frequently with a limp and complaints of back pain. Abnormalities of the bone, such as metaphyseal banding, periosteal reactions, osteolysis, osteosclerosis, or osteopenia, can be revealed by radiography in many patients. As these changes do not affect treatment and outcome, routine diagnostic imaging studies (except for chest radiograph to rule out mediastinal mass) are not necessary.

The complete blood count generally reveals abnormalities in more than one lineage; anemia, neutropenia, and thrombocytopenia are all usually present to various degrees. Hemoglobin is commonly <8 g/dL. Profound neutropenia (<500/mm^3) occurs in 40% of patients, putting them at a high risk of infection. Initial leukocyte counts may range from very low to extremely high; presenting leukocyte counts are >10,000/mm^3 in slightly over 50% of patients and >50,000/mm^3 in approximately 20% of patients. Patients with T-ALL are more likely to present with elevated leukocyte counts than those with B-ALL [43, 44]. Leukemic blast cells are frequently, but always, observed on peripheral blood smears, and their absence does not rule out a diagnosis of acute leukemia in a patient with pancytopenia. Hypereosinophilia, generally reactive, may be present at diagnosis; hypereosinophilia in B-ALL can also be associated with the t(5;14)(q31;q32) translocation involving the IL-3 gene on chromosome 5 and the Ig heavy-chain (IgH) gene on chromosome 14 [45].

Extramedullary sites of leukemic involvement include the liver, spleen, thymus, lymph nodes, and kidney. Hepatosplenomegaly is a common physical exam finding at diagnosis, as is lymphadenopathy. Painless enlargement of the scrotum can be a sign of testicular leukemia or hydrocele resulting from lymphatic obstruction; these two causes can usually be distinguished by ultrasound.

Leukemic infiltration of the thymus can lead to the development of an anterior mediastinal mass, observed on diagnostic chest X-ray in approximately 10% of newly diagnosed patients, almost always associated with T-cell immunophenotype. Anterior mediastinal masses can lead to life-threatening airway compression as well as superior vena cava (SVC) syndrome (facial and upper limb swelling, venous distension in neck, upper chest, and arms). Pleural and pericardial effusions can also be associated with mediastinal masses, which can exacerbate respiratory distress and cardiovascular compromise.

CNS involvement at diagnosis is usually asymptomatic and is diagnosed by cerebrospinal fluid (CSF) examination.

Lymphoblasts are identified morphologically at diagnosis in the CSF in over 20% of patients, most of whom have no neurologic symptoms [46]. Rarely, patients present with signs of increased intracranial pressure (vomiting, headache, papilledema, and lethargy) related to CSF pleocytosis or cranial nerve palsy related to leukemic infiltration. Ophthalmologic examination may reveal leukemic infiltration of the anterior ocular chamber, retinal hemorrhage and/or detachment, and optic nerve infiltration, especially in patients presenting with hyperleukocytosis.

Rapid turnover of leukemia cells at the time of diagnosis, especially in patients with high leukemic cell burden, can lead to elevations in serum uric acid, potassium, phosphorus, and lactate dehydrogenase (LDH). Patients with high levels of uric acid are at risk for the development of acute renal failure secondary to uric acid deposition in the kidney. Hypercalcemia at diagnosis has been observed but is uncommon; it appears to be related to elevated levels of parathyroid hormone-related peptide and has been associated with the rare t(17;19) translocation (*E2A-HLF*) [47]. Disseminated intravascular coagulation (DIC) may also occur at diagnosis, more commonly in T-ALL than B-ALL, and is only rarely associated with severe hemorrhage [48]. Coagulopathy has also been associated with the t(17;19) translocation [49].

Differential Diagnosis

Many of the presenting features of ALL are common to other childhood illnesses. Infection due to Epstein–Barr virus, cytomegalovirus, and other viruses can present with fever, lymphadenopathy, hepatomegaly, or splenomegaly, along with atypical lymphocytes that can be confused as lymphoblasts on peripheral blood smear. Patients with pertussis or parapertussis may have marked lymphocytosis, although composed by mature lymphocytes rather than lymphoblasts.

Patients with idiopathic thrombocytopenic purpura (ITP) can present with petechiae and bruising. In contrast to ALL, ITP typically presents with isolated thrombocytopenia, often with large platelets seen on blood smear, as opposed to abnormalities in other cell lines and smear findings suggestive of marrow infiltration observed with ALL.

Aplastic anemia may present with pancytopenia, but usually without the extramedullary findings frequently noted in ALL, such as hepatosplenomegaly and lymphadenopathy. Bone pain, arthralgia, and occasionally arthritis may mimic juvenile rheumatoid arthritis, rheumatic fever, other rheumatologic diseases, or osteomyelitis; because of the difficulty in distinguishing some rheumatologic conditions from ALL, bone marrow examination should be considered before initiating corticosteroid therapy. Solid tumors with extensive marrow metastatic involvement, including neuroblastoma and rhabdomyosarcoma, may also present similarly to ALL.

The definitive diagnosis of ALL requires morphologic examination of the bone marrow along with immunophenotyping. Cytogenetics and molecular analyses should be sent from diagnostic specimens for further classification of the leukemia. While the diagnosis of ALL can usually be made from a bone marrow aspirate, it is sometimes difficult to obtain an adequate aspirate sample (due to marrow fibrosis), in which case the diagnosis can be made by morphologic examination and immunohistochemical staining of a bone marrow biopsy specimen. For patients presenting with high peripheral blast count, peripheral blood flow cytometry may also be useful.

Diagnostic Classification

Morphology and Cytochemistry

ALL is diagnosed when more than 25% of the cells in the bone marrow are lymphoblasts. Morphologic analysis distinguishes three subtypes of ALL (L1, L2, and L3) as classified by the French–American–British (FAB) schema [50]. L1 lymphoblasts are small with scant cytoplasm. The cells are characterized by a large nucleus often with clefts along the membrane and prominent nucleoli. Approximately 90% of childhood ALL cases exhibit this morphology. In contrast, L2 lymphoblasts are much larger with more abundant cytoplasm and may resemble M1 myeloblasts. The L2 morphology is present in 5–10% of pediatric ALL. The distinction between L1 and L2 lymphoblasts, however, has no prognostic relevance with contemporary therapy [51]. L3 lymphoblasts occur in 1–2% of all cases; these cells exhibit vacuoles throughout deep blue cytoplasm. L3 lymphoblasts are nearly always associated with surface immunoglobulin expression and translocations involving the *MYC* gene, and are more effectively treated with regimens for advanced-stage Burkitt lymphoma.

Immunophenotype

The immunophenotype of ALL cells refers to the compilation of specific surface antigens which reveals both the lineage and maturation stage of the lymphoid progenitor cell from which the leukemia originated (Table 17.1). Lymphoblasts can be divided into two main immunophenotypic groups: B-ALL and T-ALL. Patients with B-ALL may be further subdivided into pro-B, early pre-B, pre-B, and mature B subtypes, as discussed below.

B-ALL

Approximately 80–85% of children with ALL present with B-ALL immunophenotype, characterized by the expression of the B-cell markers CD19, CD22, and CD79a [52]. The cells lack expression of cytoplasmic (or surface) CD3 and of myeloperoxidase (by cytochemistry and antibody staining). While

[b]IgM heavy chains only

aberrant expression of myeloid antigens is not uncommon in B-ALL, co-expression of T-lineage antigens is rare [53].

Pro-B ALL is thought to be derived from a very immature B-cell precursor. It is most frequently observed in infants with ALL, especially those with *KMT2A* (*MLL*) rearrangements, and is characterized by absence of both CD10 surface expression and cytoplasmic immunoglobulin. In cases with *KMT2A* rearrangements, myeloid antigen co-expression is common [54, 55].

Early pre-B-ALL is the most common subtype of B-ALL seen in pediatric patients. Expression of CD10 and terminal deoxynucleotidyl transferase (TdT) is found in at least 90% of cases, and CD34 is expressed in more than 75% of cases [52]. CD20 (a marker of a more mature B-cell) can be detected at diagnosis in approximately 50% of cases [56], although its expression may increase during induction treatment [57]. Cytoplasmic and surface immunoglobulin are typically absent.

Pre-B-ALL, defined by the presence of cytoplasmic IgM heavy chains without detectable surface immunoglobulins, represents approximately 20–25% of cases of B-ALL [52]. In rare cases, IgM heavy chains without κ or λ light chains are also detectable on the cell surface [58], but can be distinguished from Burkitt-type leukemia by the absence of c-*MYC* translocations. Like early pre-B-ALL, pre-B-ALL cells usually express CD10 and TdT [52]. The *TCF3-PBX1* gene fusion is associated with pre-B immunophenotype; this cytogenetic abnormality is found in 20–25% of pre-B-ALL cases but in only 1% of cases with early pre-B-ALL [52, 53].

Mature B-cell ALL, which occurs in 1–2% of childhood ALL cases, is characterized by the expression of surface immunoglobulin. Cells are generally recognizable by FAB L3 morphology, as described above. CD20 is frequently expressed and CD34 is typically negative [52]. Mature B-cell ALL is characterized by the presence of c-*MYC* rearrangements caused by the translocation of this gene on chromosome 8 with one of the chromosomes containing an immunoglobulin gene, such as t(8;14)(q24;q32), t(2;8)(p12;q24), and t(8;22)(q24;q11) [59]. Mature B-cell ALL should be treated as advanced-stage Burkitt lymphoma rather than on regimens intended for childhood B-ALL [60].

T-ALL

Approximately 10–15% of children with ALL present with T-cell immunophenotype. Compared with B-ALL, T-ALL is more frequently associated with older age at diagnosis higher presenting leukocyte counts, and male predominance [44]. Mediastinal masses, when present in children with ALL, are almost exclusively observed in patients with T-cell immunophenotype.

The cell surface markers most consistently expressed in T-ALL are CD7 and CD3. Expression of the latter is confined to the cytoplasm in approximately two-thirds of cases [61]; approximately half of these cases also express cytoplasmic TCR proteins (TCRβ, TCRα, or both). In the remaining third of T-ALL cases, CD3 is expressed on the cell surface together with TCR proteins, TCRαβ, or, less commonly, TCRγδ [62]. Other markers usually expressed in T-ALL include CD2, CD5, and TdT; CD1a is detected in approximately half of the cases and two-thirds expressing CD4 and/or CD8 [52, 63]. Aberrant myeloid antigen expression may be seen in up to 15% of T-ALL [63].

Early T-cell precursor (ETP) ALL is a distinct subset of T-ALL that was first identified by gene expression profiling studies [64]. This subtype is characterized by a gene expression profile similar to that of normal thymic ETP cells, a population of recent immigrants from the bone marrow to the thymus which retains multi-lineage differentiation potential [65, 66]. ETP ALL expresses a specific immunophenotype that lacks CD1a and CD8 expression, has weak or absent CD5 expression, and expresses at least one stem cell or myeloid-associated antigen (e.g., CD34, CD117, CD13, CD33, and CD11b) [64]. ETP-ALL represents approximately 10–15% of childhood T-ALL cases and was initially thought to have an extremely poor prognosis [64, 67], although subsequent reports suggest that its outcome may not be significantly different than other cases of T-ALL [68].

Myeloid Antigen Co-expression

Up to 20–30% of lymphoblasts in childhood ALL co-express myeloid antigens. Myeloid antigen co-expression is associated with certain chromosomal abnormalities (both

favorable and unfavorable), such as *KMT2A* rearrangements, *BCR-ABL1*, and *ETV6-RUNX1*. Older studies suggested that myeloid co-expression was associated with an inferior outcome [69], but more recent reports have indicated that myeloid antigen co-expression lacks independent prognostic significance [70–72]. Distinction is made between ALL with myeloid co-expression and leukemia of ambiguous lineage or MPAL (mixed-phenotype acute leukemia), another leukemia subtype in which a predominant lineage cannot be determined. To be classified as MPAL, the 2008 WHO classification system requires that cells co-express at least two of the following three groups of lineage-defining antigens: [1] myeloid: myeloperoxidase or evidence of monocytic differentiation; [2] T-cell: cytoplasmic CD3; and [3] B-cell surface markers CD19, CD79a, CD22, and/or CD10 [73].

Cytogenetics and Molecular Genetics

There are several recurrent cytogenetic abnormalities that have been identified in childhood ALL, many with important prognostic implications, as summarized in Table 17.2. The 2008 World Health Organization (WHO) classification of ALL is based on immunophenotype and cytogenetics, as shown in Table 17.3 [73].

Cytogenetic abnormalities in childhood ALL can be subdivided into those involving [1] abnormalities in chromosome number (ploidy) and [2] chromosomal translocations and gains/deletions of chromosomal segments.

Table 17.2 Recurrent cytogenetic abnormalities in childhood B-ALL and their relation to prognosis with contemporary therapy[a]

Abnormality	Frequency[a]	Prognostic impact
Hyperdiploidy 51–65 chromosomes	33%	Favorable
t(12;21)(p13;q22) [*ETV6-RUNX1*]	25%	Favorable
t(1;19)(q23;p13) [*TCF3-PBX1*]	4%	Neutral
t(9;22)(q34;q11)	3%	Unfavorable
iAMP21	2%	Unfavorable
KMT2A (11q23) rearrangements	2% [~80% of infants]	Unfavorable
Hypodiploidy (including near haplopidy, low hypodiploidy)	1–2%	Unfavorable
t(17;19)(q22;p13) [*TCF3-HLF*]	<1%	Unfavorable
IKZF1 deletions	15%[b]	Unfavorable

[a]Frequency from Moorman et al., 2010 [77], except frequencies of *IKZF1* deletions
[b]Frequency from Clappier et al. 2015 [110]

Abnormalities of Chromosomal Number

Hyperdiploid ALL

The most common recurrent chromosomal abnormality in childhood ALL is high hyperdiploidy (defined as 51–65 chromosomes, or DNA index $\geq$ 1.16), occurring in 25–30% of cases [74]. High hyperdiploidy is characterized by nonrandom gains of chromosomes, with trisomies and tetrasomies occurring most often (listed in order of frequency) in chromosomes 21, X, 14, 18, 4, 17, 10, and 8 [75]. High hyperdiploidy frequently occurs as the sole cytogenetic abnormality, without other karytotypic aberrations, but can also be observed along with chromosomal translocations, including *BCR-ABL1* and *TCF3-PBX1*. Whole-genome and whole-exome sequencing of high-hyperdiploid ALL revealed aberrations of receptor tyrosine kinase (RTK)/Ras pathway signaling (*KRAS*, *NRAS*, *FLT3*, *PTPN11*) and histone modifiers (including *CREBBP* and *WHSC1*) in the majority of cases [76]. High-hyperdiploid ALL occurs more frequently in children with "low-risk" presenting features (age 1–10 years, presenting leukocyte count <50,000/mm^3), and when it occurs in the absence of other prognostically significant abnormalities (such as *BCR-ABL1* fusion), it has been identified as an independent predictor of favorable outcome [75, 77]. High hyperdiploid patients with trisomies of chromosomes 4, 10, and 17 have been reported to have particularly favorable outcomes [75, 78].

Near triploidy (68–80 chromosomes) and near tetraploidy (>80 chromosomes) occur in approximately 1–2% of cases of childhood ALL, and are biologically distinctive from high hyperdiploidy [79, 80]. Compared with high hyperdiploidy, near trisomy/tetraploidy is more often associated with the *ETV6-RUNX1* fusion and more frequently occurs in T-ALL patients [79–81].

Hypodiploidy

Hypodiploidy (<45 chromosomes) is much less common than hyperdiploidy in childhood ALL, and has been associated with an unfavorable outcome [82, 83]. The chromosome loss is not random; disomies of chromosomes X/Y, 8, 10, 14, 18, and 21 are preserved in the majority of cases [84]. Rather than representing a single subtype of ALL, hypodiploid ALL consists of two distinct biologic subsets, near haploidy (24–31 chromosomes) and low hypodiploidy (32–39 chromosomes), which differ strikingly on a molecular basis from each other [27]. In near haploidy, genetic alterations in RTK/Ras pathway signaling (including *NRAS*, *KRAS*, *NF1*, *MAPK*, *FLT3*, and *PTPN11*) and the lymphoid transcription factor *IKZF3* are common, while low hypodiploidy is characterized by alterations in *TP53* (observed in 90% of cases), *IKZF2*, and *RB1*. Of note, almost half of the *TP53* mutations in pediatric low-hypodiploid ALL appear to be germline [27].

Doubling of the chromosome content in hypodiploid lymphoblasts can occur, resulting in a pseudo-hyperdiploid clone. These "masked hypodiploid" cases are biologically and prognostically indistinguishable from other cases of low hypodiploidy [27]. At diagnosis, both the hypodiploid and pseudo-hyperdiploid clone may be evident; however, the doubled hypodiploid clone may be the only one detectable at diagnosis, and can be confused with true hyperdiploidy. Given the very different expected outcomes of near-haploid/low-hypodiploid (poor prognosis) and high-hyperdiploid ALL (favorable prognosis), cases of masked hypodiploidy need to be distinguished from true high hyperdiploidy for risk stratification and treatment allocation. By karyotype, the "extra" chromosomes in masked hypodiploidy mostly occur as tetrasomies from the doubling of retained disomies, while in true high hyperdiploidy, trisomies are more common then tetrasomies [84].

Chromosomal Translocations and Gains/ Deletions of Chromosomal Segments

ETV6-RUNX1

The *ETV6-RUNX1* fusion is the most frequent chromosomal rearrangement in childhood ALL. It is found in approximately 20–25% of childhood ALL, occurring nearly exclusively in B-ALL [85]. It is caused by the t(12;21)(p13;q22) which juxtaposes the 5′ portion of the *ETV6* (*TEL*) gene and the nearly complete *RUNX1* (*AML1*) gene [86]. This translocation is usually cryptic by conventional karyotyping; the abnormality is typically detected only by fluorescence in situ hybridization (FISH) or reverse transcriptase-polymerase chain reaction (RT-PCR) [86–88]. The non-translocated *ETV6* allele is frequently deleted [81, 89]. Like high hyperdiploidy, *ETV6-RUNX1* is more frequent in children aged 1–10 years [87, 90, 91] and has been shown to be an independent predictor of favorable outcome [77, 90].

The widely expressed *ETV6* gene belongs to the *Ets* family of transcription factors and *RUNX1* encodes a transcription factor that binds DNA as a heterodimer with core-binding factor (CBF) β; both *ETV6* and *RUNX1* are essential for normal hematopoietic development [92, 93]. There is evidence that the gene fusion occurs prenatally, giving rise to a preleukemic clone that requires additional postnatal genetic events for the development of ALL. For instance, analyses of neonatal blood spots of healthy babies indicated that *ETV6-RUNX1* was detectable at a 100 times the frequency of this ALL subtype in the general population [94]. Additionally, studies of five monozygotic twin pairs with concordant *ETV6-RUNX1* ALL revealed that there was discordance within each twin pair for genome-wide copy number alterations considered "driver" mutations [95].

BCR-ABL1

BCR-ABL1-positive ALL (also known as Philadelphia chromosome-positive or Ph+ ALL) occurs in 3–5% of cases of childhood ALL. The *BCR-ABL1* fusion gene results from the t(9;22)(q34;q11), which juxtaposes the 5′ portion of *BCR* and the 3′ portion of *ABL1*, encoding a constitutively activated tyrosine kinase [96]. The fusion protein varies in size, depending on the breakpoint in the *BCR* gene. In ALL, the translocation occurs most often in the minor breakpoint cluster regions, resulting in a *BCR-ABL1* fusion protein of 190 kD (p190), while in chronic myelogenous leukemia (CML), the major breakpoint cluster region is typically involved, resulting in a larger fusion protein of 210 kD (p210) [97]. Deletions of *IKZF1*, a gene that encodes Ikaros, a lymphoid transcription factor, have been observed in approximately 70% of cases *BCR-ABL1*-positive ALL [98].

BCR-ABL1 positivity in childhood ALL is associated with older age at diagnosis and higher presenting leukocyte counts [99]. Historically, patients with this subtype had a significantly worse outcome than other children with ALL, and were typically allocated to hematopoietic stem cell transplant (HSCT) after achieving complete remission [77, 100]. More recent clinical trials have indicated that the addition of imatinib, a selective inhibitor of the *BCR-ABL1* tyrosine kinase, to an intensive chemotherapy backbone may improve the prognosis for pediatric *BCR-ABL1*-positive patients and obviate the need for HSCT in first complete remission for the majority of patients [101, 102].

BCR-ABL1-Like Subtype, IKZF1 Deletions, and CRLF2 Overexpression

Lymphoblasts from approximately 15% of pediatric ALL patients have been found to have a gene expression profile similar to *BCR-ABL1*-positive ALL, but lacking the *BCR-ABL1* fusion [103–107]. This subtype, termed *BCR-ABL1*-like

(or Ph-like) ALL, is more common in older children and adolescents, and has been associated with an adverse outcome [106, 107]. *BCR-ABL1*-like ALL is characterized by a high frequency of *IKZF1* deletions, as well as overexpression of cytokine receptor-like factor 2 (*CRLF2*). Detailed genomic analyses have identified kinase-activating alterations in over 90% of patients with *BCR-ABL1*-like ALL [106], suggesting the potential for targeted interventions with tyrosine kinase inhibitors. Kinase-activating alterations appear to primarily impact the ABL-class signaling pathway (with fusions involving *ABL1*, *ABL2*, *CSF1R,* or *PDGFRB*) and JAK-STAT signaling pathway (including rearrangements of *JAK2, EPOR,* and/or *CRLF2*) [106, 108, 109].

IKZF1 deletions, including deletions of the entire gene and deletions of specific exons, are present in approximately 15% of pediatric B-ALL, with increased frequency in older children and adolescents, those with higher presenting leukocyte counts, and patients with Down syndrome [104, 110, 111]. *IKZF1* deletions are detectable in the majority of patients with *BCR-ABL1*-positive ALL [98, 112], and in 40–60% of cases with the *BCR-ABL1*-like subtype [103, 106, 107]; however, many patients with *IKZF1* deletions have neither of these abnormalities [107]. Several studies have indicated that *IKZF1* deletions independently predict the outcome in B-ALL, even when controlling for other adverse features, including *BCR-ABL1* status and high levels of minimal residual disease (MRD) [107, 110, 113, 114]. *IKZF1* deletions have also been shown to predict inferior outcome in biologically favorable subtypes, such as high hyperdiploidy [110]. Some reports indicate that the presence of an *ERG* gene deletion, observed in 3–5% of cases of B-ALL, may abrogate the adverse prognostic significance of *IKZF1* deletions when the two co-occur [115, 116].

Genomic alterations in *CRLF2*, located on the pseudoautosomal regions of the sex chromosomes, have been identified in 5–10% of cases of B-ALL and in approximately 50% of cases of the *BCR-ABL1*-like subtype [117, 118]. They are strongly associated with *IKZF1* deletions and *JAK* mutations [118–121], and are more common in children with Down syndrome, occurring in 50–60% of cases [121, 122]. They have also been reported to be more common in Hispanic patients [119]. Two alterations have been described, both of which lead to *CRLF2* overexpression: (i) a cryptic chromosomal translocation involving the *CRLF2* gene and IgH locus on chromosome 14, and (ii) interstitial deletions juxtaposing *CRLF2* with the *P2RY8* promoter in pseudoautosomal regions of the sex chromosomes, resulting in a *P2RY8-CRLF2* fusion [117–120]. Although univariate analyses have suggested that *CRLF2* abnormalities may have adverse prognostic significance, these alterations have not been shown to be independent predictors of outcome in most studies when controlling for other factors, such as *IKZF1* deletion and *BCR-ABL1*-like status [107, 119].

KMT2A (MLL) Gene Rearrangements

Rearrangements involving the *KMT2A* (*MLL*) gene occur in approximately 5% of childhood ALL cases, but in up to 80% of infants with ALL. The most common rearrangement is the t(4;11)(q21;q23) which fuses the *KMT2A* (chromosome 11) and *AFF1* (chromosome 4) genes, but multiple other fusion partners have been identified. *KMT2A* translocations are also found in AML, but particular translocations show lineage predominance; for instance the t(4;11) is found most often in ALL while the t(9;11) is more common in AML.

In ALL cases, *KMT2A* rearrangements are associated with high presenting leukocyte counts, CD10-negative B-cell immunophenotype (pro-B), and myeloid antigen coexpression [123]. Even with intensified chemotherapy regimens, infants with *KMT2A* rearrangements have an adverse prognosis, particularly those who present at a very young age (<6 months) and with extremely high leukocyte counts [124]. The prognosis of older (non-infant) pediatric patients with *KMT2A* rearrangements is not as well established, but it appears that such patients fare better than infant *KMT2A*-rearranged patients but not as well as other non-infant B-ALL patients lacking these aberrations [77, 125]. There is also controversy regarding the prognostic significance of various fusion partners. For infants with *KMT2A* rearrangements, outcome appears similarly unfavorable regardless of fusion partner [124, 125], but for older children, some (but not all) studies have found that the t(4;11) confers a worse prognosis than other translocations [125]. In one report, the t(11;19), involving *KMT2A* and *MLLT1* (*ENL*) was associated with a poor outcome in infants (all with B-ALL) but appeared to be associated with a relatively favorable progress in non-infant patients with T-ALL [126].

Gene expression profile studies indicate that *KMT2A*-rearranged ALL is characterized by overexpression of a number of genes, including *FLT3, LMO2*, HOX genes (e.g., *HOXA9*, *HOXA5*, *HOXA4*, and *HOXC6*), *NRAS,* and *KRAS* [127, 128]. The unique biology of *KMT2A*-rearranged ALL appears to be driven primarily by epigenetic dysregulation rather than somatic mutations. Whole-genome sequencing has revealed that *KMT2A*-rearranged infant ALL has one of the lowest frequencies of somatic mutations of any cancer [127]; in non-infant *KMT2A*-rearranged ALL, frequent mutations in epigenetic regulators (but not other somatic mutations) have been identified [127]. Wild-type *KMT2A* possesses a methyltransferase domain which regulates expression of multiple genes, including HOX genes; *KMT2A* rearrangements lead to disruptions in *KMT2A*'s normal epigenetic function, resulting in overexpression of multiple genes through transcriptional dysregulation [129, 130].

TCF3 Rearrangements

Approximately 5% of pediatric B-ALL cases have the balanced t(1;19)(q23;p13) or the unbalanced der [19]t(1;19)

(q23;p13), both of which juxtapose the *TCF3* (*E2A*) gene on chromosome 19 and the *PBX1* gene on chromosome 1 [131–133]. The resulting *TCF3-PBX1* fusion protein contains the transcriptional activation domains of *TCF3* linked to the DNA-binding domain of *PBX1*, thereby inappropriately activating the transcription of genes normally regulated by *PBX1*, as well as reducing wild-type *TCF3* activity [134, 135].

The *TCF3-PBX1* fusion had previously been considered a predictor of inferior outcome [136], but with contemporary therapy, it lacks prognostic significance and in general is no longer considered a high-risk feature [131, 137]. Some investigators have reported a higher rate of CNS relapse in patients with the t(1;19) [138], but this has not been confirmed by others [131].

Another fusion observed in childhood ALL involving *TCF3* is the t(17;19)(q22;p13), resulting in the fusion of *TCF3* with *HLF*, a gene that encodes another transcription factor [139, 140]. The *TCF3-HLF* fusion is rare, occurring in fewer than 1% of pediatric ALL cases, and is associated with a very poor prognosis [47, 77, 141]. ALL with the *TCF3-HLF* fusion presents with disseminated intravascular coagulation and hypercalcemia [47, 141]. Genomic profiling has revealed that *TCF3-HLF*-positive ALL is characterized by deletions in genes involved in B-cell development (*PAX5*, *BTG1*, and *VPREB1*) and by mutations in RAS pathway genes (*NRAS*, *KRAS*, and *PTPN11*) [142].

Intrachromosomal Amplification of Chromosome 21 (iAMP21)

Intrachromosomal amplification of the RUNX1 gene on chromosome 21 (iAMP21) occurs in approximately 2% of childhood ALL (almost exclusively B-ALL), and has been associated with older age at diagnosis (median age approximately 10 years) and with lower presenting leukocyte count (less than 50,000 cells/mm^3) [77, 87, 143]. It is diagnosed primarily by FISH, and is defined as three or more extra copies of RUNX1 on a single chromosome 21 (a total of five or more RUNX1 signals per cell). Initial retrospective analyses suggested that children with iAMP21 had a markedly inferior event-free survival compared with other patients [144, 145]. Subsequent reports have indicated that, with more intensive treatment, patients with iAMP21 may not have as high a risk of relapse as suggested in these initial studies [143, 146, 147].

Genetic Subtypes of T-cell ALL

T-ALL can be subdivided into multiple genetically distinct subsets, but most do not appear to be prognostically significant and are not used for treatment stratification.

Translocations involving one of the T-cell receptor loci [chromosome 14q11 (TCRα and TCRδ), 7q34 (TCRβ), or 7p14 (TCRγ)] have been observed in approximately 35% of cases of T-ALL [148]. The translocations include rearrangements of transcriptional factors to the TCR loci that are often not visible by karyotype but can be identified by FISH. Some of the more common translocations involve rearrangements of *LMO1* (11p15), *LMO2* (11p13), *TAL1*(1p32), and *HOX11L2/TLX3* (5q35) to TCRδ, *TLX1* (10q24) to TCRδ or TCRβ, and *HOXA* (7p15) to TCRβ [149]. In addition, aberrant expression of these transcription factors can occur in the absence of T-cell receptor loci rearrangements; for instance, the *TLX3/HOX11L2* locus is recurrently translocated to T-cell regulatory sequences in the proximity of the *BCL11B* locus, small intrachromosomal deletions in chromosome 1p32 result in *TAL1* overexpression, and cryptic deletions in chromosome 11p13 can lead to activation of the *LMO2* oncogene [149].

Activating mutations in the *NOTCH1* gene are present in over 50% of T-ALL cases [150]. Additionally, *FBXW7* mutations, observed in about 15% of T-ALL, lead to constitutive activation of *NOTCH1* signaling by impairing degradation of activated *NOTCH1* [151]. The prognostic significance of *NOTCH1*-activating mutations is not clear. While some investigators have reported that these lesions are associated with a favorable early response (e.g., increased sensitivity to corticosteroid prophase) and/or a decreased risk of relapse, most studies have not demonstrated that these lesions have any prognostic significance [152–155].

Other common genetic lesions observed in T-ALL include deletions in the *CDKN2A* locus at chromosome 9p21, observed in 70% of cases, and deletions of *PTEN* (5–10% of cases), which is a negative regulator of the PI3K-AKT signaling pathway [156, 157]. Additional activating mutations of *PI3K* and *AKT* genes have also been reported, suggesting that up to 40–50% of T-ALL patients may have genetic alterations impacting this signaling pathway [156]. *ABL1* rearrangements occur in about 8% of T-ALL, including the *NUP214-ABL1* fusion (the most frequent *ABL1* abnormality), a cytogenetically cryptic, complex rearrangement seen on FISH on amplified episomes [158, 159].

The early T-cell precursor (ETP) subtype appears to be molecularly heterogeneous, but distinct from other cases of T-ALL. Compared with other T-ALL cases, ETP ALL has a lower rate of *NOTCH1* mutations and significantly higher frequencies of alterations in genes regulating cytokine receptors and RAS signaling, hematopoietic development, and histone modification [160].

Prognostic Factors

Several factors have been identified as significant predictors of outcome in childhood ALL, including age, presenting leukocyte count, immunophenotype, chromosomal abnormalities, presence of morphologically detectable lymphoblasts in

the spinal fluid at diagnosis, and early response to initial therapy [161]. These factors are used to stratify the intensity of therapy, with stronger, potentially more toxic treatments reserved for those presenting with adverse prognostic features. Ultimately, the prognostic significance of any factor is treatment dependent, and the importance of a particular presenting feature in predicting the outcome may vary, depending on the therapy delivered to that patient.

Age

Age at diagnosis is a long-established prognostic factor in B-ALL, but not T-ALL [162–165]. Its prognostic significance likely reflects age-related differences in the frequencies of various underlying biologic subsets. For instance, the two cytogenetic abnormalities associated with the most favorable outcome in childhood ALL, *ETV6-RUNX1* and high hyperdiploidy, occur most frequently in children aged 1–10 years, the age group with the best prognosis: approximately 80% of children with B-ALL diagnosed between the ages of 2 and 7 years have one of these two abnormalities [91].

Infants are the age group with the worst prognosis in pediatric ALL. Nearly 80% of infants present with rearrangements of the *KMT2A* gene, compared with <5% of older children [54, 55, 124, 162]. Even when treated with intensified regimens, infants with *KMT2A* rearrangements have an unfavorable prognosis, with long-term event-free survival rates less than 50% [124, 125, 166]. Infants whose leukemia lacks a *KMT2A* rearrangement fare better, with event-free survival rates that are closer to those observed in older children [124].

Older children and adolescents (10–21 years of age) with ALL also have a less favorable outcome than children aged 1–10 years at diagnosis, although not as poor as infants. Compared with younger children, adolescents with ALL more frequently present with higher risk biologic subtypes, including T-cell immunophenotype, *BCR-ABL1* fusion, *IKZF1* deletions, and *BCR-ABL*-like subtype, and less often with more favorable cytogenetic aberrations, such as high hyperdiploidy and the *ETV6/RUNX1* fusion [106, 107, 110, 162, 167]. Multiple retrospective studies have shown that adolescents fare better with pediatric ALL regimens than on treatments designed for adults with ALL [167–170].

Leukocyte Count

The initial peripheral blood leukocyte count is a significant predictor of treatment outcome, with outcomes worsening as the leukocyte count increases [161]. The relationship between leukocyte count and risk of subsequent relapse is more firmly established for B-ALL than T-ALL [43, 44, 171]. Based on a cutoff established by Cancer Therapy Evaluation Program (CTEP) of the National Cancer Institute (NCI), many clinical trials utilize a leukocyte count of 50,000 cells/mm^3 as the cutoff to differentiate between high versus low presenting leukocyte count [161].

Immunophenotype

Historically, immunophenotype was considered an important prognostic factor, with inferior outcomes observed in patients with T-ALL. However, if treated with more intensive regimens, children with T-ALL fare as well as those with B-ALL [44]. Myeloid antigen coexpression was previously thought to be associated with an inferior outcome, but more recent reports have indicated that it is not an independent prognostic factor [72, 172].

Central Nervous System (CNS) Disease at Diagnosis

Approximately 15–20% of children with ALL present with detectable lymphoblasts in their cerebrospinal fluid [173, 174]. Some children, such as those diagnosed in infancy and those with T-cell ALL, have a higher incidence of morphologically evident CNS leukemia at diagnosis [162].

CNS status at presentation is usually classified as CNS-1 (no blast cells in spinal fluid), CNS-2 (fewer than five leukocytes per microliter with blast cells), and CNS-3 (five or more leukocytes per microliter with blast cells or cranial nerve palsy) [161]. With more frequent dosing of intrathecal chemotherapy, the prognosis of patients with CNS-2 status appears similar to those who are CNS-1 [174, 175]. CNS-3 status at diagnosis (observed in approximately 5% of patients) is associated with a higher risk of relapse (both CNS-involved and marrow-only), and is typically treated with more intensive systemic and CNS-directed therapies [174].

Traumatic lumbar punctures with lymphoblasts on cytospin have also been associated with an adverse prognosis [174, 176]. Like those with CNS-2 status, patients with traumatic lumbar punctures with lymphoblasts at diagnosis may also benefit from additional doses of intrathecal chemotherapy early in treatment [174].

Chromosomal Abnormalities and Other Genetic Lesions

Recurrent chromosomal abnormalities in childhood ALL are detailed above. Several of these have been shown to be significant predictors of outcome. Two abnormalities, the cryptic t(12;21) (*ETV6/RUNX1* fusion) and high hyperdiploidy (51–65 chromosomes or a DNA index ≥1.16), have each been associated with a favorable prognosis [77].

The most favorable outcomes in high-hyperdiploid ALL patients have been associated with the presence of trisomies of chromosomes 4, 10, and 17 [177–179]. Both *ETV6-RUNX1* and high hyperdiploidy occur more most commonly in younger, non-infant patients with B-ALL, with decreased frequency in adolescents, and are usually mutually exclusive [81, 91].

Chromosomal abnormalities associated with an unfavorable prognosis include low hypodiploidy [82, 83, 180], rearrangements of the *KMT2A* (*MLL*) gene [125, 180, 181], and *BCR-ABL1* fusion (Philadelphia chromosome) [77, 100]. The use of imatinib and other tyrosine kinase inhibitors, given in conjunction with intensified chemotherapy, appears to have favorably impacted the outcome of *BCR-ABL1*-positive ALL [101, 102]. Intrachromosomal amplification of chromosome 21 (iAMP21) has also been associated with a higher risk of relapse [144, 145], although the adverse prognostic significance of this abnormality appears to be abrogated when patients are treated on more intensive, "high-risk" therapy [143, 146, 147].

Patients with *BCR-ABL1*-like ALL (defined by gene expression profile) and/or *IKZF1* gene deletions (each representing approximately 15% of B-ALL, with a large overlap between the two groups) have an inferior outcome; each has been shown to be an independent adverse prognostic factor [106, 107, 110, 113, 114].

Early Response to Therapy

The rapidity with which a patient responds to initial chemotherapy is a significant predictor of long-term outcome. Early response to therapy has been evaluated using morphologic measures (residual microscopically detectable disease in blood or marrow) and more sensitive minimal residual disease (MRD) techniques to quantitate submicroscopic levels of disease, such as flow cytometry, PCR, and next-generation sequencing (NGS).

Morphologic Response to Therapy

On trials run by the Berlin-Frankfurt-Munster (BFM) group and several other clinical trial consortia, patients begin treatment with 1 week of corticosteroid monotherapy (and one dose of intrathecal methotrexate) prior to beginning multiagent induction chemotherapy; poor peripheral blood response at the end of that week (defined as an absolute blast count of 1000/mm^3) is an independent predictor of adverse outcome [182]. Similarly, the persistence of leukemia in bone marrow specimens obtained 7 or 14 days after beginning multiagent chemotherapy strongly correlates with increased relapse risk [183], although intensification of therapy can abrogate the adverse prognostic significance of slow early morphologic marrow response [184].

Patients who require two or more cycles of induction chemotherapy to achieve complete remission (CR) have a much worse prognosis than those who achieve CR after the first induction attempt [185–187].

Minimal Residual Disease

Minimal residual disease (MRD) evaluation involves the measurement of very low levels of leukemia using sensitive assays, such as specialized multiparameter flow cytometry, PCR, or NGS techniques. Leukemic cells are identified using targets identified at diagnosis, including leukemia-specific immunophenotypes (for flow cytometry-based assays), chromosomal translocations, or lymphoblast-specific immunoglobulin or T-cell antigen receptor gene rearrangements (for PCR- and NGS-based assays). Using these techniques, leukemia cells have been identified at levels as low as 1 in 1000 to 1 in 100,000 cells [188–192].

Many studies have demonstrated that MRD status at early time points in treatment is a significant and independent predictor of long-term outcome for patients with both B-ALL and T-ALL [188, 193–197]. For patients achieving a morphologic remission at the end of the first month of treatment, those with higher levels of marrow MRD at that time point have a higher risk of relapse than those with lower or undetectable MRD [188, 193–195, 197–201]. MRD levels measured in the peripheral blood as early as 8 days after starting multiagent chemotherapy have also been shown to be prognostically significant, especially in patients with B-ALL presenting with standard-risk features (age between 1 and 10 years, leukocyte count <50,000/mm^3) [199].

MRD levels obtained 10–12 weeks after the start of therapy (at the end of the second phase of treatment) have also been shown to be prognostically important; patients with high levels of MRD at this time point have a significantly inferior EFS compared with other patients [200–202]. The AIEOP-BFM group has defined three prognostically distinct groups of patients based on MRD measurements: (1) patients with low end-induction MRD (best outcome); (2) patients with high end-induction MRD but low MRD after the second phase of treatment (intermediate outcome); and (3) patients with persistently high MRD after the second phase of treatment (worst outcome) [200, 201].

Intensifying therapy for patients with high MRD has been shown to improve the outcome [203, 204]. MRD measurements, in conjunction with other presenting features, have also been used to identify subsets of patients with an extremely low risk of relapse. The Children's Oncology Group reported a very favorable outcome (5-year EFS of 97%) for B-ALL patients with non-high-risk presenting features (age between 1 and 10 years, leukocyte count <50,000/mm^3, CNS-1 status, and either high hyperdiploidy with favorable trisomies or *ETV6-RUNX1* fusion) and MRD levels

of less than 0.01% at both day 8 (from peripheral blood) and end induction (from bone marrow) [199].

Other Prognostic Factors

Gender

In some studies, boys appear to fare slightly worse than girls. This observation cannot be entirely explained by the rates of isolated testicular relapse, which are relatively low with contemporary treatment regimens [205, 206].

Race and Ethnicity

Lower event-free survival (EFS) rates have been reported for African-American, Hispanic, and Native American patients, even after adjustment for differences in prognostically significant presenting features [207–209]. This finding may be in part related to differences in the frequency of prognostically relevant biologic subtypes amongst racial and ethnic groups. For example, compared with Caucasians, African-American children have a higher incidence of T-ALL and lower rates of high hyperdiploidy [210]. Hispanic children also have a lower frequency of *ETV6-RUNX1*-rearranged ALL [211], and, in one study, were noted to have a higher incidence of ALL with *CRLF2* rearrangements, a finding that is associated with the *BCR-ABL1*-like subtype [119]. Lower rates of adherence to oral 6-mercaptopurine, a critical component of ALL treatment, have also been observed in African-American, Hispanic, and Asian-American patients [212, 213].

Down Syndrome

Results from several studies have indicated that children with Down syndrome have inferior outcomes compared with other pediatric ALL patients. Down syndrome patients have been reported to have both higher rates of treatment-related mortality (with significantly increased risk of infections and other treatment complications) and relapse [23, 214–216]. The increased risk of relapse may be due in part to the lower frequency of favorable biologic features (such as *ETV6-RUNX1* and high hyperdiploidy) observed in Down syndrome patients [23, 214, 216]. ALL arising in Down syndrome patients is characterized by a higher incidence of *IKZF1* deletions, *CRLF2* aberrations, and *JAK* mutations [19, 111, 122]; the presence of *IKZF1* deletions (but not *CRLF2* aberrations and *JAK* mutations) has been associated with an inferior outcome in Down syndrome patients [111, 217].

Treatment Adherence

Poor adherence to oral 6-mercaptopurine (6-MP), a key component of maintenance therapy in childhood ALL, is an important predictor of relapse [212, 213, 218]. Using an electronic cap to record the date and time of 6-MP bottle openings, investigators from the Children's Oncology Group (COG) demonstrated that there was a progressive increase in relapse rate with decreasing adherence that remained statistically significant after adjusting for NCI risk classification, chromosomal abnormalities, and other prognostically relevant variables. When 6MP adherence was lower than 90%, the risk of relapse was nearly fourfold increased [212]. Factors associated with higher risk of nonadherence included older age (≥12 years), non-white race/ethnicity, low annual household income, low parental education, single-parent households, and absence of a routine surrounding pill taking [212, 213].

Treatment

Historical Background

Over the last several decades, there has been a dramatic improvement in the prognosis of children with ALL. Improvement in cure rates can be attributed to many factors, including [1] identification of active agents and development of complex chemotherapeutic regimens designed to achieve clonal eradication and prevent emergence of drug-resistant clones; [2] improvements in supportive care; [3] recognition of the central nervous system (CNS) as a sanctuary site; and [4] identification of prognostic factors and application of risk-adapted therapy.

Prior to 1947, when the first complete remission in childhood ALL was attained by Farber and colleagues using the folate antagonist aminopterin [219], the disease was uniformly fatal with a median duration of survival of 2 months from the time of diagnosis [220]. During the 1950s, drugs such as 6-mercaptopurine, methotrexate, and corticosteroids were found to be active and induced complete remissions in the majority of patients, but cure rates remained very low due to extremely high rates of relapse [221–224]. Additional active drugs were introduced in the 1960s and 1970s, including the anthracyclines (doxorubicin and daunorubicin), L-asparaginase, and epipodophyllotoxins (etoposide and teniposide) [225–227].

In the 1960s, as effective systemic chemotherapy combinations were identified, the incidence of the CNS as an initial site of relapse became increasingly more common [228, 229]. It was hypothesized that leukemia cells, even if not morphologically evident, were present in the CNS in all patients, and that these cells were protected by the blood-brain barrier from many of the systemically administered chemotherapy agents used at the time. Thus, the concept of the CNS as a sanctuary site emerged, prompting the inclusion of CNS-directed therapy to prevent relapse. With the introduction of cranial radiation to treat subclinical CNS

leukemia in the 1970s, long-term disease-free survival rates in childhood ALL dramatically increased to 50% [230]. Although nearly all pediatric patients are now treated without prophylactic cranial radiation, the inclusion of CNS-directed therapies (such as intrathecal chemotherapy and high-dose methotrexate) remains a universal component of all successful treatment regimens.

Risk-Adapted Therapy

After the addition of CNS-directed therapy improved cure rates in the 1970s, investigators compared presenting features in patients who relapsed and those who had not to establish clinically relevant prognostic factors. Subsequent clinical trials used these prognostic factors to stratify therapy. More intensive therapy was administered to those patients considered to be at the highest risk of relapse. In contrast, some of the more morbid components of therapy were modified or eliminated for those children considered to have the best prognosis. The goal of risk-adapted therapy is to treat away adverse presenting features, so that higher and lower risk patients have similar cure rates.

For many years, pediatric clinical trials consortia applied prognostic factors differently when defining risk categories. A more uniform approach to risk classification was proposed and agreed upon at an NCI-sponsored workshop held in 1993 [161]. For patients with B-ALL, the NCI standard-risk category was defined as age between 1 and 10 years and initial leukocyte count lower than 50,000/mm^3. The remaining patients were considered to have NCI high-risk ALL. Other characteristics used by cooperative groups to classify patients as high risk include T-cell phenotype, CNS-3 status at diagnosis, and high peripheral blast count after a week of steroid monotherapy (and a single dose of intrathecal methotrexate), cytogenetics, and MRD levels obtained after the first one or two treatment phases into risk group stratification. In some cases, only cytogenetics and early response (as assessed by MRD), and not other factors, such as age and leukocyte count, are considered when assigning risk groups [200].

Treatment Phases

In general, treatment regimens for children with ALL consist of 2–3 years of multiagent chemotherapy. Treatment consists of the three main parts: (1) remission induction, (2) post-induction consolidation, and (3) continuation (or maintenance). CNS-directed therapies are included throughout all phases. With contemporary regimens, event-free survival rates exceed 80%, and overall survival rates are approximately 90% [200, 204, 231, 232] (Table 17.4).

Remission Induction

The goal of the first phase of treatment, remission induction, is to induce complete morphologic remission. Complete remission is defined as attainment of a bone marrow with normal cellular elements but fewer than 5% lymphoblasts, return of normal peripheral blood counts, and resolution of other bulk sites of disease. The remission induction phase typically lasts for 4–5 weeks, and consists of glucocorticoid (prednisone, prednisolone, or dexamethasone), vincristine, and L-asparaginase; some regimens include an anthracycline (daunorubicin or doxorubicin) for all patients while others reserve its use for higher risk patients. About 1–2% of patients die of disease- or treatment-related complications during the first month of treatment, and about 1–2% fail to fully respond and have morphologically detectable disease at the completion of the remission induction phase [231, 233, 234]. Induction failure rates tend to be higher in patients with high presenting leukocyte counts and/or T-cell phenotype [185, 186]. Overall, more than 95% of pediatric patients with newly diagnosed ALL achieve complete remission at the end of the first month of treatment, with slightly lower rates in T-ALL compared with B-ALL [138, 164, 165, 231, 235–244].

Several randomized trials have compared two glucocorticoids, prednisone and dexamethasone, during remission induction and subsequent treatment phases. Potential advantages of dexamethasone include more potent in vitro

antileukemic activity, higher free plasma levels, and better CNS penetration [245–247]. In nearly all of the randomized trials, dexamethasone was associated with superior event-free survival [234, 248, 249], although in one trial (which closed early due to toxicity concerns with dexamethasone), no advantage was demonstrated for adolescents [250]. Dexamethasone during the remission induction phase has also associated with higher rates of infection, myopathy, hyperglycemia, and behavioral issues [234, 248–250].

Most patients with initial induction failure will eventually achieve complete remission; however the chance for subsequent relapse is quite high, leading to low rates of long-term survival [185–187]. Allogeneic hematopoietic stem cell transplantation (HSCT) after complete remission is achieved (as opposed to continued chemotherapy) may improve the outcome of patients with initial induction failure [251]. In a large retrospective series, a trend for superior overall survival with allogeneic HSCT compared with chemotherapy alone was observed in patients with initial induction failure and either T-ALL (any age) or B-ALL and age greater than 6 years [187].

Post-induction Consolidation

After achieving complete remission, patients typically receive several phases of treatment designed to further decrease levels of residual disease. The intensity of post-induction consolidation is stratified by risk group, with higher risk patients receiving stronger therapy.

A commonly used post-induction consolidation regimen was first introduced by the German Berlin-Frankfurt-Munster (BFM) study group [182], and this scheme has subsequently been adopted by several other large cooperative groups, with variations in some of the doses and agents used. The BFM-type consolidation regimen generally includes (1) a "consolidation" course consisting of cyclophosphamide, low-dose cytarabine, and a thiopurine (mercaptopurine or thioguanine), followed by (2) multiple doses of either high-dose or escalating doses of methotrexate with or without leucovorin rescue, and then (3) a reinduction (or delayed intensification) course, which typically include the same agents used during the initial induction/consolidation cycles [182]. This backbone has been modified on some protocols to eliminate or truncate some of the chemotherapy courses for lower risk patients, and intensified for high-risk patients by more doses of some agents (such as vincristine, pegaspargase, and methotrexate) and/or a second delayed intensification phase [184, 242, 252–256]. Alternative post-induction regimens have been adopted by some groups, with similarly favorable outcome results as those achieved using the BFM-type backbone. For instance, the consolidation phase on trials conducted by the DFCI ALL Consortium includes 20–30 weeks of consecutively dosed L-asparaginase along with frequent pulses of vincristine and corticosteroid, and doxorubicin for higher risk patients [231, 257, 258].

Continuation (Maintenance)

A standard feature of all treatment regimens for childhood ALL is a prolonged continuation or maintenance phase, consisting of daily mercaptopurine and weekly low-dose methotrexate. The importance of this phase is highlighted by results of studies indicating that patients who are compliant with less than 95% of their prescribed mercaptopurine doses have a significantly higher risk of subsequent relapse [212, 213, 218]. Pulses of vincristine and corticosteroid are frequently added to this maintenance backbone, although their benefit remains controversial [259–262]. When vincristine/corticosteroid pulses are used, it appears that dexamethasone is superior to prednisone [248, 249, 258], but also associated with increased risk of behavioral problems and skeletal toxicities [249, 258].

6-Thioguanine has been investigated as an alternative to 6-mercaptopurine during the continuation phase, with conflicting results regarding its impact on event-free survival [263–265]. The use of 6-thioguanine during maintenance has been associated with significant hepatotoxicity, including veno-occlusive disease and cirrhosis, as well as higher remission death rates, primarily caused by infection [263, 264], and so it is not typically used in this phase.

Approximately 0.5–1% of patients have an inherited homozygous deficiency of thiopurine *S*-methyltransferase (TPMT), which catalyzes the inactivation of mercaptopurine [266]. These patients are at increased risk for acute hematologic and hepatic toxicities when given standard doses of mercaptopurine, and can only tolerate much lower dosages [267, 268]. Patients who are heterozygous for this mutation (approximately 10% of the population) have intermediate levels of enzyme activity, generally tolerate mercaptopurine better than those with homozygous deficiencies, but still require dose reductions more frequently than patients who do not carry any mutant allele [267, 268]. Polymorphisms of the *NUTD15* gene, observed most frequently in Hispanic and East Asian patients, have also been associated with extreme sensitivity to mercaptopurine, necessitating significant dose reductions to avoid severe hematologic and hepatic toxicity [269].

On most treatment protocols, maintenance chemotherapy is administered until patients have received a total of 2–2.5 years of treatment from the time of diagnosis. Previous studies suggested that boys might benefit from a more prolonged continuation phase [270], so on some regimens, boys are treated for an additional year; however, the benefit of this approach with more contemporary regimens is not clear. Attempts to shorten therapy duration from 2 years have not been successful. In a randomized comparison of 18 versus 24 months of treatment, patients receiving the shorter duration had a higher rate of relapse [271]. Similarly, very high relapse rates were observed in a nonrandomized trial on which patients received intensified therapy for only

12 months, suggesting that truncated therapy, even if intensive, is inadequate for most children with ALL [272].

CNS-Directed Therapy

Because the central nervous system (CNS) is a sanctuary site into which many of the systemically administered agents used to treat childhood ALL do not effectively penetrate, treatment that is specifically directed at treating CNS leukemia is an essential component of all treatment regimens. Options for CNS-directed therapies include cranial radiation, intrathecal chemotherapy, and CNS penetrant systemic chemotherapy, such as high-dose methotrexate with leucovorin rescue, escalating-dose methotrexate, and dexamethasone. The type of CNS-directed therapy that is used is based on a patient's risk of CNS relapse, with higher risk patients receiving more intensive treatments.

Radiation therapy was the first treatment approach successfully used to prevent CNS relapses. In the 1960s and 1970s, studies performed at St. Jude Children's Research Hospital (SJCRH) documented the effectiveness of CNS radiation (cranial or craniospinal) in children with ALL [273, 274]. Subsequent studies demonstrated that 2400 cGy cranial radiation with intrathecal methotrexate was as effective in preventing CNS relapse as craniospinal radiation without intrathecal chemotherapy [275, 276]. Because craniospinal radiation was associated with increased toxicity, including excessive myelosuppression and spinal growth retardation, cranial radiation administered with intrathecal chemotherapy became the standard form of CNS treatment in the 1970s. Increased recognition of late effects associated with 2400 cGy cranial radiation led to the use of a lower dose (1200–1800 cGy) in trials conducted in the 1980s and 1990s [258, 277, 278].

The proportion of patients receiving cranial radiation has decreased significantly over the last few decades. With contemporary regimens, nearly all pediatric patients are treated without cranial radiation, relying on other CNS-directed therapies, including multiple doses of intrathecal chemotherapy, for CNS prophylaxis. When it is used, radiation is administered only to those patients considered to be at highest risk of subsequent CNS relapse, such as those with CNS-3 status at diagnosis and T-ALL patients with high presenting leukocyte counts and/or slow early response to initial therapy.

Several nonrandomized studies have been conducted in which cranial radiation was omitted for all patients, regardless of risk group status [138, 279, 280]. These trials intensified other CNS-directed therapies for higher risk patients, including additional doses of high-dose methotrexate and/or high-dose cytarabine and increased frequency of intrathecal chemotherapy. Predictors of subsequent CNS relapse on these trials included T-cell phenotype and the presence of blasts in spinal fluid at diagnosis [138]. In a meta-analysis of aggregated data from more than 16,000 patients treated between 1996 and 2007 by ten cooperative groups, only patients with CNS-3 status at diagnosis appeared to benefit from cranial radiation therapy [281]. In this analysis, CNS-3 patients who received cranial radiation had a significantly lower rate of relapses involving the CNS compared with nonirradiated CNS-3 patients; however, the overall 5-year mortality rate for CNS-3 patients was similar whether or not they received radiation.

Treatment Sequelae

As cure rates for childhood ALL have improved over the last several decades, late effects related to the disease and its treatment have become increasingly evident. A number of late effects have been documented in long-term survivors, including neurocognitive sequelae, short stature, obesity, cardiac dysfunction, cataracts, osteonecrosis, and second malignant neoplasms.

Neurocognitive Late Effects

Long-term neurocognitive sequelae have been well documented in survivors of childhood ALL. The frequency and severity of impairments vary by treatment and patient characteristics. Children treated at a younger age, and, in some studies, female patients, are at higher risk for developing neurocognitive late effects [282–288]. The most severely impaired long-term survivors are those who received relatively high cranial radiation doses (24–28 Gy) in the 1970s. Low and low average intelligence quotients (IQs) have been frequent findings in these patients [282, 283, 289], and they also exhibit a high frequency of neuropsychological deficits, including a slow speed of processing information, distractibility, and difficulty in dealing with complex or conceptually demanding material [285, 290]. Long-term survivors treated with lower dose (18 Gy) radiation, especially those who were 3 years or older at diagnosis, appear to fare better, with less severe neurocognitive late effects. In some studies, this group of survivors does not demonstrate any significant cognitive deficits, although subtle effects can be observed in some of these patients with detailed neuropsychological testing [284, 291].

Intrathecal chemotherapy and CNS-penetrant systemic treatments (such as high-dose methotrexate) also appear to contribute to neurocognitive late effects. There is evidence that cognitive deficits are present in long-term survivors treated without cranial radiation [291–294], but these deficits do not tend to be severe and their neurocognitive function is generally within the normal range [288, 295]. In most studies of long-term survivors, nonirradiated patients have

fewer and less severe impairments than those who received cranial radiation [283, 296], although with current chemotherapy regimens and lower doses of radiation, differences between the two groups may be subtle [291]. For nonirradiated patients, greater treatment intensity of systemic and intrathecal chemotherapy has been associated with a higher frequency of neuropsychologic deficits and difficulties at school [297].

Skeletal Toxicities

Osteonecrosis, which is observed in 5–10% of children treated for ALL, is a disabling bone toxicity resulting from treatment with glucocorticoids. It is typically diagnosed during the maintenance phase or soon after the completion of therapy, frequently involves multiple joints, and can lead to chronic pain and loss of function, sometimes requiring joint replacement and other surgeries [298–300]. Rates of osteonecrosis are significantly higher in adolescents than in younger children [258, 298, 300]. Adults with ALL do not seem to have as high an incidence of symptomatic osteonecrosis as teenagers, suggesting that the hormonal and physiologic changes of puberty may render adolescents more susceptible to this complication [301]. In addition to age, other risk factors for the development of osteonecrosis include higher total doses of glucocorticoids, female sex, and high body mass index [298, 300]. In some studies, dexamethasone (when used instead of prednisone) has been associated with a higher risk of osteonecrosis, particularly in adolescents [299].

Several studies have shown that children with ALL develop osteopenia during therapy [302, 303], most likely secondary to glucocorticoid exposure, resulting in an increased risk for fractures during and immediately after treatment [304, 305]. It appears that bone mineral density improves once therapy is completed, although some degree of residual osteopenia may persist [306–309].

Cardiac Late Effects

Anthracyclines, such as doxorubicin and daunorubicin, have been associated with cardiotoxicity in long-term survivors, including left ventricular wall thinning and depressed contractility [310]. Patients treated at a young age, females, and those with Down syndrome appear to be more vulnerable to developing anthracycline-associated cardiac toxicity [311, 312]. The severity of cardiac dysfunction is correlated with higher cumulative doses of anthracycline and higher dose rates [311–314]. Over the last few decades, therapeutic regimens have been modified so that patients receive lower cumulative dosages of anthracyclines; as a consequence, symptomatic congestive heart failure has become increasingly uncommon and now only rarely occurs in long-term survivors of childhood ALL [312, 314]. However, asymptomatic echocardiographic abnormalities can still occur, sometimes developing many years after completion of therapy, and may be progressive over time [315]. Randomized clinical trials have demonstrated that use of the cardioprotectant agent dexrazoxane can reduce the frequency of long-term cardiotoxicity in patients receiving relatively high doses of anthracycline without adversely impacting event-free survival rates [316–318].

Second Malignant Neoplasms

Long-term survivors of childhood ALL are at risk for developing second malignant neoplasms (SMNs), including brain tumors, acute myelogenous leukemia (AML), non-Hodgkin's lymphomas, and carcinomas of the parotid and thyroid glands [319–321]. The overall cumulative incidence of SMNs reported in the literature ranges from 1 to 6%, depending on the treatment regimen and length of follow-up [319, 320]. In a retrospective study of 2169 patients treated between 1962 and 1998 (median follow-up 18.7 years), the overall cumulative incidence of SMN was approximately 4% at 15 years and 11% at 30 years [320]. When benign neoplasms, such as basal cell carcinoma and meningioma, were excluded from that analysis, the cumulative incidence of SMNs at 30 years was approximately 6%.

Malignant gliomas and nonmalignant meningiomas occur almost exclusively in patients who received cranial or craniospinal radiation [319, 320]. The cumulative incidence of malignant glioma in irradiated survivors appears to plateau approximately 15–20 years after diagnosis; conversely, even with 30 years of follow-up, a plateau in the incidence of meningiomas has not been observed [320]. Cranial radiation has also been associated with the development of vascular malformations, which can lead to neurological symptoms and intracranial hemorrhage [322]. Rates of secondary AML are increased in patients who receive higher total (and/or more frequent) doses of epipodophyllotoxins and alkylating agents [323–325]. Some studies have suggested that secondary leukemia risk may also be increased in patients with homozygous or heterozygous deficiencies in thiopurine methyltransferase (an enzyme involved in the metabolism of mercaptopurine) [326].

Relapse

Approximately 15% of children with ALL who achieve complete remission will subsequently relapse. Relapses tend to occur during the first 5 years after initial diagnosis, but can

occur as late as 10 years [327]. The most common site of relapse is the bone marrow, with or without overt extramedullary involvement; more uncommonly, relapse can sometimes only be detectable only in an extramedullary site, such as the CNS or testes.

Duration of initial remission is one of the most important prognostic factors at the time of relapse, with significantly worse outcomes observed in patients with shorter initial remissions [328–330]. Site of relapse also has prognostic importance, with superior outcomes observed for patients experiencing isolated extramedullary relapses compared with marrow relapses [329, 330]. Some studies have suggested that patients with combined marrow and extramedullary relapses have a better prognosis than those with isolated marrow relapses [328, 330], although this has not been consistently demonstrated [329]. T-cell phenotype and age older than 10 years at initial diagnosis have also been associated with an adverse prognosis after relapse [328–330], as has response to initial reinduction chemotherapy assessed by sensitive minimal residual disease (MRD) tests [331, 332].

Marrow Relapse

Approximately 80–90% of children experiencing a marrow relapse will achieve a second complete remission, often with agents similar to those used at the time of initial diagnosis [333, 334]; second complete remission rates are lower in those relapsing early and/or with T-ALL [328, 333, 335, 336]. Patients with persistent morphologic disease at the end of the first month of reinduction have a very poor prognosis, even if they subsequently achieve a second remission [337].

For B-ALL patients with early marrow relapses (defined as those occurring earlier than 30–36 months from initial diagnosis), allogeneic hematopoietic stem cell transplant (HSCT) has consistently been shown to be superior to chemotherapy-only approaches, although even with HSCT, long-term survival rates are less than 50% [338–340]. Patients with T-ALL, regardless of timing of relapse, are also generally treated with allogeneic HSCT because of poor survival rates with chemotherapy-only salvage therapy [341].

For B-ALL patients with a late marrow relapse, a chemotherapy-only approach leads to survival rates of approximately 50%, and it not clear that allogeneic HSCT is associated with superior outcome [328, 329, 338, 342]. End-reinduction minimal residual disease (MRD) levels strongly predict the prognosis of late-relapsing patients treated with chemotherapy only [331, 332]. Those with low MRD at this time point fare relatively well (event-free survival rates exceeding 70%), while those with higher MRD levels have a significantly greater risk of subsequent relapse [331, 332]. In one study, allogeneic stem cell transplant was associated with an improved outcome (compared to historic controls treated with chemotherapy only) in late-relapsing patients with high MRD levels at the end of reinduction [343].

For relapsed ALL patients who proceed to allogeneic HSCT, the components of the preparative regimen appear to impact the outcome; several studies have shown that regimens that include total body irradiation (TBI) are associated with better outcomes than those that do not [338, 344]. MRD levels at the time of transplant are also highly prognostic; patients with MRD-detectable disease just prior to HSCT fare worse than those with non-detectable levels [345–348].

Isolated Extramedullary Relapses

Isolated extramedullary relapses occur in fewer than 5% of patients. Using sensitive molecular techniques, submicroscopic marrow disease can be demonstrated in most children at the time of an isolated extramedullary relapse [349]. Thus, successful treatment strategies must address both the local site of relapse and submicroscopic systemic disease.

For patients with isolated CNS relapses, therapy typically involves intensive systemic chemotherapy with cranial radiation [350–352]. As with marrow relapses, patients experiencing late isolated CNS relapses have a better prognosis than those whose relapses occur earlier [329, 351–353], although a different cutoff is used to distinguish early versus late because of the overall more favorable outcome associated with extramedullary relapses. On two consecutive clinical trials conducted by the Pediatric Oncology Group, children with B-ALL and a late isolated CNS relapse (defined as initial remission duration of at least 18 months) had EFS rates exceeding 75% when treated with intensive chemotherapy and delayed cranial radiation, while patients with earlier relapses fared less well [351, 352]. It is not clear that allogeneic HSCT is associated with a survival advantage for patients with an isolated CNS relapse, even those with early relapses [354, 355]. Patients whose initial therapy included cranial radiation may have a worse prognosis after an isolated CNS relapse than previously unirradiated patients [350].

Isolated testicular relapses are uncommon, occurring in less than 1% of boys with ALL [239, 240]. For boys with isolated testicular relapses, systemic chemotherapy and testicular radiation and/or orchiectomy have resulted in prolonged second remissions in more than 80% of patients with late-occurring relapses [356, 357], with worse outcomes reported for those with earlier relapses [356, 358].

Future Directions

The improvement in cure rates for childhood ALL over the last several decades is due to the development of effective multiagent chemotherapy regimens, enhanced supportive

care, successful implementation of risk-adapted therapy, and advances in the understanding of disease biology. Despite this remarkable progress, some leukemia subtypes still respond poorly, and for patients who are successfully treated, therapy remains, to the large part, nonspecific and associated with multiple acute and long-term toxicities. Thus, there remains a need to further refine risk stratification and to develop more effective and potentially less toxic therapies.

Investigations of the genomic landscape of ALL have identified biologically distinctive subsets that may supplement or replace the currently applied clinical risk factors in order to identify those patients at highest risk of treatment failure [27, 64, 103, 104, 160, 359]. Druggable molecular lesions identified in various ALL subsets may lead to incorporation of targeted therapies, such as ABL-kinase and/or JAK-STAT inhibitors for *BCR-ABL1*-like ALL and epigenetic-modifying agents for *KMT2A*-rearranged ALL [109, 360]. In addition, research focused on germline genetic variation and pharmacogenomics may identify patient-related factors that affect the outcome and vulnerability to treatment-related toxicities, leading to more individualized therapy [361, 362]. The use of more sensitive molecular measures to assess minimal residual disease levels may enhance evaluation of early response [192, 348].

Novel therapies with the potential to improve outcomes include immunotherapeutic approaches. Although varying in their mechanisms of action, all of these approaches target cell surface antigens expressed on lymphoblasts, including CD19 and CD22 (nearly universally expressed in B-ALL), and thus represent a more targeted treatment strategy than current, nonspecific cytotoxic chemotherapy agents. Rituximab (anti-CD20 monoclonal antibody) has demonstrated benefit in adults with newly diagnosed CD20-positive ALL when given in combination with chemotherapy [363], and administration of single-agent inotuzumab ozogamycin, a recombinant immunotoxin consisting of humanized anti-CD22 antibody linked to calicheamicin, led to high complete remission rates in relapsed, refractory adult B-ALL patients [364]. Blinatumomab, a bi-specific (anti-CD3-anti-CD19 antibody) T-cell engager, has demonstrated single-agent activity in adult and pediatric relapsed B-ALL patients, and also has been shown to reduce minimal residual disease in those who had already achieved complete remission [365–367].

Cellular therapy using genetically engineered autologous chimeric antigen receptor (CAR) T-cells is an emerging and very promising immunotherapeutic approach. CAR T-cell therapy involves collection of autologous T-cells from patients, ex vivo genetic engineering to induce expression of ALL-specific chimeric antigen receptors along with additional co-stimulatory domains, and then reinfusion into the patient, typically after a chemotherapy preparative regimen [368, 369]. Phase 1 and 2 trials of CD19-directed CAR T-cells in relapsed/refractory pediatric and adult B-ALL patients have demonstrated high response rates, with some patients achieving sustained remissions without further treatment [369–371]. While there are many unanswered questions regarding CAR T-cells (duration of response, mechanisms of resistance, prevention of acute toxicities, potential long-term sequelae), the promising early outcome results highlight the potential of this treatment approach to transform therapy for relapsed and high-risk newly diagnosed ALL patients.

18 Diagnosis and Treatment of Adult Acute Lymphoblastic Leukemia

Nicola Gökbuget and Dieter Hoelzer

Introduction

Acute lymphoblastic leukemia (ALL) is the most frequent neoplastic disease in childhood and accounts for about 20% of the acute leukemias in adults. An early peak of ALL incidence occurs at the age of 4–5 years and the overall incidence is 1.4 with a male predominance. It is relatively infrequent in younger adults but the incidence seems to increase in adults aged over 50 (Chap. 13). The median age of patients in most adult ALL studies ranges from 25 to 39 years.

In the past decades substantial progress has been made in the treatment of ALL mainly based on intensified chemotherapy regimens adopted from pediatric protocols, stem cell transplantation, risk- and subgroup-adjusted therapy, and improved supportive care. With contemporary regimens complete remission (CR) rates of 90% and cure rates of 40–70% depending on age can be achieved [1]. More recently individualized treatment according to minimal residual disease (MRD) has been implemented into treatment protocols. Targeted therapy particularly with tyrosine kinase inhibitors in Ph/BCR–ABL-positive ALL but also antibody therapy has contributed to further improved outcome in subgroups of ALL.

Clinical Features

The clinical presentation of adult ALL is almost always acute and the patient usually has symptoms of only a few weeks' duration. Patients show a rapid decline in general condition and feel generally ill. In rare cases, ALL may also develop from a transient preceding pancytopenia.

N. Gökbuget, M.D. (✉) • D. Hoelzer, M.D., Ph.D.

e-mail: goekbuget@em.uni-frankfurt.de; hoelzer@em.uni-frankfurt.de

Most of the symptoms of adult patients with ALL are nonspecific and are not usually severe. The patients may complain of progressive malaise with lethargy, fatigue, and occasionally weight loss. They may also complain of fever and night sweats in the absence of clinical infection. In older patients complications of anemia such as dyspnea, angina, and dizziness may dominate the clinical picture. Adult ALL patients may have minor arthralgias and bone pain but much less frequently than in children. One-third of the patients have infections or fever. As infections, hemorrhages are also less frequent than in acute myeloid leukemia (AML). There may be a history of some easy bruising and mucosal hemorrhage. In a series of 1273 consecutive ALL patients (15–65 years) treated in the German Multicenter Trials for Adult ALL (GMALL) one-third had some signs of minor bleeding tendency such as petechiae. Fever or infections had the same frequency. A few patients may present with neurological symptoms such as headache, alteration of mental function, or cranial nerve palsies due to leukemic infiltration.

An outline of the clinical approach to a patient with adult ALL is given in Table 18.1. Physical examination will show some degree of organomegaly in most adult patients with ALL: lymphadenopathy, usually cervical, is present in about half of the patients (57%) and palpable splenomegaly (56%) or hepatomegaly (47%) also in about half. A thymic mass can be found from chest roentgenograms or computer tomograms in 15% of all adult ALL patients. The majority of these patients have a T-cell ALL, but patients with other subtypes may occasionally also present with a mediastinal mass. Massive thymic enlargement can cause dyspnea, especially when associated with large pleural effusions. Some patients with mediastinal enlargement have pericardial effusions as well.

Presentation with clinically detectable signs related to leukemic infiltration of the central nervous system (CNS) occurs in about 5–10% of adult ALL patients [2]. Risk factors for CNS involvement include a high initial white blood cell (WBC) count, T-cell phenotype, and L3 or Burkitt's morphology. CNS involvement may manifest as raised intracranial pressure with headache and papilledema without

Table 18.1 Adult ALL: clinical approach and laboratory investigation

Complete medical history, including
• Past medical history, especially heart, lung, liver, or renal disease, and diabetes mellitus (comorbidity score)
• Family history
• Occupational history
Complete physical examination, with special attention to lymphadenopathy and hepatosplenomegaly
• Temperature
• Potential sites of infection including lungs, oropharynx, and perineum
• Signs of abnormal hemorrhage
• Optic fundi
• Full neurological examination including the cranial and peripheral nerves
Diagnostic hematological studies
• Full blood examination including hemoglobin, platelet count, and white blood cell count (total and differential)
• Bone marrow aspirate and trephine biopsy
• Bone marrow cytology
• Immunological markers: T-cell, B-cell, immunological subtypes
• Cytogenetic analysis
• Molecular analysis, for prognostic markers, therapy targets, and MRD markers
Biochemical studies
• Including renal and hepatic function, serum uric acid, serum electrolytes including calcium and phosphate, blood glucose, and serum LDH
Coagulation studies
• Including prothrombin ratio, partial thromboplastin time, fibrinogen, and ATIII
Cardiac assessment
• Including electrocardiograph, echocardiogram, and other noninvasive tests of myocardial function if indicated
Chest roentgenogram: posterior–anterior and lateral
Computer tomograph, if mediastinal lymph nodes, tumor or abdominal masses are suspected
Serological studies
• ABO and Rh blood group
• HLA typing
Microbiological studies
• Culture from any infected site or lesion
• Surveillance cultures
• Serum for antibody titers, CMV, EBV, HIV, candida, aspergillosis
CSF examination
• Examination for cell count and cytocentrifuge preparation for morphology and, if necessary, immunophenotyping
Pregnancy test
Information about fertility preservation

HLA human leukocyte antigen; *PA* posterior–anterior; *CMV* cytomegalovirus; *EBV* Epstein–Barr virus; *HIV* human immunodeficiency virus

focal neurological signs or, rarely, as cranial nerve palsies, the sixth and seventh cranial nerves being most frequently involved. Careful examination of the ocular fundus must be made for leukemic infiltration as well as for hemorrhages due to thrombocytopenia.

Virtually any organ can be involved by infiltration of leukemic cells. The presence of bone lesions could be found in the earlier mentioned ALL series in only 1.2%. Also the initial involvement of the testis was very rare (0.3%). Other leukemic infiltrations were observed in the retina (0.9%), skin (0.9%), tonsils (0.5%), lung (0.5%), and kidney (0.5%). These organ manifestations present a typical clinical pattern of non-Hodgkin's lymphoma (NHL). They occur more frequently in mature B-cell ALL (32%) and T-ALL.

Diagnostic Procedures

The diagnosis of ALL is made by examination of the peripheral blood and bone marrow. Other investigations also need to be performed to further categorize and subclassify the disease and in preparation for therapy. These include cytochemical stains, immunological markers, cytogenetic analysis, and molecular genetic methods.

Peripheral Blood

Peripheral blood examination characteristically shows anemia, thrombocytopenia, and neutropenia (Table 18.2) although the total white blood cell count (WBC) is variable. The reduction in the level of hemoglobin is mild to moderate, but nearly one-third of the patients have a hemoglobin level below 8 g/dL. Although clinical bleeding due to thrombocytopenia is not very common, about half of the patients have a platelet count below 50×10^9/L. The proportion (30%) of adult ALL patients having had some history of hemorrhage corresponds well with the 30% of patients with a platelet count below 25×10^9/L. The proportion of patients with a granulocyte count below 0.5×10^9/L, usually associated with high risk of infection, was only one-fifth in this series. Only a small minority of patients had clotting defects and of these 5% had an initially decreased fibrinogen level, which might be of relevance if an immediate l-asparaginase treatment is anticipated. The WBC was reduced in 27%, and normal or modestly elevated in 60%, and 16% had a marked leukocytosis (WBC count > 100×10^9/L) at presentation. However, even in the cases where the WBC was reduced or normal, characteristic lymphoblasts could be identified on a well-stained blood smear in more than 90% (Table 18.2).

Bone Marrow

Bone marrow examination provides further material for diagnostic assessment including morphology, cytochemical stains, immunological markers, and cytogenetic and molecular analysis. Smears of the bone marrow aspirate show markedly hypercellular particles. The majority of cells are leukemic lymphoblasts. A total of 97% of the adult ALL patients had a bone marrow infiltration with leukemic lymphoblasts above 50% (Table 18.2). The normal hematopoietic elements are greatly reduced or absent but, in contrast to AML, they have essentially normal morphology. The trephine biopsy of the bone marrow will further demonstrate marked hypercellularity with replacement of fat spaces and normal marrow elements by infiltration with leukemic cells. A slight increase in marrow reticulin is seen in a small proportion of patients with ALL but much less commonly than with AML. If an adequate bone marrow aspiration is available, it remains open whether an additional biopsy should be done. In our hands a biopsy was necessary when aspiration was not possible due to heavily packed leukemic cells or increased reticulin fibers.

Laboratory Investigations

The laboratory investigations that should be performed at the time of diagnosis (Table 18.1) will serve as a baseline for subsequent studies during the induction period, and may also document metabolic abnormalities that require correction before the start of treatment or modification of drug dosage. Renal impairment, hyperuricemia, and electrolyte imbalance should be corrected if possible before treatment is begun. Serum lactic dehydrogenase (LDH) levels are markedly elevated in most patients with ALL. A full hemostatic profile should be performed to detect the very occasional adult ALL patients with disseminated intravascular coagulation or with an incidental clotting abnormality related to preexisting liver disease or liver infiltration. Besides cultures from any clinically infected site, surveillance cultures from the nose, throat, axillae, groin, vagina, perianal area, and sputum and urine are taken to detect clinically occult infection and to provide useful information about microbiological etiology if septicemia or severe infection subsequently develops. In patients with a past medical history of heart disease and in older patients where treatment with an anthracycline is anticipated, an echocardiogram with myocardial function, including the ejection fraction, should be carried out.

Cerebrospinal Fluid

The examination of the cerebrospinal fluid (CSF) is an essential diagnostic procedure in ALL to exclude or confirm initial CNS disease. There are different opinions as to when the first lumbar puncture should be done. Early recognition of CNS disease is clinically important because more aggressive CNS therapy is required for such patients. Therefore a diagnostic puncture should be done if possible before initiation of systemic chemotherapy. This procedure is restricted to patients with an adequate platelet count which can be achieved by platelet transfusion (>20 × 10^9/L), an absence of manifest clinical hemorrhages, and without a high WBC. For safety reasons patients should receive intrathecal methotrexate at

the first lumbar puncture. Clearly this procedure necessitates an atraumatic lumbar puncture and should only be performed by experienced physicians since in childhood ALL blood contamination of the CSF was associated with a higher relapse risk. In pediatric studies nowadays CNS disease at diagnosis is classified into four groups: CNS1 (no blasts in CSF), CNS2 (<5 WBC/μL with blasts), CNS3 (≥5 WBC/μL with blasts), and TLP+ (traumatic lumbar puncture with ≥10 RBC/μL with blasts) [2]. CNS involvement in adult ALL is generally defined as CNS3 or the presence of signs of CNS involvement in CT or MRT or neurological symptoms not otherwise explainable, e.g., cranial nerve palsies.

Differential Diagnosis

Difficulty is rarely experienced in establishing the diagnosis of ALL. Viral infection may cause lymphadenopathy and hepatosplenomegaly with lymphocytosis in the blood and bone marrow and, although the distinction can usually be made on clinical and morphological grounds, the results of viral antibody titers, lymphocyte surface markers, and cytogenetic analyses may be required. The leukemic phase of non-Hodgkin's lymphoma can mostly be recognized by clinical and morphological features, by the type and pattern of immunological cell surface markers, and by the degree and distribution of bone marrow infiltration. In the rare cases with a low bone marrow infiltration an arbitrary distinction between ALL and lymphoblastic lymphoma is usually chosen according to the degree of infiltration, above or below 25%. With more advanced immunological marker application, mixed leukemias having myeloid as well as lymphoid surface markers are diagnosed, which might be allocated to a treatment strategy for either ALL or AML; recent data show more favorable outcomes with ALL regimens for biphenotypic leukemias [3]. They have to be distinguished from cases with ALL and coexpression of myeloid markers, which is rather frequent in immature subtypes such as pro-B-ALL or early T-ALL. These patients are treated with ALL strategies.

Occasionally, difficulties can occur in distinguishing Ph/BCR–ABL-positive ALL from primary lymphoid blast crisis of CML. Sometimes final diagnosis can be done only after treatment initiation. In ALL patients achieving complete clinical remission (CR), the peripheral blood count shows normal values, whereas CML cases may revert to a chronic phase with pathological left shift.

Classification

There is a wide heterogeneity within ALL. Therefore accurate morphological classification, determination of the immunological phenotype, and cytogenetic and molecular genetic analysis, which are of prognostic and therapeutic relevance, should be performed in every case of ALL, including older ALL patients. In addition, in all patients, material from the time point of diagnosis should be sent to a reference laboratory in order to identify individual markers for detection of minimal residual disease.

Morphology and Cytochemistry

Bone marrow aspirates and blood smears are stained with Wright's or Wright's-Giemsa stain and the blast cells may be classified according to the French–American–British (FAB) classification. Clinical relevance of FAB subtypes is limited to the detection of the L3 FAB subtype which is characteristic for mature B-ALL. This subtype is important to identify since different treatment approaches are used. In the new WHO classification ALL is classified together with lymphoblastic lymphoma into B-precursor lymphoblastic leukemia/lymphoma, T-precursor lymphoblastic leukemia/lymphoma, and Burkitt's leukemia/lymphoma [4]. The further subclassification is of less relevance for management of adult ALL.

The cytochemical stains to discriminate between AML and ALL are Sudan black, myeloperoxidase, and chloracetate or nonspecific esterase. These reactions are negative in ALL, negativity being usually defined as less than 3% of leukemic blast cells positive. Cytochemical stains to confirm ALL are periodic acid-Schiff (PAS) and acid phosphatase. The PAS stain will show coarse granules or block positivity in at least some cells of most patients with adult ALL of the L1 or L2 type, the incidence of positivity being approximately 60–70% in both groups. The acid phosphatase reaction is positive in 20–30% of all ALL being more specific for T-ALL. About 70% of patients with T-ALL will show strong and localized paranuclear staining with acid phosphatase. PAS or acid phosphatase reactivity is, however, not restricted to ALL and since it can be positive in some cases (M5) of AML the additional reactions for peroxidase and acetate esterase must be negative.

Immunophenotyping

The main aim of immunophenotyping of leukemic blast cells is to distinguish between AML and within the ALL between B- or T-lineage ALL by using monoclonal antibodies to pan-B (CD19), pan-T (CD7), and pan-myeloid surface antigens (CD13, CD33, CDw65). To detect early lymphoid or myeloid differentiation, lineage-specific markers which are first exhibited in the cytoplasm (cy) of B-cell (cyCD22), T-cell (cyCD3), and myeloid precursor cells (myeloperoxidase) are used. To define further maturational stages within the B- and T-cell lineages, markers more specific for

Table 18.3 Immunological, morphological, cytogenetic, and molecular characterization of ALL[a]

Subtypes	Marker	Incidence[a] (%)	FAB subtype	Frequent cytogenetic aberrations	Fusion transcripts and mutations

particular maturational stages are used: for B-lineage CD20, cy immunoglobulin μ heavy chain (cyIgM), and surface immunoglobulin (sIg), and for T-lineage CD1, CD2, CD4, CD8, and surface sCD3. The maturation stages are not identified by the presence or absence of a single antigen but by a pattern of antigen expression. One widely used classification system for immunologic subtypes in ALL has been proposed by the EGIL group [5]. More recently early T-precursor ALL has been described as a specific subtype of T-ALL, characterized by a unique gene expression and surface marker profile [6]. For further details on immunobiology of ALL refer to Chap. 15.

With the availability of more specific monoclonal antibodies 98–99% of the acute leukemias can now be reliably classified by immunological marker analysis. In addition, ALL can be subdivided according to various maturational stages of B- or T-lineage, whereby it is assumed that they are in differentiation arrest corresponding to normal maturational stages. Immunological classification of ALL subtypes is summarized in Table 18.3.

B-Lineage ALL

With the analysis of CD10 (the common ALL antigen), cyIgM, and sIg, the B-lineage ALL can be subdivided into three subgroups of B-cell-precursor ALL and mature B-ALL. Virtually all B-precursor ALLs are positive for HLA-DR and TdT. Pro-B-ALL (also termed pre-pre-B-ALL, null-ALL, CD10-negative ALL) is the most immature subtype of the B-ALL lineage. This subtype is characterized by the expression of CD19, cyCD22, and mostly CD24, while CD10, cyIgM, and SIg are negative. Common ALL, the major immunological subtype in childhood as well as in adult ALL, is characterized by the expression of CD10 in combination with CD19, cy or sCD22, and CD24. Common ALL blast cells do not carry markers of relatively mature B-cells such as cyIgM or sIg. Pre-B-ALL is characterized by the expression of cyIgM, being negative in common ALL but otherwise identical with all other markers, such as CD19, cy or sCD22, CD24, and only very rarely CD10 may be absent in this subtype. In most adult clinical studies pre-B-ALL is included in the common ALL category. In most studies common ALL is defined by surface antigen expression of CD10 on 20% or more of leukemic cells and the diagnosis of pre-B-ALL by cyIgM in 10% or more of blast cells.

Leukemic blast cells in mature B-ALL, also termed Burkitt's leukemia, express sIg and B-cell antigens including CD19, CD20, CD22, CD24, and usually CD10. In contrast to the B-precursor ALLs, leukemic cells in B-ALL are mostly negative for TdT. Most B-ALLs can be identified morphologically as L3 FAB subtype.

T-Lineage ALL

Early T-ALL is characterized by the expression of cyCD3 with no additional differentiation markers. CD2 is generally negative. In cases positive for CD2 but negative for CD4, CD8, sCD3, and CD1a, an early T-ALL is present as well. Cortical T-ALL, also referred to as thymic T-ALL, is characterized by the expression of CD1 in combination with CD7, CD5, and CD2, and sometimes also sCD3, CD4, and CD8. Mature T-ALL is characterized by positivity for sCD3, CD7,

CD5, and CD2 while CD1 is negative. CD4 and CD8 are present in most cases. In the newly described entity of early T-precursor ALL (ETP) by definition, blasts in ETP ALL express CD7 but lack CD1a and CD8, and are positive for one or more of the myeloid/stem cell markers [4].

Myeloid Antigen-Positive ALL (My + ALL)

Immunophenotyping has shown the existence of acute leukemia cases in which the blast cells express markers supposedly specific for or associated with another cell lineage. The myeloid-antigen-associated monoclonal antibodies that are used for the detection of My + ALL are CD13, CD14, CD15, CD33, and CDw65. The reported frequencies of My + ALL differ widely, ranging from 5 to 46% depending on the definition, and an approximate figure for adult My + ALL may be 18%. Commonly a case is considered as My + ALL if 20% or more of the blast cells are reactive with the myeloid-lineage-associated monoclonal antibodies. The expression of myeloid antigens is associated with certain subtypes of ALL such as pro B-ALL or early T-ALL. Myeloid coexpression should be differentiated from biphenotypic leukemia. The EGIL group has proposed a score for identification of biphenotypic acute leukemia [5].

Table 18.4 Characteristics of immunological subtypes of adult ALL[a]

Subgroup	Clinical/laboratory characteristics	Relapse kinetics and localization
B-lineage		
Pro-B-ALL	– t(4;11)/ALL1-AF4 (70%) – High WBC (>100/mL) (26%) – Frequent myeloid coexpression (>50%)	– Mainly BM (>90%)
c-ALL/ pre-B-ALL	– Higher age (24% > 50 year) – Ph/BCR–ABL (40–50%) – m-BCR (70%), M-BCR (30%)	– Mainly BM (>90%) – Prolonged relapse kinetics (up to 5–7 year)
B-ALL	– Higher age (27% > 50 year) – Frequent organ involvement (32%) – Frequent CNS involvement (13%)	– Frequent CNS (10%) – Short relapse kinetics (up to 1–1½ years)
T-lineage		
	– Younger age (90% < 50 year) – Frequent mediastinal tumors (60%) – Frequent CNS involvement (8%) – High WBC (>50/mL) (46%)	– Frequent CNS (10%)/ extramedullary (6%) – Intermediate relapse kinetics (up to 3–4 years)

[a]Data based on German multicenter trials of adult ALL

Frequency and Clinical Features of Immunological Subtypes

The frequency of immunological subtypes in adult ALL shows distinct differences from that in childhood ALL. Approximately 84% of the children have a B-precursor ALL and common ALL is, with 63%, the most frequent subtype, whereas this subtype is only observed in one-half of adult ALL patients. There is a significantly higher proportion of the pro-B-ALL, with 12% in adults compared to only 5% in children. Mature B-ALL is rare in both childhood and adult ALL. Adult T-ALL, with 23%, has a twofold higher incidence in adults than the 13% observed in children. As in the B-lineage the most immature form, pre-T-ALL, has a higher incidence in adults compared to children.

The clinical features of the immunological subtypes of ALL are quite distinct. The immature pro-B-ALL has a peak in infants less than 1 year old and is associated with high WBC, massive hepatosplenomegaly, CNS disease, and myeloid coexpression, and approximately 70% of the patients show t(4;11). Nearly one-half of the patients with c-ALL or pre-B-ALL show the translocation t(9;22) and the incidence increases with age. Mature B-ALL is characterized by frequent abdominal tumor masses, often organ involvement, an increased incidence of CNS leukemia, and a male preponderance. T-ALL is associated with mediastinal masses in nearly half of the patients, occasionally associated with pleural and pericardial effusions, an increased incidence of organomegaly, a higher incidence of CNS disease, a high WBC count, and male prevalence. The major clinical differences between immunological subtypes of adult ALL are summarized in Table 18.4.

Cytogenetics and Molecular Genetics

Cytogenetic and molecular genetics abnormalities are independent prognostic variables for predicting the outcome of adult ALL (Chap. 16). In several multicenter studies, clonal chromosomal aberrations could be detected in approximately 62–85% of adult ALL patients. The most frequent numerical chromosomal aberrations are hypodiploid karyotype with less than 46 chromosomes (4–8%), hyperdiploid karyotype with 47–50 chromosomes (7–15%), or greater than 50 chromosomes (7–8%). The most frequent structural aberration is the translocation t(9;22)/Philadelphia chromosome (P+ ALL). Other translocations occur less frequently and are mostly associated with distinct immunological subtypes such as t(4;11) (3–4%) in pro-B-ALL, t(8;14) (5%) in mature B-ALL, t(1;19) (2–3%) in pre-B-ALL, and t(10;14) (3%), 9p– (5–15%), 6q– (4–6%), and 12p aberrations (4–5%) mainly in T-ALL.

The Ph chromosome t(9;22)(q34;q11) results from a translocation involving the breakpoint cluster region of the BCR gene on chromosome 22 and the ABL gene on chromosome 9. One-third of adult ALL patients with a Ph chromosome show M-BCR rearrangements (resulting in a 210 kDa protein), similar to patients with CML, whereas two-thirds have m-BCR rearrangements (resulting in a 190 kDa protein).

Currently a new subgroup with prognostic and therapeutic relevance is discussed. The "Ph-like" or "BCR-ABL-like" ALL is characterized by a gene expression profile similar to Ph-positive ALL. A part of the patients also show translocations or mutations of ABL or JAK genes, which can potentially be targeted by tyrosine kinase inhibitors [9, 10]. Patients with this subtype of ALL show an inferior prognosis in childhood and adults with lower rates of molecular responses [9–11]. A prospective and validated diagnostic identification of Ph-like ALL is currently not possible but identification of targetable lesions may be helpful in individual patients with refractory disease.

The most frequent form of 11q23 abnormalities in ALL is t(4;11)(q21;q23). The translocation is frequently detected in infant leukemia and in patients with the pro-B-ALL subtype (CD10 negative). The overall incidence in adults is approximately 5%. Typical molecular aberrations in ALL with associated cytogenetic translocations and immunological subtypes are summarized in Table 18.3.

Blasts cells with a low hypodiploid karyotype represent another high-risk entity which is frequently associated with TP53 mutations [12].

Overall the observed incidence of the majority of cytogenetic aberrations is very low and therefore the options of correlation to clinical outcome and even more therapeutic consequences are limited. The most relevant markers can be identified by molecular analysis as well. Nevertheless, cytogenetic analysis is still recommended as a routine diagnostic method in ALL. It is highly recommended to store biomaterials from each ALL patient for potential future analyses, e.g., focused on targetable lesions.

Detection of Minimal Residual Disease

Conventional microscopic evaluation of bone marrow smears has a detection limit of 5%. With methods for detection of MRD, residual blast cells can be detected and measured quantitatively below this level with a sensitivity of 10^{-4}–10^{-6}. With these methods individual follow-up analyses can be performed in patients with clinical and morphological CR. ALL is an "ideal" disease for detection of MRD since more than 90% of the patients show individual clonal markers. Most experience has been accumulated with MRD detection by flow cytometry and PCR (overview in [13]).

MRD detection by flow cytometry targets individual leukemia-specific combinations of surface antigens and reaches a sensitivity of 10^{-4}. PCR detection may target the expression of leukemia-specific fusion genes such as BCR–ABL, which may be detected in 30–40 of adult ALL cases. A more widespread applicability is reached with detection of clonal rearrangements of immunoglobulin heavy-chain (IgH) or T-cell receptor (TCR- β, −δ, −γ) gene rearrangements. This method reaches a sensitivity of 10^{-4}–10^{-6} and combinations of two or more target structures can be identified in more than 80% of ALL patients. For this method the best level of standardization has been reached regarding methodology and reporting and interpretation of results for clinical trials [14]. MRD detection with any method should be restricted to experienced laboratories, which participate in quality control rounds taking place on an international level.

Markers for MRD detection have to be established at the time of first diagnosis. Therefore diagnostic material has to be provided to a specialized laboratory.

Supportive Care

The management of adult patients undergoing induction therapy for ALL requires intensive treatment of initial complications and supportive care to prevent and manage the infectious, hemorrhagic, metabolic, and psychological problems that may arise.

Metabolic Abnormalities

A few general measures can be started at once. Sufficient fluid intake to guarantee urine production of at least 100 mL/h throughout induction therapy reduces the risk of uric acid formation. This may require parenteral fluid administration when the patient's oral intake is inadequate because of nausea or difficulty in swallowing. If the venous system does not offer an easy approach, access by catheter or port is advantageous when anticipating a longer period of induction therapy or when part of the therapy will be carried out on an outpatient basis.

Hyperuricemia is frequently present at diagnosis; it may worsen following the initiation of chemotherapy and, if not treated, can lead to renal failure. Adequate doses of allopurinol (300–600 mg/day) should be given and the urine alkalinized before chemotherapy. Allopurinol has to be reduced when 6-mercaptopurine is given. In patients with high risk of tumor lysis, uratoxidase may be used for prevention of hyperurikemia.

In patients presenting with renal impairment, an attempt must be made to reestablish renal function before chemotherapy is started. Renal failure is often observed in patients

with Burkitt's lymphoma or B-ALL with abdominal tumor masses and can be resolved by a gentle pretreatment with cyclophosphamide (C) combined with dexamethasone (P) or dexamethasone (DX) or steroids alone.

The acute tumor lysis syndrome is most frequently seen in patients with B-ALL or T-ALL but may also occur in other subtypes with high WBC or large tumor mass. Massive and rapid tumor cell lysis leads to hyperkalemia, hyperphosphatemia, hyperuricemia, and hypocalcemia, which can largely be prevented by the C + P/DX treatment.

Infections

Approximately one-third of adult ALL patients present with infections at diagnosis. Fever or infection at the time of admission is mainly associated with severe granulocytopenia, especially if the granulocyte count is less than 5×10^9/L but may also be due to immunological deficiency (e.g., CD4 lymphopenia) or mucosal lesions. Combination chemotherapy causes additional hematological toxicity and at least 50% of adults undergoing induction treatment will experience severe or life-threatening infections. The incidence of infections with gram-positive bacteria has increased—especially those due to more frequent use of indwelling catheters. Fungal infections also occur more frequently.

Much attention has been paid to prophylactic measures against infection. They include oral hygiene using antiseptic soaps and mouthwashes and disinfection of the anogenital region. Other precautions include reverse protective isolation and air filtration, if available, which can reduce especially the risk of Aspergillus infections. Simple precautions that can always be carried out are no live plants in the room, no humidifiers, no i.m./s.c. injections if avoidable, no uncooked vegetables, no unpeeled fruits, and no visitors having any kind of infection. Prevention and management of infections are discussed in detail in Chaps. 49 and 51.

Hematopoietic Growth Factors

The use of hematopoietic growth factors (HPGFs) such as colony-stimulating factor–granulocyte (G-CSF) is a valuable component of supportive therapy during the treatment of ALL. There is no indication that these CSFs stimulate leukemic cell growth in a clinically significant manner. The majority of clinical trials demonstrate that the prophylactic administration of G-CSF significantly accelerates neutrophil recovery and several prospective randomized studies also showed that this is associated with a substantially reduced incidence and duration of febrile neutropenia and of severe infections [15, 16]. The enhanced marrow recovery allows closer adherence to the dose and schedule of chemotherapeutic regimens.

The advantage of G-CSF administration is particularly evident in patients at high risk for prolonged granulocytopenia. Furthermore, scheduling appears to be important. When CSFs are first given at the end of a 4-week chemotherapy regimen, potential benefits are limited. Therefore it is noteworthy that G-CSF may be given in parallel with chemotherapy without aggravating the myelotoxicity of these specific regimens [15, 16] and that this scheduling is an important determinant of the clinical efficacy.

Hemorrhage

The thrombocytopenia present in one-third of the patients at diagnosis will worsen following chemotherapy, requiring transfusion of platelet concentrates. Platelet transfusions should be given for bleeding and to prevent bleeding when platelet counts are below 20×10^9/L especially during febrile periods, which interfere with platelet function. When a long induction period is anticipated and there is a likelihood that a patient will need frequent platelet transfusions it might be preferable to start with HLA-matched platelets immediately, if this is logistically possible (technical facilities, costs), to avoid refractoriness to random platelets. The issue of platelet transfusions is discussed in detail in Chap. 54.

L-Asparaginase treatment leads to a decrease in fibrinogen and ATIII and may thereby enhance the risk of thrombosis and bleeding. So far no standards have been defined for substitution of both factors although it is done in many trials.

Chemotherapy

The approach to therapy of adult ALL has evolved along similar lines to that successfully employed in childhood ALL. An induction therapy is followed by a postremission or consolidation therapy. Whereas the induction phase of therapy is usually well defined, the postremission therapy may consist of different consolidation cycles, including reinduction or stem cell transplantation. In addition there is a CNS prophylaxis throughout the whole therapy and maintenance treatment.

Traditionally successful treatment protocols for adult ALL are based on pediatric approaches. The overall outcome is evident from the published studies in younger ALL patients listed in Table 18.5. Complete remission (CR) rates in modern protocols reach 90% with approximately 5% early

Table 18.5 Results of recent trials with pediatric based regimens in adult ALL

Study	Year	*N*	Median age (range)	CR rate (%)	Survival (%)
Ribera et al.[a] [17]	2008	81	29 (15–30)[a]	98	69 (6 years)
Huguet et al. [18]	2009	225	31 (15–60)	93	60 (3 years)

Stock et al. [20]	2014	296	24 (17–39)	nr	78 (2 years)
Rytting et al. [21]	2014	84	21 (13–39)	94	74 (4 years)
De Angelo et al. [22]	2015	92	28 (18–50)	85	67 (4 years)

[a]Standard risk only

death during induction and 5% failure to achieve a remission. Overall survival and leukemia-free survival range between 40 and 70% with a large variability according to subgroups of ALL with around 30–50% survival for high risk, 40–70% for standard risk, 50–70% for Ph+ ALL, and 70–80% for mature B-ALL.

Initial Treatment

In patients with a large leukemic cell burden, that is, a high WBC and/or massive organomegaly, cell reduction with a cautious preinduction therapy is recommended. In patients with high WBC count (>100 × 10^9/L), where hyperviscosity due to leukostasis with cerebral impairment may occur, leukopheresis may be considered. However, such technical facilities may not be available and these patients can also be managed with a gentle prephase chemotherapy consisting of vincristine or cyclophosphamide and prednisone or dexamethasone in nearly all cases without complications. Prephase treatment is suitable anyway in order to stabilize the patients and complete all diagnostic procedures before the start of induction treatment.

Remission Induction

Standard induction therapy for ALL includes prednisone, vincristine, anthracyclines, mostly daunorubicin, and also L-asparaginase. Further drugs, such as cyclophosphamide, cytarabine (either conventional or high dose), mercaptopurine, and others, are added in many protocols, sometimes named as early intensification.

Steroids such as prednisone and prednisolone have been most frequently administered. Dexamethasone shows a higher antileukemic activity in vitro and a better penetration of the cerebrospinal fluid. Extensive use of DX without interruptions may, however, be associated with an increased risk of septicemias and fungal infections, which may be circumvented if treatment time is reduced.

The most frequently used anthracycline is *daunorubicin* (DNR). Several study groups have replaced the usual weekly applications, as in the BFM-based protocols, by higher doses of DNR (45–80 mg/m^2) on subsequent days. In one recent trial the intensified use of daunorubicin failed to improve response rates [23]. Thus it remains open whether intensified anthracyclines are beneficial for adult ALL at all, for all subgroups and age groups. Intensive anthracycline therapy may be associated with an increased induction mortality. Therefore, intensive supportive care and probably the use of growth factors are recommended with these types of protocols.

Asparaginase (A) does not affect the CR rate but improves LFS. If not used during induction therapy, it is often included as part of the consolidation treatment. Three different A preparations with significantly different half-lives are available: native *E. coli* A (1.2 days), Erwinia A (0.65 days), and pegylated *E. coli* A (PEG-L-A) (5.7 days). The availability may vary between different countries. In order to reach equal efficacy, the application schedule has to be adapted and is generally daily for Erwinia, every second day for *E. coli*, and 1–2 weeks for PEG-L-A. The latter asparaginase preparation has the advantage of less frequent administrations and more even activity distribution. In a considerable proportion of adult ALL patients A induces laboratory changes, e.g., coagulation disorders and liver transaminases with unclear clinical impact [24] and in fewer patients severe complications such as hepatopathies or pancreatitis. A-induced toxicities are not always predictable and may lead to treatment delays in individual patients. Consistent management of toxicities is essential [25]. On the other hand, ASP is recognized as an extremely important drug for the treatment of ALL due to its unique mechanism of action and resistance. Optimization of A therapy is therefore a major aim for management of adult ALL.

Definition of Complete Remission

Complete remission is defined as a state in which there is no clinical or laboratory manifestation of leukemia. The peripheral blood count and bone marrow appearances are within normal limits except for abnormalities attributable to chemotherapy; the marrow blast cell count is less than 5%; also examination of the CSF shows no blast cells. CR includes also the disappearance of organomegalies, but it should be noted that the persistence of splenomegaly is not always due to leukemic infiltration.

Table 18.6 Definition of response in ALL

Conventional definition		Evaluation of MRD	
Complete remission	• <5% blasts in bone marrow smear and • Regeneration of peripheral blood count and • Disappearance of all extramedullary manifestations	Molecular remission	Negative MRD status detected with a standardized method and a minimum sensitivity of 0.01%
		Molecular failure	Positive MRD-status above 0.01%
Relapse	• Detection of more than 5% blasts in bone marrow after prior achievement of CR[a] or • Reappearance of extramedullary manifestations	Molecular relapse	Increase of MRD above 0.01% after prior achievement of molecular CR

[a]In case of 5–10% blasts in regenerating marrow a repeated bone marrow assessment is recommended in order to distinguish blasts form hematogones

Definition of complete remission was recently extended by the definition of MRD response or molecular response. An international consensus workshop has defined technical prerequisites for MRD-based response evaluation mainly for PCR-based measurement of individual gene rearrangements. In patients with a marker with sensitivity of at least 10^{-4}, complete MRD response is defined as a negative status of MRD. MRD failure is defined as MRD level above 10^{-4} [14]. MRD response is strongly associated with prognosis. Therefore MRD-based response evaluation is a new endpoint for clinical trials (Table 18.6).

Failure of Induction Therapy

With current protocols failure rates after induction are generally around 10%. The rate of early death depends on age and ranges from <3% in adolescents to 20% in patients >60 years of age. The main cause of death in approximately two-thirds of the patients is infection, in part fungal infection. Beyond mortality also morbidity, e.g., due to extended cytopenias and subsequent infections such as fungal pneumonias, has to be considered which may compromise further treatment and dose intensity. The remaining nonresponders may achieve a partial remission or may be refractory to standard treatment. These patients have an extremely poor prognosis. They are therefore candidates for experimental treatment approaches or consideration for an SCT, even if not in CR but in good partial remission.

Consolidation Therapy

When in ALL CR is achieved, treatment has to be continued in order to eliminate residual leukemia after induction chemotherapy and thereby prevent relapse as well as emergence of drug-resistant cells because a high percentage of patients show MRD after induction therapy. Continuation or postremission therapy consists of intensification or consolidation and maintenance. Consolidation/intensification refers either to high-dose therapy, the use of multiple new agents, or readministration of the induction regimen (reinduction). SCT is also included in postremission therapy in many trials. In most studies that involve repeated consolidation cycles over the entire treatment period, it is difficult to analyze critically the effect of the different treatment phases on outcome.

Intensive consolidation is standard in the treatment of ALL although consolidation cycles in large studies are very variable and it is impossible to evaluate their individual efficacy. In general it seems that intensive application of high-dose methotrexate (HDMTX) is beneficial. Depending on age, in adults dosages are probably limited at 1.5–3 g/m^2 if given as 24-h infusion. Otherwise toxicities, particularly mucositis, may lead to subsequent treatment delays and decreased compliance. From pediatric ALL trials there is increasing evidence that intensified application of asparaginase leads to improved overall results. In adult ALL this approach appears to be useful particularly in consolidation, where less toxicity can be expected compared to induction. Several studies have also demonstrated that a reinduction improves outcome.

The most important feature of consolidation is probably to administer rotating cycles with short intervals. However after several consolidation cycles some adult patients tend to develop prolonged cytopenias, which lead to delays of subsequent chemotherapies. Therefore a balance between bone marrow toxic and less toxic cycles may be important. For future studies in adult ALL stricter adherence to protocols with fewer delays, dose reductions, and omissions would be an important contribution to therapeutic progress.

Maintenance

Maintenance up to a total treatment duration of 2½ years even after intensive induction and consolidation is still standard for adult ALL; all attempts to omit maintenance led to inferior outcome. MTX preferably given intravenously (i.v.) or orally and mercaptopurine (MP) given orally are the backbone of maintenance. It may be important to aim for

leukocyte counts below 3000/μL during maintenance [26]. Intensification cycles with vincristine and steroids did not provide additional benefit at least in pediatric trials using intensive reinduction [27]. Furthermore in adults prolonged steroid therapy may lead to an increase of late effects such as osteonecrosis. Randomized trials also failed to demonstrate an advantage of intensified maintenance with HD cycles although the compliance in these trials is unclear.

Adults often show poor compliance to intensive maintenance due to toxicities and moreover social reasons. Even for conventional maintenance compliance may be a problem. In Ph+ ALL maintenance with kinase inhibitors appears to be of utmost importance after chemotherapy as well as after stem cell transplantation. Overall, for further improvement of outcome the physicians' and patients' compliance to maintenance therapy seems to be essential.

Central Nervous System Therapy

Prophylactic CNS Therapy

Without some form of prophylactic CNS therapy, around 30% of adults with ALL will develop overt CNS leukemia [2]. Prophylactic CNS therapy in ALL is essential due to several reasons: CNS leukemia is more easily prevented than treated; once CNS leukemia has developed, it is generally followed by systemic relapse shortly after; and effective CNS prophylaxis also prevents systemic relapse.

Several treatment options are available for prevention of CNS relapse: intrathecal (i.th.) therapy, cranial irradiation (CRT), and systemic high-dose chemotherapy (overviews in Ref [2]). I.th. therapy is usually based on MTX as single drug but combinations with AC and/or steroids are used in some studies. The route of application is generally lumbar puncture. CRT (18–24 Gy in 12 fractions over 16 days) may be administered with or without parallel i.th. therapy. Systemic HD chemotherapy may comprise HdAC or HdMTX since both drugs reach cytotoxic drug levels in the CSF and showed effectivity in overt CNS leukemia.

Various combinations of these approaches have been used in adult ALL trials but the issue of CNS prophylaxis has not been addressed prospectively. For analysis of published trials, it has to be considered that most authors only report the frequency of isolated CNS relapses. However, in a significant proportion of adult ALL patients combined CNS and bone marrow relapses occur. Overall there is evidence that CNS relapse rates decrease with increasing intensity of prophylaxis and with the number of applied modalities.

The role of CNS irradiation in different subtypes of adult ALL remains to be determined. In pediatric patients considerable late effects of CNS irradiation are observed and effective CNS prophylaxis is achieved by high doses of systemic methotrexate treatment. In adults similar doses cannot be administered due to toxicities. Therefore the role of CNS irradiation may be different; in addition there are no reports on similar late effects compared to those observed in children.

In current trials with effective CNS prophylaxis the incidence of CNS relapse is below 5–10%. It is influenced by several risk factors such as immunophenotype (T-ALL, B-ALL), extreme leukocytosis, high leukemia cell proliferation rate, high serum LDH levels, and extramedullary organ involvement. Risk-adapted CNS prophylaxis may be based on these features.

Recently a liposomal preparation of cytarabine has been used for treatment of CNS relapse of lymphoma and ALL and was evaluated in several protocols for prophylaxis of CNS relapse. Due to the preparation a prolonged cytotoxic activity and a more even distribution in the CSF are observed [28]. Therefore fewer applications, i.e., every 2 weeks are required. However combination regimens of liposomal cytarabine with systemic high-dose therapy have to be defined carefully since neurological toxicities may occur [29].

Therapy of Established CNS Disease

About 5–10% of adult ALL patients present with manifestations of CNS leukemia. The incidence is correlated to the immunological subtype and is higher in T-ALL and mature B-ALL. Treatment of overt CNS leukemia is usually undertaken with either i.th. MTX alone, in combination with AC or hydrocortisone, or CRT. I.th. MTX is administered 2–3 times per week and until two consecutive CSF examinations show no evidence of leukemic infiltration. Following the establishment of a remission there is some evidence that continued maintenance i.th. chemotherapy at less frequent intervals is beneficial in prolonging the duration of CNS remission. When adult ALL patients with CNS leukemia at diagnosis are treated adequately, they have no inferior outcome with regard to LFS or CNS relapse rate. However there might be an increased risk of prolonged cytopenias during induction due to the systemic effects of intensified intrathecal therapy.

Stem Cell Transplantation

SCT is an integral part of treatment strategy for adult ALL. Bone marrow and to an increasing extent peripheral blood are used as stem cell source. Despite a great number of trials the indications for SCT in first CR, scheduling, and procedures are still not defined satisfactorily. The potential

advantages of SCT (short treatment duration, favorable outcome in some trials) must be balanced to the disadvantages (mortality of 20–30%, morbidity, late complications, reduced quality of life) and assessed in relation to the improving outcome of conventional and targeted chemotherapy regimens.

The role of SCT in postremission therapy is one major question in the management of adult ALL. The recommended indications for SCT varied over the time [30–32]. With the broader application of pediatric based regimens the indication is defined more restrictively. More recently, the guidelines and many prospective trials are in favor of transplantation in patients with high-risk features. This applies particularly for younger patients treated with intensive pediatric based chemotherapy. In older patients, due to increasing transplant-related mortality, only dose-reduced conditioning regimens can be considered. Future clinical trials will show whether this approach would be superior to chemotherapy regimens.

Overall according to guidelines overall survival for high-risk patients (with varying definitions) was superior for SCT compared to chemotherapy, whereas the role of SCT in standard risk remained open. The need for SCT in specific genetically defined groups of ALL, such as BCR-ABL1-positive or MLL-positive cases, remains to be defined. Allogeneic SCT is currently carried out for MLL-rearranged ALL in most trials and, in the largest study conducted to date, better results have been observed compared with chemotherapy [33]. In younger standard-risk patients, treated with pediatric based regimens, SCT is not recommended by most groups in order to avoid acute mortality and long-term effects.

MRD is considered as the most important factor to guide the decision of chemotherapy or SCT after consolidation. Data from recent studies have shown that SCT offers better results than chemotherapy in patients with high MRD levels after consolidation, regardless of the conventional risk factors at baseline [34]. The question remains open whether SCT is justified in patients with conventional high-risk features but low or negative MRD after consolidation, for whom OS rates ˃50% are expected with chemotherapy. An analysis of the French group demonstrated an advantage of SCT in patients with MRD-positive ALL only [35]. Since historical trials mostly did not consider MRD as a decision tool for SCT, future prospective studies are required to answer this question.

Finally there is a general agreement that SCT is clearly the best therapeutic option for patients in second or later CR [30, 31, 36]. A summary of current indication is given in Table 18.7. Since the outcome of ALL with and without SCT is influenced by numerous factors such as type of SCT, donor match, posttransplant regimens, age, MRD status, and availability of targeted therapies, the indication may change over time.

Table 18.7 Recommendations for SCT in adult ALL (modified from [32, 36])

Treatment phase	Transplant option	Recommendations
CR1	Allogeneic SCT	• Recommended in all patients with persistent MRD • Not recommended in standard-risk patients with sustained molecular remission • Unclear indication in high-risk patients with sustained molecular remission
CR1	Autologous SCT	• Inferior compared to allogeneic SCT and chemotherapy in randomized trials • Maintenance therapy after transplant and negative MRD status may improve outcomes
CR ≥ 2	Allogeneic SCT	• Allogeneic SCT recommended in all patients

Donor Type for Allogeneic SCT

There is sufficient evidence that sibling and very-well-matched, unrelated donors (MUD) SCT can be considered equivalent options in terms of results, and therefore MUD SCT can be offered to patients lacking a sibling donor [32, 36]. Umbilical cord blood can be an alternative source when an HSCT is needed urgently or when the search for a very-well-matched, unrelated donor is unsuccessful [30, 37]. Haploidentical SCT could be an option in patients without a matched sibling or MUD, but prospective comparative studies are lacking. Particularly new approaches for haploidentical SCT with post-transplantation cyclophosphamide provide promising results [38]. Autologous SCT is considered inferior to chemotherapy and to allogeneic SCT [39]. The intensity of pretreatment has an important impact on the outcome of autologous SCT, since it leads to reduction of tumor load. It may still be an option in MRD-negative patients unfit for allogeneic SCT and was successful in Ph-positive ALL [40]. Maintenance therapy after autologous SCT, e.g., with MP and MTX, or imatinib in Ph+ ALL—particularly in MRD-positive patients—is also a useful approach.

Conditioning Regimens

There is no standard MAC regimen, but total body irradiation-based regimens seem to have better antileukemic activity than busulfan-based preparative regimens [30, 41]. Regimens with reduced intensity (RIC) are increasingly considered as an option

for older patients with high-risk ALL or patients with contraindications for myeloablative conditioning [42], but no prospective comparative studies between these two types of preparative regimens have been conducted in young, fit patients.

Factors for Outcome of SCT

Relapse rate and transplant-related mortality both range between 25 and 30%. Although TRM is strongly correlated with age, the upper age limit for SIB–SCT has increased continuously up to 50–55 years. There is evidence that a graft-versus-leukemia (GvL) effect is also present in ALL, as indicated by several observations, such as lower relapse risk in patients with acute and/or chronic GvHD, lower relapse risk after matched unrelated donor SCT, and induction of remission by withdrawal of prophylaxis against GvHD or donor lymphocyte infusions (DLI) in single patients with relapsed ALL.

Furthermore posttransplant monitoring of MRD is of increasing importance to improve the outcome of SCT.

Prognostic Factors in ALL

ALL is not a uniform disease but characterized by subgroups with different biological and clinical features and cure rates. For various parameters prognostic value for either the achievement of remission or for remission duration has been established in adult ALL [1]. At the present time the following are the most important prognostic features: age, initial WBC, immunophenotype, abnormal cytogenetics, or molecular genetics, and to an increasing extent response criteria such as time to achieve CR and MRD (refer to Table 18.10 discussed later in this chapter).

Age

Age is probably the most important prognostic factor. There is a continuous decrease in outcome with increasing age from childhood to elderly ALL patients. In adults, OS ranges up to 70% below 30 years to 20–30% above 50–60 years. In contrast to other prognostic factors age cannot be used to identify patients who could benefit from SCT as done by some groups because outcome of SCT also decreases with increasing age. Actually improved treatment strategies have to be claimed for older patients as well as for young adults with ALL.

Older Patients with ALL

The median survival time in older ALL patients is 3–14 months. There are several reasons that may account for this. Increased hematological and nonhematological toxicity (e.g., hepato- and cardiotoxicity) results in a higher morbidity and mortality during induction therapy. The death rate during induction therapy for older patients above 65 years reaches 20–30%. Incomplete drug administration and extended intervals between cycles of therapy may lead to inferior long-term results. There is a higher frequency of adverse biological features in adults; thus the incidence of Ph+ ALL patients increases from 3% in children to 20–30% in patients above 50 years. The incidence of unfavorable immunophenotypes such as early T-ALL and pro-B-ALL is also higher in older patients. There is, however, no good evidence that within an identical biological subtype of ALL the leukemic blast cells in elderly ALL patients are more resistant than in younger patients.

The optimal treatment for older ALL patients remains to be defined. Registries give an impression on the overall outcome of unselected older ALL patients [43–46]. Survival rates in patients older than 60 years were 10–25% [44, 45] (Table 18.8) with only marginal improvement over the past decades.

30–70% of the older patients are allocated to palliative therapy mainly due to poor performance status at diagnosis. Most studies have shown an advantage of more intensive therapy (Table 18.8). There is no evidence that palliative approaches are associated with lower rates of early mortality or better quality of life.

If older patients are treated according to protocols designed for younger patients, one major problem is the toxicity and early mortality [47]. Patients may acquire severe infections, non-predefined treatment modifications occur frequently, and treatments may be interrupted or even stopped due to severe complications.

More recently several study groups have developed protocols specifically for older ALL patients (Table 18.9) that have the theoretical aim to provide a chance of cure on the one hand and to limit toxicity, early mortality, and hospitalization duration on the other and thereby maintain as much quality of life as possible. Specifically asparaginase seems to be less well tolerated in older patients during induction [48, 49]. Therefore it would be advisable to start asparaginase in older patients later during consolidation.

Table 18.8 Outcome of different strategies to treatment of older ALL patients (adapted from [51])

Approach	Age	*N* studies	*N* patients	CR (%)	Early death (%)	Survival
Population based	≥65	*4*	*n.r.*	40	n.r.	6–30%
Palliative	60–91	4	94	43	24	7 months
Intensive	60–92	12	519	56	23	14%
Age specific	55–85	11	653	72	18	42%

[b]Estimated from Kaplan–Meier curve

The majority of complications in older ALL patients are observed during induction; thus there is still space for intensification of consolidation therapy. Based on this assumption a consensus treatment protocol for older patients with ALL was defined by the European Working Group for Adult ALL (EWALL) based on a pediatric based protocol developed by the German Multicenter Study Group for Adult ALL (GMALL). The median age of this cohort was 65 years [55–85]. In 268 patients the CR rate was 76%, early death rate 14%, mortality in CR 6%, continuous remission 32%, and survival 23% at 5 years [50]. Patients younger than 75 years with an ECOG performance status below 2 had 86% CR rate, 10% early death, and 36% survival at 3 years.

Overall, pediatric based regimens in ALL are undoubtedly successful and should be scheduled with prospectively defined adaptations with respect to tolerability in older patients. The most important modification of induction therapy in older patients is probably omission of asparaginase, and flexible, reduced dose of anthracyclines. In consolidation, intensified treatment should be attempted and during this treatment phase even asparaginase may be surprisingly well tolerated at moderate doses.

Adolescents and Young Adults with ALL

Several groups have published data comparing the outcome of young adults with "pediatric" protocols to those with so-called adult protocols (most recently in [60]). The reason to select specifically these protocols for comparison is not evident because compared treatment regimens were rather different. The "adult" protocols used for comparison often yielded results below the average; one reason may be that several of these protocols were focused on SCT. In contrast to the studies selected for comparison, several other study groups for adult ALL already apply modified pediatric protocols (Table 18.5) with survival rates of 60% and more in young adults up to 30 years.

These regimens are associated with considerable side effects in adults, particularly liver toxicities and pancreatitis due to asparaginase, polyneuropathies due to vincristine, and avascular bone necrosis. Results are promising at short follow-up but it remains open whether this approach will be feasible, up to which age, at less experienced centers, how selection of patients is handled, and whether it will lead to an improvement of overall results.

On the other hand the attempt of adult ALL study groups to define uniform protocols for ALL ranging from 18 to 75 years is not successful. Currently study groups for adult ALL develop into two directions and [1] either use unmodified pediatric protocols for young adults up to the age of 25–30 years or [2] use modified pediatric protocols, e.g., the BFM-based GMALL protocol for the whole group or adult ALL with additional intensification in young adults. One important aim is dose intensification with a better adherence to time schedules with as few as possible. Another aim is to integrate more successful treatment elements from pediatric trials such as vincristine, dexamethasone, asparaginase, reinduction therapy, and maintenance. The opportunity to use targeted therapies developed in adult ALL studies is useful also for young adults.

White Blood Cell Count

Elevated WBC at diagnosis (>30–50,000/μL) as poor prognostic feature has been confirmed in various trials. The biological reason for the highly resistant behavior of B-precursor ALL with high WBC is unclear. Probably in the future additional molecular markers can help to clarify the underlying mechanisms. Due to the high relapse rate evaluation of MRD, use of experimental drugs and SCT modalities seems particularly important.

Immunophenotype

Immunologic subtypes are associated with different presentation and prognosis and distinct cytogenetic and/or molecular aberrations.

Pro-B-ALL/t(4;11)

Pro-B-ALL and/or t(4;11)-positive ALL is considered as high-risk subgroup in nearly all trials [33]. It appears to be particularly susceptible to high-dose cytarabine-based regimens and SCT as reported from the GMALL studies [61].

Common/Pre-B-ALL

Common(c)/pre-B-ALL bears a large proportion of Ph+ ALL. Based on prognostic factors it can be subdivided into an SR and an HR group with significantly different outcome of 50–60% and 30–40% OS, respectively; 40–50% of patients with common/pre-B-ALL show expression of CD20 on the cell surface. It has been demonstrated that CD20 expression is associated with poorer outcome [62]. Recently promising results have been reported for the addition of rituximab to chemotherapy with a benefit regarding LFS and OS particularly in younger patients [63]. Recently a randomized study confirmed the benefit of rituximab in combination with chemotherapy, which did not impact the CR rates but contributed to higher molecular response rates and improved long-term outcome [64].

T-ALL

Outcome of T-lineage ALL is generally considered superior compared to B-lineage [65]. It comprises the subtypes early T-ALL, thymic (cortical T-ALL), and mature T-ALL with inferior outcome for early T-ALL and favorable outcome for thymic T-ALL. Some groups consider very high WBC (>100.000) also a poor prognostic feature in T-ALL [66].

The biological relevance of immunophenotype is underlined by the fact that overexpression of HOX11, HOX11L2, SIL-TAL1, and CALM-AF10 is associated with subtypes, i.e., maturation states of thymocytes (reviewed in [8]). Some groups observed inferior outcomes for early T-ALL [67, 68] and high expression of the transcription factors ERG and/or BAALC [69]. Low expression of ERG and BAALC was associated with favorable outcome [69] as well as overexpression of HOX11, which is associated with thymic T-ALL [70]. Notch1-activating mutations were identified in up to 50% of T-ALL cases [71, 72]. Notch mutations are correlated with thymic T-ALL and a favorable prognosis. An alternative risk model for T-ALL defines cases with mutations of Notch1 or FBXW7 lacking RAS or PTEN mutations as a favorable subgroup whereas patients with RAS or PTEN mutations lacking Notch1 or FBWW7 mutations are considered as high-risk ALL [73]. The prognostic impact of early T-precursor ALL within early T-ALL remains to be defined [68]. Overall the question of which risk model is most suitable depends on treatment strategies and their historical development in study groups.

Five percent of T-ALL shows the NUP214-ABL1 aberration, which may identify a target population for imatinib therapy [74]. The variety of new prognostic markers can impossibly be integrated in current risk models but may moreover serve to identify pathogenetic mechanisms and therapeutic targets.

With current treatment regimens CR rates of more than 90% and an LFS 50–70% can be achieved in T-ALL. The role of stem cell transplantation within T-ALL remains to be defined [35].

Mature B-ALL

Mature B-ALL is grouped according to the WHO classification together with Burkitt's lymphoma and treated according to a specific concept. Treatment is based on childhood B-cell ALL studies that significantly improved outcome. The drugs responsible for the improvement were high doses of fractionated cyclophosphamide, ifosfamide, HDMTX (0.5–8 g/m^2), and HDAC in conjunction with the conventional drugs for remission induction in ALL, given in short cycles at frequent intervals over a period of 6 months.

The application of these childhood B-cell ALL protocols in original or modified form also brought a substantial improvement for adult patients with B-cell ALL. More than 80% of the cases of mature B-ALL or Burkitt's lymphoma express CD20 on their surface. Further significant improvement of survival rates to 80–90% was achieved by the application of rituximab in combination with chemotherapy [75].

B-cell ALL has a higher incidence of CNS involvement at diagnosis, and of CNS relapse. Therefore, effective measures against CNS disease, such as HDMTX and HDAC as well as intrathecal therapy, are important components of treatment regimens. On the other hand, maintenance treatment has been omitted. Because relapses occur almost exclusively within the first year in childhood as well as in adult B-cell ALL studies, patients thereafter can be considered as cured.

Ph/BCR–ABL-Positive ALL

The translocation t(9;22) and the respective fusion gene BCR–ABL until recently marked the most unfavorable subgroup of adult ALL. Ph/BCR–ABL (Ph+) ALL nearly

exclusively occurs in conjunction with B-precursor ALL (c-ALL, pre-B-ALL). The incidence increases with age. In Ph+ leukemia the BCR–ABL fusion gene is causally involved in leukemogenesis and is considered to be essential for leukemic transformation. With a selective inhibitor of the ABL tyrosine kinase (imatinib) cellular proliferation of BCR–ABL-positive CML and ALL cells can be inhibited selectively. Phase II trial demonstrated a CR rate of 29% in relapsed/refractory Ph+ ALL with imatinib as single drug [76].

The use of imatinib in combination with chemotherapy contributed to a significant improvement in the outcome of newly diagnosed Ph+ ALL. As compared with the pre-imatinib era, CR rates improved from 60–70% to 80–90% or even higher and outcome was much better, with survival reaching approximately 50%, compared with ≤20% in the pre-imatinib era [77–82]. Imatinib in combination with chemotherapy is now considered the standard treatment of Ph-positive ALL.

Historically a subsequent stem cell transplantation was considered as the only chance of cure in patients with Ph+ ALL. It remains a matter of debate whether this is still true in the imatinib era. A recent report confirmed that allogeneic SCT is still associated with a better relapse-free survival in younger Ph+ ALL patients [83]. Younger patients may receive standard myeloablative conditioning, but the role of reduced-intensity conditioning (RIC)-SCT in older patients remains to be prospectively evaluated. After SCT prophylactic imatinib maintenance is probably the best option to prevent post-SCT relapse [84]. The optimal TKI for first-line treatment, and the question whether in patients with favorable response to treatment SCT may be avoided remains matter of discussion.

The incidence of Ph+ ALL increases with age and older patients are usually not candidates for allogeneic SCT. Nowadays, older patients with Ph+ ALL may have a better chance to achieve a CR than patients with Ph-negative ALL. The GMALL study group conducted a first randomized study to evaluate the efficacy of imatinib single-drug induction compared to chemotherapy. The remission rates were 96% and 50%, respectively [85]. The Italian study group focused on first-line therapy with TKI and steroids only. With imatinib (800 mg) and prednisone for induction followed by imatinib single-drug treatment the CR rate, survival, and disease-free survival were 100, 74, and 48% after 1 year [86]. A subsequent trial with dasatinib (140 mg) and prednisone followed by dasatinib single-drug treatment was not specifically designed for older patients (range 24–76 years). The CR rate was 92% and survival was 69%. Post-remission therapy was at the discretion of the treating physician and 14 of 19 patients with TKI monotherapy relapsed with a high frequency of T315I mutations [87].

The largest prospective study so far in older patients with Ph+ ALL used an EWALL chemotherapy backbone with vincristine, dexamethasone, and dasatinib (140 mg) for induction. Consolidation and maintenance according to the EWALL backbone were combined with intermittent dasatinib applications. In 71 patients the CR rate was 96%. The regimen was feasible and the survival after 5 years of follow-up was 36%, which is promising. Persistent MRD above 0.1% after induction and consolidation was associated with a poorer remission duration of only 5 months [88]. A subsequent EWALL trial with a similar backbone but nilotinib (400 mg BID) instead of dasatinib was started subsequently. Again a high CR rate of 97% was reported. Thirty percent of patients achieved a complete molecular remission after induction [89]. Overall, there is increasing evidence that second-generation TKIs in combination with dose-reduced chemotherapy can induce very high CR rates with low mortality in older patients. The rate of molecular remissions appears to be higher compared to imatinib-based regimens. Moderate intensive consolidation therapies in combination with TKIs are tolerated well. Long-term results have to be assessed after 5 or more years and show a still high rate of relapses. New approaches may include reduced intensity SCT, MRD-based change of TKI, or use of new immunotherapies.

Also in younger patients there is a trend towards dose-reduced chemotherapy in induction. A randomized trial showed lower early mortality and higher CR rate in patients receiving imatinib, combined with less intensive chemotherapy compared with those receiving HyperCVAD/imatinib [83]. Once CR has been reached, autologous SCT might also be a good option, at least in patients who have reached a good MRD response, or in those who cannot tolerate allogeneic SCT [83, 90].

In patients with persistent MRD or progressive disease, the recommendation is to switch to another TKI while screening for TKI resistance mutations, and then to adapt TKI choice according to the resistance profile. The third-generation TKI ponatinib is currently the only option in patients progressing with the T315I mutation. First results with ponatinib in newly diagnosed Ph+ ALL are promising but toxicity risks have to be considered, particularly in older, comorbid patients [91].

Treatment Response and Minimal Residual Disease

Longitudinal minimal residual disease (MRD) evaluation during treatment with the aim to assess individual response identifies one of the most important available prognostic factors. The role of MRD as independent prognostic factor has been confirmed in large cohorts of pediatric and

adult ALL (reviewed in [13]). MRD evaluation has two major applications in the management of adult ALL, (1) redefinition of clinical response, failure, and relapse and (2) utilization as prognostic factor, and both are finally used for treatment decisions.

Redefinition of Response

In contemporary trials for adult ALL, CR rates of 85–90% can be reached. The cytological response rate is often favorable, but MRD evaluation reveals differences in subgroups [34]. The molecular CR may be defined as a negative MRD status below 10^{-4} (0.01%) after induction and ranges in adult ALL from 50% for Ph+ ALL treated with imatinib to 80% for SR ALL. Thus molecular CR rate defined according to international standards [14] is an important new endpoint for efficacy evaluation after induction but also after consolidation or salvage cycles (Table 18.6).

During treatment and follow-up molecular relapse, defined as MRD above 10^{-4} after prior achievement of molecular CR, is highly predictive of cytological relapse [34]. Molecular bone marrow relapse is also often present in patients with apparently isolated extramedullary relapse. In clinical trials it should be treated similarly to cytological relapse.

If MRD-based endpoints are used in clinical trials, standardization of methods and definitions is extremely important. It is so far achieved for PCR analysis of individual gene rearrangements [14] and BCR–ABL whereas for flow cytometry or newer methods based on next-generation sequencing international standards for MRD evaluation were not defined so far.

MRD as Prognostic Factor

MRD is a significant prognostic marker at any time point. Early achievement of molecular CR identifies a subgroup of patients with very favorable prognosis. However in the GMALL studies these were only 12% of SR patients [92]. Adult ALL patients reach molecular CR later than children and later time points are more predictive of relapse risk. In the GMALL studies 25–30% of the patients did not achieve molecular CR after induction and first consolidation and nearly all of them relapsed [34]. Similar results were reported by others (reviewed in [13]). SCT can contribute to an improved outcome of patients with high persistent MRD [34, 93]. However patients with high MRD before SCT or persisting MRD after SCT have a poorer outcome [94].

The application of MRD as prognostic factor is complicated by the fact that it has to be combined with "conventional" factors. MRD identifies additional HR patients in those with conventional SR but also good-risk patients in those with conventional HR features, who are usually scheduled for SCT. Thus MRD as prognostic factor depends on time point, treatment protocol, general risk stratification, and planned therapeutic consequences.

Integrated Risk Classification

All risk factors are to a certain extent specific for a defined treatment protocol and used with variations by different study groups. Beyond established factors and factors suggested by individual study groups (Table 18.10), a variety of molecular markers newly detected by microarray analysis have been proposed as prognostic factors [32]. All of these factors can

Table 18.10 Prognostic factors for risk stratification of adult ALL[a]

	Good	Adverse	
		B-lineage	T-lineage
At diagnosis			
Clinical parameters	**WBC < 30,000/μL**	**WBC > 30,000/μL**	WBC > 100,000/μL
Immunophenotype	Thymic T	**Pro B** (CD10−) Pre B (CD10−)	Early T (CD1a−, sCD3−) Mature T (CD1a−, sCD3+)
Cytogenetics/molecular genetics/gene expression profiles	TEL-AML1 HOX11[a] NOTCH-1 9p del Hyperdiploid	**t(9;22)/BCR–ABL** **t(4;11)/ALL1-AF4** t(1;19)/E2A-PBX Complex aberrations Low hypodiploid/near tetraploid	HOX11L2 CALM-AF4 Complex aberrations Low hypodiploid/near tetraploid
Individual response during treatment			
Prednisone response	Good	Poor	
Time to CR	**Early**	**Late (>8–12 weeks)**	
MRD after induction	**Negative/< 10^{-4}**	**Positive > 10^{-4}**	
Age			
	<25 years, <35 years	**>35 years, >55 years, >70 years**	

[a]Generally accepted factors are printed in *bold*

impossibly be integrated in a conventional risk model, which mainly aims to identify patients for SCT in CR1. They may rather stimulate analysis of underlying mechanisms, drug targets, or invention of treatment adaptations. The major aim of future risk stratification in ALL is therefore to identify at diagnosis patients with an increased risk of relapse who are candidates for a stem cell transplantation. The second aim is to identify treatment targets for the use of targeted therapy approaches. During the course of disease the individual response of the patients can be considered by MRD evaluation. This may lead to reconsideration of the indication for SCT, e.g., not to offer a patient with high-risk factors the transplant if he or she is MRD negative or to transfer patients to SCT despite the lack of high-risk factors if he or she remains MRD positive. In the future additional factors such as pharmacogenomic markers or resistance patterns may be considered for treatment stratification.

Treatment of Relapsed or Refractory ALL

Published data show response rates to first salvage of around 40% and overall survival rates below 20% [95, 96]. Patients with late relapse respond to repeated induction therapy in more than 70% of the cases. However, in adult ALL the majority of relapses occur early and the CR rate is clearly below 40%. This was confirmed in a recent international reference analysis [97]. In early relapse the apparent chemotherapy resistance may be overcome by new immunotherapies.

In more than 90% of the cases of B-precursor ALL CD19 is expressed on the surface of blast cells. The bi-specific antibody blinatumomab is directed to CD19 and on the other hand attracts with a CD3 domain cytotoxic T-cells. These cells come in close proximity to the CD19-positive target cells and induce serial killing. A phase II trial in unfavorable cases of relapsed/refractory ALL showed in 189 patients a CR rate of 43% with 82% molecular remissions [98]. The median survival was 6.1 months. In a randomized trial in a similar patient population with early or refractory relapses the CR rate was 44% for blinatumomab compared to 25% for standard chemotherapy. Survival rates were 7.7 months for blinatumomab compared to 4.0 months with standard chemotherapy [99]. More favorable response rates and superior survival were achieved in patients with molecular failure or molecular relapse. The molecular response rate was 78% and the median survival 36 months [100] indicating that the MRD setting is optimal for response and long-term outcome.

Also CD22 is expressed in more than 90% of the cases of B-precursor ALL. The CD22 antibody inotuzumab is conjugated to the cytotoxin calicheamicin. In a randomized trial in relapsed/refractory ALL CR rates of 81% compared to 29% with high-dose cytarabine-based chemotherapy were described. The median survival for patients treated with inotuzumab was 7.7. months [101].

Another promising option is immunotherapy with genetically modified T-cells. These so called chimeric antigen receptor (CAR) T-cells are produced ex vivo from patient-derived T-cells and carry an antigen receptor directed to lymphatic blasts such as CD19 together with several signal transduction elements. The cells are infused after a cytoreductive and immunosuppressive chemotherapy. First results in smaller trials mostly in pediatric ALL cohorts are promising but also demonstrated considerable toxicity [102].

Future treatment of relapsed B-precursor ALL will strongly depend on immunotherapy. However, despite improved response rates, the long-term survival is only around 6 months and the chance of cure strongly depends on subsequent stem cell transplantation. The optimal use of potent new antibody and cell therapies still has to be defined. For individual patients the relapse treatment should be selected based on availability of targeted therapies, age, general condition, type of involvement, and availability of donors. Any longer treatment-free intervals should be avoided. By consequent measurement of MRD and early therapeutic intervention, relapses may be at least partly avoided.

Long-Term Follow-Up and Late Effects

As a result of improved survival rates, more patients with adult ALL are long-term survivors. In pediatric ALL and to a lesser extent adult ALL patients long-term effects of treatment can occur and they should be considered during aftercare of the patients [103]. This includes cataract, infertility, bone necrosis, fatigue, secondary malignancy, hormonal disorder, or psychiatric diseases.

19 Diagnosis and Treatment of Acute Myeloid Leukemia in Children

Brenton G. Mar and Barbara A. Degar

Introduction

Acute myeloid leukemia (AML) accounts for 15–20% of acute leukemias diagnosed in children and about 5% of childhood cancer diagnoses. Less than 1000 new cases of AML are diagnosed in children each year in the United States [1]. In the past 30 years, survival rates for children with AML have progressively improved, although not as dramatically as for children with acute lymphoblastic leukemia (ALL) [2]. During this period, the components of AML therapy have remained essentially unchanged. Incremental improvements in outcome are attributable to a number of factors including increased treatment intensity, optimized supportive care, and application of stem cell transplantation. With recent advances in molecular diagnostics and the emergence of targeted approaches, AML therapy is poised to enter a new age of accelerated progress. This chapter focuses on factors specifically relevant to AML in children.

Epidemiology and Pathogenesis

AML is primarily a disease of adults, with the median age at diagnosis in the seventh decade of life. In children, the incidence of ALL far exceeds the incidence of AML [1]. Within the pediatric population, the incidence of AML varies by age with a small peak in the first 2 years of life and then gradual rise after the second decade of life, as depicted in Fig. 19.1.

Although the vast majority of pediatric AML is thought to be sporadic in nature, the contribution of inherited leukemia predisposition has become significantly more appreciated over the past decade as more familial myelodysplastic syndrome (MDS), acute leukemia, and marrow failure syndromes have been described. A large genomic study of germline material from 1120 pediatric cancer patients found that 8.5% of all patients and 4% of leukemia patients had a pathogenic or probably pathogenic mutation in a cancer predisposition gene [3]. Importantly, a positive family history of cancer was only present in 40%, demonstrating that germline predisposition remains an underappreciated and under-evaluated concern, which can impact future risk of relapse, second malignancy and other sequelae, transplant conditioning, and transplant donor selection. Although germline screening for predisposition is not (yet) universally recommended for pediatric AML patients, clinicians should have a high index of suspicion for considering a germline workup in the right clinical context. A comprehensive review of these disorders and their diagnostic workup is beyond the scope of this chapter, but we highlight several important syndromes and concepts.

First, there exist cancer predisposition syndromes in which hematological neoplasms are merely one class of several cancers which are at significantly increased risk. These include Bloom syndrome, ataxia telangiectasia, neurofibromatosis type I, and others. In addition, familial MDS and AML syndromes associated with germline mutations have also been described, which can be organized into three groups. In the first group are those with thrombocytopenia, platelet dysfunction, and an increased risk of myeloid and other hematopoietic neoplasms, including constitutional mutations in RUNX1 [4], ANKRD26 [5], and ETV6 [6]. A second group has increased risk of MDS/AML with associated organ manifestations, which include GATA2, TP53, TERT, and TERC. A final group, which includes mutations in CEBPA, SRP72, and DDX41, has increased risk of MDS/AML and no thrombocytopenia and organ dysfunction. Lastly there are bone marrow failure syndromes, including Fanconi anemia, Shwachman-Diamond syndrome ,and dyskeratosis congenita, which also have an elevated risk for transformation to MDS or AML.

Although not familial, Down syndrome deserves special attention as a germline syndrome associated with increased risk of leukemia. Babies with Down syndrome (DS) exhibit

a unique pattern of abnormal myelopoiesis in the neonatal period which is usually transient and self-resolving. Myelodysplastic syndrome (MDS) and/or AML (also known as myeloid leukemia of Down Syndrome, or ML-DS) develops later in some of these babies. After the first few years of life, the incidence of AML declines to non-DS baseline levels concomitant with a rise in the incidence of ALL in children with DS (see ML-DS below).

Increased AML risk is also associated with exposure to DNA-damaging agents in the form of chemotherapy or therapeutic, diagnostic, or environmental radiation. As the number of survivors of childhood and adult cancer grows, the population at risk for this complication increases. The risk period for the development of myelodysplasia and overt AML is influenced by the therapeutic class of the genotoxic therapy previously administered. Also, both cumulative dose and administration schedule appear to matter [7]. Secondary leukemias that arise after exposure to topoisomerase II inhibitors, such as epipodophyllotoxins and anthracyclines, characteristically present as overt AML, without a preceding phase of myelodysplasia. These leukemias occur relatively early, peaking at 2–3 years after drug exposure. Balanced translocations, especially rearrangements involving the MLL (KMT2A) gene at chromosome 11q23, are characteristic of AMLs that occur in association with these agents [8]. Frequent, intermittent schedule of administration of etoposide is associated with a higher risk of treatment-related leukemia [9]. In contrast, exposure to alkylating agents is characteristically associated with leukemias that evolve in the setting of MDS occurring more than 5 years after drug exposure. Deletions involving chromosomes 5 and 7 are often observed [8].

Other environmental and lifestyle factors do not appear to contribute strongly to the incidence of AML in children. Studies linking childhood AML to exposure to environmental toxins, pesticides, fetal exposure to cigarettes, drugs or alcohol, parental age, and birth weight have been suggestive but so far inconclusive [10].

Clinical Presentation

Children with acute leukemia, whether AML or ALL, typically present with symptoms related to bone marrow infiltration, including pallor, fatigue, fever, petechiae, and bruising. Hepatosplenomegaly is common. Less often, AML cells can also form solid masses, referred to as myeloid sarcoma or chloroma, or infiltrate tissues such as the gingiva and skin. This may occur with or without concomitant peripheral blood or bone marrow involvement. Extramedullary involvement is associated in particular with young age, monoblastic differentiation, and certain cytogenetic abnormalities [11].

In children with AML, the white blood cell count at presentation may be low, normal, or high and circulating blasts may be present or absent. 15–20% of children present with a white blood cell count of 100,000 cells/μL or more [12–14]. Rarely, circulating blasts are detected on screening blood work performed in the absence of symptoms. When the white blood cell count is extremely elevated, patients may experience signs and symptoms related to impaired tissue perfusion that results from hyperviscosity and microvascular obstruction. Leukostasis is a significant risk in AML patients with white blood cell counts over 100,000. Respiratory

compromise and central nervous system (CNS) manifestations are of primary concern. Concomitant renal dysfunction and metabolic derangement due to spontaneous tumor lysis syndrome and hemorrhagic diathesis due to thrombocytopenia and disseminated intravascular coagulopathy (DIC) exacerbate the problem. As in adults, DIC with or without hyperleukocytosis is a particularly prominent feature of acute promyelocytic leukemia (APL). The role of leukapheresis remains controversial in children with hyperleukocytosis. In conjunction with prompt initiation of cytoreductive chemotherapy and aggressive management of tumor lysis syndrome, the procedure might reduce the risk of early death in selected patients with very high WBC (>200,000) and monoblastic leukemia [15]. Due to risk of bleeding, leukapheresis is discouraged in patients with APL [16].

The diagnosis of AML may be established when leukemic blasts are circulating in the peripheral blood. However, bone marrow aspiration/biopsy is usually recommended to fully characterize the leukemia. In every new case of AML, the possibility of APL must be considered, since this entity demands urgent initiation of specific therapy (see below). Leukemia cytogenetics, FISH, and molecular tests for subchromosomal genetic alterations, such as FLT3-ITD, should be obtained. Although institutional protocols may differ on which exact studies are sent, molecular studies are increasingly important in determining treatment and predicting prognosis. The option to bank leukemia samples for future studies should always be offered when possible.

Examination of CSF is an important part of the diagnostic evaluation in new-onset leukemia, although it may be delayed or deferred in the setting of coagulopathy. CSF sampling is usually performed in conjunction with administration of intrathecal chemotherapy when the diagnosis of acute leukemia has been established. A summary of commonly recommended studies for the diagnostic evaluation of pediatric AML is shown in Table 19.1.

Table 19.1 Diagnostic evaluation of suspected pediatric AML

Initial workup and staging
• History and physical exam, including family history for malignancies and hematological disorders
• Complete blood count with differential
• Electrolytes, including calcium, phosphorous, uric acid, and lactate dehydrogenase
• Liver function tests, including AST, ALT, bilirubin
• Prothrombin time (PT), partial thromboplastin time (PTT), international normalized ratio (INR), fibrinogen, d-dimer
• Peripheral blood flow cytometry, if circulating blasts are present
• HLA typing for potential transplant
• Chest radiograph
• Ophthalmology exam
• Echocardiogram, electrocardiogram
• Consider central access options
• Consider fertility-preservation options
• Consider research specimen banking, if available
• Bone marrow aspirate
– Morphology, flow cytometry, karyotype, FISH for prognostic AML cytogenetics including t(8;21), inv. [16], MLL, t(15;17), −7, +8
– FLT3 internal tandem duplication
– PML/RAR if suspected or confirmed APL (consider also from blood)
• Bone marrow biopsy
• If no coagulopathy, diagnostic/therapeutic lumbar puncture

Classification

AML is a morphologically, cytogenetically, and molecularly heterogeneous set of diseases and its classification strongly influences prognosis and therapy. Many classification schema have been developed over time, for example, the French-American-British (FAB) classification system, which used morphologic criteria to divide AML into eight groups (M0: acute myeloblastic leukemia with minimal differentiation, M1: acute myeloblastic leukemia without maturation, M2: acute myeloblastic leukemia with maturation, M3: acute promyelocytic leukemia, M4: acute myelomonocytic leukemia, M5: acute monocytic leukemia, M6: acute erythroid leukemia, and M7; acute megakaryocytic leukemia) [17, 18]. However, with increasing understanding of AML biology, particularly in adults, recurrent genetic and cytogenetic alterations have become integrated with classification. This is reflected in the introduction of World Health Organization (WHO) classification of myeloid neoplasms and acute leukemia in 2001, which was revised in 2008 and again in 2016 (Table 19.2).

Because AML is primarily a disease of adults, it is not surprising that the WHO classification schema has limited applicability to pediatric AML. This is illustrated by the fact that in a study of 639 children with AML, AML-NOS (not otherwise specified) is the largest group [19].

Cytogenetic and Molecular Features of Childhood AML and Their Role in Risk Stratification

In large part, the limited applicability in pediatric AML of the genetic and cytogenetic approach driving the WHO classification is driven by age-related differences in the molecular features of adult and childhood AML. Many of the common cytogenetic abnormalities vary considerably by age (Fig. 19.2), and common pediatric alterations that are uncommon in adult AML are not well represented in the WHO classification. For example, although *KMT2A (MLL)* has over 120 described fusion partners [6, 7] and is translocated in

Table 19.2 World Health Organization 2016 classification of myeloid neoplasms and acute leukemia

Acute myeloid leukemia (AML) and related neoplasms
AML with recurrent genetic abnormalities
AML with t(8;21)(q22;q22.1);RUNX1-RUNX1T1

APL with PML-RARA
AML with t(9;11)(p21.3;q23.3);MLLT3-KMT2A
AML with t(6;9)(p23;q34.1);DEK-NUP214
AML with inv. [3](q21.3q26.2) or t(3;3)(q21.3;q26.2); GATA2, MECOM
AML (megakaryoblastic) with t(1;22)(p13.3;q13.3);RBM15-MKL1
Provisional entity: AML with BCR-ABL1
AML with mutated NPM1
AML with biallelic mutations of CEBPA
Provisional entity: AML with mutated RUNX1
AML with myelodysplasia-related changes
Therapy-related myeloid neoplasms
AML, NOS
AML with minimal differentiation
AML without maturation
AML with maturation
Acute myelomonocytic leukemia
Acute monoblastic/monocytic leukemia
Pure erythroid leukemia
Acute megakaryoblastic leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis
Myeloid sarcoma
Myeloid proliferations related to Down syndrome
Transient abnormal myelopoiesis (TAM)
Myeloid leukemia associated with Down syndrome
Acute leukemias of ambiguous lineage
Acute undifferentiated leukemia
Mixed-phenotype acute leukemia (MPAL) with t(9;22)(q34.1;q11.2); BCR-ABL1
MPAL with t(v;11q23.3); KMT2A rearranged
MPAL, B/myeloid, NOS
MPAL, T/myeloid, NOS

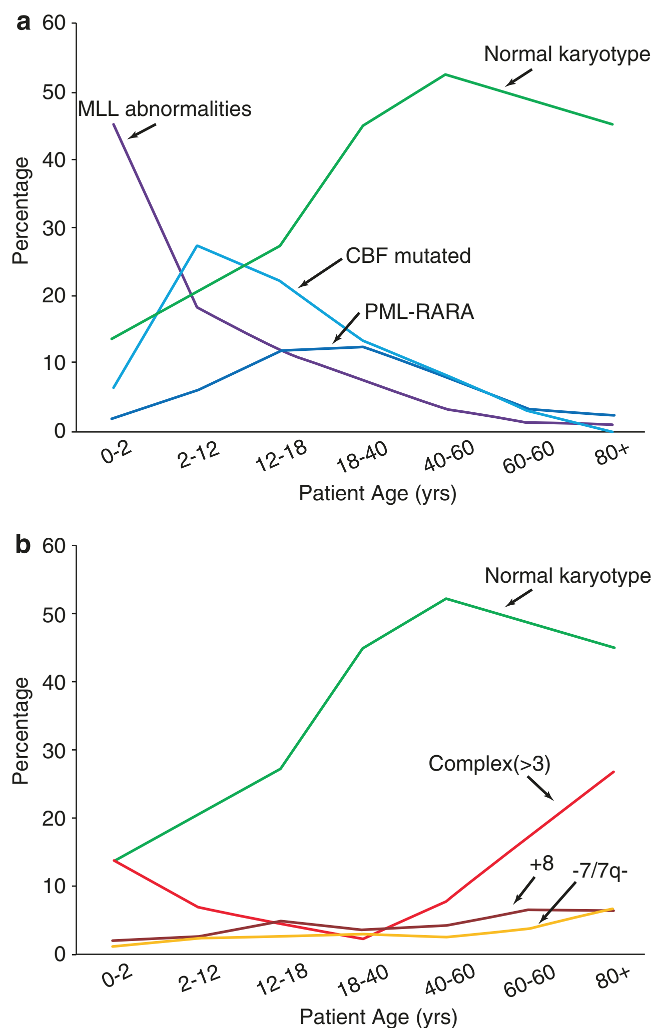

Fig. 19.2 Frequency of molecular abnormalities in AML by age. (**a**) Abnormalities more common in pediatric AML, with normal karyotype AML as a reference. (**b**) Abnormalities more common in adult AML. Data summarized from Cruetzig et al. Cancer 2016

50% of infants and 25% of children with AML, it is uncommon in older adults. As a consequence, the WHO criteria in 2008 and 2016 recognize only the most common fusion protein, t(9;11)(p21.3;q23.3); MLLT3-KMT2A (previously known as MLL-AF9) [8], leading AMLs with other KMT2A translocations to be classified as AML-NOS, despite their differential impact on prognosis.

Other pediatric centric molecular features are recognized however, for example, the favorable risk core-binding factor (CBF) group, with t(8;21) or inv.(16) and t(16;16), is very common (>25%) in childhood AML, while uncommon in older adults with AML. PML-RAR is common (>10%) in adolescents and young adults with AML, while uncommon in young children and older adults over 60. In contrast, cytogenetically normal, complex karyotype and losses of 5q and 7 are more common in older adults.

Although the frequencies of specific cytogenetic abnormalities vary, most abnormalities retain a similar clinical meaning in pediatric compared to adult AML (Table 19.3). However there are a few notable exceptions. Both monosomy 7 and 7q- are poor risk markers in adults, while children with 7q- do relatively well compared to those with monosomy 7 [19–21]. Since 11q23 rearrangement is more common in children, more data is available regarding the prognostic impact of specific KMT2A translocations in pediatric AML, which is variable. The t(6;11)(q27;q23), t(10;11)(p12;q23), and t(10;11)(p11.2;q23) translocations have been specifically associated with unfavorable outcomes, while

Table 19.3 Prognostic cytogenetic alterations in pediatric acute myeloid leukemia

Favorable	
t(8;21)(q22;q22)/RUNX1-RUNX1T1	[21, 24]
Inv(16)(p13.1;q22)/CBFb-MYH11	[21, 24]
Mutated NPM1 without FLT3-ITD	[25, 26]
Biallelic mutations of CEBPA	[27, 28]
t(1;11)(q21;q23)/MLLT11-KMT2A	[22]
t(15;17)/PML-RARA	[24]
Intermediate or unclear	
t(9;11)(p12;q23)/MLLT3-KMT2A	[22]
Other KMT2A fusions	[22]
Unfavorable	
t(6;11)(q27;q23)/MLLT4-KMT2A	22
t(10;11)(p12;q23)/MLLT10-KMT2A	[22]
t(10;11)(p11.2;q23)/ABI1-KMT2A	[22]
t(6;9)(p23;q34)/DEK-NUP214	[29, 30]
t(5;11)(q35;p15.5)/NUP98-NSD1 with FLT3-ITD	[31, 32]
Inv(16)(p13.3q24.3)/CBFA2T3-GLIS2	[33, 34]
FLT3-ITD	[26, 35]
Monosomy 7	[19, 20, 21]
t(9;22)/BCR-ABL	[21]
5q abnormalities	[21]

t(1;11)(q21;q23) is favorable, and others appear to have little impact on prognosis [22]. The prognostic significance of other cytogenetic lesions is emerging in pediatric AML, but is not yet validated [23].

In addition to cytogenetic alterations, nearly all cases of adult AML have multiple pathogenic somatic single-nucleotide variants (mutations) and some copy number variants that can be identified by next-generation sequencing techniques, with the most frequently altered including *FLT3, NPM1, DNMT3A, IDH1, IDH2, TET2, RUNX1, TP53, CEBPA, WT1, KIT*, the Ras pathway (*NRAS, KRAS, PTPN11*), splicing (*U2AF1, SF3B1, ZRSF2*), and the cohesion complex (*STAG2, SMC3, RAD21*) [36]. Although studies have been limited to small cohorts, often assaying only a few genes, variants in most of these genes have been far less common. For example, *FLT3-ITD* (25% vs. 12%) and mutations in *CEBPA* (35% vs. 8%), *IDH1* or *IDH2* (17% vs. 2%), and *DNMTA* (22% vs. 0%) [37] are all significantly more frequent in adult versus childhood AML patients.

The cell of origin, order, number, and which combinations of mutations are required for AML development remain an active field of investigation, beyond the scope of this chapter. Gilliland and colleagues previously proposed a model in which AML develops from a combination of "class II" mutations, which primarily cause a differentiation arrest and increased self-renewal, with "class I" mutations that cause increased proliferation and survival [38]. Such class I mutations include activating mutations in the Ras pathway as well as constitutive activation of receptor or cytoplasmic tyrosine kinases such as *FLT3* and *KIT*. The contribution of many recently described mutations, such as those in epigenetic regulators, splicing, and cohesin complex, are incompletely understood and their effects on differentiation, self-renewal, and proliferation are under investigation.

Increasing evidence is accumulating that some of these somatic variants, particularly in *DNMT3A*, *TET2*, *ASXL1*, *JAK2*, and *SF3B1*, may be an initial event in the pathogenesis of adult AML. Several studies [39–41] have now documented the existence of detectable, pathogenic, persistent, and typically subclonal variants in these genes in the blood of healthy volunteers, which likely represent the expansion of mutated hematopoietic stem cells and is now termed clonal hematopoiesis of indeterminate potential (CHIP) [42, 43]. These mutations are associated with an increased risk of transformation to a hematopoietic malignancy; they are more frequent in patients with unexplained cytopenias [44] and have been documented in non-leukemic hematopoietic stem cells of leukemic patients [45] and the blood samples of patients prior to the development of AML [46]. The prevalence of CHIP increases dramatically with age, with over 10% affected of those over 70 years or older, but is rare in healthy adults under 40 [39], which is thought to be related to age-related accumulation of DNA damage. The near absence of these variants in healthy young people and low prevalence in childhood AML suggest that most childhood AML may have a very different etiology than most adult AML.

Immunophenotype Analysis at Diagnosis in Pediatric AML

The diagnosis of AML, to be distinguished from ALL and MPAL, has been greatly assisted by the advent of flow cytometry and immunophenotyping. An aberrant immunophenotype can be detected on myeloid blasts in 95% of cases [47] at diagnosis, commonly with expression of myeloid and stem cell markers CD13, CD15, CD33, CD34, CD56, and CD117 as well as lymphoid markers such as CD7, CD10, and CD19. Some specific immunophenotypes are correlated to cytogenetics or outcomes and should be noted.

Minimally differentiated M0 FAB subtype of AML is rare and a poor prognostic marker [48]. The good prognostic t(8;21)(q22;q22) translocation is more frequently found in pediatric patients, in the FAB M2 subtype, and often associated with extramedullary tumors, chloromas, and splenomegaly. They also have a specific immunophenotype, with positivity for the B-cell cell-associated marker CD19, as well as CD13, CD34, CD56, and HLA-DR, while CD2 and CD7 are rarely expressed and CD33 is weak [49].

In FAB M3, acute promyelocytic leukemia (APL) blasts co-express CD13, CD33, and CD9 but are negative for HLA-DR, CD15, CD10, or CD11b. In addition to distinct morphologic features, this immunophenotype will be one of the earliest hints that a newly presenting patient has APL and could benefit from the early initiation of tretinoin (see below).

M6 erythroleukemia is rare in childhood AML but associated with a poor outcome, particularly induction failure and death [50]. The megakaryocytic M7 FAB subtype may be suspected based on morphology or histochemistry, and is confirmed by immunophenotypic analysis (identification of platelet or megakaryocytic antigens CD41 and CD61) [18]. It is frequently associated with Down syndrome, and is in fact the most common type of AML in young children with Down syndrome, where it has a favorable prognosis. In contrast, M7 AML in non-Down syndrome patients is rare and carries a poor prognosis [50].

Loken and colleagues [51] recently described a pediatric restricted high-risk immunophenotype with bright CD56, dim to negative CD45 and CD38, and a lack of HLA-DR, named the RAM phenotype (after a particular patient's initials). These patients were significantly younger (1.26 years old vs. 10.1) and lacked FLT3-ITD, CEBPA, or NPM1 mutations and were all considered standard-risk cytogenetics; however, they were more frequently MRD positive (84% vs. 33%), had lower EFS (16% vs. 51%), and OS (26% vs. 66%) compared to the non-RAM cohort.

Treatment

Treatment of AML in children is similar to adults, but outcomes in children are superior in all risk groups [12, 52]. Overall survival for pediatric AML exceeds 60% with current treatment protocols [23]. Treatment is separated into two phases: remission induction and post-remission consolidation. Approximately 90% of children achieve remission after one or two cycles of intensive induction chemotherapy [53]. The choice of post-remission consolidation is determined by risk group which is, in turn, based on the combination of disease characteristics and treatment response. Broadly speaking, lower risk patients in first complete remission are allocated to receive additional cycles of combination chemotherapy while higher risk patients are typically referred for allogeneic hematopoietic cell transplantation (HCT). Allocation to HCT is not based solely on the existence of a matched family donor, as it was in the past. For AML patients who relapse, HCT in second remission is generally considered the best option for the possibility of cure.

Remission Induction

For decades, the combination of cytarabine plus an anthracycline has remained the mainstay of induction therapy for newly diagnosed AML. Multiple clinical trials in childhood AML have examined different cytarabine doses and schedules, different anthracyclines, and addition of a third agent. Despite these efforts, no clear optimal combination and schedule have been defined. Currently in the United States, induction therapy typically consists of cytarabine, daunorubicin, and etoposide (ADE 10 + 3 + 5) based on the series of trials conducted by the United Kingdom Medical Research Council (MRC) [54, 55]. Bone marrow examination is performed to assess response to chemotherapy around days 21–28 of induction I. If residual leukemia is present, a second cycle of chemotherapy may be immediately initiated. Otherwise, induction II begins when peripheral blood counts recover. Morphologic assessment of early treatment response is notoriously challenging. Application of multiparameter flow cytometry and molecular studies significantly improves the accuracy of the hematopathologists' interpretation [56]. Depending on genetic and clinical factors, response to induction I, and provider preference, a second cycle of ADE or a more intensive combination, such as high-dose cytarabine with mitoxantrone [13], is administered in induction II. After two cycles of induction chemotherapy, about 90% of children with de novo AML will achieve remission, defined as <5% marrow blasts by morphology and/or flow cytometry. Among the subset of patients who do not achieve this milestone, refractory disease is the cause in the majority, in most studies. However, early death due to toxicity is also a significant problem [14, 57, 58].

Monitoring Treatment Response

In addition to the initial immunophenotypic, cytogenetic, and genetic features, response to therapy is a strong predictor for relapse and long-term outcome. Morphologic induction failure, unquestionably, portends a dismal prognosis, but occurs in only a small minority of cases and unfortunately nearly half of patients that achieve complete remission (CR) will eventually relapse. Modern assessment of treatment response involves the measurement of minimal residual disease (MRD), which is typically performed by sensitive multidimensional flow cytometry after induction chemotherapy; however RT-PCR analysis of leukemia-specific transcripts [59] and genomic DNA assessment of mutation clearance have been studied as well.

Flow cytometry for aberrant immunophenotypes post-induction is the most generalizable method and has been shown to be prognostic in childhood AML and predicts relapse risk in multiple studies. For example, in the St. Jude AML02 trial [58], the presence of high MRD by flow after one course of induction was associated with a 3-year cumulative incidence of relapse of 39% compared with only 17% for patients with no detectable MRD. The relapse rate was particularly high for patients with MRD >1% after one course of therapy and for those with any detectable MRD (>0.1%) after two courses of induction chemotherapy.

At relapse, 88% of pediatric AML cases demonstrated an antigenic shift in at least one marker [60]. Because immunophenotype can vary greatly and aberrancy can be subtle, it is important to perform multiparameter flow cytometry, especially in cases of minimal disease detection, which should not be restricted to the immunophenotype detected at presentation. In contrast to adult AML trials, flow-based MRD is well accepted and used by most pediatric cooperative group to determine which patients receive high-risk therapy (in combination with clinical, cytogenetic, and genetic features).

Consolidation Chemotherapy

Consolidation therapy for pediatric AML in first complete remission is determined by risk group. It is generally agreed that the core-binding factor (CBF) leukemias have a reasonably good chance of cure with chemotherapy alone. For these patients with so-called low-risk cytogenetics, the up-front toxicity of HCT in first complete remission is not warranted [61, 62]. On the opposite end of the spectrum, high-risk AML is variably defined among cooperative groups and the definition continues to evolve. General consensus has emerged for many of the more frequent subtypes and scenarios, taking into account both disease features and response to therapy. High-risk characteristics include poor response to initial therapy, AML arising in the setting of MDS or prior treatment, presence of FLT3-ITD with high allelic ratio, and presence of adverse cytogenetics such as monosomy 7, monosomy 5, del5q, and other specific rare translocations [14, 55, 63–65]. HCT from the best available donor is typically, although not universally, considered the treatment of choice for children with high-risk AML in first complete remission, even though a clear benefit from HCT has been difficult to demonstrate in prospective [66] and retrospective trials [67]. A loosely defined intermediate-risk group is comprised of patients with neither low-risk nor high-risk features. For this population, the risk-benefit analysis related to consolidation chemotherapy versus HCT is closer to neutral. Individual factors, such as the availability of a matched family donor, may be taken into consideration in selecting the best consolidation strategy.

For patients who do not proceed to HCT in first remission, post-remission treatment usually consists of additional cycles of intensive consolidation chemotherapy, including some exposure to cytarabine at high dose (≥1 g/m^2/dose) [65, 68]. Although the optimal number of cycles is not determined, a total of four cycles of multiagent chemotherapy is relatively standard in the United States at this time. This is primarily based on results from the MRC AML12 trial which demonstrated that three cycles of consolidation chemotherapy did not improve event-free or overall survival in comparison to two cycles [55]. With current intensive chemotherapy, children with CBF leukemia can expect event-free survival in the range of 80% and overall survival in the range of 90% at 3 years [13, 58]. The influence of risk group on outcome is depicted in Fig. 19.3 [58]. Maintenance chemotherapy has no proven benefit in childhood AML [69, 70], with the exception of APL [71].

Extramedullary Disease

The incidence of central nervous system (CNS) involvement is higher in children with AML compared to ALL. However, the impact that it has on prognosis, and therefore on treatment, is less important. CNS involvement in AML is associated with higher presenting WBC count, younger age, and certain karyotypic abnormalities. CNS-directed therapy in the form of intrathecal chemotherapy, in addition to CNS-penetrant systemic chemotherapy is incorporated into all contemporary treatment protocols for pediatric AML. Prophylactic cranial radiation is not routinely used. CNS3 status, which is defined as ≥5 WBC/μL and blasts present on cytospin, occurs in about 10% of children with AML [72]. For these children, intensification of intrathecal chemotherapy is recommended. The management of CNS2 status (<5 WBC with blasts seen) is variable. Although CNS involvement does not appear to confer a significant impact on overall prognosis, it is associated with a higher risk of CNS relapse [72, 73].

Soft-tissue masses, referred to as myeloid sarcoma or chloroma, are identified occasionally in children with newly diagnosed AML. The pattern and prognostic impact of this are linked to associated karyotypic changes. As mentioned above, cutaneous involvement (“leukemia cutis”) is characteristically seen in babies with *KMT2A (MLL)*-rearranged AML (Fig. 19.4). Orbital, parameningeal, and CNS masses

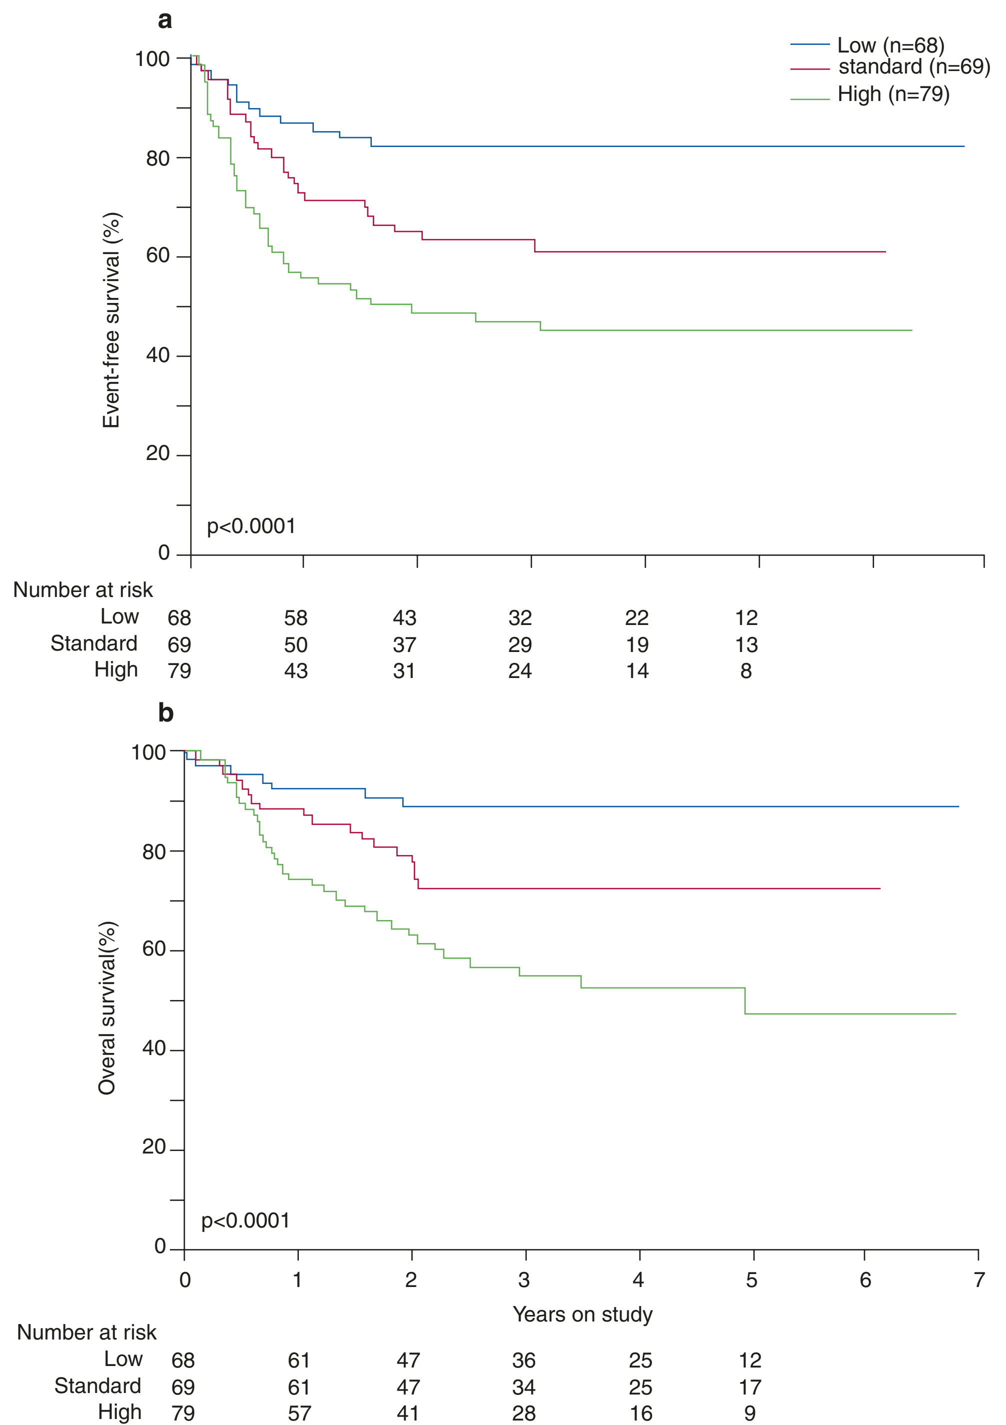

Fig. 19.3 Treatment outcome according to risk group on St. Jude AML02. Reproduced with permission from Rubnitz, et al. Lancet Oncology 2010

are characteristic of AML in older children in association with favorable cytogenetics [74]. Although focal radiation may have a role in selected cases for the acute management of myeloid tumors that threaten permanent consequences due to their location or in the palliative setting, there is no established benefit to addition of focal radiation to myeloid tumors that respond well to chemotherapy [75]. Apparently "isolated" extramedullary disease is viewed as a harbinger of systemic illness both at initial diagnosis and at relapse and should be treated as such [76].

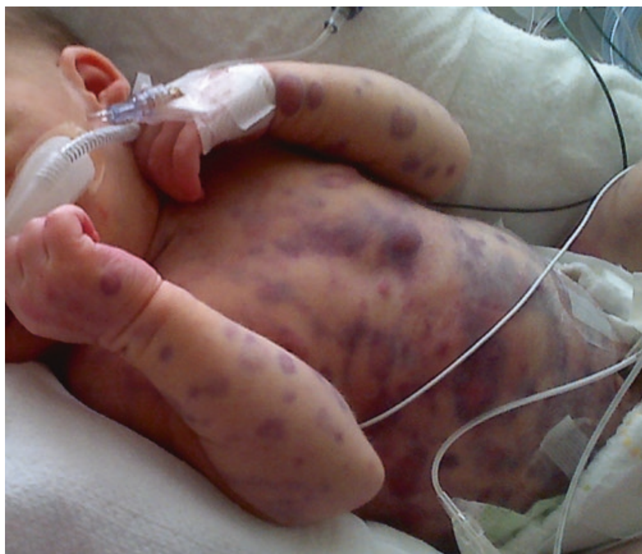

Fig. 19.4 Leukemia cutis in a newborn infant with KMT2A (MLL)-rearranged AML

Newer and Targeted Agents

Due to the suboptimal outcomes in pediatric AML, novel therapies targeting a broad variety of mechanisms are in development. These include second-generation nucleoside analogs, such as clofarabine, which is more resistant to deamination than classical agents such as cytarabine [77], new formulations of traditional chemotherapy, such as CPX-351, a liposomal formulation of daunorubicin and cytarabine, and targeted agents such as kinase inhibitors, monoclonal antibodies, epigenetic modulators, and others. Since AML is much more common in adults, novel therapies are generally studied and often shown to have activity in adults before being used in pediatric studies.

As noted above, the presence of the FLT3 internal tandem duplication is an adverse prognostic feature in children [35, 78] as it is in adults. Several FLT3 inhibitors that range in specificity and potency already exist that have been, or are being, tested in adult AML. These drugs include midostaurin, sorafenib, quizartinib, gilteritinib, and crenolanib [79]. The multikinase inhibitor midostaurin was approved for adults with AML with certain FLT3 mutations in 2017, however data in children is limited at this time. The multikinase inhibitor sorafinab, which is FDA approved for certain solid tumors, also has activity against some FLT3 mutations, with reported clinical activity in relapsed pediatric AML [80] and some use in the post transplant setting [81].

Gemtuzumab ozogamicin is a humanized monoclonal antibody directed against CD33, a protein that is expressed on the surface of a high proportion of AML blasts but not on hematopoietic stem cells. The antibody is covalently linked to an antitumor antibiotic, calicheamicin. The drug was approved in 2017 for AML in patients aged 2 and older [82]. Children's Oncology Group (COG) AAML 0531 [14] demonstrated that addition of gemtuzumab was associated with a statistically significant positive effect on event-free survival through reduction of relapse. High expression of the target antigen, CD33, is associated with response to the drug [83]. Additional immunoconjugates, including vadastuximab talirine (SGN-CD33A) [84], are in development for AML.

Many other classes of agents show promise in AML and are currently under investigation. Epigenetic modifiers are a broad class including drugs that inhibit histone deacetylase (vorinostat) and DNA methyltransferase (azacitidine and decitabine) which are being studied in relapsed pediatric and adult AML. DOT1L inhibition is being studied in children and adults for KMT2A (MLL)-rearranged AML. Other strategies being investigated with new clinical agents include IDH1 and IDH2 inhibition, proteasomal inhibition, exportin inhibition, ubiquitination modulation, and chimeric antigen receptor T-cell therapy [53, 85].

Acute Promyelocytic Leukemia

Acute promyelocytic leukemia (APL) is a unique AML subtype characterized by the presence of reciprocal translocation involving chromosomes 15 and 17 leading to the production of a promyelocytic leukemia (*PML*)-retinoic acid receptor alpha (*RARA*) fusion protein. APL is a disease of older children and young adults. APL accounts for about 10% of pediatric AML and it is distinctly uncommon in children under 10 years. The molecular features of APL are described above and elsewhere in this text. In children as in adults, the treatment of APL differs significantly from other AML subtypes and the overall prognosis is markedly better. But APL is associated with a high risk of early death, due primarily to hemorrhage. Therefore, clinicians must be on alert for this entity because prompt and accurate diagnosis is critical to successful management.

APL is characterized morphologically by the appearance of large hypergranular myeloid blasts with prominent Auer rods. The hypogranular variant (M3v), which is more common in children [86], may be more difficult to distinguish from other AML subtypes. Typically, the blasts co-express CD13, CD33, and CD9 but do not express HLA-DR, CD15, CD10, or CD11b. Blasts of the hypogranular variant typically express CD2 [87]. Demonstration of the molecular fusion of PML gene on chromosome 17 and the RARA gene

on chromosome 15 by RT-PCR, FISH, or karyotype is the key to diagnosis. RT-PCR is the preferred modality since it is rapid, specific, and quantitative.

Disseminated intravascular coagulopathy (DIC) is a significant and potentially life-threatening feature of new-onset APL. Transfusions should be provided to maintain the platelet count ≥30–50 K and fibrinogen level ≥100–150 mg/dL. To address the underlying cause of the bleeding diathesis, emergent initiation of leukemia-directed therapy in the form of tretinoin is recommended at the first suspicion of the disease [16]. Delay in starting tretinoin is associated with a higher risk of early hemorrhagic death [88]. In children, there is an estimated 7.4% risk of death within the first 7 days of APL diagnosis [89].

The introduction of tretinoin into the treatment of APL in the late 1980s transformed the management and the prognosis of this disease. Tretinoin is now a standard component of APL therapy in children. Tretinoin causes differentiation of malignant promyelocytes, sometimes leading to marked increase in the peripheral leukocyte count. Differentiation syndrome occurs in 10–20% of children being treated with tretinoin for APL [90–92]. Higher presenting WBC is a risk factor for the development of this complication of therapy which is characterized by fever, hypotension, pulmonary infiltrates, and renal insufficiency. Aggressive supportive care, administration of dexamethasone, and early introduction of cytotoxic chemotherapy are recommended. Temporary interruption of tretinoin is indicated in severe cases. Pseudotumor cerebri is an important side effect of tretinoin that occurs more commonly in children than in adults [90–92] warranting the use of a lower starting dose of tretinoin in children.

While it is true that APL is associated with an unacceptably high risk of early morbidity and mortality, the overall prognosis for children with APL is significantly better than most other AML subtypes. Treatment with combination of chemotherapy and tretinoin results in event-free and overall survival in the range of 75 and 90%, respectively [90, 91]. As in adults, the intensity of treatment is risk stratified based on presenting white blood cell (WBC) count, with high risk defined as presenting WBC >10,000 cells/dL. Although highly effective, these chemotherapy regimens are lengthy (almost 3 years in duration due to inclusion of a maintenance phase) and associated with potential for significant late effects (especially cardiotoxicity related to high cumulative anthracycline exposure). Exciting recent studies in adults have demonstrated that APL can be cured in many cases with combination of tretinoin and arsenic trioxide with little or no cytotoxic chemotherapy [93]. Arsenic has been shown to be effective and tolerable in children with relapsed APL [94] and in small series of children with newly diagnosed APL [95, 96]. Ongoing clinical trials are examining the use of arsenic and tretinoin as up-front therapy for pediatric APL with concomitant reduction or omission of cytotoxic agents and shortening of treatment duration.

Myeloid Leukemia of Down Syndrome

Children with Down syndrome (DS) are at a 10–20-fold increased risk for developing leukemia. The pattern of disease is unique, comprising neonatal transient abnormal myelopoiesis (TAM), MDS/AML, and ALL. In the first 5 years of life, the risk of myeloid leukemia is about 150 times higher in DS children compared with non-DS children [97].

Myeloid blasts are identified in the peripheral blood smears of approximately 10–15% of newborns with DS. The blasts typically, but not always, express immunophenotypic markers of megakaryoblasts, including CD41, CD42b, and CD61 [98]. Despite the fact that the abnormal cells are morphologically and immunophenotypically indistinguishable from acute megakaryoblastic leukemia (AML M7), they almost always disappear with little or no specific treatment. This process, known as transient abnormal myelopoiesis (also called transient leukemia or transient myeloproliferative disorder) is unique to babies with constitutional and mosaic trisomy 21. In the context of trisomy 21, acquisition of a truncating mutation in the GATA-1 transcription factor in a fetal liver-derived hematopoietic stem or progenitor cell results in expansion of the myeloid blast population. GATA-1 mutation is invariably present in DS babies with clinical TAM. Surprisingly, GATA-1 mutation was also detected in about 20% of DS infants without clinical evidence of TAM. These babies have so-called silent TAM [99].

The main clinical feature of TAM is leukocytosis with circulating blasts. There is currently no defined absolute blast threshold for the diagnosis of TAM. In a systematic review of 48 patients with TAM, the median age at diagnosis was 1 week, median WBC was about 30x10e9/L, and median peripheral blast percentage was 25%. Hepatosplenomegaly was present in more than half and liver dysfunction occurred in about one-third. Even though circulating blasts resolved in nearly all of the patients within a mean of 2 months, almost 20% of the patients died. Mortality in babies with TAM is most often attributed to hepatic fibrosis and liver failure [98]. Survival is associated with the absence of both hepatomegaly and life-threatening symptoms [100]. Treatment with very-low-dose cytarabine appears to decrease the risk of death in babies with severe TAM. However, chemotherapy treatment has never been shown to influence the risk of ML-DS later in childhood [101].

About 20% of TAM patients go on to develop myeloid leukemia before the age of 4 years. As in TAM, immunophenotypic markers of megakaryoblastic differentiation are observed in most cases and GATA-1 mutation is present in all cases. In association with evolution to ML-DS, additional "cooperating" mutations involving genes that encode cohesin complex components, epigenetic regulators, and/or signaling molecules are acquired [102]. In some children with ML-DS, a history of clinical TAM is absent. Presumably, these patients previously experienced undiagnosed "silent" TAM. Taking the incidence of silent TAM into account, it is estimated that progression to ML-DS occurs in about 5–10% of TAM cases [103] (Fig. 19.5).

ML-DS is a subtype of childhood AML that is clinically distinct and warrants distinct treatment. The median age at presentation is in the second year of life and the onset of the disease is often indolent, with gradual progression of cytopenias. ML-DS patients who do not meet the AML threshold of 20% blasts in blood or marrow often fulfill WHO criteria for MDS. In contrast to TAM, successful treatment of ML-DS requires chemotherapy. However, the intensity of chemotherapy necessary to cure ML-DS is less than de novo AML in children without DS. In fact, in an analysis performed by the Children's Cancer Group, higher intensity chemotherapy led to significant treatment-related toxicity in children with ML-DS, substantially offsetting the potential benefit in terms of leukemia control [57]. Since the late 1990s, treatment protocols designed specifically for children with ML-DS have progressively reduced treatment intensity while preserving good results with overall and event-free survival at around 80% [104–106]. Older age, higher presenting white blood cell count, and "normal" karyotype are associated with a significantly worse prognosis [107, 106].

Relapsed and Refractory AML

AML that is refractory to initial treatment or recurs after initial treatment represents a significant therapeutic challenge. Refractory disease occurs in about 5% and relapse affects about 30% [108]. Approximately half of relapses occur within 1 year, and almost all occur within 4 years of initial diagnosis [109, 110]. Long-term disease control can be accomplished in a minority of these patients but, in general, requires attainment of remission followed by HCT. For patients with relapsed AML, favorable cytogenetics [111], longer duration of first complete remission (i.e., ≥1 year from initial diagnosis), and receipt of HCT after relapse are associated with better outcomes [112].

There is currently no standard re-induction protocol for children with relapsed AML. Like up-front therapy, relapsed therapy mainly relies on the use of cytarabine with or without an anthracycline. Newer agents, including the purine analogues fludarabine, clofarabine, and cladribine, are incorporated into some regimens. Several combinations have been tested in children including fludarabine, cytarabine, idarubicin (Ida-FLAG) [113], mitoxantrone, cytarabine [114], fludarabine, cytarabine +/− liposomal daunorubicin [115], clofarabine, and cytarabine [116]. With any combination,

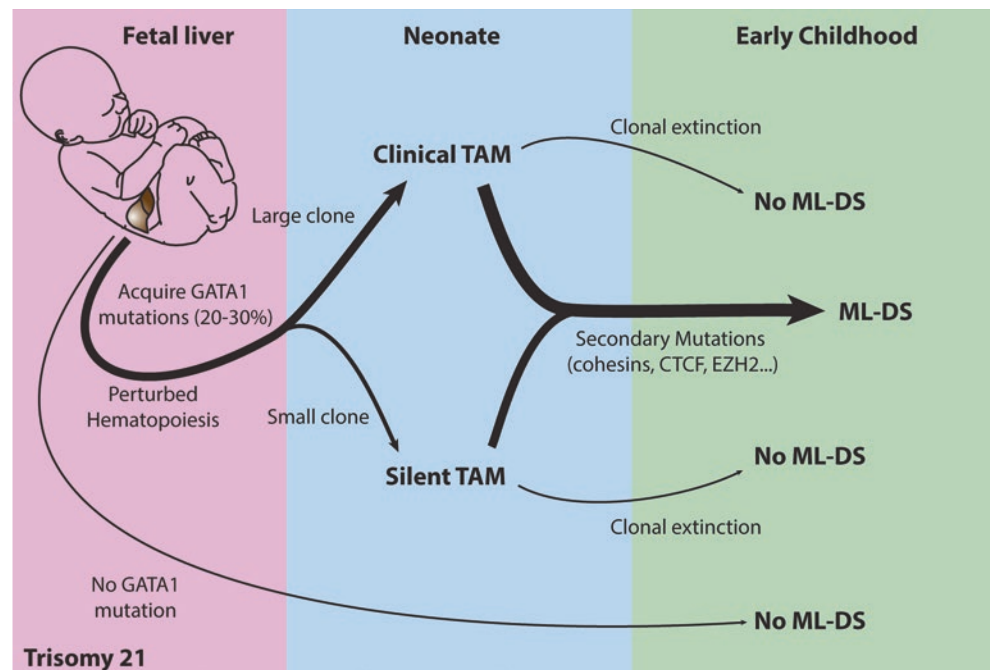

Fig. 19.5 Progression of transient abnormal myelopoiesis to Down syndrome-myeloid leukemia

complete remission is achieved in about 60–70% and many of these patients are able to proceed to HCT. MRD before HCT is a strong predictor of survival [117]. Both subsequent relapse and high treatment-related toxicity are major obstacles to overall survival. Treatment with novel and/or targeted agents, preferably in the context of clinical trials, may be an option for some patients.

The prognosis for patients with relapsed APL is much more favorable than for other relapsed AML subtypes. A role for autologous HCT has been demonstrated for those patients who achieve a second molecular remission [118]. In contrast, relapsed/refractory ML-DS is associated with a dismal prognosis [119].

Treatment Toxicity and Supportive Care

Improved survival in childhood AML is the product of maximizing treatment intensity in coordination with optimizing supportive care. Current treatment protocols appear to be reaching the inevitable limit of dose intensification. The severity and importance of treatment-related risks differ in children compared to adults. In general, children have fewer comorbidities and they tolerate myelosuppression better than adults. However, effects on growth and development matter much more. For children under 1 year of age and those who have a body surface area of less than 0.6 m^2, cytotoxic chemotherapy doses are adjusted, either as percent reduction or by basing calculations on weight instead of body surface area.

All children undergoing treatment for AML experience repeated episodes of prolonged and profound myelosuppression. Infections are the main cause of treatment-related morbidity and mortality. Unsurprisingly, the incidence of infection correlates with treatment intensity [120]. The use of bacterial and fungal prophylaxis is now recommended [121] as this does appear to reduce the rate of severe bacterial and invasive fungal infections [122]. In addition, prophylaxis against pneumocystis pneumonia is advised. The benefit of granulocyte colony-stimulating factor (filgrastim) remains controversial. When addition of prophylactic filgrastim was studied in a randomized fashion in the context of intensive chemotherapy in the Berlin-Frankfurt-Muenster (BFM)-98 study, the duration of neutropenia was shortened but the rate of severe infections was not reduced. However, in an analysis of the COG AAML0531 study, in which infections were collected and monitored prospectively, filgrastim prophylaxis was associated with a statistically significantly lower rate of bacterial infections [123]. However, its use is not without risk. A higher incidence of relapse was observed in children treated with filgrastim whose AML expressed a specific G-CSF receptor isoform [124]. At this time, routine use of filgrastim is not recommended.

Most children treated for AML receive substantial cumulative exposure to anthracyclines, often greater than 360 mg/ m^2. As a consequence, survivors are at high risk of long-term cardiac sequelae [125, 126]. Dexrazoxane has not been extensively studied in pediatric AML, but it might reduce cardiotoxicity [127]. Cardiotoxicity is a particular concern for children with DS [128]. After completion of treatment, patients should be monitored for cardiac late effects according to established guidelines [129].

Conclusions

Among pediatricians, it is often said that children are not just small adults. Although pediatric and adult AML share many features, there are important differences in terms of epidemiology, etiology, cytogenetics, and molecular genetics which influence therapy and outcome. Today, childhood AML is a curable disease in more than half of the cases. From the “glass is half-full” perspective, this fact unquestionably represents a major accomplishment. But, much more progress needs to be made to improve outcomes for all children and to reduce the burden of treatment. Progress is needed in many areas including molecular diagnostics, refinement of risk stratification, optimization of chemotherapy, development of targeted agents, and application of conventional and novel transplant strategies. Better outcomes also depend on advances in supportive care and implementation of best clinical practices. The way forward requires cooperation among pediatric oncology providers, scientists, and the pharmaceutical industry and on our patient’s ability to access and participate in well-designed clinical trials.

Diagnosis and Treatment of Adult Acute Myeloid Leukemia Other than Acute Promyelocytic Leukemia

20

Peter H. Wiernik

Introduction

Acute myeloid leukemia (AML) includes all acute leukemias characterized by cells of other than lymphoid origin. AML subgroups with special clinical features have been defined by morphologic, immunologic, cytogenetic, and molecular techniques as discussed in Chaps. 14, 15, and 16. All subtypes other than acute progranulocytic leukemia (APL) are discussed in this chapter and APL is discussed in Chap. 21.

From a patient management point of view, the most serious pathologic consequence of AML is usually pancytopenia, rather than the production of leukemic cells. Therefore, management of AML requires prophylaxis and treatment of life-threatening complications of the absence of normal blood elements as well as eradication of the neoplastic clone from which the leukemic cells are derived. Prevention and treatment of the challenges to health posed by pancytopenia are discussed in the section "Supportive Care." It will be evident from those chapters that the management of a patient with AML is complicated and must be provided by a coordinated team of healthcare professionals thoroughly versed in the clinical nuances and complications of the disease, treatment of the disease, and impact of this catastrophic illness on patient, family, and society if optimal results are to be achieved. Such care is usually available only at major institutions and it is strongly recommended that, in general, the patient with AML be referred to such an institution immediately after the diagnosis is made. Some patients may not wish to be treated with curative intent and therefore need not be referred.

Clinical Features of AML at Presentation

AML is diagnosed primarily in adults, although it can occur at any age. The median age at diagnosis in most large series is in the fifth or sixth decade, and the sexes have an approximately equal incidence. There is usually only a vague history of lethargy or lassitude prior to diagnosis, but approximately one-fourth of patients present with a serious infection of soft tissue or the lower respiratory tract associated on occasion with septicemia. Most patients have petechiae as evidence of intracutaneous capillary bleeding, but rarely more serious bleeding may be present initially. Bleeding gums after teeth brushing lead to the diagnosis in some cases. Lymphadenopathy is unusual in AML and splenomegaly is found in less than 25% of patients. If hepatomegaly is present it is almost always due to a cause other than AML in a de novo patient. Gingival hypertrophy (Fig. 20.1) is found in approximately half of patients with acute monocytic (FAB M5) or myelomonocytic (FAB M4) subtypes of AML. M4 and M5 patients have the highest incidence of all forms of extramedullary infiltration including leukemia cutis, and central nervous system (CNS) disease [1]. In some series granulocytic sarcoma is more common in patients with the M2 subtype of AML who demonstrate the t(8;21) cytogenetic abnormality. Perirectal lesions such as fissures or abscesses [2] may be present initially or during severe granulocytopenia at any time, especially in patients with M4 and M5 subtypes. The FAB subtypes defined by morphology and histochemistry, and the distribution of the subtypes among patients with AML, are identified in Table 20.1. More recent classifications based on cytogenetics and molecular characteristics are shown in Tables 20.2 and 20.3.

An elevated white blood cell (WBC) count is found in approximately one-third of patients with AML at diagnosis, and an equal number of patients have a normal WBC count or leukopenia. Hyperleukocytosis (WBC count >100,000 cells/μL) is uncommon, but may require special therapeutic interventions when present (see text to come). Blast forms

Table 20.1 The French–American–British (FAB) Classification for AML

FAB type	Definition	% of adult AML patients
M0	Undifferentiated AML	5
M1	AML with minimal maturation	15
M2	AML with maturation	25
M3	Acute promyelocytic leukemia	10
M4	Acute myelomonocytic leukemia	20
M4E	Acute myelomonocytic leukemia with eosinophilia	5
M5	Acute monocytic leukemia	10
	(a) Monoblastic (b) Monocytic	
M6	Acute erythroid leukemia	5
M7	Acute megakaryocytic leukemia	5

Table 20.2 WHO Classification of AML with recurrent genetic abnormalities [3]

Karyotype abnormalities	Gene abnormalities
AML with t(8;21)(q22;q22)	RUNX1-RUNX1T1
AML with inv(16)(p13.1q(22) or t(16;16)(p13.1q22)	CBEB-MYH11
APL with t(15;17)(q22;q12)	PML-RARα
AML with t(9;11)(p22;q23)	MLLT3-KMT2A
AML with t(6;9)(p23;q34)	DEK-NUP214
AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2)	GATA2, MECOM
Acute megakaryoblastic leukemia with t(1;22)(p13.3;q13.3)	RBM15-MKL1
AML with	Mutated NPM1
AML with biallelic mutations of	CEBPA
Provisional: AML with	BCR-ABL1

Table 20.3 European LeukemiaNet Risk Stratification of AML [4, 5]

Risk groups	Included
Favorable	t(8;21); RUNX1-RUNX1T1
	Inv(16) or t(16;16); CBFB-MYH11
	Mutated NPM1 without FLT3-ITD and normal karyotype
	Biallelic mutated CEBPA and normal karyotype
Intermediate I	All cases with a normal karyotype except those in the favorable-risk group
	Wild-type NPM1 with or without FLT3-ITD
	Mutated NPM1 without FLT3-ITD
Intermediate II	t(9;11); KMT2A
	Cytogenetic abnormalities not favorable or adverse
Adverse	GATA2-MECOM (EVI1)

are present in the peripheral blood of 85% of patients with AML before treatment. Therefore, about 15% of patients will not have a firm diagnosis made by examination of peripheral blood alone. The absolute granulocyte count is reduced in virtually all patients with AML and is less than 500 cells/ μL in approximately half of patients on the first examination. Thrombocytopenia is virtually universal and as many as one-third of patients will present with a platelet count <20,000/μL and they are candidates for immediate prophylactic platelet transfusion. Moderate anemia is the rule, but severe anemia may be found in patients with active bleeding other than petechial, or in patients in whom the diagnosis was delayed.

All patients with AML require bone marrow aspiration and biopsy. A biopsy is necessary to determine marrow cellularity. While the marrow is usually markedly hypercellular in de novo patients it may be hypocellular, especially in older patients, patients with secondary AML after treatment of another neoplasm with chemotherapy or radiotherapy, or patients who have developed AML after certain nonmalignant hematologic entities such as paroxysmal nocturnal hemoglobinuria [6]. Obviously, the marrow specimen must be obtained from a previously unirradiated site. It is important to assess marrow cellularity before and after treatment so that meaningful comparisons can be made. The pretreatment and subsequent marrow aspirates should be examined for morphology, histochemical reactions, immunophenotype, karyotype, and certain genetic mutations as discussed in this and other chapters in this section. Marrow aspirates submitted for immunological, cytogenetic, and molecular studies must be collected in heparin or acid citrate dextrose (ACD).

Leukemic blast cells account for at least one-half of marrow-nucleated elements in approximately 75% of AML patients at presentation. In elderly patients the leukemic cells may be less numerous. Usually, a diagnosis of AML is not made unless blasts account for at least 30% of the marrow white cells. Serial examinations in some patients will be necessary to determine the correct diagnosis and the rate of progression of the marrow infiltration. Rarely, the number of marrow blasts may increase slowly in some patients over several months or longer. It may be possible to withhold chemotherapy temporarily in some patients under those circumstances, especially elderly patients, as long as they are clinically well and the blood platelet and granulocyte counts are not dangerously low (<20,000/μL and <1000/μL, respectively).

The marrow aspirate may reveal other abnormalities in addition to leukemic cell infiltration. In patients with the M4 subtype relative erythroid hyperplasia is often present, despite anemia. There may be increased numbers of eosinophil precursors, especially in the M4E variant. Megakaryocytes are usually reduced in number except in secondary leukemia developing in a patient with polycythemia vera or primary thrombocytosis. Patients with the M7 subtype may have morphologically recognizable megakaryocytosis, but more often cell surface immunological or electron microscopic studies will be necessary to establish the lineage of the leukemic cells. Bone marrow necrosis may be evident prior to therapy [7], or discovered after therapy [8], especially in septic patients, and myelofibrosis may be detected in secondary leukemia or the FAB M7 subtype. Both marrow necrosis and myelofibrosis impair prognosis.

A minimal or moderate elevation in serum uric acid concentration is found in at least 50% of patients with AML. Serum lactate dehydrogenase levels may be elevated, especially in M4 or M5 subtypes, but usually to a lesser degree than in patients with acute lymphocytic leukemia (ALL). Lysozyme (muramidase) is elevated in the serum [9, 10] and urine of patients with M4 and M5 subtypes. As is the case with serum uric acid, levels of lysozyme directly reflect the body burden of tumor. Serial determinations of lysozyme may aid in evaluating response to therapy in patients with initial elevations [10].

AML is not simply a disease of the bone marrow and blood. Dysfunction of a number of organs may result directly from leukemic infiltration or indirectly from other consequences of the disease, and may dominate the clinical picture. Petechiae resulting from capillary hemorrhage secondary to thrombocytopenia are the most common skin and mucous membrane lesions. They tend to occur on dependent or traumatized areas of the body surface and may become confluent over some areas, especially in obese patients. Petechiae also occur on the surface and in the parenchyma of internal organs, but such lesions are usually clinically silent. Painless, nontender, small, raised nodules of leukemic cells may be palpable on the skin (leukemia cutis) of a small minority of patients with AML, especially those with M4 or M5 subtypes [11, 12], and approximately half of patients with leukemia cutis have an NPM1 mutation in their leukemia cells [13]. Such lesions are usually pink in color and not pruritic (Fig. 20.2). On rare occasion, leukemia cutis may be evident before bone marrow or other evidence of the disease is discovered [11], or it may be the first sign of relapse. Leukemia cutis has rarely been noted solely around central venous catheter exit sites or other injection sites [14, 15]. Leukemia cutis does not alter prognosis, but can be disturbing to the patient or even grossly disfiguring [16]. The lesions usually involve the entire corium, and the cells comprising them may have a different phenotype than the leukemic marrow cells [11]. The discordance may be due to partial differentiation of the skin lesion cells into macrophages [11].

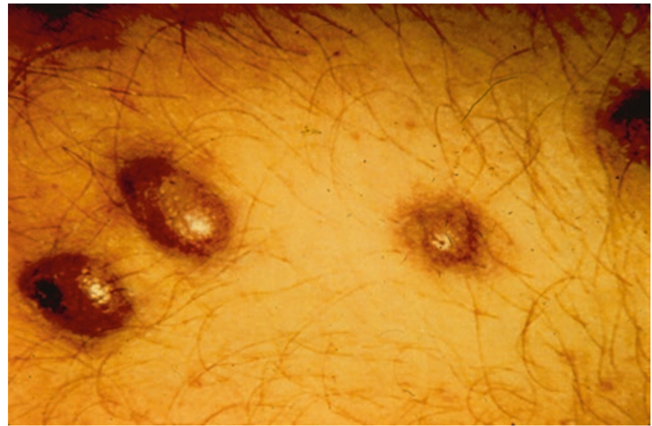

Fig. 20.2 Leukemia cutis in a patient with FAB M4 subtype of AML. The raised papules are due to leukemic infiltration of all layers of the corium

The lesions almost always respond to systemic chemotherapy rapidly, even if a complete remission is not ultimately obtained.

Rarely, a patient, especially a young patient, with AML will present with or develop a large subcutaneous or other mass of leukemic cells termed a granulocytic or myeloid sarcoma. On occasion, there is no other evidence of acute leukemia [17, 18]. Such lesions may also arise from subperiosteal areas of bone, particularly ribs, sternum, and orbit [19]. Granulocytic sarcoma of bone is rare, and other bone lesions such as radiographically seen metaphyseal lines that occur frequently in children with ALL are even rarer in adults.

Granulocytic sarcomas may occur in ovary [20], uterus [21], breast [22], cranial or spinal dura [23] (Fig. 20.3), and gastrointestinal tract [24] including liver [25], lung [26], mediastinum [27], prostate [28], and other organs and may present diagnostic difficulties in the absence of the usual

manifestations of AML [17, 29]. Such lesions may present as primary tumors of the organs involved, or suggest the diagnosis of lymphoma, plasmacytoma, or eosinophilic granuloma [30]. Typical AML may be discovered simultaneously, later, or never. A Wright-stained touch preparation of the lesion may help immeasurably in establishing the correct diagnosis. Immunohistochemical studies of fixed tissue may also be helpful in addition to routine histological studies [31, 32]. When isolated granulocytic sarcomas occur without other evidence of AML, radiotherapy [33] or surgery may be indicated. Although there is some evidence that treatment of an isolated granulocytic sarcoma with systemic chemotherapy will prevent the later occurrence of typical AML [34], this is not always the case and it is best to withhold systemic therapy until frank leukemia develops unless the granulocytic sarcoma cannot be treated locally.

Granulocytic sarcomas may occur more frequently in patients with M2 AML and t(8;21) [23, 35, 36], but it is clear that they also occur in patients with other cytogenetic abnormalities [37]. Their increased frequency as paraspinal tumors with t(8;21) may be related to the co-expression of a neural cell adhesion molecule (CD56) expressed by leukemic cells with that karyotype [38].

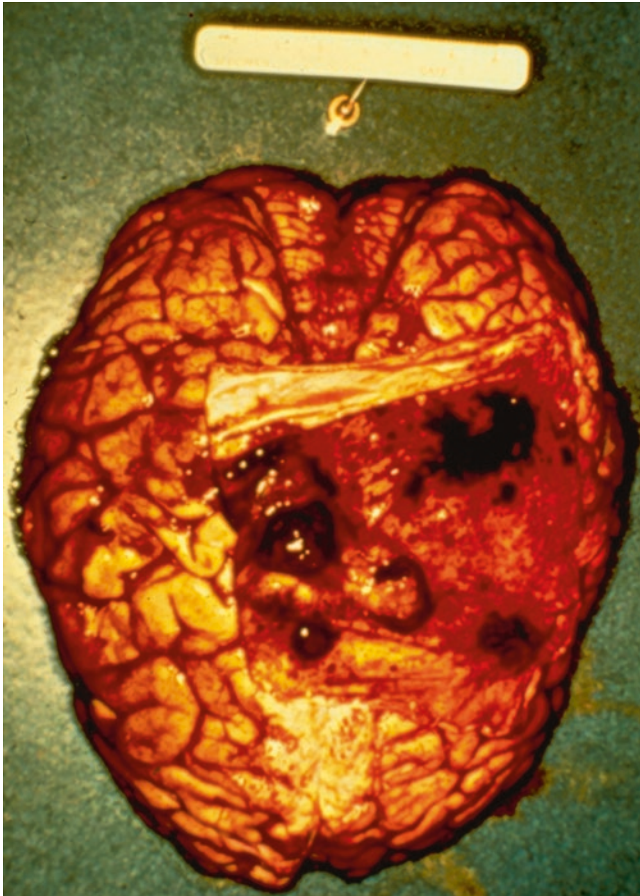

Fig. 20.3 A granulocytic sarcoma arising from the dura of the brain in a patient with FAB M2 subtype of AML with t(8;21) karyotype. The dura has been retracted to expose several dark nodules of tumor, which were *dark green*, due to myeloperoxidase contained in the cytoplasmic granules of the myeloid blast cells. The color fades when exposed to light

Acute febrile neutrophilic dermatosis (Sweet's syndrome) is a rare skin disorder that occurs in 1% of patients with AML for unknown reasons. It is more common in AML patients with FLT3 mutations [39]. The syndrome is characterized by fever, multiple painful papular and erythematous cutaneous eruptions, and a dense dermal infiltrate of mature granulocytes [40, 41]. A rapid response to glucocorticoids is usually obtained [42].

Fundic hemorrhage (Fig. 20.4) due to thrombocytopenia or leukemic infiltration of the retina may be found in patients of all ages with acute leukemia [43], including adults with AML [44].

Retinal leukemic infiltration is uncommon, is essentially confined to those patients with extreme hyperleukocytosis (blood blast count >200,000/μL), and is seen as one or more Roth-like spots with surrounding hemorrhage upon fundoscopic examination. Such lesions should be immediately irradiated if sight in the affected eye is to be preserved, but hemorrhage alone responds to successful platelet transfusion [44]. Other fundoscopic findings, such as cotton-wool spots; central vein obstruction; and vitreous, choroidal, or macular hemorrhage, are occasionally found [43, 44]. Certain treatments, such as high-dose cytarabine, may cause conjunctival and corneal pathology that results in impaired visual acuity [45]. The lesions resolve and normal visual acuity returns after discontinuation of the drug, and the problem can be prevented or attenuated with glucocorticoid ophthalmic drops administered during cytarabine treatment in most patients [46].

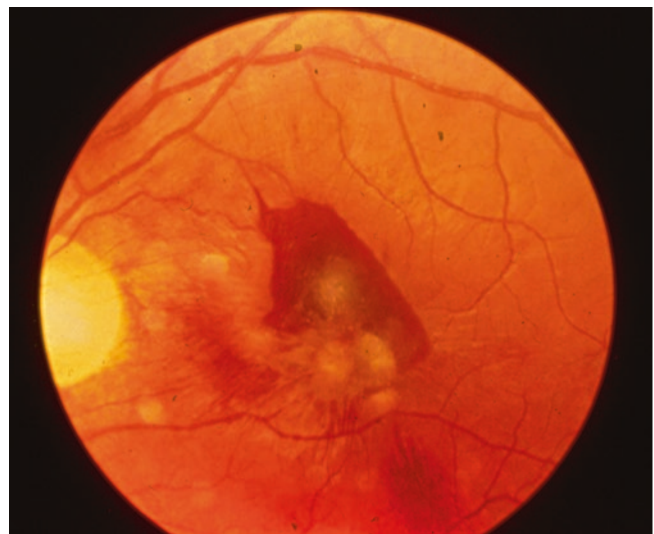

Fig. 20.4 Fundic hemorrhage in an AML patient with thrombocytopenia

Pulmonary dysfunction in patients with AML usually results from infection, which is discussed in Chaps. 53 and 54. A rare patient may develop dyspnea with or without an asthma-like syndrome due to pulmonary capillary leukostasis [47]. Such patients often have high blood blast counts [48, 49] and usually have the M3, M4, or M5 subtype of AML, but the frequency of this syndrome in patients with moderate degrees of leukocytosis may be underestimated [47]. The chest radiograph may be normal, show a ground-glass appearance suggestive of hemorrhage, or reveal diffuse alveolar consolidations [50]. This complication is frequently not recognized premortem, especially in patients with unrevealing chest radiographs [51]. Therefore, a therapeutic trial of bilateral low-dose whole-lung irradiation should be considered in an AML patient who has inexplicably developed progressively deteriorating pulmonary function [52–54]. A special form of this problem may occur after all-*trans* retinoic acid (ATRA) or arsenic trioxide therapy for acute promyelocytic leukemia and is fully discussed in Chap. 23. Severe and often fatal bilateral pulmonary hemorrhage may occur in end-stage patients who are thrombocytopenic and refractory to platelet transfusion, or in patients with a coagulopathy. This problem rarely arises during initial treatment. Although such hemorrhage has usually been ascribed to severe thrombocytopenia it may occur after successful platelet transfusion and other evidence suggests that its cause may be multifactorial. Diffuse alveolar cell damage may precede the hemorrhage, and cytoplasmic swelling and bleb formation have been noted in both capillary endothelial and alveolar lining cells in such patients [55]. While it is possible that these histologic changes represent toxic effects of extravascular blood, similar changes have resulted from cytarabine administration [56] or sepsis [57].

Heart conduction defects, murmurs, pericarditis, and congestive heart failure secondary to leukemic infiltration have been reported in AML [58–60]. Rarely, leukemic cardiac infiltration may occur in the absence of other evidence of AML [61]. These lesions are quite responsive to radiotherapy, which should be considered when leukemic infiltration of the heart cannot be ruled out [33].

It is important to have a dentist examine a patient with AML prior to therapy. Periodontal infections are common when AML is diagnosed and they may result in septicemia in a granulocytopenic patient. Dental extractions may be required [62] before initiation of chemotherapy, but often dental infections can be managed medically without interruption of leukemia treatment [63]. Other problems experienced by patients with AML in the region of the head and neck include leukemic infiltration of or hemorrhage into oropharyngeal structures that result in dysphagia or obstruction [64–66]. Leukemic infiltration of the inner, middle, and external ear has also been reported [67, 68].

As noted earlier, perirectal abscess and rectal fissure may develop in AML patients especially with the M4 or M5 FAB types. A small mucosal tear exquisitely painful on defecation or examination associated with fever may be the only indication of this potentially serious problem in a granulocytopenic patient, since infiltration and inflammation are often minimal [69]. Such lesions are usually the result of infection with gram-negative organisms, and bacteremia is frequent if proper treatment is delayed.

Necrotizing enterocolitis, or typhlitis, previously thought to occur primarily in children with acute leukemia, is described with increasing frequency in adults with AML who have been treated intensively [70]. Common symptoms include abdominal pain and distention with or without lower gastrointestinal bleeding. Abdominal radiographs may show only a nonspecific bowel gas pattern or lesions as serious as pneumatosis intestinalis, usually in the right colon. The lesions consist of mucosal ulcerations with inflammatory or leukemic infiltrates and usually involve the cecum but may also involve the ileum or the ascending colon. Bacteremia or fungemia frequently accompanies these lesions. Medical management may suffice [71], but surgery, which is usually successful when appropriate supportive care is available, may be required in some cases [72].

Renal dysfunction secondary to leukemic infiltration of the kidney or urate nephropathy is uncommon in adults with AML. Leukemic infiltration of the prostate [73] may obstruct the flow of urine and may rarely require irradiation. In most instances, however, induction chemotherapy will completely resolve the problem. Rarely, prostatic infiltration may be the first and only evidence of AML. Under no circumstances should a urinary catheter remain in place in a granulocytopenic AML patient.

Testicular relapse is common in ALL, especially in children, and has also been reported in adults with AML [74]. Postrelapse survival is frequently compromised in such patients.

Potassium wasting and other evidence of renal tubular dysfunction may occur in patients with the M4 and M5 subtypes who excrete lysozyme (muramidase), which is toxic to the proximal renal tubular epithelium [10]. The problem resolves with reduction of the tumor cell mass with chemotherapy. Lactic acidosis is a rare but difficult problem in AML [75]. Patients usually have large, vacuolated leukemic cells that may be difficult to accurately classify histologically. The etiology of the acidosis is obscure. Most patients have poorly controlled disease, and many have significant hepatic leukemic infiltration. The acidosis may require phenomenal quantities of alkali for control even after a partial remission of the leukemia is obtained.

Patients with AML may develop hypercalcemia [76], but hypocalcemia is more common. The latter may be a result of increased endogenous phosphorus production secondary to destruction of leukemic cells by either ineffective leukopoiesis, chemotherapy, or both, but septicemia and nephrotoxic antibiotics are frequently contributing factors [77]. On rare

occasion, hypocalcemia and hypophosphatemia may result from accelerated bone formation stimulated by leukemic cells [78].

Patients with AML subtypes M4 and M5 often present with hypocholesterolemia, which is thought to be due to increased low-density lipoprotein catabolism by mature monocytic phagocytes. Cholesterol levels return to normal with remission, and fall again with relapse of the leukemia [79].

Rarely, an AML patient presents with a markedly elevated peripheral blood blast cell count (>200,000 blasts/μL). This is a medical emergency since such a patient has approximately a 25% chance of a fatal intracerebral hemorrhage within a day or two [80–82]. This potential catastrophe is the result of intracerebral leukostasis secondary to increased blood viscosity. The hyperviscous blood causes sludging of blast cells at the low-pressure venous end of the capillary bed, which leads to plugging and eventual rupture of the vessel. The bleeding that then occurs would go unnoticed in most organs, but not in the brain. Those patients who undergo induction therapy with hyperleukocytosis are at risk for tumor lysis syndrome, which can be fatal even if recognized early [83]. Therefore, prophylactic emergency treatment directed at rapidly lowering the blood blast count and destroying established intracerebral foci of leukemic cells must be initiated at once (see discussion to come). A more common manifestation of CNS leukemia is meningeal infiltration with leukemia cells, which may arise from petechial hemorrhage in the meninges. Less than 2% of AML patients will have CNS leukemia at diagnosis. They are usually <45 years old, have a high WBC count of at least 50,000/μL, and have M4 or M5 FAB type (1). With proper treatment CNS leukemia at presentation does not impair prognosis. However, an isolated CNS relapse carries a poorer prognosis [1].

Many patients with AML are anergic to a battery of intradermal skin tests. This finding is of little clinical significance today since modern therapy has eliminated cutaneous anergy as a poor prognostic factor in AML. Some AML patients have decreased serum concentration of IgG and increased IgM concentration of unknown significance at presentation. Immunoglobulin levels usually normalize during induction therapy. On rare occasions, a serum paraprotein is present initially, which disappears after chemotherapy [84, 85]. Most patients with AML have a normal ability to raise a secondary antibody response [86, 87].

Diagnosis of AML

A thorough evaluation of a patient suspected of having AML must be conducted in a systematic fashion. A complete history should be taken with emphasis on exposure to medications, chemicals, and radiation, and the presence or absence of other diseases associated with an increased incidence of AML, including other neoplasms. A thorough family history should be taken, since a surprising number of patients with AML have a history of hematologic disorders in the family.

A complete physical examination is essential. If the patient is febrile, a thorough search for a focus of infection (periodontal disease, hemorrhoids, sinusitis, otitis, pharyngitis, pneumonia, abscess) must be made. The presence or absence of lymphadenopathy, splenomegaly, optic fundus pathology, CNS leukemia including cranial nerve palsy, and bleeding must be established. Granulocytopenic patients should not routinely undergo digital rectal examination.

Required peripheral blood studies include hematocrit, WBC count, platelet count, and differential WBC count. The peripheral blood smear should be examined by an oncologist or hematologist with experience in hematologic malignancies. A bone marrow biopsy and aspiration should be obtained from the posterior iliac crest with a Jamshidi needle or similar instrument. If it is impossible to obtain a posterior iliac crest aspirate, an attempt to obtain one from the sternum just under the ridge of the sternal angle with an Illinois or similar needle should be made. It is important to learn to perform these procedures properly from someone with experience. The biopsy is necessary to determine marrow cellularity and to assess the extent of the leukemic infiltrate. The aspirate should be examined after thin air-dried preparations are made, preferably on cover slips. No anticoagulant should be added to the aspirate obtained for routine staining and histochemistry, since some anticoagulants cause morphologic abnormalities in the leukemic cells, such as vacuolization, which may lead to diagnostic confusion. Aspirate smears should be stained with Wright's stain and a battery of histochemical reactions as detailed in Chap. 16. Such stains facilitate differentiation among the various AML subgroups, and between AML and ALL, and are required for proper French–American–British (FAB) classification. An iron stain should also be obtained on the biopsy to assess iron stores, and on the aspirate to identify sideroblasts often found in secondary AML, especially after treatment for Hodgkin's disease or multiple myeloma, and ringed sideroblasts that may be found in erythroleukemia (FAB M6).

An aspirate anticoagulated with heparin or ACD should be sent for immunophenotypic, cytogenetic, and molecular studies. The importance of these studies in the diagnosis of AML is detailed in Chaps. 17 and 18, and may give important prognostic information as discussed below.

Certain blood chemistry studies are required for proper assessment of the patient. Serum electrolytes, uric acid, lactate dehydrogenase, creatinine, lysozyme, and blood urea nitrogen should be determined. Routine coagulation studies and a plasma fibrinogen concentration are especially important in a patient suspected of having the M3 subtype of AML. Since hypogranular variants of that subtype exist, it is

important to study all patients initially. It should be remembered that some antibiotics commonly used in leukemia patients may cause abnormalities of coagulation unless vitamin K is administered prophylactically.

It is only necessary to examine the cerebrospinal fluid (CSF) routinely in asymptomatic AML patients with the M4 subtype. A lumbar puncture should only be performed in thrombocytopenic patients after a successful platelet transfusion has elevated the platelet count to 75,000/μL or more and in patients with a coagulopathy only after the plasma fibrinogen level has risen above 100 mg percent. Only 25-gauge needles should be used. The CSF obtained should be studied for routine parameters and, in addition, a cytocentrifuged specimen should be studied after staining with Wright's stain. Some training is required to accurately assess such specimens. Occasionally ependymal and other cells will be seen that may be mistaken for leukemic cells by the untrained observer. An elevated β_2-microglobulin CSF concentration may suggest occult CNS leukemia [88].

A posteroanterior and lateral chest radiograph should be obtained primarily as a baseline in an asymptomatic patient. Rarely, a mediastinal mass will be observed. This finding may confuse the observer unless one is aware of this rare manifestation of granulocytic sarcoma in AML [27].

Finally, the patient's blood should be typed and at least two packed red cell units cross matched with the patient's blood should be available at all times. If the patient has circulating lymphocytes the HLA type should be determined so that this information is available if bone marrow transplantation is contemplated in the future or if HLA-compatible platelet transfusions become necessary. At the same time, family members who agree to donate platelets, granulocytes, or bone marrow to the patient should also be HLA typed.

Preparation for Induction Therapy

It may not be necessary to begin induction chemotherapy immediately upon the diagnosis of AML. It is best to spend a day or two diagnosing the leukemic disorder precisely and resolving whatever medical emergencies are evident or developing.

Thrombocytopenic hemorrhage is more easily prevented than treated. Therefore, an AML patient with a platelet count less than 15,000–20,000/μL is a candidate for prophylactic platelet transfusion, which is discussed fully in Chap. 57. Prophylactic platelet transfusion has virtually eliminated hemorrhage as a cause of death during induction therapy. Platelet transfusion should not be given to a patient with a coagulopathy until low-dose heparin therapy is begun, or the coagulopathy may be aggravated.

An AML patient with a serious, uncontrolled infection at the time induction therapy is begun has a greatly reduced chance of remission. Therefore, documented or suspected infection should be under treatment and showing clear evidence of resolution before the institution of chemotherapy whenever possible. It is especially important not to begin chemotherapy until infection is controlled if the patient has circulating granulocytes. If absolute granulocytopenia exists in an infected patient, chemotherapy and antibacterial antibiotic therapy should be started simultaneously. Empiric broad-spectrum antibiotic therapy should be instituted immediately in a febrile granulocytopenic AML patient [89]. It should be remembered that fever may be the only clue to a serious infection in such a patient since the usual signs and symptoms of infection, which are largely due to granulocytic infiltration of infected tissues, may be absent [90]. Infection prevention and treatment for patients with AML are fully discussed in Chaps. 52 and 53, respectively.

The prophylaxis of intracerebral hemorrhage secondary to hyperleukocytosis [91] usually consists of emergency irradiation to the entire cranium with 600 cGy in a single dose and the administration of oral hydroxyurea (3 g/m^2 given daily for 2 days). The former will resolve already established intracerebral foci of leukemia, and the latter will rapidly reduce the blood blast count and thereby reduce blood viscosity, which is necessary to prevent reformation of intracapillary collections of blasts. Emergency leukapheresis has also been reported to be effective in this setting [92]. The procedure requires the availability of a blood cell separator and has not been demonstrated to be more effective than simple hydroxyurea administration. Management of hyperleukocytosis solely with hydration, urinary alkalinization, and allopurinol has been reported to be effective in infants [93] but is not recommended for adults.

Urate nephropathy is unusual in AML, except in patients with hyperleukocytosis or organomegaly due to leukemic infiltration. However, it is prudent to begin allopurinol (300 mg orally, daily for 1 or 2 days) before induction therapy and equally prudent to discontinue the drug after the marrow has become hypocellular following chemotherapy. Unnecessary prolongation of allopurinol administration may result in cutaneous eruption, which occurs with about 20% of prolonged courses of the agent or, on rare occasion, permanent marrow aplasia [94]. Patients who present with elevated serum uric acid concentration and an unusually large tumor load due to hyperleukocytosis or granulocytic sarcoma will require double or triple the usual allopurinol course initially, or treatment with recombinant urate oxidase (rasburicase) [95, 96].

Infection prevention methods should be instituted before induction therapy. The patient should be placed in strict reverse isolation in a meticulously cleaned room with air supplied only through high-efficiency particulate (HEPA) air filtration systems.

A triple-lumen Hickman catheter or similar device should be installed prior to treatment to facilitate blood drawing and intravenous therapy. If at all possible, the catheter should be placed at a time when the patient has circulating granulocytes, and use of the catheter should be restricted to personnel who have been specifically trained in the proper use and care of such devices.

Special consideration needs to be given to the pregnant patient with AML. Commonly administered induction agents other than idarubicin [97] can be given with relative safety to mother and fetus during the third and probably the second trimester [98–100] and should be given at doses based on actual body weight [101]. Children born to mothers undergoing induction therapy for AML during those trimesters have experienced only minor problems at birth and after long-term follow-up [98–102]. However, the use of lipophilic idarubicin during pregnancy may result in neutropenia and/or cardiac dysfunction in the neonate [97]. Induction therapy during the first trimester is very likely to result in abortion [99], and the diagnosis of AML itself in the first trimester may cause spontaneous pregnancy loss [101]. It may therefore be prudent to induce abortion under controlled circumstances in the first trimester. Rarely, spontaneous temporary remission of untreated AML may occur after cesarean section [22], or other event, usually a pyogenic infection [103].

Chemotherapy for AML

Chemotherapy for AML is administered in two stages: induction therapy followed by consolidation therapy. Allogeneic or autologous bone marrow transplantation may follow consolidation therapy in some circumstances, or consolidation therapy may be followed by or replaced by long-term maintenance therapy in other circumstances. The latter approach is not commonly used, although there is a rationale for it [104–106]. The purpose of induction therapy is to achieve complete clinical and hematological remission, which is defined as the absence of all clinical evidence of leukemia as well as a normocellular marrow devoid of leukemic cells and with normal trilineage hematopoiesis. Peripheral blood counts and differential WBC count are usually within the normal range in patients in complete remission, although in a minority of cases the platelet count may not recover to normal levels [107, 108]. Patients without complete platelet recovery may have impaired long-term survival compared with others [108, 109]. In patients whose AML is characterized by a specific gene mutation, quantitation of that mutation in marrow or peripheral blood cells [110] after complete hematologic remission is obtained may yield significant prognostic information with regard to the likelihood of relapse and even drive postremission therapy decisions. Such minimal residual disease testing is likely to become standard in the near future, once technical details are worked out [111–113]. The purpose of postremission therapy is to reduce the body burden of subclinical leukemia to, theoretically, zero. There is overwhelming evidence to support the concept of postremission therapy in that in virtually all studies in which outcome with and without postremission therapy has been prospectively compared, disease-free and overall survivals are greater in patients who continue treatment while in complete remission. Furthermore, most available data demonstrate a dose–response relationship for postremission therapy so that, in general, cure rates are higher with postremission dose-intense regimens than with regimens of lesser dose intensity. While there is no question that intensive postremission therapy is currently necessary in order to achieve optimal results, some studies have suggested that intensification of induction therapy may improve disease-free and overall survival despite no improvement in remission rate [114].

Although there is little evidence that the major FAB subtypes respond differently to standard induction therapy for AML, the development of ATRA therapy for the M3 subtype suggests that more subtype-specific therapy for AML may be developed in the future and that remission induction by mechanisms other than leukemia cell kill may be possible. There is already evidence that some dose-intense postremission regimens may be more beneficial in AML patients with favorable cytogenetics than in others [115].

There is no need for CNS prophylaxis in adult AML. The frequency of overt CNS leukemia is less than 1–2%, and cytarabine is virtually always used during induction therapy in intravenous doses that result in therapeutic CSF levels.

Results of induction therapy vary depending on a variety of prognostic factors. Patient age is the oldest recognized such factor. Patients over the age of 60–65 years have significantly lower complete response rates to induction therapy in most studies. Cytogenetic abnormalities are divided into favorable, intermediate, and unfavorable groups with respect to prognosis for complete response to therapy, and overall survival. The favorable group includes inv(16), t(8;21) without kit mutations, and t(15;17). A normal karyotype has an intermediate prognosis as does t(8;21) with kit mutation, and monosmy 5 or 7 (usually seen in secondary AML) as well as a complex karyotype have an unfavorable effect on prognosis [115]. See Tables 20.2 and 20.3.

More recently a number of genetic aberrations that affect prognosis in AML patients treated with currently available therapy have been identified [116]. In some instances, new treatments have been devised that partially offset the poor prognosis associated with some of these mutations. FLT3 mutation is one of the most common mutations seen in AML. The fems-like receptor tyrosine kinase (FLT3) expressed by immature

hematopoietic cells is important for the normal development of hematopoietic stem cells. Activating mutations caused by either an internal tandem duplication (ITD) or multiple amino acids in the juxtamembrane region or point mutation in the activation loop of the tyrosine kinase domain (TKD) are present in approximately 30% of patients with de novo AML. FLT3-ITD mutation is the most common molecular abnormality associated with adult AML. FLT3-ITD mutation occurs in patients with all FAB and cytogenetic designations, but is most common in patients with FAB M3. Such mutations have a negative impact on disease-free and overall survival in patients with a normal karyotype but have little influence on prognosis of patients with favorable or unfavorable cytogenetics. Recently developed inhibitors of these mutations given with standard induction therapy partially neutralize the activity of FLT3 mutations in the laboratory [117, 118] and partially negate the impaired prognosis conferred by these mutations in the clinic [119–121].

A number of other molecular prognostically significant factors have recently been identified, such as NPM1, CEBPA, IDH1, IDH2, and WT1 mutations, and they have the potential for becoming therapeutic targets in the future. NMP1 is frequently mutated in AML and preclinical studies suggest that cells with the mutation may undergo apoptosis with retinoic acid or arsenic trioxide treatment [122]. In a study of 148 AML patients 60 years old or older with normal cytogenetics, Becker et al. [123] reported that 56% of the patients had NPM1 mutations and those patients had a higher complete response rate [84% vs. 48% for patients without the mutation ($p < 0.001$)] as well as significantly longer disease-free and overall survival. The prognostic impact of the mutation was observed predominantly in patients at least 70 years old. Others have reported similar results [124]. See Table 20.4.

Damm et al. [125] found that patients with normal cytogenetics and a single-nucleotide polymorphism located in the mutational hot spot of the WT1 gene had improved relapse-free and overall survival compared with others, and Dufour et al. [126] reported that patients with normal karyotype biallelic CEBPA gene mutations, compared with those with monoallelic mutations or wild-type CEBPA, had significantly better overall survival after standard therapy. Conversely, Kornblau et al. [127] reported that highly phosphorylated Foxhead transcription factor (FOXO) in leukemic cells is a significant negative prognostic factor for survival in AML, independent of karyotype. Phosphorylated FOXO levels were higher in patients with FLT3 mutations, and were associated with higher WBC counts and a higher percent of blood and marrow blast cells.

In general, approximately 65–70% of unselected patients with de novo AML will achieve complete remission after one course of induction therapy. At least 30%, and perhaps as many as 40%, of complete responders will be cured after appropriate postremission therapy. In some studies long-term results are significantly better in women [128] and in virtually all studies they are better in patients <60 years old. Results of induction therapy are likely to improve as inhibitors of diver mutations are developed.

An excellent review of the molecular biology of AML has recently appeared [129].

Table 20.4 Examples of gene alterations affecting prognosis in AML [111, 129–135]

Gene	Prognostic effect	FAB type
FLT3-ITD	Poor with intermediate karyotype	
RUNX1	Poor	43% in M0
TP53	Poor-almost always with complex karyotype	36% in M6
FOXO phosphorylated	Poor	
EVI1	Poor	
IDH1, IDH2	Conflicting data	
DNMT3A	Poor if normal karyotype	26% in M2
KIT	Poor in CBF AML	
MLL-PTD	Poor	
TET2	Poor with intermediate karyotype	
TET2 hypomethylation	Very favorable	
NPM1	Favorable in FLT3-ITD mutation negative	42% in M1 57% in M4 49% in M5a 70% in M5b
CEBPA biallelic	Favorable	
WT1	Favorable if other than normal karyotype Unfavorable with normal karyotype	

PTD partial tandem duplication, *CBF* core-binding factor

Induction Therapy

The standard induction regimen for adults with AML for decades has been the two-drug combination of daunorubicin and cytarabine, and complete response rates on the order of 65% in unselected patients have regularly been reported with that combination [136–140] in unselected patients. Patients over the age of 60 years usually have a lower response rate. In a prospective, randomized ECOG study elderly patients treated with a standard induction regimen plus GM-CSF had a higher response rate, lower rate of infection, and lower death rate [141]. However, a similar study utilizing an investigational GM-CSF derived from *Escherichia coli* showed no advantage for the growth factor [142]. The ECOG study demonstrated that GM-CSF does not stimulate leukemia when used after marrow hypoplasia occurs, since patients receiving the growth factor did not have shorter disease-free or overall survival [141].

A commonly used induction regimen is a continuous intravenous 7-day infusion of cytarabine given at the rate of 100 mg/m^2 per day, plus daunorubicin given as 3 daily bolus injections of 45 mg/m^2 each, beginning on the first day of treatment. However, recent data suggest that much larger doses of daunorubicin may be more efficacious than standard doses. Fernandez et al. [143] randomly allocated 657 patients with previously untreated AML aged 17–60 years to cytarabine, 100 mg/m^2/day as a continuous 7-day I.V. infusion plus daunorubicin 45 mg/m^2 daily for 3 days or daunorubicin 90 mg/m^2 on the same schedule. The results were recently reported after more than 80-month median follow-up [144]. The higher daunorubicin dose resulted in a higher complete response rate (71% vs. 59%) and improved overall survival (median 25.4 months vs. 16.6 months, respectively). Only patients aged <50 years benefited from the high-dose therapy. The median overall survival with high-dose daunorubicin was 44.7 months compared with 20.7 months for the standard-dose patients younger than age 50. Patients with favorable cytogenetics benefited the most from the high-dose regimen but those with intermediate and unfavorable cytogenetics may have done so as well, but his could not be confirmed on univariate analysis. Patients with FLT3-ITD, NPM1, IDH, or DNMT3A mutations benefited as well from high-dose daunorubicin, and the high-dose induction regimen was required for the favorable impact of the NPM1 mutation on the disease to be evident. The rates of serious adverse events were similar in the two groups, but longer follow-up of survivors will be needed before that fact can be verified. Löwenberg et al. [145] conducted a similar study in older patients. They randomized 813 newly diagnosed AML or high-risk refractory anemia patients aged 60–83 years to receive daunorubicin at one of the two doses used in the Fernandez study [143] and cytarabine, 200 mg/m^2/day in a continuous 7-day infusion. The CR rate was 64% with the 90 mg/m^2 daunorubicin dose and 54% with the 45 mg/m^2 dose. Overall survival was similar in the two groups, but patients aged 60–65 years had greater event-free (29% vs. 14%) and overall (38% vs. 23%) survival with the 90 mg/m^2 dose of daunorubicin. A Korean study using the same regimens reported a higher complete response rate, and longer event-free and overall survival with similar toxicity in 383 patients ≤60 years old [146]. These three studies are interesting, but they need to be viewed critically. In many published studies the response rates with standard-dose daunorubicin are better than those reported in at least one of these studies [143] and similar to the results obtained with the daunorubicin 90 mg/m^2 dose. Patients who receive a total of 270 mg/m^2 daunorubicin with one course of the high-dose daunorubicin will probably not be able to receive retreatment in the future with an anthracycline should the need arise. Furthermore, the long-term toxicity of the high-dose daunorubicin regimen is unknown.

Burnett et al. [147] randomized 1206 patients, mostly younger than 60 years, with previously untreated AML or high-risk myelodysplastic syndrome to receive daunorubicin, 90 or 60 mg/m^2 on days 1, 3, and 5, combined with cytarabine, 100 mg/m^2/day as a 10-day continuous infusion. All patients received a second induction course with daunorubicin, 50 mg/m^2 on days 1, 3, and 5. There was no difference in complete response rate overall or 2-year overall survival in any subgroup. However, 60-day mortality was significantly increased in the patients who received daunorubicin, 90 mg/m^2. Although there are differences in the design of this study and the Fernandez study described above [143, 144] the results of the two studies are completely at odds with each other, especially with respect to toxicity of daunorubicin, 90 mg/m^2. Other smaller studies have addressed the question of daunorubicin dosage intensification. Prebet et al. [148] concluded from a retrospective study of AML newly diagnosed patients with core-binding factor that relapse-free survival was significantly better with daunorubicin 90 mg/m^2 than with daunorubicin 60 mg/m^2 and that there was a trend ($p = 0.07$) for a superior 2-year overall survival with the former. Another small retrospective study concluded that daunorubicin 90 mg/m^2 improved overall survival compared with daunorubicin 60 mg/m^2 [149]. Pautas et al. [150] compared daunorubicin 80 mg/m^2 daily for 3 days with idarubicin 12 mg/m^2 daily for 3 days or, in another group, daily for 4 days in 468 patients with ages ranging from 50 to 70 years. All patients received cytarabine as well. Both idarubicin schedules resulted in a significantly higher complete response rate than did daunorubicin, but there was no difference in relapse rate, event-free survival, or overall survival among the treatments.

From a meta-analysis of six randomized controlled trials Gong et al. [151] found significant improvement in complete response rate, event-free survival, and overall survival with daunorubicin 90 mg/m^2 compared with lower daunorubicin doses, but no differences in disease-free survival, relapse rate, or toxicity. Another meta-analysis found that both high-dose daunorubicin (90 mg/m^2 × 3 and 50 mg/m^2 × 5 studies lumped together) and idarubicin, 12 mg/m^2 × 3, achieve 5-year survival rates of 40–50% in patients ≤60 years of age [152]; another such study in adults showed that both high-dose daunorubicin and standard-dose idarubicin were superior to standard-dose daunorubicin in achieving complete response and long-term survival [153].

Dose intensification of daunorubicin during induction is not a new idea. Greene et al. [154] studied daunorubicin as a single dose of 180 mg/m^2 in 1972. Only a 25% complete response rate was obtained in 16 previously untreated patients aged 26–73 years. Seven of the 16 patients died during induction therapy and the rest suffered unacceptable toxicity.

Taken together, these data indicate that daunorubicin, 90 mg/m^2/daily × 3, is superior induction therapy for AML patients <60 years of age, compared with 45 mg/m^2. What is not clear is whether the higher dose is better than daunorubicin 60 mg/m^2 or a standard dose of idarubicin [155].

Daunorubicin, standard dose, and cytarabine were prospectively compared in six major randomized studies with an identical regimen except for the substitution of idarubicin, standard dose, for daunorubicin [156–162]. There were no significant differences in toxicity between the two treatments in any of the studies. In three of the studies [157–159] the complete response rate was superior with idarubicin plus cytarabine and the differences were significant for patients under the age of 60 years, and disease-free and overall survivals were significantly greater in idarubicin-treated patients in three of the studies [157, 158, 161]. The idarubicin–cytarabine regimen was significantly more effective in remission induction in patients with hyperleukocytosis than the daunorubicin–cytarabine regimen in the two studies in which that question was examined [157, 158]. In an Italian study for patients over the age of 55 years no difference in response rate or duration or survival was noted between the two treatments, but a significantly greater number of complete responders achieved remission with one course of idarubicin and cytarabine than with daunorubicin and cytarabine [161] and in a Japanese study no differences in outcome were noted [162]. In the ECOG study [156] of 349 patients over the age of 55 years the complete response rates were 40%, 43%, and 43% with the daunorubicin, idarubicin, and mitoxantrone regimens, respectively, and the differences were not significant. The median disease-free survival was 5.7, 9.7, and 6.9 months, respectively, but again the differences were not significant. A recent meta-analysis reported that idarubicin in induction therapy prolonged overall survival and disease-free survival, increased the complete response rate, and reduced the relapse rate compared with daunorubicin, although toxicity was greater with the former [163]. For patients under the age of 70 years the differences in complete response rates were greater (46%, 53%, and 52%, respectively), but the differences were still not significant. These data taken together strongly suggest that idarubicin is a more effective anthracycline than daunorubicin in the treatment of adult AML, especially in younger patients, and this fact was confirmed by a meta-analysis of 1052 patients randomized to receive daunorubicin or idarubicin, both at standard dosing, with cytarabine [164]. These clinical observations are consistent with the more favorable clinical pharmacokinetics of idarubicin [165] compared with those of daunorubicin, and with the observation that the intracellular accumulation of idarubicin is decreased to a much lesser degree by P-glycoprotein than that of daunorubicin [166].

Many investigators interpret currently available data to suggest that idarubicin should replace daunorubicin in the treatment of adults with AML, and an appropriate treatment regimen is detailed in Table 20.1.

In three randomized, prospective large studies the combination of mitoxantrone and cytarabine was compared with daunorubicin and cytarabine for induction therapy in adults with AML [156, 167, 168]. The standard dose and schedule of cytarabine were employed and mitoxantrone 12 mg/m^2 given daily for 3 days was substituted for daunorubicin in one arm of each study. No significant difference in outcome with respect to complete response rate, disease-free or overall survival, or toxicity was observed in any of the studies.

The addition of etoposide to the standard daunorubicin and cytarabine regimen improved disease-free and overall survival without improving the response rate, especially in patients less than 50 years of age in one study but not in others [169, 170].

Holowiecki et al. [171] reported that the addition of cladribine to a standard daunorubicin and cytarabine induction regimen increased the complete remission rate and overall survival at 3 years compared with the two-drug regimen in 652 newly diagnosed patients with AML ≤60 years of age. The survival advantage for the three-drug regimen was noted in patients ≥50 years of age, those with hyperleukocytosis, and those with unfavorable cytogenetics. These results deserve confirmation.

Hills et al. [172] performed a meta-analysis of studies in which gemtuzumab ozogamicin 3 mg/m^2 or 6 mg/m^2 was added to standard induction therapy or not, for adults with AML, and found that the agent prolonged survival at 5 years in patients without unfavorable cytogenetics. Both doses resulted in the same outcome but the lower dose was less toxic, as found in other studies [173]. This agent is no longer available in the USA but it clearly deserves further study.

Zeidner et al. randomized 165 newly diagnosed patients aged 18–70 years with intermediate or poor cytogenetics to cytarabine, 100 mg/m^2/day, as a continuous intravenous 7-day infusion plus daunorubicin, 90 mg/m^2, or a cyclin-dependent kinase inhibitor, alvocidib (formerly known as flavopiridol), together with cytarabine and mitoxantrone (FLAM). The complete response rate with FLAM was 70% compared with 46% for high-dose daunorubicin and cytarabine [174]. Further study of alvocidib in AML is planned.

Ravandi et al. [175] studied 62 patients with previously untreated AML with a median age of 53 years with the FLT3-ITD inhibitor sorafenib, cytarabine, and idarubicin. FLT3 mutations were present in 23 patients and 10 had unfavorable cytogenetics. A complete remission was obtained by 79% and an additional 8% attained a complete remission with incomplete platelet recovery. Interestingly, a 95% complete response rate was achieved in the patients with FLT3-ITD mutations. With a median follow-up of 52 months, the median survival for all patients was 29 months. Although this was a small study, it clearly suggests that sorafenib in

patients with FLT3-ITD mutations deserves further study. Other inhibitors of FLT3-ITD have yielded impressive results as well [176, 177].

High-dose cytarabine in induction therapy has been evaluated in a number of studies. In two early studies it was associated with greater toxicity than standard-dose cytarabine but there was no improvement in complete response rate or survival [178, 179] and a meta-analysis involving 5945 patients concluded that high-dose cytarabine led to a lower relapse rate than did standard-dose cytarabine but no improvement in complete response rate or overall survival [180]. In a more recent study, high-dose cytarabine produced a higher complete response rate and better overall survival especially in patients younger than 46 years and in patients up to 60 years of age with unfavorable cytogenetics or FLT3-ITD mutation [181]. In the most recent study [182] no advantage for high-dose cytarabine in induction was observed. High-dose cytarabine during induction is not recommended.

The addition of sorafenib, a tyrosine kinase inhibitor, to standard induction therapy led to significant improvement in event-free and overall survival after a median follow-up of 36 months, compared with placebo in one study of 267 evaluable patients ≤60 years [183]. Grade 3 or 4 toxicity was significantly higher in the sorafenib group, however.

Toxicity of Induction Therapy

Virtually all patients treated with the regimen recommended in Table 20.5 will develop total capital alopecia, which is often more disconcerting to young men than to others. Attempts to prevent alopecia with scalp tourniquets or hypothermia caps are ill advised during leukemia treatment since the scalp may become a pharmacologic sanctuary when such methods are employed.
